AA-01. The Marriage of Ferromagnetism and Superconductivity: A New Twist. *S.D. Bader*[1] *1. Argonne National Laboratory, Bridgman, MI, United States*

Nanocomposite hybrid materials enable the creation and tailoring of new properties from known component materials. [1-3] This is especially interesting when dealing with materials whose properties tend to be mutually exclusive, as in ferromagnets (F) and superconductors (S). When superconductivity and ferromagnetism co-exist, rather intriguing and even quite spectacular properties can develop. Theory predicts long-coherence-length, spin-triplet superconductivity at the F/S interface with an inhomogeneous magnetization [4]. Magnetic non-collinearity is a crucial but not quantitatively controlled parameter in most experiments inferring spin triplet superconductivity. In this work, we use Nb, and an epitaxial exchange spring Py/Sm-Co bilayer with uniaxial in-plane anisotropy in the Sm-Co layer [5]. Due to the interfacial exchange coupling, a tunable non-collinear spin spiral can be achieved by rotating the sample in fixed field. At a fixed temperature within the superconducting transition, starting from a collinear magnetic configuration, as the spin spiral's winding angle increases, the superconducting critical current first increases, peaks, and then decreases. The twist to the story is that this dependence is unanticipated. This tells us that there is new physics yet to captured in F/S theories.

AA-02. Electric Field Control of Magnetism. *R. Ramesh*[1] *1. Physics / MSE, UC Berkeley, Berkeley, CA, United States*

Complex perovskite oxides exhibit a rich spectrum of functional responses, including magnetism, ferroelectricity, highly correlated electron behavior, superconductivity, etc. The basic materials physics of such materials provide the ideal playground for interdisciplinary scientific exploration with an eye towards real applications. Over the past decade the oxide community has been exploring the science of such materials as crystals and in thin film form by creating epitaxial heterostructures and nanostructures. Among the large number of materials systems, there exists a small set of materials which exhibit multiple order parameters; these are known as multiferroics, particularly, the coexistence of ferroelectricity and some form of ordered magnetism (typically antiferromagnetism). The scientific community has been able to demonstrate electric field control of both antiferromagnetism and ferromagnetism at room temperature. Current work is focused on ultralow energy (1 attoJoule/operation) electric field manipulation of magnetism as the backbone for the next generation of ultralow power electronics. In this lecture, I will describe our progress to date on this exciting possibility. The lecture will conclude with a summary of where the future research is going.

8:00

AA-03. Topology in Spintronics: Majorana, etc. *K. Wang*[1] *1. Departments of Electrical and Computer Engineering, Materials Science and Engineering, Physics and Astronomy, UCLA, Los Angeles, CA, United States*

Energy dissipation has become the major challenge for the present electronics. Recent advances of physics involving topology in spintronics have made possible many low dissipation device possibilities. First, topological transition can be used to control spin textures. A large spin orbit coupling (SOC) is also shown to give rise to topological insulator with spin momentum lock, quantum anomalous Hall, and a large spin-orbit torque or SOT. As the result of these and other related efforts, a field of topological spintronics now emerges via interfacing topological insulators with other spintronic materials. Furthermore, topological material heterostructures composed of, e.g., antiferromagnets and superconnectors are shown to offer additional new physics. I will discuss some of these exciting physics and potentials. In particular, our recent experimental results have shown the convincing evidence of the half-integer quantized conductance plateau ($0.5\ e^2/h$) for the one-dimensional chiral Majorana fermion at the proper topological phase transitions using a quantum-anomalous-Hall/superconductor heterostructure. This half-integer quantized conductance plateau ($0.5\ e^2/h$) gives a firm signature in the quest of searching the elusive Majorana fermion for the first time in 80 years. Our finding offers a new direction for robust topological quantum computing to minimize the de-coherence challenge of today's quantum computer. *The work was in part supported by ERFC-SHINES, MURI-ARO, TANMS, and FAME

B1-02. Gilbert damping constant in exchange biased ferromagnetic/antiferromagnetic bilayers. *T. Ikebuchi*[1], T. Moriyama[1], H. Mizuno[1], K. Oda[1] and T. Ono[1] *1. Institute for Chemical Research, Kyoto University, Uji, Japan*

Recent research suggests that it is possible to manipulate the antiferromagnetic moments by the interaction between electron spins and local moment (spin torque effect) [1]. In our previous study, we investigated, based on the spin pumping theory [2], the spin torque effect by looking at the spin current dissipation, or the effective Gilbert damping constant, in exchange-biased FeNi/FeMn (a metallic antiferromagnet) films [3]. In this work, we particularly study an insulating antiferromagnet NiO in which the conduction electron spins are considered irrelevant to the spin torque effect inside the NiO. The exchange-biased NiO (t_{NiO} nm) / $Fe_{20}Ni_{80}$ (t_{FeNi} = 3, 5, 7 nm) / SiO_2 (5 nm) multilayers were sputtered on a thermally oxidized Si substrate. The films were then photolithographically patterned into a 10-μm-wide and 20-μm-long strip attached to a coplanar waveguide made of a Ti/Au layer. We performed ferromagnetic resonance (FMR) measurements based on the homodyne detection technique [3]. FMR spectra were taken, at room temperature, by sweeping an external field with a fixed frequency. The Gilbert damping constant was estimated from frequency dependence of the FMR linewidths. We found that the Gilbert damping constant effectively increases with increasing t_{NiO} as shown in Fig. 1. The t_{NiO} dependence is well fitted with the spin pumping model assuming a spin diffusion in NiO [2, 4]. The fitting yields the spin diffusion length ~20 nm and the spin mixing conductance at the NiO/FeNi interface ~75 nm^{-2}. Furthermore, we investigated the correlation between the Gilbert damping constant and the relative angle between the swept external magnetic field direction and the exchange bias direction (see Fig. 2). The relative angle dependence of the Gilbert damping constant does not seem to be as clear as the case for a metallic antiferromagnet [3], suggesting the details of the magnetic structure inside the insulating antiferromagnet may give insignificant effect on the damping enhancement.

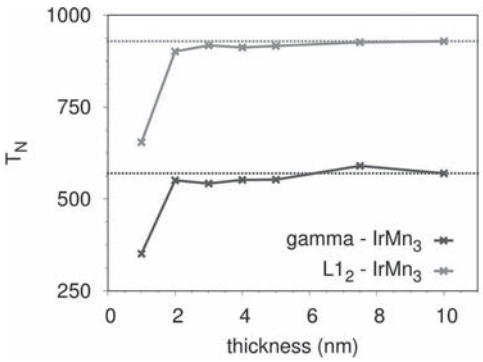
B1-03. Manipulation of spin current in antiferromagnetic insulator. *D. Hou*[1] *1. AIMR, Tohoku University, Sendai, Japan*



Effective spin current manipulation is the key process to realize the spin-based transistor and unfortunately proved to be quite challenging in the electron-based spin channels, in which the propagation of spin current relies on the isotropic electron diffusion. Recent works show that spin can transmit through antiferromagnetic insulators [1,2], in which itinerant electrons cannot pass, indicating alternative methods for spin manipulation. In this talk, the speaker will introduce their recent progress in the effective manipulation of spin current in antiferromagnetic insulator with the methods different from those in conductive materials. The spin current switching by the phase and magnetic structure control will be discussed, with the introduction of two novel concepts: spin colossal magnetoresistance and spin dichroism [3-6]. These findings pave the road towards antiferromagnetic-insulator-based spin transistor and memory.

B1-04. Finite Size Effects in Antiferromagnetic Materials. *S. Jenkins*[1], R. Chantrell[1] and R.F. Evans[1] *1. Department of Physics, University of York, York, United Kingdom*

Antiferromagnetic spintronics is a newly emerging field which has renewed interest in antiferromagnetic (AFM) materials. This is because they are resistant to pertubation from magnetic fields, they display ultra fast dynamics and interesting magnetotransport effects. The Neel temperature is the antiferromagnetic equivilent of the Curie temperature and sets the thermal threshold for data retention in a device. Most spintronics applications are for ultrathin films and therefore the finite size dependence of the Neel temperature is important for device operation. For the technologically relevent AFM γ-$IrMn_3$, the bulk Neel temperature is around 750K, but it has been proposed that it is stongly thickness dependant[1]. Here we have developed atomistic spin models of two technologically important antiferromagnets γ-$IrMn_3$ and MnAu, considering localised atomic spin moments coupled with Heisenberg exchange [2]. The temperature dependent properties of the system are simulated using a metropolis Monte Carlo algorithm. Our model successfully reproduces the magnetic ground state spin configurations and bulk Neel temperatures of γ-$IrMn_3$ and MnAu[3]. We have performed a systematic study of the thickness dependence of the Neel temperature, shown in Fig. 1. The finite size effect is small for this material except for the smallest film thicknesses, where a catastrophic drop in the Neel temperature is seen. We have found that this is due to the existence of point defects at the surface which leads to large fluctutaions of surface spins. We will also present results on the effects of interface mixing and comparative results for $L1_2$ IrMn thin films.

Thickness dependance of the Neel temeprature for γ-$IrMn_3$ and $L1_2$-IrMn

B1-05. Field-driven antiferromagnetic domain switching in single crystalline CoO(001) film. *J. Xu*[1], M. Jia[2], G. Chen[3], Q. Li[4], A.T. N'Diaye[5], E. Arenholz[6] and Y. Wu[7] *1. Antiferromagnetic (AFM) spintronics has drawn significant attention recently due to its potential for low power consumption information storage and processing. Controlling AFM domains (spin axis, domain size) is essential in this context [1,2,3]. Typically, AFM domains and the alignment of their spin axis are controlled through exchange coupling [4,5,6] or field cooling of FM/AFM bilayers [6], where the AFM domain switching process is influenced by the magnetization reversal of the ferromagnetic layer. Information about the AFM spin axis in these cases is obtained indirectly from the remanent magnetization of the ferromagnetic layer. However, it is preferred in order to understand the AFM domain switching process, to measure the AFM spin axis directly and study pure AFM materials. In this contribution, we report studies investigating the AFM domain switching process in single crystalline CoO(001) thin films. We measured the AFM spin axis directly using X-ray magnetic linear dichroism (XMLD). We find that the AFM spin axis in CoO domains can be aligned by applying an external field during a field cooling process, and that below the Néel temperature the CoO spins are aligned perpendicular to the cooling field along the CoO<110> direction. We believe this is due to the spin-flop coupling effect between applied fields and AFM ordered spins during field cooling, as shown in Fig. 1. The field-driven AFM spin switching only occurs above a critical temperature close to the Néel temperature. Moreover, this critical temperature is higher, i.e. closer to the Néel temperature for weaker applied fields, reflecting the competition between the thermal fluctuation and the Zeeman energy. Our work provides a direct method to understand the AFM domain switching process.

Time resolved scanning transmission x-ray microscopy (TR-STXM) is one of the few magnetic imaging techniques that is capable of simultaneously measuring on the nm length and ps time scales of modern magnetic devices. Up to now TR-STXM measurements have exclusively made use of x-ray magnetic circular dichroism (XMCD) to achieve magnetic contrast. XMCD suffers the limitation however that it is sensitive to the net magnetisation, consequentially for some samples (such as antiferromagnets) it cannot be used. In contrast x-ray magnetic linear dichroism (XMLD) is sensitive to the axis of magnetisation, and as such can be used in different systems [1, 2]. Furthermore, the two techniques used together may provide complementary information on the magnetisation of ferrimagnetic samples, XMCD, being sensitive to the magnetisation along the optical axis, XMLD being sensitive to the orientation of the Néel axis in the plane perpendicular to the optical axis, or in terms of a thin film sample typical to TR-STXM, to the out-of-plane and in-plane magnetisation respectively. Here we present the first use of XMLD for imaging magnetic dynamics with TR-STXM. We use this

technique to characterise vortex, domain wall and spin wave dynamics in the ferrimagnetic insulator and magnonic material of choice yttrium iron garnet (YIG,185nm LPE). Our findings demonstrate a novel and important advance in time resolved magnetic x-ray microscopy opening the door to the study of ultrafast magnonics based on antiferromagnets.

B1-07. Spin-orbit torque of PtMn/CoFeB evaluated by extended harmonic Hall measurement. *R. Itoh*[1], Y. Takeuchi[1], S. Duttagupta[2], S. Fukami[1,3] and H. Ohno[1,3] *1. Lab. for Nanoelectronics and Spintronics, RIEC, Sendai, Japan; 2. Center for Spintronics Research Network, Tohoku University, Sendai, Japan; 3. Center for Spintronics Integrated Systems, Tohoku University, Sendai, Japan*

Spin-orbit torque (SOT) generated by in-plane current application to magnetic heterostructures allows an efficient control of magnetization direction. Heterostructures with antiferromagnet (AFM)/ferromagnet (FM) stack is an attractive system for applications [1,2], and understanding of the SOT generation mechanism is of crucial importance for successful implementation. While a theoretical work pointed out a characteristic mechanism inherent to AFM that exhibits an intrinsic spin Hall effect [3], there have been few experimental studies on evaluation of SOT in AFM/FM systems [4,5]. Here we evaluate SOT in various heterostructures with AFM PtMn and FM CoFeB using an extended harmonic measurement technique [6,7] to obtain clues to understand the mechanism of SOT generation in AFM/FM systems. The studied heterostructures consist of a Pt (or Ru)/$Pt_{38}Mn_{62}$/CoFeB multilayers with various PtMn and CoFeB thicknesses. The films are processed into Hall-bar structures using photolithography and Ar-ion milling. The 1st and 2nd harmonic Hall voltages are measured while applying AC current and rotating an external magnetic field (H_{ext}) in the film plane [6,7]. Figure 1(a) shows azimuthal angle (ϕ) of H_{ext} dependence of 2nd harmonic Hall resistance ($R_2\omega$) for various H_{ext} with the fitting curves. Field-like (FL) component of SOT is directly obtained from the fitting. Slonczewski-like (SL) component of SOT is obtained from the slope of the linear fit to the dependence of SL torque-induced resistance (R_{SL}) on the inverse of the sum of H_{ext} and effective anisotropy field (H_K^{eff}) shown in Fig. 1(b) (y-intercept is due to the anomalous Nernst and spin Seebeck effects). An effective spin Hall angle, or a SOT efficiency, of around 0.1 is obtained, which is comparable to the value in Pt/CoFeB structures. Spin diffusion length and underlayer material dependence will be discussed based on the results obtained from various stack structures. A portion of this work was supported by the ImPACT Program of CSTI, JST-OPERA, and JSPS KAKENHI Grant Number 17H06093.

B1-08. Probing the Energy Barrier for Resistive Switching in Antiferromagnetic $Sr_3Ir_2O_7$. *M.C. Williamson*[1,2], S. Shen[1,2], G. Cao[3], J. Zhou[2], J. Goodenough[2] and M. Tsoi[1,2] *1. Physics, University of Texas at Austin, Austin, TX, United States; 2. Texas Materials Institute, Austin, TX, United States; 3. Physics, University of Colorado, Boulder, CO, United States*

Antiferromagnetic (AFM) materials are expected to improve stability, scalability, and speed of magnetic memory applications thanks to the insensitivity of AFMs to magnetic fields and their high natural frequencies. Of particular interest are AFM transition metal oxides (TMO) as their properties can be tuned using various external stimuli, thus opening an entirely new dimension to the field of spintronics. We have previously demonstrated that the transport properties of AFM TMOs can be tuned by an externally applied electric field [1, 2] – e.g. a reversible resistive switching induced by an electric bias was found in $Sr_3Ir_2O_7$ with potential applications for writing in AFM memory applications. The switching was tentatively attributed to electric-field driven lattice distortions/structural transition. In this work [3], we probe the energy barrier associated with this transition using time-resolved measurements of the switching. We observe an exponential dependence of the switching probability on both applied bias and temperature consistent with thermal activation over an energy barrier. We quantify the changes in the energy barrier height with respect to the applied bias and find a linear decrease of the barrier with increasing bias. Our observations support the potential of AFM TMOs for spintronic applications.

B1-09. Heat Assisted Switching of AFM CuMnAs Memory Cell.
Z. Kašpar[1,2], K. Olejník[1], V. Novák[1] and T. Jungwirth[1,3] *1. Academy of Sciences of the Czech Republic, Prague, Czechia; 2. Charles University in Prague, Prague, Czechia; 3. School of Physics and Astronomy, Nottingham, United Kingdom*

The discovery of current induced manipulation of antiferromagnetically ordered magnetic moments using staggered spin-orbit field [1] triggered an extensive interest in antiferromagnetic spintronics [2]. This discovery breaks the major barrier on the route towards using these materials in devices with picosecond dynamics speed and with immunity against external magnetic field. In our recent study of CuMnAs memory cell exposed to picosecond THz radiation we have shown [3] that the temperature plays an important role in the writing process in a broad interval of pulse lengths ranging from few milliseconds to one picosecond. Here we further elaborate on the role of temperature and investigate the current induced switching of antiferromagnetic memory cell at different working temperatures from the perspective of temperature evolution during the writing pulse, reading signal amplitude, and retention time. Special attention was paid to disentangling the effects coming from Joule heating and from the staggered spin-orbit field in a CuMnAs memory device equipped with an independent nanopatterned heater. The results indicate that the temperature achieved during the pulse is critical: the change of the state of antiferromagnetic moments takes place only above certain threshold temperature, which clearly points to the heat assisted nature of the current induced switching.

The nitrogen-vacancy (NV) color center in diamond is an exceptional atomic-scale system with a coherent electronic spin degree of freedom that can be initialized and measured optically. These properties make the NV attractive for applications ranging from quantum information to nanoscale metrology. Here, we measure the Zeeman shift of the NV ground state spin to quantitatively determine the local magnetic field at the NV. By incorporating a single NV into the tip of a monolithic diamond AFM probe and scanning it over a sample surface, we image the stray magnetic field of the sample at nanoscale resolution.[1] This versatile technique enables the study of magnetism in a wide range of materials and environmental conditions, from cryogenic to room temperature. Here, we apply scanning NV magnetometry to image the formation of antiferromagnetic domains in a granular thin film of Cr_2O_3 as it transitions from paramagnetic to antiferromagnetic order.[2] In combination with Zero-Offset Hall Magnetometry[3], we characterize key material properties of the film, including local critical temperature and inter-granular exchange.

B1-11. Material Systems for Skyrmions in Co-based Ferro-/Antiferromagnetically Coupled Multilayers.
H. Jia[1], *B. Zimmermann*[1] and S. Blügel[1] *1. Peter Grünberg Institut and Institute for Advanced Simulation, Forschungszentrum Jülich, Jülich, Germany*

Magnetic skyrmions, in particular antiferromagnetic (AFM) skyrmions, are considered as ideal candidates for high storage density information carriers due to the suppressed skyrmion Hall effect and a small size by canceling dipolar fields. So far searching for materials that can host AFM skyrmions is still a challenging task. Magnetic multilayers (MMLs) with composite structures provide a great opportunity to design materials that can host magnetic spin spirals, skyrmions or domain walls with optimal properties. In particular, the antisymmetric exchange interaction, known as Dzyaloshinskii-Moriya interaction (DMI), created at the surfaces and interfaces of metallic multilayers plays a determining role. Here, we explore the magnetic interactions of multilayers {*Z*|Co|Pt}, where we take for *Z* prominent 4*d* transition metals, noble metals, as well as Zn and Cd. We base our investigations on first-principles calculations employing the relativistic full-potential linearized augmented plane-wave (FLAPW) method, as implemented in the FLEUR code (www.flapw.de). We find that the DMI in these multilayers is originating from the heavy-metal Pt layer, but it can be drastically tuned through the presence of the third layer, *Z*, exceeding the large value of the bare Co/Pt interface. In combination with AFM interlayer exchange coupling (IEC) and taking into account the spin-stiffness and magnetic anisotropy, we predict *Z*=Cd or Zn to be interesting material combinations to realize Skyrmions in a synthetic AFMs. We dig deeper into the {Pd|Co|Pt} and {Rh|Co|Pt } multilayers, where we find strong DMI or strong AFM IEC between the Co layers, and can tune the coupling strength by varying the number of Pt layers. We even find regimes where a non-collinear order along the *c* axis arises due to frustrated exchange. We further relate the strength of the DMI to another quantity, which is much faster to calculate and serves as a discriminator for high throughput screening of chiral magnetic multilayers. *Financial support by EU Horizon 2020 via FET-Open project MAGicSky and a JARA-HPC Supercomputing grant.

B2-01. Magnetic Design of Multi-Component Nanoprobes for Biomolecular Diagnostics. *H. Brueckl*[1], A. Shoshi[1], M. Haslinger[2], T. Mitteramskogler[2], M. Muehlberger[2], J. Schotter[3] and S. Schrittwieser[3]
1. Department for Integrated Sensor Systems, Danube University Krems, Wiener Neustadt, Austria; 2. PROFACTOR GmbH, Steyr/Gleink, Austria; 3. AIT Austrian Institute of Technology, Vienna, Austria

The development of novel multifunctional nanoparticles with hybrid magnetic and plasmon-optical properties opens new possibilities in their application as nanoprobes for immunodiagnostics [1, 2]. Our innovative breakthrough is the reliable fabrication of such hybrid nanoparticles by thin film technology and nanoimprint lithography, and their transformation into immuno-sensing nanoprobes via biofunctionalization. A main obstacle of such nanoprobes is their tendency to agglomerate in solution due to magnetic and electrostatic attractive interaction. Although tailored repulsive electrostatics by surface charges can successfully prevent the agglomeration to a certain degree, the minimization of magnetic interaction would be highly desirable. Towards this goal, we will discuss several paths how to engineer the magnetic part in our nanoprobes, experimentally and by micromagnetic simulation. Fortunately, the physical fabrication of the nanoprobes by thin film deposition and nano-imprinting offers the unique advantage to tailor shape and thickness to the highest degree and uniformity (fig. 1). The following designs are discussed in comparison to single elliptical magnetic layers: a) elliptical double layers with stray-field-coupled magnetization, b) elliptical double layer with antiparallel indirect exchange-coupled magnetization, and c) circular and elliptical single layer with vortex magnetization (fig. 2). The authors acknowledge funding from the Federal Ministry of Transport, Innovation and Technology (BMVIT) supported by the Austrian Research and Promotion Agency (project LAMPION, #861414).

Among the different needs for bio-sensing, point-of-care and point-of-use applications require devices which are portable, and allow fast and cheap analyses. For these, magnetic nanoparticles have a great potential, as far as they are combined with a separation method (as the paper-based flow immunoassay in Fig. 1) and an adequate sensor [1]. The ideal sensor should be able to quantify the particles without compromising the simplicity of the analysis. With this in mind, a device has been designed consisting of a microtrack deposited on an insulating substrate whose impedance is monitored while scanning the immunoassay. The presence of particles increases the measured impedance (Fig.1). This principle of detection uses of the influence of the permeability of the particles and does not require the application of a magnetizing field, which considerably reduces its complexity. In this work we aim to elucidate the best conditions to optimize the sensitivity of the magnetic particle sensor. Numerical calculations based on finite element method (FEM) [2] are performed to study the dependency on the frequency, the excitation voltage and the shape, dimensions and material of the sensing microtrack. Its impedance is calculated with and without a particle medium with a given permeability in its proximity. The presence of particles mainly affects the imaginary part of the impedance. The real part is nearly insensitive to it. However, due to the skin effect, the real part increases hugely and becomes dominant, decreasing the sensitivity of the element to the presence of magnetic particles. In consequence, for a given material with a given conductivity, there is an optimum thickness of the element for each measuring frequency. FEM calculations confirm the existence of a maximum in the sensitivity and predict the optimum thickness (Fig. 2). Experimental measurements are performed to contrast these findings.

T_2 CA are defined by their relaxivity, r_2, which is dependent on both the saturation magnetization (Ms) and size of the NPs [1,2,4]. In this study, effect of Gd_5Si_4 NPs of varying sizes and concentrations are investigated on T_1, T_2 and T_2* (effective/observed T_2) relaxations times. Gd_5Si_4 NPs categorized into three fractions (named S1, S2 and S3) based on average sizes of 586 nm, 287 nm and 135 nm respectively as analyzed from SEM images (Fig. 1). XRD analysis on the combined samples shows that Gd_5Si_4 is the major phase while Gd_5Si_3 and GdSi are present as the minor phases in all fractions (Fig. 1). Magnetic properties measured in VSM reveal that the Curie temperature (Tc) decreases for Gd_5Si_4 phase from 312 K for S1 to 304 K for S2 and is undetectable in S3. The M-H curves at 300 K exhibits ferromagnetic behavior descending to paramagnetic as we move from S1 to S3 fraction (Fig. 1). Prior to MRI measurements, NPs are diluted in solution with low-temperature 2% agarose with the following dilutions - 1:20, 1:200, 1:2000 and 1:20000. MR data were acquired on the 21.1 T (900 MHz) magnet. The results shown in Table 1 indicate that higher concentrations of NPs shorten the T_2 and T_2* relaxation times and the contrast disappears rapidly at higher dilutions. The S2 fraction at 1/20 dilution shows notably shortened T_1 and T_2 relaxation times compared to the other two fractions. Although S1 has higher Gd_5Si_4 phase volume fraction and larger average particle size compared to S2, further investigation is needed inorder to establish the reason for shortened relaxation times compared to the S1 fraction.

B2-04. Influence of pH on Dynamic Magnetic Susceptibility of Iron-oxide Nanoparticles in a Chitosan Hydrogel Matrix. *M.C. Villamin*[1] and Y. Kitamoto[1] *1. Materials Science and Engineering, Tokyo Institute of Technology, Yokohama, Japan*

Ferrogels consisting of iron oxide nanoparticles (FeO*x* NPs) embedded in chitosan hydrogel (CH) are of recent interest due to desirable properties of both the FeO*x* NPs and the CH, along with their many potential biomedical applications [1-4]. There have been proposals on using the CH sensitivity to various chemical stimuli for biosensing applications. However, actual demonstrations have been scarce. In the present study, we demonstrate the effect of pH on the magnetic relaxation of the FeO*x* NPs embedded in a macroscopic-size CH. Alternating current (AC) susceptibility via commercial PPMS system and the swelling rate (SR) of the FeO*x*-CH were measured. For each measurement, the FeO*x*-CH was submerged into a solution to control its pH. The FeO*x*-CH was also characterized by using XRD, TEM and SEM. XRD and TEM reveal that the FeOx NPs are magnetite with 10-20 nm diameter. SEM observations show that CH have porous structure. SR results of the FeOx-CH at different pH conditions are shown in Fig. 1. It shows that the swelling increases as the pH decreases. Actual image of FeOx-CH is also shown in the inset of Fig. 1. On the other hand, the peaks in the frequency dependence of the imaginary part of AC susceptibility (M") at different pH condition are shown in Fig. 2. This is extracted from the fitted Gaussian function of the data as a function of frequency (inset of Fig. 2). The position of the M" peak is typically associated with the magnetic

relaxation time, with f≈1/τ, where τ is the relaxation time [5-6]. It is evident that there is a shift in the M" peak position to higher frequency upon decrease of the pH solution. Generally, there are two magnetic relaxation mechanisms in magnetic nanoparticles and these are Neel and Brownian relaxations [7]. By decreasing pH, the CH swells, and it is inferred that the swelling enhances the Brownian relaxation. Hence, a shift to a high frequency is indeed expected. These results demonstrate a promising technique to magnetically detect chemical change that may be useful for biosensing applications.

B2-05. Study of Magneto-Optical Nanocapsule as Promising Temperature Sensor in Magnetohyperthermia. *L.C. Figueiredo*[2], B. Sikora[1], P. Kowalik[1], T.d. Castro[2], S.W. da Silva[2], E. Mosiniewicz-Szablewska[1] and P.C. Morais[2] *1. Institute of Physics, Polish Academy of Sciences, Warsaw, Poland; 2. Institute of Physics, University of Brasília, Brasília, Brazil*

The main goal of this study was the synthesis of magneto-optical nanocapsule (MONC) able to perform magnetohyperthermia (MH) while recording local temperature using upconversion [1-3]. The MONCs comprises an optically-active $NaF_4(Er,Yb)$ nanocrystal core with a silicon oxide (SiO_2) shell layer encapsulating magnetite nanoparticles (MNPs). Study using magnetic resonance (MR) followed protocol [4,5] and showed that the oleic acid-coated MNPs presented ferrimagnetic behavior below 265 K while revealing a narrow paramagnetic signal above 265 K. We claim that charge accumulation at the magnetic nanoparticle surface-oleic acid coating interface accounts for the observed paramagnetic signal, once quenching of this signal is observed while replacing the oleic acid coating by the SiO_2 layer due to the MNPs' encapsulation procedure. Moreover, MR angular variation experiments show that the magnetic anisotropy field of the MONC reduces by about one-third in comparison with the magnetic anisotropy field of the MNPs, which is credited to the absence of magnetic dipole-dipole interaction among the encapsulated MNPs. This means that the hyperthermia effect mechanism is basically provided by the Néel relaxation process. Therefore, we envisage that modulation of the MNPs content within the MONC can be successfully-used to modulate the outcome of the MH effect. Temperature-dependent study of the MONC was performed by photoluminescence (PL) experiments using a NIR 980 nm wavelength laser. Our finding showed increasing PL intensity of the 521, 539 and 654 nm PL bands, thus supporting the potential use of the MONC as a temperature sensor [3]. Additionally, the MONC was tested for hyperthermia effect under oscillating magnetic field (523 kHz, 200 Oe). The temperature was increased up to 6 °C after 60 minutes of oscillating field exposition. The mild temperature increase is very likely due to the lower content of MNPs within the SiO_2 shell layer and it shows how promising this material platform is for modulation the hyperthermia effect upon increase of the encapsulated magnetic phase. Finally, MH was performed with the MONC while collecting the PL signal, thus corroborating the temperature sensing capability of the as-prepared platform.

B2-06. Specific Loss Power of Gd_5Si_4 for Self-regulating Magnetic Hyperthermia: Effects of Particle Size. *Z. Boekelheide*[1], Z.A. Hussein[1], S. Hunagund[2], S.M. Harstad[2], A.A. El-Gendy[3] and R.L. Hadimani[2] *1. Lafayette College, Easton, PA, United States; 2. Mechanical and Nuclear Engineering, Virginia Commonwealth University, Richmond, VA, United States; 3. Physics, University of Texas at El Paso, El Paso, TX, United States*

Gd_5Si_4 is a promising material for self-regulating magnetic hyperthermia in which overheating is prevented by the material's Curie temperature T_C [1]. The T_C of Gd_5Si_4 is near the optimal treatment temperature, and can be tuned by either substituting Si with Ge or microstructuring [2,3]. Previous results on poly-disperse ball-milled micro- and nano-particles have shown a reduced T_C and a specific loss power (SLP) on the low side of the wide range of values observed for potential hyperthermia materials [4]. The wide particle size range caused difficulty in interpreting the relationship between the microstructure and the magnetic and thermal properties. Here, we discuss the particle size dependence of the SLP of Gd_5Si_4 micro- and nano-particles. Particles were synthesized by ball-milling of bulk Gd_5Si_4 ingot [4]. After ball-milling, the particles were suspended in ethanol. Samples were collected from the sediment obtained after the following times: 50 min, 3 hrs 30 min, 16 hrs, 96 hrs, and the supernatant. Scanning electron microscope images of the particles (Fig. 1) show longer sedimentation times lead to smaller average size, as expected. Average particle sizes ranged from 780 nm (50 min) to 140 nm (supernatant). SLP was measured in 0.5 mL of water with 0.6% PEG. The values were calculated from the slope of the heating curve between 21-22° C in an applied alternating magnetic field at frequencies between 220-225 kHz. SLP for the highest field (0.064 T) is shown in Fig. 2. The sample with the largest particle size has similar SLP to the poly-disperse sample [4] while the samples with smaller particle size have lower SLP. This suggests that the SLP of the poly-disperse sample is dominated by the larger particles. Vibrating sample magnetometer data shows lower magnetization for the smaller samples, suggesting that magnetic properties are strongly influenced by particle microstructure. Size-separation by sedimentation of ball-milled Gd_5Si_4 particles does not yield small, effective particles. To attain small Gd_5Si_4 particles appropriate for therapeutic use, alternate methods would be required.

B2-07. Magnetic ZnO@Fe_3O_4 Core-Shell Nanostructure for Magnetic Hyperthermia and Bio-imaging applications. *J. Gupta*[1,2], K. Barick[1], P. Hassan[1] and D. Bahadur[2] *1. Chemistry Division, Bhabha Atomic Reseach Centre Trombay, Mumbai, India; 2. Department of Metallurgical Engineering & Materials Science, Indian Institute of Technology Bombay, Mumabi, India*

Combining two materials having different functional properties has become a current research area for biomedical applications. The progress of nano-platforms brings a new non-invasive imaging and therapeutic tools for cancer. Here, biocompatible and multifunctional magnetic Fe_3O_4-ZnO core–shell nanostructure has been developed by using a soft chemical approach. Fe_3O_4-ZnO core–shell is well characterized by various sophisticated characterization techniques such as X-ray diffraction (XRD), Transmission electron microscopy (TEM), X-ray photoelectron spectroscopy (XPS), UV-visible absorption, photoluminescent spectroscopy and physical properties measurement system (PPMS). X-ray diffraction (XRD) confirms the presence of both Fe_3O_4 and ZnO phases.XPS analysis confirms the magnetite phase of Fe_3O_4 nanodots in the core-shell structures. TEM micrograph clearly reveals that 5 nm Fe_3O_4 nanodots are well decorated with ZnO nanoparticles shell. This multi-functional approach will facilitate magnetic targeting and generation of reactive species under an external AC magnetic field, providing therapy a smart therapeutic agent for cancer. Fe_3O_4-ZnO core–shell conserves the intrinsic superparamagnetic behaviour of its constituent-Fe3O4with a magnetization value of ~ 36.5 emu/g. The aqueous colloidal stability, optimal magnetization, and good specific absorption rate (under external AC magnetic field) of Fe_3O_4-ZnO core–shell particles perform as an effective heating source for thermal therapy. Cytotoxicity studies exhibit the reduction of cellular viability for human cervical cancer cells (HeLa). Further, A combined effect of thermo-therapy and generation of reactive oxygen species under AC magnetic field results in a synergistic effect on the cancer cell death. Therefore, these results indicate that core–shell is sufficient materials for magnetic hyperthermia and bio-imaging.

In the field of nanomedicine, there is a strong interest for the development of smart nanoparticles that target specific cells, due to their therapeutic potential and biomedical applications. Iron nanowires (NWs) are biocompatible nanoparticles that can be manipulated wirelessly like nanorobots, and they can be coated with various biological agents. Studies suggest that these NWs can induce death in cancer cells by a magnetomechanical effect, where the nanowires are vibrated inside of the cells by a magnetic field (MF). The aim of this work is to functionalize iron NWs with CD44 antibodies, a cell surface marker that is highly expressed in acute myeloid leukemia (AML) cells compared to normal blood cells, in order to target these cells and develop new approaches for their treatment. Iron NWs with an average diameter of 40 nm and a length around 3μm were fabricated by electrochemical deposition into nanoporous alumina templates. They were coated with APTES in order to conjugate them with antibodies via a covalent bond between the carboxilic group on the antibodies and the amine group of the APTES using a commercial cross-linking component. To confirm the antibody maintained antigenicity after binding to the NWs, enzyme-linked immunosorbent assay, immunoprecipitation and Western blot were used. In addition, the cytotoxicity effects and the transcriptomic changes of both Antibody-NWs and bare iron NWs on AML cells in the presence and absence of a magnetic field were studied. The iron NWs functionalized with antibodies showed a high level of biocompatibility in the absence of a magnetic field. Antibody-NWs showed

an increase in the targeting efficiency compared to bare NWs, based on the Western blot assay. Cell death was induced as early as 10 min following the application of a MF to the cells incubated with Antibody-NWs. These results indicate the potential for the use of functionalized iron nanowires in the treatment of AML. We thank the King AbdulFAziz City for Science and Technology (KACST) General Directorate of Research Grants, Basic Research Grants Program, for financial support (grant 151F34FTA).

B2-09. Magnetic Nanoparticle Distribution in PNIPAM Microgels and the Magnetic Response. *M.U. Witt*[1], S. Hinrichs[2], M. Hermes[3], B. Fischer[2], A. Schmidt[3] and R. von Klitzing[1] *1. Solid State Physics, Technical University Darmstadt, Darmstadt, Germany; 2. Physical Chemistry, University of Hamburg, Hamburg, Germany; 3. Physical Chemestry, University of Cologne, Köln, Germany*

In the field of multifunctional microgels the variability of systems is large. Starting from the built-in of co-monomers to get a system that is sensitive to the pH, over the incubation of gold nanoparticles to use light as an external stimuli or using magnetic nanoparticles (MNP) to add a magnetic response [1]. The usage of Nanoparticles for triggering a response to external stimuli requires information about the internal structure of the microgel. Therefore it is of high interest to look at the distribution of BIS (corsslinker of the microgel). The usual prepared microgels are synthesized by the batch method published by Pelton et al. [2]. The second synthesis is the feeding method. The feeding method is a small variation of the synthesis published by Acciaro et al. [3] for homogenously crosslinked microgels. The microgels and the magnetic microgels are investigated with dynamic light scattering (DLS), atomic force microscopy (AFM), transmission electron microscopy (TEM) and Zetasizer. Beside the measurement of the microgel characteristics first measurements of the magnetic response of the magnetic microgels will be shown. The homogeneity of the crosslinker distribution is the key factor for a homogenous distribution of CoFeO4 nanoparticles inside the microgels. Offering a higher response of the magnetic microgel to an externally applied magnetic field than previous experiments have shown [1]. Two systems are compared, one with a structure close to be core/shell like and one with isotropic distribution of the MNP inside the microgels. The two magnetic microgels are shown in Fig.1 and Fig. 2. The gray value of the microgels is a measure for the crosslinker distribution inside the microgel. Beside a relative comparison between two microgels the TEM images show the magnetic nanoparticle distribution inside the microgel. The presented hybrid material offers future application as sensors and actuators and in drug delivery systems, using the magnetic nanoparticles as guidance and triggers.

B2-10. Fe_3O_4@Astragalus Polysaccharides Core-Shell Nanoparticles for Treating Iron Deficiency Anemia and Magnetic Resonance Imaging. K. Wang[1], *X. Xu*[1] and Y. Jiang[1] *1. School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing 100083, China*

Iron deficiency anemia (IDA) is a common nutritional disease in modern society. One billion people are suffering from IDA reported by World Health Organization. [1] The superparamagnetic Fe_3O_4 nanoparticles (NPs) can be used as an iron supplement for IDA treating and a magnetic resonance imaging (MRI) contrast agent candidates. [2] Unfortunately, the exposed Fe_3O_4 NPs have poor solubility and biocompatibility. Therefore, the surface of the Fe_3O_4 NPs needs to be suitably engineered to acquire improved biocompatibility. Astragalus polysaccharides (APS) is one of the main active components of Astragalus, a common traditional Chinese medicine, possess good biocompatibility and growth of red blood cells (RBC) stimulant. [3] Considering these features of APS and Fe_3O_4 NPs, it is reasonable to hypothesize that the Fe_3O_4@APS NPs should be a potential candidate for IDA therapeutic applications and MRI contrast agents. In this work, we report our study on the Fe_3O_4@APS NPs synthesized using a two steps approach involving hydrothermal synthesis and consequence esterification. As shown in Figure 1, Transmission electron microscopy (TEM) and Dynamic light scatting studies show that APS is attached on the surface of uniform dispersed Fe_3O_4 NPs. Cytotoxicity assessment in Hela cells proved the good biocompatibility and low toxicity of the Fe_3O_4@APS NPs. The Fe_3O_4@APS NPs was treated in rats for IDA and characterized by

MRI. As shown in Figure 2, the RBC of IDA treatment in rats take on good therapeutic effect with Fe_3O_4@APS NPs intragastric administration, which is contributed by both iron element supplement from Fe_3O_4 and the APS stimulated hematopoietic cells generation. The T_2 weighted image of mice demonstrates that the Fe_3O_4@APS NPs have a significant signal enhancement effect as a MRI contract agent. This study of Fe_3O_4@APS NPs presents a possibility to design functional nanocomposites using purified natural component from Chinese medicine for biologic applications.

B3-01. Quantization Effects in Novel Magnetic Nanobridge Based STT-MRAM Cell Driven by Gate-All-Around Vertical Select Nanowire Transistor. *G.D. Demin*[1,2], A.F. Popkov[1,2] and A.V. Popov[2] *1. Laboratory of Physics of Magnetic Heterostructures and spintronics for energy-efficiency information technologies, Moscow Institute of Physics and Technology (State University), Dolgoprudny, Russian Federation; 2. Laboratory of Research of nano- and microsystem devices, National Research University of Electronic Technology (MIET), Moscow, Russian Federation*

The magnetoresistive random-access memory technology, using the spin-transfer torque phenomena in magnetic heterostructures (STT-MRAM), can become a real alternative to existing semiconductor memory devices (both to embedded dynamic memory (DRAM) in mobile systems, and to static cache memory (SRAM) for microprocessors), which is due to its non-volatility, high speed and demonstrated potential for scaling down to 11 nm [1]. However, the prospects for further scaling and power consumption of STT-MRAM directly depend on the architecture of the memory device, where the key factor is the size of the select transistor, which, in turn, determines the drive current to write/read the logic state in magnetoresistive memory cell. More recently, a new design of high-density 3D STT-MRAMs with magnetic tunnel junctions (MTJ) based on array of gate-all-around (GAA) vertical silicon nanowire (VSN) transistors was proposed [2]. Theoretical analysis of this concept showed a nearly two-fold decrease in drive current compared to STT-MRAM based on planar MOSFETs, while maintaining a good write margin. It should be noted that reducing the transverse dimensions of conductive nanostructures in STT-MRAM to transverse dimensions less than 10 nm causes the appearance of quantization effects [3]. These effects can play an important role in the performance of STT-MRAM, where the conductance quantization in GAA VSN transistors occurs at deeply scaled technology nodes [Dasgupta2017], while the effect of quantum oscillations of spin-transfer torques in spin-valve-like magnetic nanobridges (Fig. 1), as storage elements for spintronic devices, which was considered previously in [5], may lead to the variation of threshold switching currents. In this work we analyzed these quantization effects on switching efficiency and performance parameters of magnetic nanobridge based STT-MRAM with GAA vertical select device. This study may be useful in the development of a new generation of high-density STT-MRAM, where it is important to take into account the quantum-mechanical dimensional effects that arise when scaling down to the 10 nm node and beyond.

B3-02. Reducing the switching current with a Dzyaloshinskii-Moriya interaction in nanomagnet with perpendicular anisotropy. S. Takamatsu[1], K. Yamada[2] and *Y. Nakatani*[1] *1. University of Electro-communications, Tokyo, Japan; 2. Gifu University, Gifu, Japan*

Reducing the switching current(I_{sw}) keeping the thermal stability in nanomagnets with perpendicular anisotropy are key factors in the development of STT-MRAM, which is expected to be a next generation nonvolatile memory[1][2]. In this paper, we investigated the effect of the Dzyaroshinskii-Moriya interaction (DMI) on the switching current and the thermal stability in nanomagnets[3-5]. It is expected that the magnetization structure and the swiching mechanism of nanomagnets will be changed by DMI, therefore not only the swiching current but also the thermal stability will be changed. We investigated the conditions to reduce the switching current keeping the thermal stability by DMI using micromagnetic simulations. In the simulation, a circular disk with 30 nm of the diameter and 2 nm of the thickness was used as the recording layer of STT-MRAM. The thermal stability factor (Δ) changes by the perpendicular anisotropy constant (K_u) and the DMI. We investigated the condition to keep $\Delta = 60$[6] by simulations. Figures 1 and 2 show the effect of the Gilbert damping constant, pulse width, and DMI on the normalized switching current density. I_{sw} decreased 50% in maximum with increasing DMI for small α or short pulse cases. The results are explained as follows. In the previous study, an empirical equation of I_{sw} was derived (Eq. 1) [6]; $I_{sw}=2eM_sV/\mu_B gP(\alpha\gamma 2K_u/M_s+C_1/t_p)$ (1) where, $C_1=[\ln\{(1-\cos\theta_c)/(1+\theta_c)\}-\ln\{(1-\cos\theta_i)/(1+\cos\theta_i)\}]$, θ_i is the initial magnetization angle with respect to the easy magnetization axis, and θ_c is the critical angle. The right side of Eq. 1 has two terms. It is necessary to increase

K_u as D is increased, therefore the first term increases. However, θ_i increases as D is increased, and then C_1 is decreased, therefore, the second term decreases. The first term is small for small α case, I_{sw} is determined mainly by the second term, therefore, I_{sw} decreases as D is increased. On the other hand, when α is large and t_p is long, the second term decreases, therefore, I_{sw} increases as D is increased.

B3-03. Perpendicular magnetic tunnel junctions using the ultrathin electrode of $D0_{22}$ or $L1_0$ MnGa and the effect of the Mn modifications.

K. Suzuki[1], Y. Miura[2], R. Ranjbar[1], L. Bainsla[3], A. Ono[1], Y. Sasaki[4] and S. Mizukami[1] *1. WPI-AIMR, Tohoku University, Sendai, Japan; 2. Electrical Engineering and Electronics, Kyoto Institute of Technology, Kyoto, Japan; 3. WPI AIMR, Tohoku University, Sendai, Japan; 4. Department of Applied Physics, Tohoku University, Sendai, Japan*

$L1_0$ and $D0_{22}$ ordered MnGa alloy films exhibit a large perpendicular magnetic anisotropy (PMA), a small saturation magnetization, and a low damping constant [1]. These properties are attractive for the spin-transfer-torque (STT) based spintronic devices. Recently we found that the B2-ordered CoGa is an excellent seed layer for the growth of ultra-thin films of $L1_0$ MnGa, and then we demonstrated the perpendicular magnetic tunnel junctions (p-MTJs) and spin-orbit toque magnetization switching [2-5]. Here we investigate the p-MTJs with the ultrathin electrode of Mn_xGa_{1-x} with different composition and the Mn modification to improve the tunnel magnetoresistance and PMA. The stacking structure of the p-MTJs is MgO(001) substrate/Cr(40)/CoGa(30)/Mn_xGa_{1-x}(1, 3)/Mn($t_{Mn=}$0, 0.8)/Mg(0.4)/MgO(2)/ CoFeB(1)/Ta(3)/ Ru(5) (thickness is in nm). The Mn concentration x were 0.5, 0.61, and 0.76, corresponding to the stoichiometric $L1_0$, off- stoichiometric $L1_0$, and the nearly stoichiometric $D0_{22}$ phase, respectively. The detail of growth process were found in Ref. [6]. Figure 1 shows the room temperature TMR curves with different composition of MnGa without Mn modification ($t_{Mn=}$ 0 nm). The MTJs with the $L1_0$-$Mn_{50}Ga_{50}$ electrode showed very small TMR of about 1% and small coercivity of 0.6 kOe. On the other hand, the MTJs of $D0_{22}$-$Mn_{76}Ga_{24}$ electrode showed higher TMR ratio, 13%, and larger coercivity, 13 kOe. Interestingly, the Mn modification showed futher enhanced TMR ratio. Figure 2 shows the room temperature TMR curves of the MTJs with the 1-nm-thick $L1_0$ $Mn_{61}Ga_{39}$ electrode with and without the Mn modification, $t_{Mn=}$0 and 0.8 nm, respectively. The enhancement of the TMR ratio up to 19.5% was clearly observed with the Mn modification, being larger than that in the MTJ with $D0_{22}$ Mn_3Ga electrode [6]. The MTJs with the MnGa electrode with other compositions also exhibited the similar enhancement. This work was partly supported by ImPACT and KAKENHI (16K14244, 17K14103).

B3-04. Optimization of half-Heusler PtMnSb alloy films for spintronic device applications. *Z. Wen*[1,2], T. Kubota[1,2] and K. Takanashi[1,2] *1. Center for Spintronics Research Network (CSRN), Tohoku University, Sendai, Japan; 2. Institute for Materials Research, Tohoku University, Sendai, Japan*

Half-Heusler compounds with the chemical formula of *XYZ* (where *X* and *Y* are transition metals, and *Z* is a *p*-block element) have attracted increasing attention as a class of novel materials for spintronics duo to their non-centrosymmetric structure and unique electronic band structures. [1-4] Among the half-Heusler compounds, a group of alloys was predicted to have half-metallic band structure. The half-metallic band structure can produce high spin polarization and is beneficial for magnetoresistance devices as well. Recently, current-perpendicular-to-plane giant magnetoresistance (CPP-GMR) devices with half-Heusler NiMnSb electrodes were reported and room-temperature CPP-GMR effect was observed. [5-8] The development of new half-Heusler alloys is required not only for magnetoresistance devices but also for spin-orbit-torque investigations. PtMnSb, as a kind of half-Heusler alloys, was reported to have a half-metallic band structure theoretically. [9] To date, spintronic devices using the half-Heusler PtMnSb compound were rarely reported. In this work, half-Heusler PtMnSb alloy films were fabricated by a dc magnetron co-sputtering method and optimized with varying deposition temperatures. The structural properties of PtMnSb films were characterized by x-ray diffraction. The surface structures of PtMnSb films were examined by *in-situ* observation of reflection high energy electron diffraction patterns. Magnetic properties were measured by a vibrating sample magnetometer. An epitaxial growth was achieved for the PtMnSb films deposited at 200 °C. Furthermore, CPP-GMR devices as a kind of spintronic devices were fabricated with the structure of PtMnSb/ Ag/PtMnSb. Room-temperature CPP-GMR effect was firstly observed in the PtMnSb-based CPP-GMR devices. Also, in comparison with other half-metallic Heusler alloys, a large anisotropic magnetoresistance ratio with negative sign was observed in the PtMnSb films, which could be attributed to high spin-orbit interactions in the PtMnSb films owing to Pt. This work was partially supported by the KAKENHI (No. 25220910, No. 17K14652) from the Japan Society for the Promotion of Science (JSPS), and the Advanced Storage Research Consortium (ASRC).

B3-05. Bias Dependence of Magnetoresistance in MTJ Containing Ferromagnetic Insulator. K. Sate[1], S. Honda[1,2], Y. Kayama[3], Y. Sonobe[3] and *H. Itoh*[1,2] *1. Department of Pure and Applied Physics, Kansai University, Suita, Japan; 2. Center for Spintronics Research Network, Osaka University, Toyonaka, Japan; 3. Samsung R&D Institute Japan, Yokohama, Japan*

Magnetic tunnel junctions (MTJ's) containing a ferromagnetic insulator attract much attention because of the potential application for STT-MRAM. The Joule heating generated at the insulator is expected to reduce the coercive force and then to lower the current needed for the magnetization reversal. Also a large magnetoresistance (MR) is expected in the MTJ due to the spin-filter effect [1]. We have shown in our previous work [2] that a large MR is obtained at the zero bias limit for an epitaxial MTJ of FM electrode/ NM spacer/ FI barrier/ NM electrode, where FM, FI, and NM are ferromagnetic metal, ferromagnetic insulator, and nonmagnetic metal, respectively. In this work, we clarify how the MR depends on the bias in the MTJ. We calculate spin-dependent electrical currents under a finite-bias for a one-dimensional free electron model which potential profile is shown in Fig. 1. The transfer matrix method and the Landauer formula are used to calculate the currents for both parallel (P) and antiparallel (AP) configurations of the magnetizations between FM and FI. The MR ratio is estimated by the currents using the definition given in Fig. 1. In Fig. 1, it is shown that the MR ratio at the zero bias limit oscillates with respect to the NM spacer thickness. The oscillation is due to the quantum well formed at the NM spacer. The bias dependence of the MR ratio is shown in Fig. 2 for several NM spacer thicknesses which are denoted in Fig. 1 by A, B, C, and D. The MR ratio of A (solid curve) is almost independent of the bias whereas the others depend on. This result indicates that the bias dependence of the MR ratio can be suppressed by optimizing the NM spacer thickness.

B4-01. Thermal contribution to the Spin-Torque-Diode Sensitivity Induced by the Tunnel Magneto-Seebeck Effect in Magnetic Tunnel Junctions. *G.D. Demin*[1,2] *1. Laboratory of Physics of Magnetic Heterostructures and spintronics for energy-efficiency information technologies, Moscow Institute of Physics and Technology (State University), Moscow, Zelenograd, Russian Federation; 2. Laboratory of Research of nano- and microsystem devices, National Research University of Electronic Technology (MIET), Moscow, Russian Federation*

Currently, one of the most promising magnetoresistive devices for a new generation of microwave holographic systems and computer vision is the microwave detector based on the spin-transfer torque diode effect in magnetic tunnel junctions (MTJ), demonstrating microwave characteristics that outperforming the limiting capabilities of semiconductor Schottky diodes [1]. The key problem for its practical implementation is the difficulty of achieving high sensitivity of such a spin-torque diode at high frequencies, which requires finding new ways to meet this challenge. In our previous studies, we carried out a detailed theoretical analysis of the possible methods of spin-torque diode frequency tuning and increasing its microwave sensitivity by varying the bias current and via soft exchange pinning of both magnetic layers in MTJ in the absence of magnetic field [2, 3]. However, time-varying temperature gradient in MTJ, resulting from the thermal heating of the tunnel structure by alternating current, can create an additional contribution to the volt-watt sensitivity of the spin-torque diode. This is connected with the tunnel magneto-Seebeck effect and the thermal-induced spin current into a free magnetic layer [4, 5] and was not considered before. In this work we performed a three-dimensional finite-element modelling of the thermal emission in real MgO-barrier MTJs under the microwave irradiation (Fig. 1), on the basis of which the variable components of thermal spin-transfer torques were calculated and the thermal contribution to the spin-torque-diode sensitivity associated with them was determined. It also was shown that for certain magnetic and geometric parameters of the MTJ the impact of the thermoelectric effects becomes comparable with the impact of the current-induced spin-transfer torque effects on the microwave sensitivity of the spin diode. The results obtained can play an important role in the development of new types of spin-torque diode based on magnetic tunnel junctions and microwave spin-caloritronics devices [6].

B4-02. Dephasing assisted spin transport. *S. Borlenghi*[1], S. Iubini[2] and A. Delin[1] *1. Department of materials and nano-physics, KTH Royal Institute of Technology, Stockholm, Sweden; 2. Dipartimento di Fisica e Astronomia, Università di Firenze, Florence, Italy*

A decade ago, it has been shown that transport in quantum dissipative systems can be enhanced by the presence of dephasing noise [1]. This counter-intuitive phenomenon occurs in disordered systems, where different local frequencies suppress coherent transport, and a certain level of dephasing can broaden the resonance lines of neighbouring sites, allowing for the population transfer. This effect appeared as a general feature of quantum systems, that can be described using the language of (Markovian or not) quantum master equations. This discovery fostered an intense research activity that aimed at understanding and exploiting dephasing in a variety of systems, including quantum dots [2], optical fibers [3], photosynthetic reactions [4] and other biological systems [5]. In this talk, we show that dephasing assisted spin transport, due to magnon propagation, occurs in a chain of classical spins described by the Landau-Lifshitz-Gilbert (LLG) equation. The effect can be described using the language of the non-equilibrium discrete nonlinear Schrödinger equation (DNLS) [6] that constitutes an approximation of the LLG equation for small amplitude deviations of the spins from their equilibrium position [7]. The DNLS is a very general oscillator model, suggesting that this result can be found in a large class of both quantum and classical systems, and can be exploited in magnetic nanodevices for spin caloritronics and energy harvesting.

Recently the formation of magnon Bose-Einstein Condensates (BEC) in extended films attracted large attention [1,2]. In previous studies the conditions for the formation of the BEC are artificially created by parametric pumping [3]. Here we present a fundamentally new approach. Fast DC current pulses applied to yttrium-iron-garnet (YIG)/Pt microstructures (see Fig.1) result in a strong heating. Consequently, this leads to an increased number of magnons, distributed over the whole spectrum. Once the current is switched off, the locally heated, micro-sized system cools down rapidly. Hence, the magnon and the phonon system are driven out of equilibrium, which results in a redistribution of high frequency magnons to the bottom of the spin-wave spectrum due to four-magnon scattering processes and damping. A strong increase of the magnon density at the bottom of the spectrum is observed using time-resolved Brillouin light scattering microscopy (see Fig. 2). A theoretical model is developed, which describes the redistribution of magnons. This results in an increase of the chemical potential up to the bottom of the spin-wave band. Our experiment shows, that the BEC formation depends on the magnon temperature and the timescale of the cooling process. This research has been supported by ERC Starting Grant 678309 MagnonCircuits, ERC Advanced Grant 694709 Super-Magnonics and DFG Grant DU 1427/2-1.

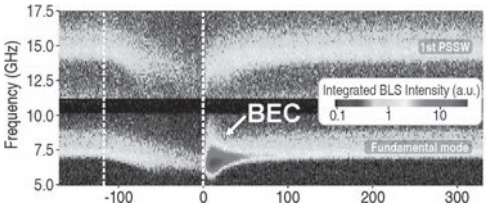

Fig. 2. Time resolved BLS spectrum, the fundamental mode at a frequency of 7.5 GHz and the first perpendicular standing spin wave at a frequency of 15.0 GHz are shown. The dashed white lines indicate the time, when the DC pulse is present. The BEC formation can be observed after the pulse is switched OFF.

B4-04. Observation of Longitudinal Spin Seebeck Voltage in Chemically Synthesized $Y_3Fe_5O_{12}$ Films.
K. Yamada[1], Y. Kurokawa[2], K. Kogiso[1], H. Yuasa[2] and M. Shima[1] *1. Department of Chemistry and Biomolecular Science, Faculty of Engineering, Gifu University, Gifu City, Japan; 2. Graduate School and Faculty of Information Science and Electrnical Engineering, Kyushu University, Fukuoka, Japan*

The thermoelectric conversion element using the spin Seebeck effect (SSE) has attracted attentions not only physical properties but also industrially as it has a simple structure [1-3]. Many studies using $Y_3Fe_5O_{12}$ (YIG), which is a magnetic insulator, have been reported as material used for SSE measurements. Since YIG is a material with high Curie temperature and insulation property, and magnons propagate over long distances, it is a material suitable for SSE observation. SSE measurements using YIG are often measured on bulk sintered bodies and on thin film samples prepared by physical vapor phase method, in addition, SSE has also observed by the metal–organic decomposition (MOD) method which is a simple process such as coating process [3]. In this paper, we have investigated the observation of the SSE voltage in YIG thin films on SiO_2 substrate made by sol-gel method which is one of the simple methods for making the thin films. The YIG thin films were synthesized by co-precipitation and subsequent spin-coating process, and by annealing at 1123 K for 1 hour in air. A 5 nm Pt metal was sputtered on the YIG thin films. A temperature difference ΔT was applied between the top of the samples (Pt side) and the bottom of the SiO_2 substrate (Longitudinal SEE), and the voltages induced by SSE were measured. Figs. 1 and 2 show the dependence of the SSE induced voltage V_{SSE} on the external magnetic field for ΔT = -11.2, -5.8, 0.1, 6.2 and 12.3 K, and the result of summarizing the dependence of the saturation V_{SSE}^{Sat} on the temperature differences, respectively. The V_{SSE}^{Sat} monotonically increases as the temperature difference increases. This result indicates that it is able to observe the voltage induced by SSE in the YIG thin film made by the sol-gel method. It is also found that the V_{SSE} is almost equivalent to that generated by bulk YIG or other methods.

B4-07. Scaling Of The Spin Seebeck Effect In Bulk And Thin Films.
K. Morrison[1], *C. Cox*[1] and A. Caruana[2] *1. Physics, Loughborough University, Loughborough, United Kingdom; 2. ISIS Neutron Source, STFC Rutherford Appleton Laboratory, Didcot, United Kingdom*

It was recently demonstrated that a thermal gradient applied across a magnetic material can result in the generation of a spin polarised current: the spin Seebeck effect (SSE) [1]. This is observed indirectly by placing a heavy metal such as Pt in direct contact with the magnetic material such that a voltage, V_{ISHE}, is generated by the inverse spin Hall effect. One application of this effect is waste heat harvesting technologies (thermoelectrics) [2]. For conventional thermoelectrics, the figure of merit, zT, has proven especially useful as a single parameter to assess the efficiency of potential materials. For example, it allows engineers to separately assess thermal expansion matching and efficiency of operation when choosing materials for the p- and n- type pillars of a typical Peltier cell. So far, however, there is no such single measurement for spin Seebeck based thermoelectrics. Overall, there are a myriad of variables that affect the magnitude of the observed voltage in a spin Seebeck measurement. This includes, but is not limited to: the thickness of the magnetic material; the thickness of the Pt detection layer; the contact separation; the thermal conductivities of the layers; the spin diffusion length, spin Hall angle and spin mixing conductance; and the roughness of the interface. If we are to start comparing spin Seebeck measurements we need to find a standard measurement (and normalisation) procedure. Here we will present results from measurement of the spin Seebeck effect in bulk and thin film, where we demonstrate the importance of the heat flow for normalisation of SSE measurements. Finally, we will discuss the surprising result that the voltage, V_{ISHE}, is scaled not just by the contact separation and device thickness, but the area (of the device) as well.[4]

B4-09. Spin Seebeck Effect and Anisotropy in Magnetic Oxides.
V. Kalappattil[1], R. Das[1], M. Phan[1] and *H. Srikanth*[1] *1. Department of Physics, University of South Florida, Tampa, FL, United States*

Spin caloritronics based on the spin Seebeck effect (SSE) has emerged as an important area with potential impact on advanced spintronics, thermoelectric devices and waste heat recovery for power generation [1-3]. Ferrimagnetic insulator $Y_3Fe_5O_{12}$ (YIG) is one of the most widely used material for observation of the SSE because of its extremely low Gilbert damping and absence of conventional Seebeck and Nernst effects. Even though the SSE has been reported in various materials, the generated voltage is very small for technological applications. Moreover, the temperature dependence of SSE, its relationship with the magnetic anisotropy (H_K) and the interface between the ferromagnetic oxides (FM) and nonmagnetic metals (NM) have remained unexplored. A clear understanding of the temperature evolution of the longitudinal spin Seebeck effect (LSSE) in the classic Pt/YIG system and its association with magnetic anisotropy is essential towards optimization of its spin-caloric functionality for spintronics applications. We present systematic studies on YIG and demonstrate the influence of in-plane and out-of-plane magnetic anisotropy as well as switching on the LSSE in this material [3, 4]. We demonstrated that introduction of intermediate C_{60} organic layer of optimal thickness (~5 nm) dramatically enhances the SSE voltage. This enhancement is attributed to improved spin mixing conductance at the YIG/C_{60}/Pt interface and the large spin diffusion length of C_{60} [5]. We also showed a correlation of surface anisotropy and SSE on the temperature evolution of spin Hall magnetoresistance (SMR). Our study paves a new pathway for the design of novel spin-caloric materials for advanced spintronics applications.

Tohoku University, Sendai, Japan

B5-01. Improvement of reproducibility of magnetic moment detected by a SQUID magnetometer and radial offset measurement using a YIG sphere. *N. Matsumoto*[1], C. Dennis[2] and R.D. Shull[2] *1. National Metrology Institute of Japan (NMIJ), National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; 2. Materials Science and Engineering Division, Material Measurement Laboratory, National Institute of Standards and Technology (NIST), Gaithersburg, MD, United States*

We report here the reproducibility of measurements on a commercial SQUID Magnetometer (Quantum Design, MPMS) of two different yttrium iron garnet (YIG) spheres, both having a diameter of 1 mm: (1) the NIST magnetic moment standard reference material (SRM) and (2) a commercial sample. The YIG sphere was chosen because it has the smallest size among the magnetic moment SRMs, and therefore is the closest approximation to a point dipole. In an author's previous work,[1] the SRM was repeatedly measured with the SQUID for calibrating the equipment. However, reproducibility of the measured values by the SQUID was not good, as shown in Fig. 1, and its relative standard deviation was 0.9%. Kiss, et al.[2] suggested that rotating the sample rod around its axis can move the sample center towards the center of the second-gradiometer coil. Other researchers[3] calculated that the observed value of the magnetic moment will be a minimum when the radial offset is zero and that this value will increase in a "quadratic" manner with the radial offset. When the magnetic moment of the SRM YIG sphere was repeatedly measured as a function of rotation angle ϕ from 0° to 360°, we observed a sinusoidal variation in the measured values. The radial offset dependence of the observed magnetic moment was experimentally confirmed by measurements of the commercial YIG sphere placed in a hole in several cylindrical PTFE containers inside a quartz tube, wherein the distance between the center of the hole and the center of the container was *r*. The *r* dependence of the minimum from each ϕ dependent measurement series is qualitatively consistent with the theoretical curve. When the ϕ dependent measurements for the SRM in a capsule inside a plastic drinking straw were repeated 12 times as shown in Fig. 2, the relative standard deviation of the minimums improved up to 0.1%. Knowledge of these facts will be necessary for an accurate measurement of the magnetic moment of other sample forms.

B5-03. Using the Standard Linear Ramps of the CMS Superconducting Magnet for Measuring the Magnetic Flux Density in the Steel Flux Return Yoke. *V. Klyukhin*[1,2], B. Curé[2], N. Amapane[3], A. Ball[2], A. Gaddi[2], H. Gerwig[2], A. Hervé[4], R. Loveless[4] and M. Mulders[2] *1. Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russian Federation; 2. CERN, Geneva 23, Switzerland; 3. INFN Turin and University of Turin, Turin, Italy; 4. University of Wisconsin, Madison, WI, United States*

The principal difficulty in large magnetic systems those have an extensive flux return yoke [1,2] is to characterize the magnetic flux distribution in the yoke steel blocks. Continuous measurements of the magnetic flux density in the return yoke are not possible and the usual practice uses software modelling of the magnetic system with special three-dimensional (3-D) computer programs [3,4]. The 10,000-tonne flux return yoke of the Compact Muon Solenoid (CMS) magnet encloses a 3.8 T superconducting solenoid with a 6-m-diameter by 12.5-m-length free bore and consists of five dodecagonal three-layered barrel wheels around the coil and four endcap disks at each end. The yoke steel blocks, up to 620 mm thick, serve as the absorber plates of the muon detection system. A TOSCA 3-D model of the CMS magnet has been developed to describe the magnetic field outside of the solenoid volume, which was measured with a field-mapping machine. To verify the magnetic flux distribution calculated in the yoke steel blocks, direct measurements of the magnetic flux density with 22 flux loops installed in selected regions of the yoke were performed during the CMS magnet test in 2006 when four "fast" discharges of the CMS coil (190 s time-constant) were triggered manually to test the magnet protection system [5,6]. No fast discharge of the CMS magnet from its operational current of 18.2 kA, which corresponds to a central magnetic flux density of 3.8 T, has been performed that time. For the first time, in this paper we present measurements of the magnetic flux density in the steel blocks of the return yoke based on the several standard linear discharges of the CMS magnet from the operational magnet current of 18.2 kA. To provide these measurements, the voltages induced in the flux loops (with amplitudes of 20–250 mV) have been measured with six 16-bit DAQ modules and integrated offline over time [7]. The results of the measurements during magnet linear ramps performed with a current rate as low as 1–1.5 A/s are presented and discussed.

B5-04. Experimental study of the double perovskite $Sr_{2-x}La_xFeMoO_6$ compound. *B. Aguilar Reyes*[1], T. Soto Guzmán[1,5], O. Navarro Chavez[1] and J. de la Torre Medina[1] *1. Unidad Morelia Instituto de Investigaciones en Materiales, Universidad Nacional Autónoma de México, Morelia, Mexico; 5. Facultad de Ciencias Físico Matemáticas, Universidad Michoacana de San Nicolás de Hidalgo, Morelia, Mexico*

The double perovskite Sr_2FeMoO_6, is characterized by its colossal magnetoresistance, its fairly high Curie temperature (T_C ~ 410°C) and its potential applications in spintronics. The Sr ions can be partially substituted for trivalent cations, such as La, leading to non-stoichiometric $Sr_{2-x}La_xFeMoO_6$ series. This system was investigated to determine the Tc when the number of electrons per formula in the conduction band increases. The doped system was prepared by sol-gel method, with x taking values of: 0, 0.25, 0.5, 0.75 and 1.0. The thermogravimetric analysis shows a gradual increase of T_C; nevertheless the disorder induced in Fe-Mo sites decreases the magnetization. The disorder promoted preserves the neutral total charge per formula. The tetragonal crystalline structure was determined by X-ray diffraction and the microstructure was analyzed by scanning electron microscopy. Keywords: Spintronics, double perovskite, sol-gel.

B5-05. Microstructures of MnBi obtained by quenching in magnetic fields up to19 T. *R. Kobayashi*[1], M. Yamashita[1], D. Miyazaki[1], Y. Mitsui[1], K. Takahashi[2], S. Uda[2] and K. Koyama[1] *1. Kagoshima University, Kagoshima, Japan; 2. Tohoku University, Sendi, Japan*

Quenching technique is important for the obtaining the target phase of the materials. For materials processing under magnetic fields, it is important for investigating the magnetic field effects on microstructure and phase characterization for quenched sample. So far, Garcin *et al.* developed a quenching furnace in 16 T [1]. The reported cooling rate was ~200 K/s from 1173 K to 300 K. However this furnace need to install to cryogen-free superconducting magnet (CSM) with a 120 mm room temperature bore. Recently, we developed a compact furnace utilized for the conventional CSM with a 50 mm room temperature bore [2]. The reported maximum cooling rate was ~40 K/s from 643 K to 400 K under 15 T [2]. For the in-field annealing at higher temperature, radiation heat to CSM should be improved. In this study, we improved cooling jacket of our in-field quenching furnace, which can be used in high magnetic fields up to 19 T. In this system, in-field quenching from 700 K was succeeded. For evaluation of the apparatus, in-field annealing on MnBi was performed. The peritectic temperatures between MnBi and $Mn_{1.08}Bi$ + liquid was increased by applying magnetic field [3]. On the other hand, unique anisotropic microstructure is expected because of large uniaxial magnetic anisotropy [4]. MnBi samples were prepared by arc melting or reactive sintering. The condition of in-field annealing was performed at the temperature up to 700 K for 6 h. The maximum annealing temperature was above peritectic temperature of MnBi under magnetic field. Fig. 1 shows time dependence of sample temperature from 663 K. The cooling rate was evaluated to be 32 K/s, which was almost same as previous study [2]. Fig. 2 shows the microstructure of Bi-Mn obtained by in-field quenching in 19 T from 663 K. As seen in bottom edge of the sample, MnBi phase elongated and aligned along the magnetic field direction, indicating the anisotropic crystal growth. In the presentation, magnetic field effects on the peritectic reaction and the morphology will be discussed.

B5-06. Magnetic Property Modeling of Nanocrystalline Under DC-Biased Condtion. Y. Li[1], *H. Sun*[1], C. Zhang[1] and S. Yue[1] *1. Hebei University of Technology, Tianjin, 300130, China*

High frequency and miniaturization have become the development trend of electric power equipment. However, the core loss of the electric power equipment is difficult to predict and has not been completely solved, especially in the presence of DC bias. In this paper, the magnetic property of nanocrystalline FT-3KS under DC bias are measured. The hysteresis loops under different DC bias are determined using a novel approach and the corresponding core loss is calculated. Using the Steinmetz premagnetization graph (SPG), the dependence of the Steinmetz parameter (α, β, ki) on the premagnetization is shown. The experimental measurement are compared with the calculation results through SPG, which verifies the accuracy of SPG. The phenomenon of DC bias is an abnormal working condition of the power equipment. Under DC bias, the core may be deeply saturated. The exciting current and core loss of equipment increase significantly. Therefore, analyzing magnetic property of nanocrystalline under DC bias is of great significance. The experimental device is shown in Fig. 1. The DC magnetization curve of the material is approximated by Bm-Hb (Bm refers to the maximum value of the AC flux density and Hb refers to the corresponding H when the B_m reaches the maximum). The true flux density in the core is obtained by adding a DC flux density to the AC flux density. Fig. 2 shows the exciting waveforms and corresponding hysteresis loop. The Steinmetz parameters must be adjusted according to the experimental results under DC bias. DC bias can causes change in the Steinmetz parameters β and ki, but not in the parameter α. In this paper, the magnetic hysteresis loop of nanocrystalline under different DC bias is illustrated and the core loss curve is obtained. This is significant for the electromagnetic analysis and loss calculation of nanocrystalline under DC bias.

B5-07. Design, Modeling, and Construction of an H-Shaped Dipole Electromagnet for Magnetic Materials Characterization. *J. Baena*[1] *1. Grupo Electromagnetismo Aplicado, Departamento de Ciencias Físicas, Universidad EAFIT., Medellín, Colombia*

The magnetic materials properties measurement gives the potential application in multiples technologies and industries. Examining the magnetic material characterization under an intense, variable magnetic flux density is essential which allow analyzing hysteresis curves of the materials. In this paper, we propose a novel H-Shaped dipole electromagnet. The improved design relates efficient power consumption regarding input power per ratio of magnetic flux density and weight. The biaxial measurement emphasis was in an air-gap two-dimensional shape, which is 400mm2 of square cross-section and 10mm length. Seeking homogeneity and intensity, we implement a current control applied to power coils, archiving 2T with a flux/weight ratio per input power higher than $4.5x10^{-5}$T/(kgW). Reliable results are conducting in Fig.1. with the evidence of total curve reversibility, 99% linear correlation coefficient and absence of hysteresis effect throughout the characterization range. Using a FEM -magnetostatic analysis, Fig.2 shows the magnetic flux density and the distribution of the magnetic field lines were visualized and quantified. The dipolar electromagnet is composed of a yoke steel straight parallelepiped with rounded inner edges [4], which provides self–shielding for minimizing magnetic flux density losses [5]. Two steel dipoles attached to yoke with 0.08% carbon. Two reels of a non-magnetic material and thermal conductivity exceeding 209 W/mK, and two power coils wound on the reels, which are operationally arranged in the dipoles [6]. The magnetic field reached through the column was uniform according to the pole material used, with the option to increase a magnetic field choosing a suitable cap geometry, and introducing a cooling system around the coils with a proper air-gap adjustment. These specifications convert the device a versatile and scalable tool to generate a magnetic flux density necessary to perform magnetic characterization of materials.

B5-08. The Permeability of Vacuum and the Revised International System of Units. *R. Goldfarb*[1] *1. NIST, Boulder, CO, United States*

The International System of Units (SI) is expected to be revised such that all seven base units, including the kilogram, will be defined in terms of fixed numerical values of seven defining constants. The revised SI will include a redefinition of the ampere. One consequence is that the permeability of vacuum will not have a fixed numerical value but will become, in principle, a measurable quantity. The constitutive relation among magnetic flux density, magnetic field strength, and magnetization will not change. However, its expression in the centimeter-gram-second system of electromagnetic units (EMU), where the permeability of vacuum is unity, will no longer be ontologically equivalent, and quantities will not be exactly convertible to the SI. Already contrary to international convention, the still common EMU system will become obsolete.

Chemical and Engineering Materials Division, Oak Ridge National Laboratory, Oak Ridge, TN, United States*

The improper ferroelectricity in $YMnO_3$ and other related multiferroic hexagonal manganites are known to cause topologically protected ferroelectric domains that give rise to rich and diverse physical phenomena [1,2]. The local structure and structural coherence across the ferroelectric transition, however, are not well understood [3]. Here we reveal the evolution of the local structure in $YMnO_3$ using a combination of neutron total scattering and first-principles calculations [4]. The results show that, at room temperature, the local and average structures are consistent with the established ferroelectric ground state structure. On heating, both local and average structural analyses show striking anomalies consistent with increasing fluctuations of the order parameter angle from ~ 800 K up to the Curie temperature. These fluctuations result in an unusual local symmetry lowering into a *continuum of structures* on heating which coincides well with reported temperatures for which the observable polarization vanishes. This local symmetry breaking persists into the high-symmetry non-polar phase, constituting an unconventional type of order-disorder transition.

B6-02. Designing a majority gate using chiral magnetic solitons. *D. Yudin*[1], M. Pereiro[2], K. Koumpouras[3], O. Eriksson[4], A. Bergman[5] and C. Adelmann[6] *1. ITMO University, Saint Petersburg, Russian Federation; 2. Physics and Astronomy, Uppsala University, Uppsala, Sweden; 3. Lulea University of Technology, Lulea, Sweden; 4. Physics and Astronomy, Uppsala University, Uppsala, Sweden; 5. Dept. of Physics and Astronomy, Uppsala University, Uppsala, Sweden; 6. UPM, Imec, Leuven, Belgium*

A variety of magnetic interactions in magnetic materials results in the emergence of nontrivial spin textures. In particular, chiral magnetic solitons represent topologically protected spin configurations with particle-like properties. Based on atomistic spin dynamics simulations, we demonstrate that these magnetic configurations are ideal to use for logical operations, and we demonstrate the functionality of a three-input majority gate, in which the input states can be controlled by applying an external electromagnetic field or spin-polarized currents. One of the main advantages of the proposed device is that the input and output signals are encoded in the chirality of solitons, that may be moved, allowing to perform logical operations using only minute electric currents. We illustrate how the three-input majority gate can be used to perform logical relations, such as Boolean AND and OR.

B6-03. Magnetic Flux Leakage Testing of Wire Rope Defects with Instantaneous Phase Solution and Wavelet Analysis. *E. Zhang*[1], D. Zhang[1] and S. Pan[1] *1. Harbin Institute. of Technology, Shenzhen, Shenzhen, China*

Magnetic flux leakage(MFL) testing are widely used for wire rope inspection to assure its integrity and safe operation. The amplitude of strand-wave-

form magnetic signal that caused by the special helical structure of wire rope is larger than the amplitude of the defect signal. It is the main noise in MFL image processing.. In the literatures, the method of eliminating the strand-waveform noise of wire rope has the adaptive spatial notch filter and the gradient method. For a wire rope with certain structure, the axial strand-waveform comes on as a sine wave with a stable frequency approximately. So a spatial notch filter with the notch frequency equals to this frequency can eliminate the strand-waveform easily. The disadvantage of this method is that it is necessary to compute the maximum value frequency of the Fourier transform for each data of the hall sensor. The frequency of the strand-waveform is not a fixed value. It cannot completely eliminate the strand-waveform noise. The defect signal contains a part of the frequency component of the strand-waveform noise. Eliminating the strand-waveform noise will reduce the defect signal. The angle of the directional textures is almost constant in the MFL image, so a linear spatial filter is applied to the MFL image with the particular gradient matrix. The disadvantage of this method is that the corresponding gradient matrix is established by resampling the data and determining the rotation angle. This method eliminates the strand-waveform noise through different sensor data. Because there is inevitable difference between different sensor data, this method cannot eliminate the strand-waveform noise completely. In this paper, a new method is proposed to eliminate the strand-waveform noise by using the instantaneous phase solution in Hilbert transform. According to the phase continuity of the strand-waveform signal in axial and circumferential direction, the noise is eliminated in the condition of minimizing the defect information. The defects are accurately located by the wavelet analysis.

B6-04. Thermal stability and topological protection of skyrmions in nanotracks. *D.I. Cortés-Ortuño*[1], W. Wang[2], M. Beg[3], R.A. Pepper[1], M. Bisotti[1], R. Carey[1], M. Vousden[1], T. Kluyver[1], O. Hovorka[1] and H. Fangohr[3,1] *1. Faculty of Engineering and the Environment, University of Southampton, Southampton, United Kingdom; 2. Department of physics, Ningbo university, Ningbo, China; 3. European XFEL GmbH, Schenefeld, Germany*

Magnetic skyrmions are hailed as a potential technology for data storage and other data processing devices [1]. However, their stability against thermal fluctuations is an open question that must be answered before skyrmion-based devices can be designed. In this work [2], we study paths in the energy landscape via which the transition between the skyrmion and the uniform state can occur in interfacial Dzyaloshinskii-Moriya finite-sized systems. Our calculations of energy paths and corresponding energy barriers are based on the Geodesic Nudged Elastic Band Method [3]. We find three mechanisms the system can take in the process of skyrmion nucleation or destruction and identify that the transition facilitated by the boundary has a significantly lower energy barrier than the other energy paths (see Figure). This clearly demonstrates the lack of the skyrmion topological protection in finite-sized magnetic systems. Overall, the energy barriers of the system under investigation are too small for storage applications at room temperature, but research into device materials, geometry and design may be able to address this. This work has been funded by the CONICYT Chilean scholarship programme Becas Chile (72140061), EPSRC's Centres for Doctoral Training in Next Generation Computational Modelling (EP/L015382/1) and Complex Systems Simulations (EP/G03690X/1), the EPSRC's Programme grant on Skyrmionics (EP/N032128/1).

Annihilation of an isolated skyrmion through the boundary of the nanotrack. The curve refers to the energy band from the GNEBM, where the data point at the left extreme of the band is the skyrmion configuration and the right extreme is the ferromagnetic ordering (no skyrmion). Between these equilibrium states are copies of the system in different magnetic configurations that define the energy path (skyrmion escape). The energy scale of the band is scaled with respect to the skyrmion energy. Snapshots of every point in the energy band are shown at the top of the figure.

B6-05. On Hysterisis Based Random Number Generation. *I. Mayergoyz*[2] and C.E. Korman[1] *1. Electrical and Computer Engineering, The George Washington University, Washington, DC, United States; 2. ECE Department, University of Maryland, College Park, MD, United States*

Random number generation has many important applications, examples of which include cryptography, Monte Carlo simulations, statistical sampling and gambling. For these reasons, random number generation is a standard software (or hardware) component of modern computers. In the talk, we shall discuss a new hysteresis based technique for random number generation which can be efficiently implemented by using modern spintronics based nano-technology. The central idea of this random number generation is the utilization of random switching of rectangular hysteresis loop. This approach naturally leads to the generation of random binary numbers. Mathematically, this random switching can be treated as a repeated sequence of two exit problems for stationary stochastic processes. These exit problems can be reduced to the solution of initial boundary value problems for the appropriate backward Kolmogorov equations. The analytical solution of these boundary value problems can be carried out for the Ornstein-Uhlenbeck process which is the only stationary Gaussian Markov process. The latter is relevant for the development of stationary techniques for random number generation. Another (alternative) approach to the analysis of the above random switching based on stochastic processes on graphs will be discussed in the talk as well. In the discussion, special attention will be

paid to the trade-offs between the strength of thermal noise which drives the random switching of rectangular hysteresis loops and the widths of these loops which is usually controlled by magnetic anisotropy of nano-magnetic hysteretic elements. Furthermore, the effect of the sampling rate on the stationary distribution of randomly generated binary numbers will be investigated as well. At nano-scale, rectangular hysteresis loop can be realized by using standard nano-magnetic elements. For this reason, it is conceivable that hysteresis based random number generation may find many important applications in future spintronics based computer systems.

B6-06. Low Voltage Tunable Ferrite Phase Shifter. *H. Izadkhah*[1], F. Lombardi[1] and C. Vittoria[1] *1. Electrical Engineering, Northeastern University, Boston, MA, United States*

Microwave phase shifters have their most significant role in phase array antenna. In typical ferrites devices, the DC bias field aligns the static magnetization along a preferred direction. In devices such as phase shifters, tunable resonators, and filters, by changing the strength of the bias field, the interaction frequency between the microwave signal and magnetic dipoles can be controlled. DC bias field can be generated by permanent magnets or driven coils. Permanent magnets have tunability problems. On the other hand, using large electromagnets to generate a strong enough field is an impediment to miniaturize these devices. Recent progress to synthesize and fabricate magnetoelectric (ME) material with high ME coupling at room temperature [1], however, increased the hope to find a solution for the tunability of microwave devices such as phase shifters. We have both analytically and experimentally investigated the tunability of coplanar waveguide phase shifters fabricated on ferrite thin film for application in 1-10 GHz. The result demonstrates ≈20 degrees of phase shift is achieved with the application of 2V. We also found that the direction of this shift is controllable with the application of negative voltage and this change is linear as the magnetoelectric is also linear.

B6-07. Analysis of the Magnetization Effect of Permanent Magnets on the Nonlinear Magnetic Characteristic Distributions of a Balanced Armature Receiver. *D. Xu*[1], Y. Jiang[2] and S. Hwang[2] *1. School of Mechatronics Engineering and Automation, Shanghai University, Shanghai, China; 2. Mechanical Engineering, Pusan National University, Busan, The Republic of Korea*

The balanced armature (BA) receivers are widely used in hearing aid, earphone and wearable devices. As shown in Fig.1, a BA receiver integrates an electromagnetic system, a mechanical system, and an acoustic system. The magnetic circuit has an armature, a voice coil, two permanent magnets (PMs), and a magnet housing. The mechanical vibration system has a drive pin, a center diaphragm, a side diaphragm, and an armature. The armature is the shared part of the magnetic circuit and the vibration system and causes an electromagnetic- mechanical coupling between electromagnetic and mechanical fields. Based on the previous researches [1-5], the nonlinear magnetic characteristics distribution such as the total force, cogging force, force factor, flux linkage, speedance, and inductance can be obtained by analysis the magnetic circuit using equivalent magnetic circuit method or finite element method (FEM). This study investigates the influence of the magnetization level of PMs on nonlinear magnetic characteristic distributions by FEM. The analyses will show that the magnetization of PMs has a big effect on speedance, total force, cogging force and force factor, but does not affect the inductance. The cogging force can be obtained in the analyses with varying displacement and without current. But because of the saturation in armature, the cogging force is still in terms of position and current, as shown in Fig.2. The most important is that the cogging force can be treated as negative spring force of the mechanical vibration system, so the resonance frequency is decreased with higher magnetization. The distributions of other nonlinear magnetic characteristic will be shown in details in the full paper. To verify the effects of magnetization level of PMs, the sound pressure level should be measured. Both the resonance frequencies and the pressure curves will be compared. The modeling of 3D FEM simulation and the simulated resonance frequency are followed the measurement, and verified experimentally.

B6-08. Spin reorientation transition in Lanthanum doped $DyFeO_3$: A Magnetic study. *S.S. Reddy*[1], C. Reddy[1], P. Reddy[1] and V. Reddy[2] *1. Physics, Osmania University, Hyderabad, Hyderabad, India; 2. UGC DAE Consortium for Scientific Research, Indore, India*

Structural and magnetic study of Lanthanum doped $DyFeO_3$ i.e., $Dy_{1-x}La_xFeO_3$ (x=0, 0.2, 0.4, 0.6, 0.8 and 1.0) henceforth designated as DFO, La 2, La 4, La 6, La 8 and LFO are presented. Fig. 1 shows the X-ray diffraction (XRD) patterns of DFO, La 2, La 4, La 6, La 8 and LFO samples. XRD of all the samples is fitted with Rietveld refinement [1]. It is observed from the refinement that, with the increase of La doping concentration there is

overlapping of diffraction peaks at 32^0 and $33.5^0$with maximum intensity peak (33^0) and a shift in the max. Intensity peak (around $2\theta=33^0$) towards lower angles [2,3]. Fig. 2 (a) shows the temperature dependent (5–350 K) magnetization (M–T) data of DFO sample. First feature observed from the data that, DFO is exhibiting spin reorientation transition (SRT) at about spin reorientation transition temperature (T_{SR})=62 K. Because of D-M (Dzyaloshinskii-Moriya) interaction, Fe^{3+} spins reorient from Γ_4 ($G_xA_yF_z$) spin configuration to Γ_1 ($A_xG_yC_z$) and the WFM component disappears [4, 5]. One can see from Fig. 2 (b), (c), (d), (e) and (f) that La2, La 4, La 6 and La 8 samples are also exhibited spin reorientation transition phenomenon. Corresponding SRT temperature (T_{SR}) values were found to be 18 K, 7K and 3.3 K. From this, one can observe two features. First feature is, with the increase of La doping concentration, T_{SR} is moving towards the lower temperature. This is because of the fact that as the Dy^{3+} ion is magnetic, the replacement of non-magnetic La^{3+} at magnetic Dy^{3+} ion site at different proportions will result in reducing the contribution of Dy^{3+} to the magnetic interactions in $Dy_{1-x}La_xFeO_3$ samples [3]. Second one is, La 4 sample is showing a broad cusp (shown in inset) in the M-T data at T_{SR}. This means transition is not a sharp one, but it is over the range of temperature (~ 5-8 K). This broadening is due to the weakening of AFM ordering in doped samples. It is interesting to observe from the M-T data of La 8 sample, shown in (e) of Fig. 2 that, no T_{SR} was observed in this sample in the temperature range 3-350 K. As the T_{SR} is found to decrease with the increase of La doping concentration, T_{SR} of La 8 samples might be below 3 K. LFO sample is exhibiting Spin-Glass behavior [6].

B6-09. Fast Electromagnetic Analysis of the 3D Magnetic Circuit of a Balanced Armature Receiver. *D. Xu*[1], Y. Jiang[2] and S. Hwang[2] *1. School of Mechatronics Engineering and Automation, Shanghai University, Shanghai, China; 2. Mechanical Engineering, Pusan National University, Busan, The Republic of Korea*

With a growing number of demands in hearing aids, earphones and wearable devices, the study of balanced armature (BA) receiver becomes one of the hotspots on researches. In previous researches [1,2,3], the researchers asssumed the permeabilities of soft magnetic materials (SMMs), including armature and magnet housing, as infinite so that the reluctances of them can be ignored. According to their researches, the equivalent 2D modeling of the magnetic circuit of a BA receiver could be presented as Figure 1. (a), and the relative equivalent magnetic circuit (EMC) can be depicted as Figure 1 (b) while removing the reluctances in pink color. Whereafter, we improved the researches in [1,2,3] by considering the nonlinear magnetic properties of SMMs[4,5], so that the nonlinear reluctances of them were considered, as shown in Figure 1 (b). As a result, the obtained nonlinear magnetic characeteristic distributions are more accurate, but the results still have a big gap to improve compared with those by 3D finite element method (FEM). What's worse, this method did not consider the parallel flux loops in magnet housing. Even though we used 3D FEM to analyze the magnetic circuit of a BA receiver [5,6,7], it requires a significant dedication of time and effort. Therefore, to fast analyze the electromagnetic circuit and improve the accuracy, an EMC with parallel flux loops passing through magnetic housing is proposed. A cross-sectional view of a BA receiver with U shape armature is as shown in Figure 2 (a). And the relative EMC in proposed method is depicted in Figure 2 (b). Magnetic equations can be obtained and established by Kirchhoff's current and voltage law. The equations can be solved using the under-relaxed Newton Raphson iteration method [4,5,8] while considering the nonlinear magnetic properties of SMMs. The results will be verified by simulations using the 3D FEM, and more details will be presented in the full paper. The analysis method can be a fast way to obtain more accurate results, which could provide valuable information for designing BA receivers.

B6-10. Demonstration of spin-wave-based reservoir computing for next-generation machine-learning devices. *R. Nakane*[1,2], G. Tanaka[1,2] and A. Hirose[1,2] *1. IIIEE, The University of Tokyo, Tokyo, Japan; 2. EEIS, The University of Tokyo, Tokyo, Japan*

To take full advantages of IoT, machine learning devices, particularly reservoir computing devices, are required for energy-efficient information processing of time-sequential data near/at terminal devices. In this study, we show that spin-wave-based reservoir computing works well, owing to the unique characteristics of spin waves induced by our setup. Using a 100-nm-thick garnet film with the *xy* plane defined by -19μm≤(*x*, *y*)≤19μm, we simulated the interference of two spin waves excited at Exciters 1 and 2(diameter 250nm), and demonstrated input pattern estimation tasks utilizing the amplitudes of the resultant spin waves at Detectors 1, 2, and 3(diameter 100nm). Fig. 1 shows the arrangement of Exciters and Detectors around the origin of the *xy* axes. Properties of the garnet film are as follows: the saturation magnetization 100kA/m, the exchange stiffness constant 3.7pJ/m, the dumping constant 0.001, the uniaxial magnetic anisotropy constant along the *z* axis: Low (1kJ/m^3) or High (10kJ/m^3). DC external magnetic fields of 30 and 0.1 mT are applied along the +*z* and +*y* directions, respectively. The following time-sequential uniaxial anisotropy was input into both Exciters 1 and 2: (from initial time) Low (3ns), High (*X*ns), Low (3ns), and High (7ns), where X = 1.5, 2, 2.5, 3, 3.5, 4, and 4.5. Our findings are 1) spin waves almost circularly transmit, but their amplitudes were asymmetric with respect to the excitation point, 2) spin waves show input-history-dependent feature and nonlinear interference, and 3) the waveform at each Detector is different with each other. Using the envelop of the x component of the normalized spin s_x in the time range of 8-9ns(Fig. 2), X estimation task was performed; four inputs with different X were used for machine learning to determine the weight of the output at each Detector, and the rest inputs were used for estimation testing. Regardless of the selection of learning/testing inputs, the task was successful with a low root-mean square error, meaning that the spin-wave-based reservoir computing has good generalization characteristics. Therefore, it is applicable to next-generation machine-learning devices on a chip.

B6-11. Simulation and experimental tests of topological magnetic monopole in electrical circuit network. Y. Wang[1], K. Luo[2], Y. Ji[1], *J. Lu*[1], R. Yu[2] and H. Weng[1] *1. State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2. School of Physics and Technology, Wuhan University, Wuhan, China*

Dirac postulated the existence of a magnetic monopole based on the symmetry between the electric and magnetic fields in the electromagnetic law [1]. Up to now, magnetic monopole as an elementary particle is extremely difficult to be observed, although mainstream scientists believe its existence during the Big Bang and in the current universe [2]. Fortunately, in condensed matter physics, magnetic monopole as a quasiparticle can easily emerge when special topological configurations are satisfied, such as theoretical and experimental confirmation of magnetic monopole in momentum space [3], in frustrated systems like spin ice [4], in microscopic magnetic defects like Skymions [5], and in Weyl semimetal phases [6]. In contrast to material synthesis and characterization, electrical circuit network may be easily manipulated in a macroscopic way, so as to establish a bridge between the electrical engineering and topological states of matter, where the accessibility, scalability, and operability of electronics brings us a new degree of freedom to understand topological magnetic monopoles. We propose a scheme to realize topological magnetic monopole based on periodic inductor-capacitor (LC) circuit network, where at particular frequency inductors react with each other so that monopole like behavior can be produced. We demonstrate that the topological nodal-line and Weyl points can be achieve by tuning the values of the inductance and capacitance. The key characters of the topological states such as the drumhead like surface state for nodal-line states and the Fermi-arc surface states for Weyl semimetals are found in these LC circuit lattices. We also show that the Weyl points are stable within the fabrication errors of electronic components.

B7-01. Magneto-Controlled Diffraction Applied to Observe Dynamical Systems. *A.P. Tufaile*[1], M. Snyder[2], T. Vanderelli[3] and A. Tufaile[1]
1. Soft Matter Lab, EACH, Universidade de Sao Paulo, Sao Paulo, Brazil; 2. Technical Space Science Center, Morehead State University, Morehead, KY, United States; 3. Ferrocell USA, Ligonier, PA, United States

We have explored the possibility of create some representations of dynamical systems using magnetic fields and optic-fluidics. Our dynamical system is the direct observation of diffracted lines in the Ferrocell, a Hele-Shaw cell containing ferrofluid scattering light when it is subjected to a magnetic field, as it is shown in the figure. This device is an interesting tool to visualize directly magnetic contours, used to control light diffraction from a laser beam, known as jumping laserdogs [1,2], or considering the ferrofluid as a "smart nanofluid" applied in liquid robotics [3]. We present some curious properties involving scattering of light partially confined in the plane of the ferrofluid, as well as the diffraction for the transmitted and reflected light, when this system is subjected to the external magnetic field, suggesting the use of this device as light modulator or display. In addition to this, we present the comparison of some patterns obtained with light polarization using magnetic fields [4] in the Ferrocell with the patterns of magnetic contours, comparing our results with the Fresnel-Kirchoff diffraction theory, simulating some patterns with hyperbolic polynomials. We also observed some chiral properties in this system and associated them with the structure of nanoneedles present in the Ferrocell, because nanoscale particles could self-assemble into structures with unique spatial arrangements, such as helical-like structures due to the interplay of magnetic dipole-dipole, van der Walls interactions, or some entropic forces, depending on the geometry of the nanoparticles, leading to anisotropic effects. We also explore some aspects of the Geometrical Theory of Diffraction[5, 6] for the patterns observed with the Ferrocell. A. Tufaile and A. P. B. Tufaile thank CNPq and FAPESP for financial support through program Instituto Nacional de Ciencia e Tecnologia de Fluidos Complexos (INCT-FCx), FAPESP/CNPq#573560/2008-0.

We report the microwave assisted thermolysis synthesis of binary doped optical-magnetic up/down converting β-$NaGdF_4$:RE and iron-oxide/SiO_2/$NaGdF_4$:RE (RE= Ce, Eu; Yb, Er) nanoparticles. The morphological characteristics of these systems were finely tuned from elongated rod-shaped nanoparticles in β-$NaGdF_4$:RE to ovoidal nanoparticles for iron-oxide/SiO_2/$NaGdF_4$:RE. The Yb, Er activated particles provided an excellent up/down conversion luminescence emission in visible (green) and mid-infrared optical windows, under excitation wavelength of 980 nm, whereas the Ce, Eu activated systems exhibited a strong red emission ($^5D_0 \rightarrow {}^7F_2$ of Eu^{3+}) *via* Gd^{3+} sublattice upon excitation in the UV region. The magnetic hysteresis at 300 K for β-$NaGdF_4$:RE showed typical signatures of a paramagnetic system, whereas the iron-oxide/SiO_2/β-$NaGdF_4$:RE nanocomposites exhibited superparamagnetic behavior, along with the presence of a Curie-like component at high applied field, which was due to a paramagnetic contribution. The luminescence quenching effects induced by the presence of an iron oxide phase have been validated by comparing the emission and life-time decay curves of the β-$NaGdF_4$:RE with those expressed by the iron-oxide/SiO_2/$NaGdF_4$:RE. These nanocomposites showed excellent magnetic and optical responses with r1 and r2 relaxivity values as per clinically approved T1 contrast agents and significantly higher (244 ± 19 $mM^{-1}s^{-1}$, 1.5 T) than the commercial available Feridex (39-43 $mM^{-1}s^{-1}$, 1.5 T), respectively.

Magnetoplasmonics, the interaction of surface plasmons with magnetism, can provide exciting prospects in non-reciprocal nanophotonics, optically-controlled nanomagnetism and highly-efficient chemical sensing.[1,2] To gain these functionalities, one typically combines plasmonic and ferromagnetic films, alternatively – localized plasmon nanoantennas and ferromagnetic nanostructures.[3,4] Here we investigate the so far unexplored combination of molecular magnets with plasmonic nanostructures to reveal how the magneto-optical response of the former is modified in such hybrids. In order to accurately interpret the magneto-optical response of the molecular-plasmonic hybrid structure, the magnetoplasmonic behavior of the gold nanodisks was modelled and taken into account.[5,6] We found that such contribution is far from being negligible, and it is mandatory to understand the optical and magneto-optical processes taking place in the hybrid nanostructure. Leveraging on the strong overlap of the nanoantenna and the molecular resonance of a thin film (~2 nm) of the single-molecule magnet TbPc2, we demonstrate a significantly boosted magneto-optical signal from the molecular layer, indicating the possibility of sub-monolayer magnetic circular dichroism detection, which is currently only available in the soft x-rays regime at large synchrotron facilities.[7,8] This work has been financed by the EC through grant 737093 — FEMTOTERABYTE — H2020-FETOPEN-2016-2017.

B7-06. Colloidal Synthesis of Hybrid Magneto-Plasmonic Nanocrystals: an Improved Route for the Preparation of High-Performance Magneto-Optical Enhanced Materials. *A. López-Ortega*[1], M. Takahashi[2], S. Maenosono[2] and P. Vavassori[3] *1. nanomagnetism, CIC nanoGUNE, Donostia – San Sebastian, Spain; 2. School of Materials Science, Japan Advanced Institute of Science and Technology, Nomi, Japan; 3. CIC nanoGUNE Consolider, San Sebastian, Spain*

The combination of magnetic and plasmonic materials and their nanostructurization have been revealed a prominent pathway to develop novel nanophotonic materials, called magneto-plasmonic, for the active control of the light polarization using a magnetic field. Up to now, the physical growth methods have shown the only robust and reproducible, and therefore exploitable, approach to prepare these types of nanostructures. We demonstrate the chemical synthesis of magneto-plasmonic core/shell nanocrystals of high quality and with enhanced magnetic control of optical properties comparable to the best results reported for nanostructures growth by physical methods. Ag/FeCo plasmonic/magnetic core/shell nanocrystals were synthesized in a combination of hot injection and polyol approaches in high boiling point solvents. The high quality of both materials and their interphase, due to the synthetic approach choose, and the specific morphology, where the plasmonic structure is at the core region, are demonstrated to be key parameters to produce strong coupling between optical (plasmonic) and magneto-optic properties with a robust enhancement of the magneto-plasmonic interaction in the hybrid structure. Indeed, this is the first time were the magneto-plasmonic interaction between plasmonic and magnetic material synthesized through chemical routes has shown such a clear and strong effect in the magneto-optic response. These results demonstrate the huge potential of the chemical synthesis to prepare complex hybrid magneto-plasmonic nanocrystals with enhanced magneto-optic properties and pave the way to develop novel nanostructures in broader combinations of materials, elementary unit shape and size, functional substrates or even embedding them in optically compliant materials. Moreover, the colloidal character of the system can be conveniently utilized for magnetic manipulation and bio-sensing.

Finite-size effects in ultrathin magnetic films are a well-known feature. They usually play a role, when the surface and interface layers dominate over the volume contribution of the sample and have different properties, due to roughness, texture, hybridization, modified magnetic moment, or dipolar fields. For micro- and especially nanostructures these effects might be there as well—but at the side walls. Regarding the magnetization dynamics these effects lead to additional spin wave modes, e.g. localized spin wave modes (edge modes). It has been shown that these edge modes are influenced by the quality of the side walls, namely by angled side walls, edge roughness, beveled edges, or even magnetic dilution [1]. As these structures have to be prepared by means of lithography involving masks a certain edge roughness or even side wall slope are inevitable. Nevertheless, when it comes to micromagnetic simulations to corroborate or explain measurements these contributions are usually excluded from the model. Here we show, how successive trimming the sides of a 5 μm x 1 μm Permalloy stripe by a focused Ne ion beam improves the spin wave spectrum and enhances the edge mode spectrum as probed by ferromagnetic resonance (FMR). To achieve the sensitivity to detect the FMR of the weak edge modes of a single Permalloy stripe we use planar microresonator FMR [2,3]. The experimental results are corroborated by micromagnetic simulations. Including just edge roughness of ~4 nm (rms) in the simulations is enough to perfectly match the FMR experimental data. The residual edge roughness is in the order of the grain size of the polycrystalline permalloy. Although the focused ion beam and its motion are able to cut the side walls perfectly straight and vertical with sub-nm precision, the Ne ions penetrate the side wall up to 15 nm (called straggling). This is due to the collision cascade with the Ni and Fe atoms of the Permalloy causing possible lateral damage of the Permalloy lattice. Hence, we attribute the residual roughness to the ion induced damage by the lateral penetration during trimming of the side walls, and a small remaining edge roughness due to changes in sputter yield for differently oriented Permalloy grains.

To study and control the spin dynamics in a magnet it is important to understand the dynamic magnetic processes on the micro- and nanoscale [1]. A scanning transmission x-ray microscope (STXM) has been combined with X-ray magnetic circular dichroism (XMCD) spectroscopy and ferromagnetic resonance (FMR) using a novel synchronization scheme between the time structure of the synchrotron and the microwave excitation (STXM-FMR) [2]. This STXM-FMR setup visualizes the high frequency magnetization dynamics in the GHz regime with a high lateral resolution of nominally 35 nm [3]. Considering the complexity of the technique it is essential to have reliable samples' conventional FMR measurements. This magnetic characterisation is necessary for further preparation of STXM-FMR measurements and additionally can be used for interpretation and analysis of the results. In this contribution we present conventional FMR measurements with respective micro magnetic simulations. In FMR, a low-power microwave excitation of the magnetic system allows studying the magnetic anisotropy and damping close to equilibrium [4]. We discuss the results for two perpendicular magnetic micro-stripes 5x1x0,03 μm^3 each. The samples were grown using optical and e-beam lithography and investigated using conventional FMR technique with benefit of the high detection sensitivity of microresonator [2]. These studies are complemented by micro magnetic simulations of the spatial distribution of the precessing FMR-mode. Our results show the distortion of the one stripe's magnetization by the other's stray field. The influence of the stray field changes with 90 degrees rotation of the samples with respect to external magnetic field. These findings are compared to preliminary results using STXM-FMR.

The significant advantage of spin-orbit torque (SOT) for the emerging field of magnonics utilizing spin waves as a signal carrier in nano-circuits, is the possibility to exert spin-transfer torque over extended areas providing an opportunity to control the propagation length of spin waves. Another

important advantage of SOT is the possibility to implement spin-torque devices based on low-damping insulating magnetic materials, such as Yttrium Iron Garnet (YIG). We studied the effects of SOT on the propagation of spin waves in 1 micrometer wide waveguides prepared from a 20 nm thick YIG film grown by the pulsed laser deposition and covered by an 8 nm thick layer of Pt. Propagating spin waves were detected with the submicrometer spatial resolution by using micro-focus Brillouin light scattering (BLS) spectroscopy, which allows the direct characterization of the spatial decay of propagating spin waves. The results of the measurements showed that, by using SOT, the propagation length of spin waves can be increased by nearly a factor of 10. This variation corresponds to the SOT-induced increase of the spin-wave intensity at the output of a 10 micrometer long transmission line by three orders of magnitude. Additionally, the high efficiency of our system allowed us to study the regime, where the damping is overcompensated by SOT and the true amplification of spin waves is expected. We show that, in this regime, the spin system of the YIG film is strongly overdriven, which results in the suppression of the spin-wave amplification. Our observations should stimulate both the development of advanced magnonic devices and theoretical work to deepen the understanding of the interaction of spin currents with spin waves.

The observation of skyrmion crystal boosts the research of magnetic materials in the presentation of Dzyaloshinskii-Moriya interaction (DMI) and makes it as a hot topic in spintronics. Different from the Heisenberg exchange interaction, which favors collinear magnetic order, the DMI could induce non-collinear magnetic order. It has been found that DMI could also influence the spin waves (SW) propagation [1, 2], and induce the nonreciprocal SW propagation, which further stimulated the design of spintronics devices based on the SW propagation [3]. In general, previous studies only considered the isotropic DMI, which means that the DM strength between the different neighboring spins is same. However, it has been found that the DMI is strongly related to the crystalline structure [4], and in the ultrathin magnetic film grown on the heavy-metal substrate with D_{2d} symmetry, the interfacial DMI could be anisotropic with the DM strength strongly depending on the crystalline orientation between the neighboring spins [5], and such anisotropic DMI could induce the antisckyrmion [6]. In this contribution, we studied the SW nonreciprocality induced by both isotropic and anisotropic DMI through micromagnetic simulation. Through both theoretical analysis and simulation, the SW nonreciprocality can be characterized as the Spin Doppler effect (SDE) occurring in the moving ferromagnetic medium, which is similar to the SDE induced by spin current [7, 8]. The equivalent velocity of the ferromagnetic medium is found to be proportional to the magnitude of DM vector. Such SDE can be cancelled out by carefully adjusting the strengths of DMI and spin current. Under the anisotropic DMI, the SDE shows anisotropic behavior while rotating the in-plane magnetization, and the zero SDE would exist for the magnetization along particular direction even with strong DMI. In addition, in the system with strong enough DMI, the SDE velocity could be larger than the SW propagation velocity, then a spin shock wave could be observed with a sharp spin wave Mach-Cone.

B8-05. Reciprocity and dispersion relation of the pulse laser-induced magnetostatic surface waves in metals. A. Kamimaki[1,2], S. Iihama[3], Y. Sasaki[1,2], Y. Ando[2] and *S. Mizukami*[1,4] *1. WPI-AIMR, Tohoku University, Sendai, Japan; 2. Graduate School of Engineering, Tohoku University, Sendai, Japan; 3. National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; 4. Center for Spintronics Research Network, Tohoku University, Sendai, Japan*

Magnetostatic surface waves (MSSWs) in metal have been mainly investigated by electrical-antenna technique [1]. Recently, all-optical method using a pulse laser heating has been demonstrated [2-4]. However, it has been unclear whether the pulse laser-induced MSSWs is reciprocal or not. In this study, we investigated the reciprocity and dispersion relation of the laser-induced MSSWs. Thermally-oxidized Si substrate/ Ta(5)/ $Ni_{80}Fe_{20}$(20)/ Ta(5) thin film samples were fabricated using the magnetron sputtering. The MSSWs were detected by the space-and-time-resolved magneto-optical Kerr effect microscopy [4,5]. The fluence of the pump pulse was about 0.5 mJ/cm^2. Figure 1 shows the typical data of the MSSW packets in case that the external magnetic field $\mu_0 H = 0.3$ T was applied at $q_H = 4$ deg, where q_H was measured from the film normal. The data show the same amplitude and phase with respect to the propagation directions, indicating that the laser-induced MSSWs is reciprocal. Figure 2 shows the dispersion relation obtained by the Fast Fourier Transform (FFT) from the data as a function of Δt and x. The obtained data of the dispersion relation were only visible within the wave number of k_x = 2-3 rad/mm, which roughly agreed with theoretical calculation [5]. In the field of magnonics there have recently been made great advances in understanding of fundamental properties of spin-wave propagation. Complex spin-wave devices and waveguides with artificially tailored properties are extensively used to control and mold the flow of spin waves. A novel approach for extended control over the spin-wave propagation might be found in graded magnonic materials. Such materials require continuous transitions of magnetic properties, which lead to higher control of e.g. demagnetizing field. This cannot be readily solved with standard lithography techniques, yet can be achieved by employing novel materials allowing focused ion-beam (FIB) controlled change in structural order [1, 2]. In our approach we use fcc $Fe_{78}Ni_{22}$ grown on Cu(100) substrates, which offers independent control of saturation magnetization and uniaxial anisotropy direction and to combine both approaches in a single device. We employ the system for the study of spin wave propagation in waveguides with gradual magnetization transitions and in waveguides with periodic variation of magnetic anisotropy direction [Figure 1 (a)]. The confinement of spin waves as well as the propagation of spin waves in waveguides with modulated anisotropy are studied by micromagnetic simulations [Figure 1 (b)] and experimentally by Kerr microscopy and by micro focused Brillouin light scattering. To conclude, we use direct writing of magnetic elements by FIB with spatial control of saturation magnetization and the anisotropy of the structures. We show first prototypes of graded index waveguides with controllable confinement of edge modes by arbitrarily created magnetization profiles and spin wave waveguides with periodic modulation of magnetic anisotropy.

B8-07. Transmission matrix and spinwave eigenmodes of patterned magnetic system. *I. Purnama*[1] and C. You[1] *1. DGIST, Daegu, The Republic of Korea*

It has recently been shown that, by finding the spinwave (SW) eigenmodes of a magnetic system, it is possible to significantly improve the SW transmission [1]. In this work, we report on a general method to find the eigen SW input modes of any patterned magnetic system so as to obtain the maximum output signals at any observation point. First, the method assumes that both the input and the output waves are a sum of point sources across the width of the nanowire. In this way, the waves at the point-outputs ($A(t)$) and the point sources ($B(t)$), are related by:. Where, $A(t)$ and $B(t)$ are both matrices with components that correspond to each of the point-output and point-source, respectively. Meanwhile, $F(x,y,z,\omega)$ is a transmission matrix that correlates the waves of the point-outputs and the waves of the point-sources. By knowing F, it is then possible for us to obtain the eigenmodes a.k.a. the optimum input signal that can be generated to obtain the strongest signal at any observation point. Figure 1 (a)-(d) show several SW eigenmodes that are found by using this method. The results show that the SW eigenmodes of a nanowire with an in-plane magnetization can be characterized by the number of nodes, i.e. the eigenmodes are standing wave-like along the width of the nanowire with open boundary conditions. For instance, the 1st mode corresponds to the usual plane wave, which has 0 node along the width of the nanowire. The 2nd mode has 1 node at the center of the nanowire, while the 3rd mode has 2 nodes, and so on. The higher modes are shown to have higher eigenvalues at wider nanowires, i.e. the higher modes have higher transmission efficiency. The eigenmodes can then be employed in future SW-based devices to improve their signal-to-noise ratio. It is also possible to employ the eigenmodes as the input and output signals of novel SW logic devices.

B8-08. Fabrication and Characterization of individual sub-100 nm YIG Waveguides using Brillouin Light Scattering Microscopy. *B. Heinz*[1], T. Brächer[1], M. Schneider[1], P. Pirro[1], Q. Wang[1], B. Lägel[1], C. Dubs[2], O. Surzhenko[2] and A. Chumak[1] *1. Fachbereich Physik, Technische Universität Kaiserslautern, Kaiserslautern, Germany; 2. INNOVENT e.V. Technologieentwicklung, Jena, Germany*

Spin waves and their quanta, magnons, open up a promising branch of high-speed and low-power information processing [1]. Several important milestones were achieved recently in the realization of magnonic data processing devices. Nevertheless, the developed prototypes either have millimeter or micrometer sizes [2] or have been studied by means of numerical simulations only [3]. Thus, the fabrication of magnonic structures of lateral sizes down to a few tens of nanometers represents one of the main challenges in the field of magnonics. The choice of the magnetic material is also of high importance, since it defines the magnon propagation length. A material of special interest is Yttrium-Iron-Garnet (YIG) since it provides the highest known magnon lifetime. The recent revolutionary progress in the growth of high-quality YIG films with nanometer thickness [4] allows for the fabrication of nano-sized magnonic YIG conduits and paves the way for the realization of nanoscale magnonic computing systems. Spin-wave conduits with widths down to 50 nm (see Fig. 1) were investigated by means of Brillouin Light Scattering (BLS) Spectroscopy. The conduits were fabricated from a plain YIG film grown by liquid phase epitaxy [4] using electron beam lithography and subsequent ion milling. In order to measure the spin-wave lifetime, magnetization dynamics were excited via a macroscopic stripline by applying pulsed microwave currents. By carrying out time-resolved micro-focused BLS spectroscopy the decay of the magnetization dynamics was measured after the excitation pulse was switched off and the magnon lifetime was extracted. The experimental results show that the magnon lifetime in the fabricated sub-100nm structures is comparable to the value of the initial plain film and still exceeds other state of the art magnonic materials like Permalloy. This research was supported by the European Research Council Starting Grant 678309 MagnonCircuits and by the DFG (DU 1427/2-1).

B8-09. A Luneburg Lens for Spin Waves. *N.J. Whitehead*[1], F. Mushenok[1], S.A. Horsley[1], T.G. Philbin[1] and V. Kruglyak[1] *1. Physics and Astronomy, University of Exeter, Exeter, United Kingdom*

Graded index lenses have long been studied for the purpose of controlling the direction of propagating waves. The Luneburg lens [1] is a particularly useful example, focusing any incident plane wave to a point on the edge of the lens. This lens has been realized for both high and low frequency electromagnetic waves [2,3], and recently for sound waves [4]. It could also be a useful component in future wave-based computing devices, perhaps in launching or reading a plane wave using a point antenna. In this work, we demonstrate a Luneburg lens for forward-volume spin waves using micromagnetic modelling. The refractive index for spin waves in a thin film is determined by the film thickness, magnetization or the magnetic field, and so the graded index can be created by changing one of these parameters to match the required profile [5]. For ease of modelling, the lens is created by modulating the saturation magnetization in a circular region of a thin YIG-like film. We analyze the behavior of the spin waves as they move through the lens (Fig. 1), observing a significant enhancement of the wave amplitude as the wave is focused (Fig. 2).

B8-10. Fano-resonance based nanoscale spin-wave transducer, valve and phase shifter in Damon-Eshbach geometry. *K.G. Fripp*[1], V.D. Poimanov[2], F. Mushenok[1], F.Y. Ogrin[1] and V. Kruglyak[1] *1. Physics And Astronomy, University of Exeter, Exeter, United Kingdom; 2. Department of Physics and Technology, Donetsk National University, Donetsk, Ukraine*

The promise of creation of spin-wave based logic devices rests on our ability to excite spin waves with nanoscale wavelength and then to control their amplitude and / or phase, all on the nanoscale. Au et al demonstrated that a magnetic nanoelement formed above a longitudinally magnetised magnonic waveguide can act as an efficient spin-wave transducer, valve and phase shifter, each reprogrammable through switching the magnetisation in the element [1,2]. Here, we use micromagnetic simulations to extend the concept of Au et al to the case of the magnonic waveguide magnetised parallel to its width, i.e. Damon-Eshbach geometry for spin-wave propagation. This

system demonstrates the ability to control the propagation of spin waves along the waveguide via magneto-dipolar coupling to the overlaid magnetic nanoelement [1,2]. Depending upon the direction of the magnetisation of the nanoelement and waveguide by the bias magnetic field, the spin waves either can be transmitted, phase-shifted or reflected in a controlled manner. Our observations are explained in terms of the coupling of the discrete spectrum of precessional modes of the nanoelement to the continuum of the waveguide, which is a typical example of a Fano resonance. This is interpretation is supported by frequency dependent micromagnetic simulations that yield the characteristic Fano-like lineshapes for the reflection and transmission coefficients of spin waves in the waveguide. The research leading to these results has received funding from the Engineering and Physical Sciences Research Council of the United Kingdom Project No. EP/L019876/1 and from the European Union's Horizon 2020 research and innovation program under Marie Sklodowska-Curie Grant Agreement No. 644348 (MagIC).

In recent years, magnonics, the research of spin waves, has become a very prominent topic in magnetism research. The prospect of possible technological applications in future computing and communication has played a major part in this development. Yttrium iron garnet (YIG), a ferrimagnetic insulator, has received a lot of attention in this field because of its remarkably low intrinsic damping, which translates into a long maximum spin wave propagation distance [1]. The most commonly used measurement techniques for spin waves are ferromagnetic resonance (FMR), Kerr microscopy (MOKE) and Brillouin light scattering (BLS), which are all limited in spatial resolution to at best 200 nm. However, for applications the devices and spin waves need to be a lot smaller. Time-resolved scanning transmission x-ray microscopy (TR-STXM) can directly image spin waves with a resolution in space and time of down to 18 nm and 10 ps [2]. YIG has been a challenge for STXM in the past because of its need for a bulk single crystal growth substrate. Over the course of last year our group successfully mastered this challenge and we can now present the world's first TR-STXM measurements of spin waves in a YIG film. The sample has been prepared using a focused ion beam (FIB) device for slicing a lamella from a 185 nm thick YIG film and was transferred onto a standard silicon nitride membrane [3](see figure 1). Spin waves were excited by RF currents running through a 2 μm wide copper stripline crossing the lamella (see figure 1). Our experiments recorded multiple spin wave modes coexisting in the sample. Most prominent among them are the well-known Damon-Eshbach and backward volume mode (see figure 2), which fit well into the respective dispersion predicted by theory, as well as diagonal modes likely caused by the confinement. We are convinced that these experiments will open up new possibilities in magnonics. The ability to directly image spin waves in YIG at the nanoscale can provide valuable insights for fundamental and especially for application oriented research in this field.

B8-12. Integrated magnonic half-adder. Q. Wang[1], T. Brächer[2], P. Pirro[1] and *A. Chumak*[1] *1. TU Kaiserslautern, Kaiserslautern, Germany; 2. Physics, TU Kaiserslautern, Kaiserslautern, Germany*

Spin waves and their quanta, magnons, open up a promising branch of high-speed and low-power information processing [1]. Several important milestones were achieved recently in the realization of separate magnonic data processing devices including logic gates [2], a magnon transistor [3], and units for non-Boolean computing [4]. Nevertheless, the realization of an integrated magnonic circuit consisting of at least two logic gates is still a challenge. Here we demonstrate such an integrated circuit at the example of a magnonic half-adder – see Fig. 1. The half adder can be constructed using AND and XOR logic gates, as it is shown in Fig. 1a. In this device, binary data is coded into the spin-wave amplitude in a way that a spin-wave of a certain amplitude defines a logic "1" while its absence represents a logic "0". Figure 1c shows that the information from each input "A" and "B" of the half adder is split in order to be processed independently in the XOR and AND logic elements. In order to "cross" the spin-wave waveguides, a recently developed nano-sized spin-wave directional coupler is used [5]. The XOR logic gate represents a simple spin-wave combiner and the output signal "S" is given by the interference of two waves of opposite phases. The key element of the AND logic gate is a nonlinear magnonic ring which acts as a cavity and suppresses the spin-wave propagation in the nearly located spin-wave waveguide. The increase in the spin-wave amplitude in the presence of both input waves results in an non-linear shift of the spin-wave dispersion and in the "opening" of the transmission in the spin-wave waveguide. The functionality of this nano-sized magnonic circuit is investigated and tested by means of numerical simulations. This research was supported by the European Research Council Starting Grant 678309 MagnonCircuits.

Recently, data transmission with spin waves (SWs) has become one of the most promising directions for the next generation information devices due to its low heat dissipation. In order to achieve the goals of lossless and novel SWs propagations, a large number of magnetic materials has been studied. Among them, yttrium iron garnet (YIG) has the lowest known damping factor, which supports the long propagation distance, while the magnetic metals, permalloy (Py), has relatively low damping factor and high saturation magnetization (M_s). In this work we studied spin waves propagation in patterned YIG stripes magnetized with 1kOe field applied in the sample's plane and perpendicular to the stipe direction. While the main contribution with the characteristic peak frequency of ~5 GHz was found to originate from the subset of hybridized spin waves propagating along the stripe and occupying the central area of the sample, a well-defined, edge-localized spin waves with lower frequency of ~3.5 GHz was also observed. The edge-localized mode demonstrates excellent phase coherency, thus could be of particular interest for further focused studies. Furthermore, we have found that it is possible to control the frequency of this mode by adjusting a local demagnetizing field along of the edge, by, for example placing an additional patterned structures in close proximity and along the edge of the YIG stripe. Such this hybrid supports two district frequencies of the spin waves independently propagating along two edges of the stripe. We believe that unique characteristics of SWs integrated in a single waveguide opens perspectives for the fabrication of innovative logic elements based on constructive or destructive SW interference.

B9-01. Fulvalene Magnetic Metal Halides. *H. Gokturk[1] 1. Ecoken, San Francisco, CA, United States*

Dimetallafulvalene compounds were synthesized in 1980s by reacting metal carbonyls with dihydrofulvalene to obtain fulvalene bridged carbonyl complexes such as fulvalene diruthenium tetracarbonyl, FvRu2(CO)4 [1]. Such compounds are promising for photo-isomeric storage of solar energy, because the compound transforms to an isomer after absorbing a photon. Ferromagnetic cobalt (Co) and anti-ferromagnetic chromium (Cr) were also included in the above study to obtain FvCo2(CO)4 and FvCr2(CO)6, respectively. However a comparison of magnetic properties with and without carbonyls showed that carbonyl ligands suppressed magnetism [2]. In this research metal halides, for example cobalt chloride (CoCl2), are investigated as starting materials in place of metal carbonyls to obtain fulvalene metal halides such as FvCo2Cl2 and FvCrCl2. Calcium (Ca) is also included as a non-magnetic atom of valence 2 to compare with Co and Cr. Properties of the chosen compounds are calculated using DFT method with B3LYP functional and Pople type basis sets. Total spin (Ts) is zero for compounds containing Cr and Ca. Optimal spin value for compounds containing Co is determined by searching minimum energy for a range of spin values from 0 to 3. Spin density (Sd) values obtained in the calculation show how total spin is distributed among individual atoms, especially the metal atoms. Energy storage (Es) capability of each compound is derived from the difference between energy of the isomer and that of the ground state. Results indicate that both Cr and Co maintain part of their magnetic properties with Cl ligands. In addition, FvCr2Cl2 maintains about 60% of the energy storage capability of FvCr2.

B9-02. Influence of Design Parameters on On-Load Demagnetization Characteristics of Switched Flux Memory Machine. *H. Yang[1]*, H. Lin[1], Z. Zhu[2] and S. Lyu[1] *1. School of Electrical Engineering, Southeast University, Nanjing, China; 2. Department of Electronic and Electrical Engineering, The University of Sheffield, Sheffield, United Kingdom*

I. INTRODUCTION Recently, the switched flux principle [1] is extended to memory machines [2] to combine the advantages of the convenient online magnetization control and rotor robustness [3]-[4]. Meanwhile, high efficiency can be maintained over a wide range of speeds and loads since a current pulse is employed to repetitively magnetize low coercive force (LCF) magnets. In this paper, the influences of design parameters on the unintentional demagnetization behavior of the newly developed switched flux hybrid magnet memory machine (SF-HMMM) are evaluated. Thus, the general design guideline for preventing this undesired demagnetization effect is established. Finally, a SF-HMMM prototype is tested to experimentally verify the theoretical analyses. II. UNINTENTIONAL DEMAGNETIAZTION PHENONMENON Fig. 1 (a) shows the SF-HMMM configuration, which is characterized by the tangentially magnetized NdFeB PMs, and the radially magnetized LCF PMs sandwiched between the outer stator ring and inner "U" stator segments. The open-circuit field distributions before or after q-axis current excitation (I_q=40A) are shown in Fig. 1. The majority of the LCF PMs are demagnetized during the on-load operation. The severe magnetic saturation under the heavy load operation are responsible for this unexpected demagnetization. III. INFLUENCE OF DESIGN PARAMETERS ON UNINTENTIONAL DEMAGNETIZATION For the 6-stator pole SF-HMMMs with various rotor pole numbers, the working points of the central point in the LCF PM as functions of various design parameters before or after loaded operation are shown in Fig. 2. Overall, the SF-HMMMs with higher rotor pole numbers show better unintentional demagnetization withstand capability than their low-rotor pole counterparts. In addition, the wider rotor pole width relieves the on-load demagnetization due to the larger circulating permeance within the stator/rotor aligning parts. The detailed analysis results, design guideline and experimental verification will be presented in the full paper.

B9-03. Magnetic and thermoelectric properties of Fe-Ti-Sn alloys.
T. Saito[1] and *S. Kamishima*[1] *1. Chiba Institute of Technology, Chiba, Japan*

Fe_2TiSn-type Heusler compounds are very attractive due to the promise they hold as candidates not only for magnetic but also thermoelectric materials [1]. There have been several reports providing calculations on Fe_2TiSn-type Heusler compounds [2,3], but the fundamental properties of these materials have not yet been reported. Since the magnetic properties of not only Fe_2TiSn Heusler compounds but also Fe_3Sn compounds are interesting [4,5], we produced $Fe_{3-x}Ti_xSn$ (x = 0–1) alloy ingots in this study. XRD studies revealed that the Fe_3Sn specimen consisted of the Fe_3Sn phase and that the $Fe_{3-x}Ti_xSn$ (x = 0.25–1) specimens consisted of the Fe_2TiSn phase. The Fe_2TiSn specimen showed low saturation magnetization, indicating that Fe_2TiSn alloy is unsuitable for use as a magnetic material. However, the saturation magnetization of the $Fe_{3-x}Ti_xSn$ (x = 0–1) specimens increased with increasing Fe content, and the Fe_3Sn specimen exhibited a high saturation magnetization of 112 emu/g. The thermoelectric properties of these alloys were investigated. Figure 1 shows the dependence of the Seebeck coefficient of the $Fe_{3-x}Ti_xSn$ (x = 0–1) specimens on the temperature. The Fe_2TiSn specimen showed a large Seebeck coefficient in the measured temperature range. This suggests that Fe_2TiSn alloy is a good candidate for a thermoelectric material. The Seebeck coefficient of the $Fe_{3-x}Ti_xSn$ (x = 0–0.75) specimens decreased as the Fe content increased. The $Fe_{2.75}Ti_{0.25}Sn$ specimen had a small Seebeck coefficient in the measured temperature range. This indicates that the substitution of Fe for Ti in the Fe_2TiSn alloy resulted in a decrease in the Seebeck coefficient. On the contrary, the Fe_3Sn specimen showed a large negative Seebeck coefficient. Thus, the Fe_3Sn phase is also a candidate for a thermoelectric material. In conclusion, the magnetic studies revealed that the Fe_3Sn phase is ferromagnetic and the Fe_2TiSn phase is not ferromagnetic. As a result of the thermoelectric measurements, both the Fe_2TiSn phase and the Fe_3Sn phase were found to be good candidates for thermoelectric materials.

B9-04. Changes in Microstructures and Magnetic properties of Fe-B-Cu-C Ribbons by Annealing Conditions.
K. Lee[1], M. Kim[1], M. Choi[1] and J. Kim[1] *1. Materials Science and Chemical Engineering, Hanyang University, Ansan, The Republic of Korea*

Fe-based soft magnetic materials have been widely adopted due to their high saturation magnetization density (Ms). The coercivity of them can be effectively reduced by the formation of nano-crystalline grains with isotropic and homogeneous microstructures. In order to obtain the nano-crystalline structure, a rapid solidification process (RSP) has been widely used to fabricate Fe-based amorphous ribbons. However, this process limits the Fe concentration of the ribbons because they should contain amorphous forming and grain growth inhibitor elements. This indicates that an understanding of microstructural development during the subsequent annealing process after RSP should be critical to increase the saturation magnetization density. In this study, the Fe content of the ribbons was maintained above 84 at% to achieve a saturation magnetization density of 1.8 Tesla or higher [1]. Fig. 1 shows changes in the magnetic properties of $Fe_{84.3}B_{13.7}Cu_1C_1$ amorphous ribbons that were heated to 390, 400, 410 (first exothermic peak starting temperature determined by DTA), and 420°C by a rapid thermal process (RTP) with a heating rate of 80°C/min and cooled down. Fig. 2 shows the Transmission Electron Microscope (TEM) micrographs of these ribbons. As shown in the figure, nano-crystalline grains with facets were formed in the amorphous matrix of the ribbons annealed above 400°C. In addition, the size and density of these facet grains sharply increased with increasing the annealing temperature. This microstructural development is known to result from the existence of the constitutional supercooling between the interfaces, which increases the growth rate of the grains [2]. Thus the control of the annealing conditions is critical to obtain the optimum magnetic properties. In this presentation, we will discuss two step annealing conditions to control the microstructures of the ribbons.

B9-05. Recrystallization, texture evolution, and magnetostriction behavior of rolled $(Co_{70}Fe_{30})_{99.8}NbC_{0.2}$ sheets during low-to-high temperature heat treatments. *Y. Zhao*[1], X. Gao[1], X. Bao[1], J. Li[1] and X. Mu[1] *1. State Key Laboratory for Advanced Metals and Materials, University of Science and Technology Beijing, Beijing, China*

In this work, the effect of heat treatment on texture evolution and magnetostriction of rolled 0.3mm thick $(Co_{70}Fe_{30})_{99.8}NbC_{0.2}$ sheets has been investigated. Results indicated that the primary recrystallization temperature of $(Co_{70}Fe_{30})_{99.8}NbC_{0.2}$ sheets was 600 °C. Holding the cold rolled sheet at 600 °C for one hour significantly reduced its saturation field of magnetostriction. Annealing the $Co_{70}Fe_{30}$ sheets between 600 °C and 700 °C for 1 h, the sheets retain the texture which was formed during the cold rolling process. Meanwhile, the magnetostriction of sheets remains around 65 ppm with increasing annealing temperature from 600 °C to 700 °C. As annealing temperature increases to 800 °C, the proportion of cubic texture markedly increased, and the magnetostriction obviously increases to 100 ppm. The clear correlation among heat treatments, recrystallization, texture, and magnetostriction provides an essential understanding for $(Co_{70}Fe_{30})_{99.8}NbC_{0.2}$ alloy sheets.

B9-06. Magnetostriction caused by crystallographic orientation and morphological alignment in $TbFe_2$ alloy. *T. Liu*[1], M. Dong[1], P. Gao[1], Y. Xiao[1], Y. Yuan[1] and Q. Wang[1] *1. Northeastern University, China, Shenyang, China*

Crystallographic orientation or morphological alignment has been evidenced to exhibit an obvious influence on physical properties of materials [1]. RFe_2 (R: rare earth) compounds, for instance, $TbFe_2$, are a kind of magnetostrictive materials and have a huge magnetostrictive anisotropy [2]. Previous studies have produced <111> oriented RFe_2 compounds and induced an obvious increase of the magnetostrictive performance [3,4]. However, if both crystallographic orientation and morphological alignment are simultaneously possessed in the compounds, the relationship between their effects on the magnetostrictive property is still not well understood. In this work, we solidified a $TbFe_2$ alloy in various high magnetic fields. By controlling the magnetic flux density, we produced microstructures with different crystallographic orientation and morphological alignment. We studied the influences of crystallographic orientation and morphological alignment on the magnetostrictive performance of the alloys and discussed the relationship between their influences. The microstructures of $TbFe_2$ alloys indicate that the alloy solidified at 1 T shows the best morphological alignment along the magnetic field direction, followed in descending order by the alloys solidified at 4.4 T, 2.2 T, and 0 T (Fig. 1). The XRD patterns show that the alloy exhibits a random orientation at 0 T, high <110> orientation at 1 T, <110> and <111> mixed orientation at 2.2 T, and high <111> orientation at 4.4 T (Fig. 2(a)). The magnetostriction measurement suggests that the alloy solidified at 4.4T shows the highest magnetostriction, followed in descending order by those solidified at 1 T, 2.2 T, and 0 T, although the alloy at 2.2 T shows a better magnetostrictive performance at low magnetic fields than that at 1 T (Fig. 2(b)). The above results indicate that both the crystallographic

orientation and the morphological alignment can alter the magnetostrictive performance of the RFe_2 compounds, and their influences exhibits a competition.

B9-07. Defective Onion-Like Carbon-Coated $FeSn_2$ Nanocapsules: One-Pot Synthesis and Application as Anode Material for Lithium-Ion Batteries. *S. Or*[1] and D. Han[1] *1. Electrical Engineering, Hong Kong Polytechnic University, Hong Kong, Hong Kong*

To overcome the principal shortcomings of large volume change-induced particle pulverization and lack of electrical contact in Sn-based anodes [1],[2], defective onion-like carbon-coated $FeSn_2$ ($FeSn_2$/DOLC) nanocapsules are synthesized, and their microstructural and electrochemical properties are evaluated for potential application as an anode material in lithium-ion batteries (LIBs). The synthesis of the $FeSn_2$/DOLC nanocapsules involves an one-pot procedure of reducing particle size, introducing a Sn-based intermetallic compound, combining the intermetallic compound with a conductive phase. The phase, morphology, microstructure, and composition studies (Fig. 1) of the $FeSn_2$/DOLC nanocapsules with XRD and TEM reveal that the $FeSn_2$/DOLC nanocapsules are composed of a crystalline $FeSn_2$ nanoparticle coated by a layer of defective onion-like carbon shell. The electrochemical evaluations (Fig. 2) indicate that the $FeSn_2$/DOLC nanocapsules exhibit a highly stable capacity of up to 519 $mAhg^{-1}$ with a large capacity retention of ~89.4% after 100 cycles at 50 mAg^{-1}. A superhigh rate performance with an improved capacity retention of ~97.2% is achieved when the rate is returned from 4 Ag^{-1} to 50 mAg^{-1}. The addition of the DOLC shell to the $FeSn_2$ nanoparticles not only can confine their growth within a closed volume, but also can enhance the overall electronic conductivity and give rise to good cyclability and superior rate capability in comparison with the $FeSn_2$ nanoparticles without the DOLC shell.

B9-08. Design of a Novel Electromagnetic Energy Harvester with Dual Core for Deicing Device of Transmission Lines. S. Paul[1], S. Bashir[1] and *J. Chang*[1] *1. Mechatronics System Research Lab, Electrical Engineering, Dong-A University, Busan, The Republic of Korea*

The present work proposes the design of a novel combined core electromagnetic energy harvester for powering the *ice shedder* [1], a deicing device, used for the transmission lines. The proposed model uses a combined core, made with Silicon (*Si*) and Nickel (*Ni*) steel to takes advantages of both the core materials such as the high magnetic flux density, low eddy current loss and high permeability. The design is performed using the finite element analysis (FEA). To obtain a high power output from the energy harvester, five different models are analysed, first three models consider the core material property to improve the output characteristic: (i) Model I (core with *Si* steel) (ii) Model II (core with *Ni* steel) (iii) Model III (Combined *Si*-*Ni* cores), as shown in Fig.1(a)~(c). For the dual core (Model III), the inner core is made with the *Si* steel while the outer core is of *Ni* steel. Even though *Ni* steel core provides a high relative permeability with low hysteresis losses, it suffers from the low saturation flux density. To prevent the hard saturation of the core, airgap is introduced in Model I~III, which is also needed to mount it around the transmission lines. Next two models (Fig. 1(d) and 1(e)) explore different airgap designs to provide a low reluctance path for the flux density,

by modifying the linear airgap of Model III with V shaped and stepped airgap. The induced voltages of the models under different airgap length are plotted in Fig. 2. For a constant airgap length, the modification of the airgap improves the output voltage hence harvested energy compared to the previous three models with the linear airgap. Model IV and V produced 54V and 61.54V compared with the 43V in case of Model III, with a constant airgap of 0.2 mm. Furthermore, from Fig. 2, the increase in the airgap length, reduces the induce voltage by increasing the airgap reluctance. Moreover, for model III, analysis results by varying the airgap ratio and radial position of cores are listed in Table I and II, which shows these variations do not improve the induced voltage. Further analysis considering the monocrystalline core, core losses and the effect of core saturation level on power output will be presented in the extended manuscript.

B9-09. Study of dynamic behavior of magnetostrictively patterned flexible micro-wings. *C. Cho*[1], Y. Hong[1], J. Chiao[1] and Y. Chen[1]
1. Department of Mechanical Engineering, Inha University, Incheon, The Republic of Korea

In this research new concept of micro shell which can be remotely actuated by controlling magnetic field is introduced. Since a new concept was introduced for microactuation based on magnetostriction. Most of magnetostrictive actuators have been developed as a bimorph cantilever type, composed of the magnetostrictive amorphous Tb-Fe and Sm-Fe thin filmes on a polyimide substrate. As a basic study for mechanical behavior of magnetostrictive film on a substrate, this research investigates how much the elastic energy of magnetostrictive film (volume) influences on mechanical behavior of the cantilevered film-substrate system. To this end the total energy including the elastic energy of magnetostrictive film is formulated and minimized to compute the elastic curve of neutral axis of the bimorph cantilever. The effects of the elastic energy of film are investigated by reviewing three magnetostrictive unimorph cantilevers and a bimorph cantilever. It is widely accepted that the film elastic energy is neglected in estimating total energy of the film and substrate due to the smaller volume (or thickness) of film compared to the substrate. However, the negligence leads to a considerable error specially in evaluating magnetostrictive coefficients. In other words, elastic energies between film and substrate, rather than volume ratios are more important. So the bending stiffness should depends on elastic energy by the film volume. By using this finding, a deliberate pattern design on the substrate can make a designated deformation of the system as desired. For studying a dynamic behavior of the patterned micro-wings this paper constructs a finite element model with in-plane and out-of-plane displacement for large deformation of the magnetostrictive thin film actuator of a wing shape, specially patterned to make a desired dynamic behavior like a bird's wing. By using a simpler model for the purpose of validating the computational model of the wing, the numerical results of magnetostriction analysis from the developed finite element model for the simpler model were compared with experimental results.

B9-10. Magnetostriction in Fe-Al Alloys Doped with Terbium. *M.C. Grijalva Castillo*[1], J.S. Uribe Chavira[2], M.O. Adelani[2], C. Santillan-Rodriguez[2], R. Sáenz-Hernandez[2], M. Botello-Zubiate[2] and J. Matutes-Aquino[2] *1. CONACYT - Centro de Investigación en Materiales Avanzados, S.C., Chihuahua, Mexico; 2. Centro de Investigación en Materiales Avanzados, S.C., Chihuahua, Mexico*

In recent years, there has been strong interest in producing low-cost magnetostrictive materials for various industrial applications, such as stress and torque sensing, energy harvesting, structural health analysis, among others. Besides exhibiting high magnetostriction at room temperature under low magnetic fields, these materials should also be easy to produce, inexpensive, easily machinable, and resistant to corrosion. A good candidate for these applications is Galfenol (iron-gallium alloys) which exhibited moderate magnetostriction in polycrystalline form. Recently has been reported a drastically improvement in the magnetostriction coefficient (up to -886 ppm perpendicular magnetostriction) of polycrystalline Galfenol melt spun ribbons doped with rare earths such as Tb [1-3] and Dy [4]. Authors associated the enhanced magnetostriction with the strong local magnetocrystalline anisotropy caused by the dopant. This raises the question if using similar technique with Fe-Al alloys should produce similar results. Therefore, in this work we have studied the magnetostrictive coefficient in Fe-Al alloys doped with Tb. Arc melting and subsequent annealing in vacuum atmosphere was used to prepare the alloys. Ribbons were obtained by melt spinning at the cooper wheel velocities of 10, 20 and 30 m/s. The composition of the samples was verified by energy dispersive X-Ray spectroscopy microanalysis. The crystalline structure was observed by X-ray diffraction using Cu Kα radiation and Rietveld refinement. Magnetostriction was measured using two methods: strain gauge technique and using a Quantum Design Dilatometer for a Physical Properties Measurement System (PPMS) with an applied magnetic field up to 1 Tesla at room temperature. The effect of the dopant concentration and copper wheel velocity is discussed.

B9-11. Optimal Design Algorithm of Synchronous Reluctance Motor considering Magnetic Saturation in the Rotor. *W. Kim*[1], S. Choi[1], H. Kong[1], D. Kim[1], J. Bae[3] and S. Lee[2] *1. Dept. of Energy IT, Gachon University, Seongnam-Si, The Republic of Korea; 2. Intelligent Information Technology Fusion, Busan University of Foreign Studies, Busan, The Republic of Korea; 3. Electrical Engineering, Dongyang Mirae University, Seoul, The Republic of Korea*

This paper presents a study on the design parameters considering magnetic saturation effect in the rotor core. The magnetic saturation is the cause for the variation of reluctance torque which is related to d-axis and q-axis inductance difference. In order to analyze the saturation effect of synchronous reluctance motor (SynRM), two rotor design parameters of thickness of main d-axis segment and q-axis end rip are selected. The torque and torque ripple are analyzed considering magnetic saturation by the design parameters. The reluctance torque is verified by the comparison of experiment and FEM simulation of d-axis and q-axis inductance of proto basis model.

The self-assembly of magnetic molecules on supporting surfaces provides potentially very interesting magnetic nano-devices. In a previous work we have evaporated wheel molecules of formula $\{Cr_{10}(OMe)_{20}(O_2CCMe_3)_{10}\}$, abbreviated $\{Cr_{10}\}$ (Fig. 1a), by direct sublimation in UHV on a Ag(110) single-crystal [1]. In powder form, the Cr-Cr interaction may be ferro- or antiferromagnetic, yielding to a paramagnetic molecule with ground state S=9 (implying that two Cr spins lie anti-parallel to the other eight, at T and H zero) [2][3]. For the powder the χT increases below 10 K, indicating average intracluster ferromagnetic behavior. In this work, the molecules are deposited onto the Au(111) surface. The STM image in Fig. 1b shows a monolayer of $\{Cr_{10}\}$ molecules, self-organized in a quasi-hexagonal 2D network. XMCD measurements were performed on the monolayer (1ML) and multilayer (14 ML) samples at the $L_{2,3}$ edges of Cr at T=1.8 K and magnetic field up to $\mu_o H$=6T. Magnetization and susceptibility were measured by SQUID magnetometry on the powder and the 14 ML samples (Fig. 2). In contrast to the powder sample, the 14 ML sample shows an overall intracluster antiferromagnetic coupling (χT decreases below 10 K). The M(H) XMCD determination of the $\{Cr_{10}\}$ 14 ML scales nicely to the SQUID measurement, with absolute values of the average Cr moment (m_{Cr}=1.89 μ_B). The M(H) XMCD for the 1ML sample is lower than the 14ML, evidencing a quenching effect of the substrate on m_{Cr}. Neither of the ML's show any anisotropy. Monte-Carlo simulations for the $\{Cr_{10}\}$, performed considering Cr(III) as individual S=3/2 spin entities coupled via Heisenberg interactions, allow to determine the exchange constants for the powder and 14 ML samples. In short, the self-assembly of 1ML $\{Cr_{10}\}$ molecules on Au(111) modifies the Cr-Cr intramolecular exchange pathways leading to a dominant antiferromagnetic intracluster coupling, and decreases the average Cr magnetic moment.

B10-02. Canonical ensemble calculations of the magnetic susceptibility for a spin-1/2 spherical kagome cluster with Dyzloshinskii-Moriya interactions by using microcanonical thermal pure quantum states. *K. Inoue*[1], Y. Maeda[1], H. Nakano[2] and Y. Fukumoto[1] *1. Tokyo University of Science, Noda, Chiba, Japan; 2. University of Hyogo, Ako-gun, Japan*

The spherical kagome system is an antiferromagnetic spin cluster defined on an icosidodecahedron, which has 30 vertices and 20 corner-sharing triangles, and an experimental realization is achieved in $\{W_{72}V_{30}\}$ [1]. Although, for cluster magnets, stepwise structures are expected in zero-temperature magnetization curves, $\{W_{72}V_{30}\}$ shows no such structure, which may be ascribed to Dyzloshinskii-Moriya (DM) interactions [2]. In this work, we present our calculated magnetic susceptibility for the spherical kagome cluster with DM interactions to compare with an existing experimental result. DM interactions break the conservation of total spin and get the evaluation of magnetic susceptibility to be more difficult. As for kagome-lattice antiferromagnets with DM interactions, Rigol and Singh calculated magnetic susceptibility up to a 15-site cluster to understand the experimental susceptibility of Herbertsmithite [3]. They calculated all eigenvalues under magnetic fields *H*, and evaluated magnetic susceptibility from the second-order coefficient in *H* of the free energy. Instead, we use the method of microcanonical thermal pure quantum (mTPQ) states to carry out calculations for the 30-site spherical kagome cluster. The mTPQ state is configured to reproduce the equilibrium value in the smooth microcanonical ensemble with a density

operator $(l–h)^k$, where h is the Hamiltonian density of the system and l is an arbitrarily selectable real number not less than the maximum eigenvalue of h [4]. We first show that the mTPQ states with sufficiently large l reproduce the equilibrium value in the canonical ensemble. In our susceptibility calculations, we apply magnetic fields, whose strength is chosen to be 10% of the exchange parameter, and calculate the induced magnetizations by using the mTPQ states. The susceptibility is obtained by dividing the magnetizations by the field strength. Although mTPQ expectation values contain statistical errors and the division process by a small field strength enhances the error, we find the present calculation procedure results in meaningful data. It is also found that the DM interaction moves theoretical susceptibility closer to the experimental one.

During the last decade, Single-Molecule Magnets (SMMs), which are discrete molecules showing slow relaxation of the magnetisation in the absence of long-range magnetic order, have gained increasing interest due to their potential applications in spintronics and quantum information processing [1,2]. The ultimate goal is to obtain total control over the electronic spin relaxation [3]. More recently, the focus has been on lanthanide based SMMs, showing strong spin-orbit coupling [3]. Here, the relaxation is linked to the energetic structure of the crystal field levels. Designing a ligand environment that will provide the optimal crystal field splitting, is however a complicated task. In general, tunnel splittings are expected to be suppressed by crystal field environments with sufficiently high-order symmetry [3]. Here we present a study on two dysprosium based SMMs. We determine the crystal field parameters by inelastic neutron scattering and measure the spin relaxation by ac-susceptibility. We find that a change of the crystal field symmetry from non-linear (C_4) to pseudo-linear (D_{4d}) in an otherwise unaltered complex results in a five-fold reduction of the tunnel splitting, from 327 s^{-1} to 63 s^{-1} [4]. This effect is striking, although not as large as the factor 200 predicted by the Prokof'ev-Stamp theory [5].

Molecular overlayers on ordered substrates have a broad field of application in catalysis, sensing, molecular electronics, etc. Recent studies of FePc on Ag(110) have shown that sub-monolayer phases are catalitically active [1]: in oxygen-dosed phases, O_2 intercalates between the molecules and the surface, substantially changing the Fe magnetic moment. Reversible switching of this moment in low-density FePc phases upon an oxygenation - annealing cycle has been demonstrated [2]. A continuous FePc monolayer on Ag(110) displays several phases, with different FePc density as a function of the molecular coverage. At low coverage, two degenerate but structurally distinct low-density superstructures simultaneously appear after a ~ 450 K annealing, namely a c(10×4)- and a p(10×4)-phase. At higher coverages, a denser oblique phase O(1±4,4-+3) is stablished after annealing. At even higher coverage, denser phases do form, namely a "quasi-square" phase (R3) and a square phase (SQ) [3]. The different FePc phases have been oxygen-dosed (10-100 L). Remarkably, in oxygen-dosed phases O_2 dissociates and intercalates between the molecules and the surface substantially changing the Fe magnetic moment. X-ray absorption combined with STM images allow us to determine the effectivity of the oxygenation procedure, as a function of the 2D structural phase, and to correlate it with the average magnetic moment as measured by XMCD at the Fe $L_{2,3}$–edges. Sum rule analysis yield the spin and orbital magnetic moments for each sample. It is concluded that all characterised phases display planar anisotropy, and the values of m_s^{eff} are about one order of magnitude larger than m_L in clear contrast to the FePc molecule in bulk or in multilayer, wich shows a much larger orbital moment [4]. Our work shows how oxidation and therefore magnetic moment switching depends on the steric facility for the molecules to form the Ag(110)-Oxygen-FePc ensemble, which is geometrically hampered in high density phases.

B10-05. Transition Metal Cluster Single-Molecule Magnets from Coupling of Low-Coordinate Metal Centers. *K. Chakarawet*[1], P.C. Bunting[1] and J. Long[1] *1. University of California, Berkeley, Berkeley, CA, United States*

Ever since the discovery of magnetic bistability in the dodecanuclear manganese cluster $Mn_{12}Ac$,[1] research in the field of single-molecule magnets has much focused on increasing the spin reversal barrier, *U*, formulated as $U = |D|S^2$ (for integer spin system). However, theoretical work indicates that the zero-field splitting parameter, *D*, for such metal cluster single-molecule magnets are inversely proportional to S^2, and thus preventing the realization of large spin reversal barrier via creating large spin clusters.[2] In contrast, research in mononuclear transition metal single-molecule magnets has progressed significantly over the past few years, with a two-coordinate cobalt complex being shown to exhibit the barrier as high as 413 cm^{-1}.[3] However, through-barrier relaxation poses a new challenge, as the relatively small spin of such system is more susceptible to perturbations. We will describe our effort to utilize low-coordinate, anisotropic metal centers in building metal clusters, in order to combine the large anisotropy as exhibited in mononuclear system with the large spin as achieved in multinuclear system. The investigation of tetranuclear metal phosphinimidinate clusters $M_4(NP^tBu_3)_4$ (M = Co, Ni)[4] containing low-coordinate metal centers will be discussed. Oxidation of the compounds to the cationic $[M_4(NP^tBu_3)_4]^+$ species will also be presented. The metal centers are shown to be engaged in strong electronic communication by means of electrochemistry and magnetometry. The magnetic properties of these molecules will be discussed, with the focus on the results that large spin ground states and large magnetic anisotropy can be achieved simultaneously in such system. Notable findings include the largest effective spin reversal barrier for transition metal cluster single-molecule magnet of 87 cm^{-1} found in $[Co_4(NP^tBu_3)_4][B(C_6F_5)_4]$.[5]

B10-06. Magnetic Properties of 2D Conductive MOFs, M-CAT-1. *Y. Misumi*[1], Z. Zhang[1] and K. Awaga[1] *1. Nagoya University, Nagoya, Japan*

Metal-organic frameworks (MOFs) are porous material formed by metal ions and organic ligands. Recently, 2D conductive MOFs, which have an extended π conjugation and a high conductivity, have been developed. Among them, M-CAT-1, which consists of 2,3,6,7,10,11-hexahydroxytriphenylene (HHTP) and metal ions, crystallizes into a honeycomb structure (Figure 1 [1]). In the present work, we carried out the magnetic measurements on M-CAT-1 with M = Co, Ni, and Cu. The temperature dependences of the magnetic susceptibilities follow Curie-Weiss paramagnetic behavior, which are consistent with the electronic/spin configurations, Co^{2+} ($S = 3/2$), Ni^{2+} ($S = 1$), and Cu^{2+} ($S = 1/2$). It is also found that the three compounds are EPR active even at room temperature. This is probably caused by the fact that HHTP in these MOFs are in a radical state. The variable-temperature EPR indicates that the signal shapes and *g*-factors depend on temperature significantly. We will discuss the interaction between the metal ions and the ligand radicals.

B10-07. Quantum Spin Liquid State in an Organic Hyperkagome Lattice of Mott Dimers. *A. Mizuno*[1], Y. Shuku[1] and K. Awaga[1] *1. Nagoya University, Nagoya, Japan*

A quantum spin liquid (QSL) state is an exotic solid-state property which is caused by spin frustration[1]. Various frustrated magnets, which have been investigated as QSL candidates, are characterized by no long-range magnetic ordering and gapless spin excitations. However, the nature of QSLs is still a matter of debate, and the spin excitations in QSL materials have been widely discussed. Many QSL candidates thus far possess 2D triangular and kagome lattices, and magnetic anisotropy, interlayer interactions, and structural deformations in them strongly affect their ground states. Thus, it is reasonable to expect quantum spin liquid states in 3D frustrated magnets with $S = 1/2$ isotropic Heisenberg spins. In the present research, we prepared a 3D organic frustrated magnet and investigated the detailed magnetic and thermal properties. These measurements revealed a 3D spin liquid state with an unusual temperature dependence of the heat capacity for this spin liquid state. One of the polyhedral π-conjugated acceptors, (−)-naphthalene diimide (NDI)-Δ (Fig. 1)[2], is used as a component of the 3D frustrated magnet. We prepared the radical anion salt of (−)-NDI-Δ, $(TBA)_{1.5}$[(−)-NDI-Δ] (TBA = tetrabutylammonium), and revealed a K_4 structure[3] (or srs net[4], etc.) formed by the 3-way branched intermolecular π-π overlaps between the NDI moieties (Fig. 2(a)). This spin lattice was identical to the hyperkagome lattice with isotropic $S = 1/2$ spins (Fig. 2(b), [5]), which is an ideal system of a 3D spin frustration. The magnetic susceptibility showed no long-range magnetic ordering down to 0.07 K in spite of 3D magnetic interactions with a Weiss constant of $\theta = -15$ K. No long-range magnetic ordering was also confirmed by ^{14}N NMR measurements. The low-temperature heat capacity measurements down to 68 mK indicated the presence of the heat capacity for the spin liquid state, which can be fited to the power law of $T^{0.62}$. These measurements strongly suggested the formation of a spin liquid state in the hyperkagome lattice.

B10-08. Verdazyl-Pincer Ligands: Building Blocks for Molecules with Unusual Magnetic Properties. *D.J. Brook*[1], C. Fleming[1], D. Chung[1] and R. Heindl[2] *1. Chemistry, San Jose State University, San Jose, CA, United States; 2. Physics, San Jose State University, San Jose, CA, United States*

The combination of transition metal ions with radical ligands has been a fruitful approach to the development of molecular magnetism. The ligands provide additional spins, as well as mediating magnetic interaction between the metal ions, and influencing the electronic structure of the metal itself. While studies with nitronyl nitroxides provided just exchange interactions, redox active ligands such as semiquinones, have introduced more exotic magnetic phenomena such as valence tautomerism and long range coupling mediated through delocalized electrons. Verdazyls are a series of heterocyclic free radicals that are relatively underutilized, but have great potential as radical ligands. Early studies demonstrated their structural versatility and ability to bridge metal ions as well as providing exceptionally strong exchange interactions. More recent studies have also shown that they are redox active, providing a rich area for further investigation. We have developed the synthesis of a dipyridyl subsitituted verdazyl 'pincer' ligand that shows very strong ferromagnetic exchange with nickel ions.[1] (Figure 1) We report here the complexes of the same ligand with iron and cobalt which highlight the redox properties of the ligand, producing examples of valence tautomerism (with Co), and spin dependent delocalization (with Fe), both also featuring very strong magnetic exchange (Figure 2). In the former case, the crystalline compound is best described as a Co^{2+} ion coordinated by two neutral radical ligands, but upon dissolution it exists in equilibrium with a Co^{3+} valence tautomer. In the latter case, reduction of the Fe^{2+} system by one electron switches the metal ion from low spin (S=0) to high spin (S=2) while the additional electron is delocalized over both ligands. This delocalization results in very strong ferromagnetic exchange between the remaining ligand unpaired electron and the metal ion, ultimately resulting in a disproportionally large increase in effective moment for a single electron reduction. These remarkable phenomena, taken together with the fact that verdazyls can also act as bridging ligands, suggest that verdazyl coordination may be a very productive area for discovery of new magnetic materials.

B10-09. Experimental Evidence for Enhancement of Quantum Coherence Near an Atomic-clock Transition in the Cr_7Mn Molecular Nanomagnet. *J.R. Friedman*[1], C. Collett[1], K. Ellers[1], N. Russo[2], K. Kittilstved[2], G. Timco[3] and R. Winpenny[3] *1. Department of Physics and Astronomy, Amherst College, Amherst, MA, United States; 2. Department of Chemistry, University of Massachusetts, Amherst, MA, United States; 3. Chemistry, University of Manchester, Manchester, United Kingdom*

Molecular nanomagnets have significant potential for use in quantum information processing. The ability to chemically engineer the molecules' anisotropy and environment affords them a unique flexibility among potential qubits. Atomic-clock transitions - radiative transitions that take place at an avoided level crossing - can enhance coherence times (T_2) due to the reduced sensitivity of the transition frequency to environmental fluctuations [1]. The Cr_7Mn molecular nanomagnet is a spin-1 system that has been demonstrated to have T_2 times on the order of microseconds at low temperatures when sufficiently diluted [2]. We performed spin-echo measurements on this molecular magnet in the vicinity of an avoided level crossing that occurs at zero magnetic field. Our samples are diluted by co-crystallizing Cr_7Mn with Ga_7Zn, a diamagnetic isostructural analogue. Using a loop-gap resonator tuned to the tunnel splitting of Cr_7Mn, ~4 GHz, we observe Rabi nutation and spin echo, enabling characterization of both T_1 and T_2 times. We find that T_2 is indeed enhanced at zero field, evidence of an atomic-clock transition. This finding, in conjunction with dilution and synthetic strategies to further enhance T_2, make this molecule a viable candidate for use as a spin qubit.

[1] M. Shiddiq et al., Nature 531, 348 (2016). [2] A. Ardavan et al., Phys. Rev. Lett., 98, 057201 (2007).

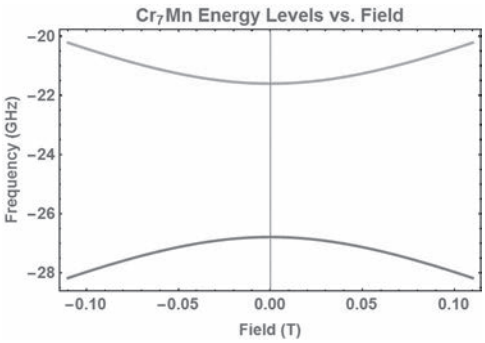

Fig. 1. Low-energy states for Cr_7Mn. The two lowest states of this spin-1 system are shown as a function of magnetic field. An energy gap occurs at zero field due to the molecule's intrinsic anisotropy. Radiative transitions between these two states at zero field are atomic-clock transitions, immune to magnetic field fluctuations to first order.

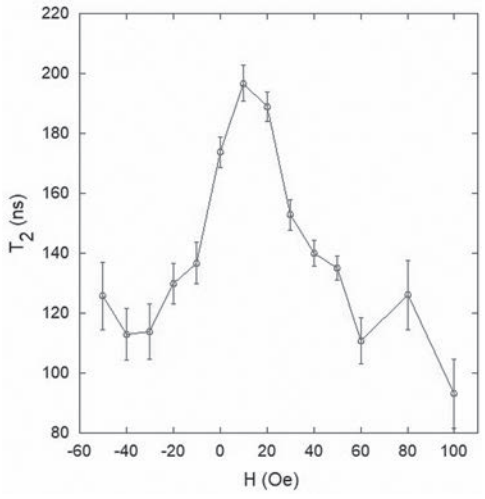

Fig. 2. Field dependence of T_2 for Cr_7Mn. T_2 was measured from spin echo decay at 1.8 K using a radiation frequency of 4.4338 GHz and a 10% dilute sample. The data shows a pronounced peak near zero field, where the transition occurs at the center of the avoided level crossing. The observed enhancement of T_2 provides compelling evidence of an atomic-clock transition occurring in this molecular nanomagnet.

B10-10. Photoinduced Decrease in Magnetization in Core@Shell Nanoparticles of RbCoFe@KNiCr PBA. *J.M. Cain*[1], A.C. Felts[1], D.R. Talham[1] and M.W. Meisel[2] *1. University of Florida, Gainesville, FL, United States; 2. Department of Physics, University of Florida, Gainesville, FL, United States*

$Rb_xCo[Fe(CN)_6]_y@K_aNi[Cr(CN)_6]_b$ coordination polymer core@shell heterostructure nanoparticles show a photoinduced decrease in magnetization when irradiated below the T_c = 70 K of the normally non-photoactive $K_aNi[Cr(CN)_6]_b$ [1]. This decrease can be attributed to a magnetomechanical effect, in which the $Rb_xCo[Fe(CN)_6]_y$ core undergoes a charge transfer-induced structural transition during cooling which strains the epitaxially-grown $K_aNi[Cr(CN)_6]_b$ shell. This structural transition is reversed through irradiation with white light at low temperature (T < 125 K), relieving the strain in the shell and, if the shell is magnetized, affecting a large decrease in the low-field magnetization. Previously, a simple model was developed which tied the depth to which the magnetization is affected to the penetration depth of structural microstrain observed in the shell using powder X-ray diffraction (PXRD) [2]. However, only one core size was studied, and a deeper understanding of the underlying mechanism is afforded by knowing how both the structural and magnetic strain depths evolve with core size. By studying core@shell heterostructures using three different core sizes, we found the strain depth in the shell increases from 45 nm to 110 nm upon changing the core size from 125(±13) nm to 575(±113) nm. Motivated by the PXRD results, a new quantitative model was developed which no longer relies on a 'rigid' core [2]. The trends observed, with previous results showing a change in the magnetic anisotropy of the $K_aNi[Cr(CN)_6]_b$ shell upon irradiation [3], suggest a domain-scale origin for the photoinduced decrease in magnetization, and spin-polarized small-angle neutron scattering studies are underway. * Supported by NSF DMR-1644779 (NHMFL), DMR-1708410 (MWM), DMR-1405439 (DRT).

B10-11. Chiral Effects on Magnetic Materials. *K. Inoue*[1] *1. Chemistry, Hiroshima University, Higashihiroshima, Japan*

The spin-spin magnetic interaction is classified into symmetric and anti-symmetric interaction. This symmetry means that the energy of the spin state is symmetric at a positive or negative angle between the spins. For example, exchange interactions and magnetic dipole interactions are given as the inner product of the spin vector, which is equivalent to the symmetric function of the cosine function. Therefore, spin exchange interaction and

magnetic dipole interaction are classified as symmetric interactions. On the other hand, the Dzyaloshinskii-Moriya (DM) interaction is classified as an anti-symmetric interaction, and the energy of the state is not equal to the angle of the positive and negative spins, in this case the spin structure will have non-collinearity. When this kind of handedness (or chirality) appears in the structure of atoms or molecules in a magnetic crystals, it affects the way that the spins arrange themselves through the Dzyaloshinskii-Moriya (DM) interactions [1,2-4, 6]. In a centrosymmetric structure, these interactions cancel out. Therefore, even though the chiral properties depend on the symmetry, they can be understood and manipulated at the mesoscopic level, independently of the structural details. [5, 7-13] The crystals belong to chiral space group and have long range magnetic ordering are still rare and difficult to design of crystals. The crystal design of molecule-based chiral magnetic materials is often use chiral induction with chiral ligands for coordination compounds. But the crystal design of inorganic chiral magnets is not established. [14-16] In this presentation, we would like to discuss how chirality influence on spin systems. B10-12. Anomalous antiferromagnetic state observed in the π-*d* molecular conductor λ-(BETS)$_2$FeCl$_4$. *Y. Oshima*[1], T. Lee[2,1], H. Cui[1] and R. Kato[1] *1. Condensed Molecular Materials Laboratory, RIKEN, Wako-shi, Japan; 2. Hokkaido University, Sapporo, Japan*

λ-(BETS)$_2$FeCl$_4$ is a molecular conductor, which consists of the conducting π-electron in the BETS molecule and the magnetic *d*-electron in the $FeCl_4^-$ anion. This system has a paramagnetic metal (PM) phase in the high-temperature region, but becomes simultaneously antiferromagnetic and insulating at T_N = 8.3 K thanks to the strong π-*d* interaction. Furthermore, the PM state is recovered above B_s=10.5 T when the magnetic moment of Fe^{3+} is fully saturated. The ground state of this antiferromagnetic insulating (AFI) phase is under debate for the past few decades since anomalous behavior such as a giant dielectric response or huge excess specific heat is observed nearby the phase boundary of the AFI and PM phase (see Ref. [1] for review). Here, we report our multi-frequency electron spin resonance (ESR) measurements in λ-(BETS)$_2$FeCl$_4$, which covers the whole AFI phase, in order to understand more deeply the AFI ground state. We have observed for the first time anomalous behavior of the antiferromagnetic resonance (AFMR) thanks to the multi-frequency ESR system up to 220 GHz. The frequency and resonance field diagram of AFMR at 2 K for *B//c*-axis is presented in Fig. 1. Conventional easy-axis mode of AFMR is observed below 4 T. However, the AFMR mode deviates from the easy-axis mode to the hard-axis mode above 4 T. Moreover, splitting of the AFMR signal is observed above 6 T. These results suggest that the antiferromagnetic easy-axis changes above 4 T, and two kinds of electronic states exist above 6 T. This is a surprising result since it is considered that the antiferromagnetic state of λ-(BETS)$_2$FeCl$_4$ is not affected up to the saturation field of B_s=10.5 T [1]. The temperature and magnetic field dependence of our multi-frequency ESR results will be presented in detail, and the AFI ground state will be discussed in relation with the observation of the dielectric anomaly within the AFI phase [2].

B11-02. Decoding quantum criticalities from fermionic/parafermionic topological states. *G. Zhang*[1] *1. Physics, Tsinghua University, Beijing, China*

In the Fock representation, we propose the generalized matrix product states to describe one-dimensional topological phases of fermions/parafermions. The defining feature of these topological phases is the presence of Majorana/parafermion zero modes localized at the edges. It is shown that the single-block bipartite entanglement spectrum and its entanglement Hamiltonian are described by the effective coupling between two edge quasiparticles. Furthermore, we demonstrate that sublattice bulk bipartition can create an extensive number of edge quasiparticles in the reduced subsystem, and the symmetric couplings between the nearest neighbor edge quasiparticles lead to the critical entanglement spectra, characterizing the topological phase transitions from the fermionic/parafermionic topological phases to its adjacent trivial phase. The corresponding entanglement Hamiltonians for the critical entanglement spectra can also be derived.

B11-03. Influence of La doping in the electronic and magnetic properties for the Sr_2FeMoO_6 compound. *F. Estrada Chávez*[1,2], B. Aguilar Reyes[3], O. Navarro Chavez[3] and M. Avignon[4] *1. Facultad de Biología, Universidad Michoacana de San Nicolás de Hidalgo, Morelia, Mexico; 2. Escuela Nacional de Estudios Superiores, Unidad Morelia, Universidad Nacional Autónoma de México, Morelia, Mexico; 3. Unidad Morelia Instituto de Investigaciones en Materiales, Universidad Nacional Autónoma de México, Morelia, Mexico; 4. CNRS, Université Grenoble Alpes, Grenoble, France*

The half-metallic ferromagnetic double perovskites are very attractive due to its spintronics applications, in particular, the ferromagnetic Sr_2FeMoO_6 system, because of its fairly high Curie temperature ~450 K, half-metallic character and complete spin polarization. Additional to the well-known disorder in Fe-Mo double perovskites, the La-doping induces disorder on Fe/Mo ions, which compete with the increases of the Curie temperature in above system. In this work, we study the effect of cationic disorder on the spin polarization of the Sr_2FeMoO_6 compound when divalent Sr is replaced by trivalent La ions. We present an electronic approach using the Green's function technique and the renormalization perturbation expansion method, where the localized Fe-spins and conduction Mo-electrons interacting via a double-exchange-type mechanism. In our model, electronic correlations are also included among the conduction electrons within a dynamical mean-field approach. Our results show the influence of disorder on the electronic and magnetic properties as a function of La doping.

B11-04. Asymmetry of the density of states and magnetic exchange interactions in Hund's metals. *A. Katanin*[1], A. Belozerov[1,2] and V. Anisimov[1,2] *1. M.N. Miheev Institute of Metal Physics UB of RAS, Ekaterinburg, Russian Federation; 2. Ural Federal University, Ekaterinburg, Russian Federation*

We discuss the effect of the asymmetry of the density of states on a possibility of Hund's metal behaviour and the way of calculation of the respective exchange interactions between frozen-spin states, corresponding to local moments. We find that quasiparticle damping and the formation of local magnetic moments due to Hund's exchange interaction are enhanced by asymmetry of the density of states; the properties of Hund's metal are mainly observed close to half filling, on the same side of half filling as the maximum of the density of states, and become stronger with increasing asymmetry. We also suggest the way to calculate the magnetic exchange interaction of Hund's metals within the supercell DMFT approach. We discuss implication of the obtained results to alpha-iron, for which ab initio calculations show a possibility of realization of Hund's metal behavior, and obtain the respective momentum- and temperature dependences of the magnetic susceptibilities and magnetic exchange interaction in this substance.

B11-05. Phenomenological Mean-Field Analysis of Metamagnetism in Heavy Fermion Compounds. *K. Matsumoto*[1] and S. Murayama[2] *1. Graduate School of Engineering, Muroran Institute of Technology, Muroran, Japan; 2. Graduate School of Engineering, Muroran Institute of Technology, Muroran, Japan*

Metamagnetism observed in some heavy fermion compounds is an intriguing phenomena. Though the metamagnetic behaviors of Ce-based heavy fermion compounds are investigated mainly within microscopic theories, they are also studied by using the Landau-like free energy density. [1] To explain the experimental data quantitatively, we can extend this Landau-like free energy density theory toward two directions. First, since the entropy in the Landau-like free energy density is not accounted exactly, we use the accurate entropy expression, i.e. the Bragg-Williams entropy with the sub-lattice magnetization m in the condition of $m<1$. We obtain more plausible magnetization curves than those of the Landau-like theory. Second, since the theoretical results are under the *constant volume* condition and the experiments are carried out under the *constant pressure* condition, we should correct the theoretical analyses for the experimental behaviors. We obtain the transform formula between the theoretical results and the experimental data using the scaling theory of Matsuhira et al. [2] Thus, the improvement of the both directions can lead us to more reliable phenomenological description for the Ce-based heavy fermion compounds. We apply this improved theory to $CeRu_2Si_2$(the conventional metamagnetism), CeTiGe(the first order metamagnetic transition), and $CeRh_2Si_2$(the metamagnetic transition from the antiferromagnetic- to the highly polarized state). As the results,

we successfully obtain the magnetic phase diagrams of the three compounds which are comparable to the experimental observations.

B11-06. Energy of a Finite Three-Dimensional Electron Gas System. *O. Ciftja*[1] *1. Department of Physics, Prairie View A&M University, Prairie View, TX, United States*

We consider a fully spin polarized (spinless) finite three-dimensional electron gas system where a small number of electrons is confined in a finite cubic domain. The cubic region is treated as a uniform jellium background of positive charge to guarantee overall charge neutrality. A Hartree-Fock (HF) approach leads to an integral representation of the energy of the finite system in terms of certain auxiliary functions, but exact analytical results are not feasible for a finite system of this nature. In order to simplify the overall treatment of the problem, we introduce an approximation that leads to analytic results for the energy without any significant loss of accuracy. The quality of this approximation is assessed via numerical tools by comparing the approximated analytic results to the numerically exact ones obtained from simulations. Instances in which one can calculate the HF energy by using the approximated result instead of the computationally unyielding numerically exact one are discussed. It is found that the accuracy of the approximation only improves as the number of electrons in the system increases and the approach leads to the exact HF energy in the thermodynamic limit. The results derived apply to finite nanoscale systems of electrons confined along all directions of space in typical three-dimensional semiconductor quantum dot systems where the depleted domain is approximately cubic in shape.

B11-07. A novel solution of the 2D Hubbard model within a four-pole approximation. A. Di Ciolo[1] and *A. Avella*[1,2] *1. Dipartimento di Fisica "E.R. Caianiello", Università degli Studi di Salerno, Fisciano, Italy; 2. UoS di Salerno, CNR-SPIN, Fisciano, Italy*

We present a novel solution of the 2D Hubbard model in the framework of the Composite Operator Method (COM) [1-3] within a four-pole approximation. First, we solve the corresponding 2-site system within an operatorial approach highlighting the crucial role played by the spin fluctuations and identifying the composite operators describing such excitations. Accordingly, we adopt a basis of four fields: the two Hubbard operators plus two fields describing the Hubbard transitions dressed by the nearest-neighbor spin fluctuations. This approximate solution is in remarkable agreement with the 2-site exact one as well as the corresponding 2D approximate solution performs very well once compared to advanced (semi-)numerical methods from the weak- to the strong- coupling regime for all relevant values of doping and temperature, being by far less computational-resource demanding. Moreover, this solution, by treating the spin fluctuations with extreme care and featuring a well-developed momentum selectivity, opens up the possibility to directly address the underdoped-cuprate puzzle (Fermi arcs, pseudogap, non-Fermi liquid behavior, extreme momentum dependence of spectral properties, ...), on a level before possible only including explicitly a residual self-energy in the calculations [3]. Therefore, we adopt this approximation to study the single-particle properties of the 2D model in the strong coupling regime (small doping and low temperatures) where the effects of the spin fluctuations are more relevant and induce anomalous features in all analyzed properties that can be put in direct connection with those measured for the underdoped cuprates.

B11-08. Dislocation-mediated quantum melting. *A. Beekman*[1] *1. Department of Physics, Keio University, Yokohama, Japan*

Already in their early papers, Kosterlitz and Thouless envisaged the melting of solids by the unbinding of the topological defects associated with translational order: dislocations. The resulting phases have partial or complete translational symmetry but rotational rigidity, the symmetry structure of liquid crystals. Here we consider the topological melting of strongly-correlated solids as a zero-temperature quantum phase transition. Employing a generalization of particle-vortex duality, the Nambu–Goldstone modes of the solid, phonons, are mapped onto gauge bosons. Therefore these can be called "stress photons", and they mediate long-range interactions between the dislocations. The phase transition to the liquid-crystalline phase is a proliferation (or condensation) of dislocations, restoring translational symmetry. Consequently, the stress photons undergo a Meissner-like effect and decay exponentially, signaling the loss of shear rigidity in the liquid crystal. Nambu–Goldstone modes related to rotational rigidity emerge as soon as translational symmetry is restored, and are intrinsically linked to the appearance of the dislocation condensate. Furthermore, electrically charged liquid crystals are automatically real superconductors as well. We have recently

reviewed this theory in 2+1 dimensions, where dislocations are particle-like [1]. The extension to 3+1 dimensions entails dislocation strings, while the phonons dualize into two-form Kalb–Ramond gauge fields. Considering an appropriate Ginzburg-Landau-type theory for two-form gauge fields, we can enumerate the quantum analogues of columnar, smectic and nematic liquid crystals and their hydrodynamics modes [2]. This work was inspired by electronic spatial orderings in high-temperature superconductors, and we make several general predictions for stripe melting. Moreover there is recent evidence for an atomic quantum liquid-crystalline phase ("quantum hexatic") in helium monolayers [3]. We use our effective theory to investigate the critical properties of this solid-to-hexatic quantum phase transition.

B11-09. Theory of Temperature-dependent Collective Excitations in Excitonic Insulators. *F. Xue*[1] and A.H. MacDonald[1] *1. Physics, University of Texas at Austin, Austin, TX, United States*

Semimetals with small gaps are predicted to be unstable against long-range Coulomb interaction that lead to exciton condensation and to an excitonic insulator state. From a symmetry point of view the excitonic insulator ground state of an indirect gap system is indistinguishable from a charge density wave state that forms due to electron-phonon interactions and Fermi-surface nesting. Both mechanisms leads to energy gaps and spatial inhomogeneity. Motivated by a recent momentum-resolved electron energy-loss spectroscopy study of soft collective modes in the semimetal 1T-TiSe_2 [1], we develop a fluctuating mean-field theory to study temperature-dependent collective excitations. The model includes both intraband and interband excitations and direct and exchange interactions, and allows for the formation of an exciton condensates at low temperatures. To identify different collective modes from the intraband and interband continuum, we study both intraband (\tau_0-\tau_0) and interband (\tau_x-\tau_x) linear response. When the system does not support an exciton condensate, only thermally-excited intraband plasmons are supported by intraband excitations, and only exciton collective modes are supported by interband excitations. However, interband and intraband excitations are coupled when the condensates form. Interband excitons then contribute to the \tau_0-\tau_0 linear response function at low temperature, and Higgs modes appear on the \tau_x-\tau_x response. We comment on the implications of our theory for the interpretation of the recent observations in [1].

B12-01. Existence of spin-liquid states in the Kitaev-Heisenberg ladder. *C. Agrapidis*[1], J. van den Brink[1,2] and S. Nishimoto[1,2] *1. Institute for Theoretical Solid State Physics, Leibniz Institute for Solid State and Materials Research (IFW) Dresden, Dresden, Germany; 2. Department of Physics, Technical University Dresden, Dresden, Germany*

It is widely accepted that the Kitaev-Heisenberg (KH) model on a honeycomb lattice is a good minimal model for some candidate spin liquid materials (e.g. α-$RuCl_3$). Though the KH hamiltonian has been studied in 2D, systematic analysis including finite-size scaling is still lacking due to numerical difficulties. Whereas very precise analysis is possible for 1D and quasi-1D KH systems. We study the KH ladder using the exact diagonalization and density matrix renormalization group techniques. We present its phase diagram as a function of an angle parameter ϕ, having defined the Kitaev interaction as $sin\phi$ and the Heisenberg one as $cos\phi$. Remarkably, we find that the phase diagram has a resemblance to the one suggested for the same model on the honeycomb lattice [1], showing similar phases, namely spin-singlet, zig-zag, ferromagnetic-*xy*, ferromagnetic-*z*, stripy and two spin liquid states around the Kitaev points ($\phi=\pm\pi/2$). We also present some results in the presence of magnetic field and discuss the spin-liquid properties.

B12-02. Quantum-Disordered Ground State with Singlet Gap of the Spin-1/2 Square-Lattice Random J_1-J_2 Heisenberg Antiferromagnet $Sr_2CuTe_{1-x}W_xO_6$. *M. Watanabe*[1], N. Kurita[1] and H. Tanaka[1] *1. Tokyo Institute of Technology, Meguro-ku, Japan*

Theoretical studies demonstrated that the exchange randomness in the frustrated quantum magnets suppresses the spin ordering and induces the spin-liquid-like ground state with increasing the degrees of randomness [1,2]. The spin-liquid-like state is considered to be valence-bond-glass (VBG) state, where the spin singlet is formed between not only nearest-neighbor spins but also distant spins with random coupling energies. We present the low-temperature magnetic properties of $Sr_2CuTe_{1-x}W_xO_6$, which is characterized as an $S=1/2$ square-lattice random J_1-J_2 Heisenberg antiferromagnet. The nearest-neighbor interaction J_1 is dominant in Sr_2CuTeO_6 [3], while the next-nearest-neighbor interaction J_2 is dominant in Sr_2CuWO_6 [4]. We can expect that the partial substitution of Te^{6+} for W^{6+} produces the randomness in J_1 and J_2 interactions, which leads to the spin-liquid-like state. Polycrystalline samples of $Sr_2CuTe_{1-x}W_xO_6$ ($x=0$, 0.1, 0.2, 0.3, 0.4, 0.5, 1) were synthesized by a solid-state reaction. We performed magnetization and specific heat measurements systematically. For the mixed system $0.1 \le x \le 0.5$, Curie-like paramagnetism was observed in the low-temperature magnetic susceptibility. The *T*-linear component was clearly observed in the low-temperature specific heat. These results are expected for the gapless valence-bond-glass states. No signatures indicative of long-range order or spin-glass state was also observed in susceptibility and specific heat data. It is noteworthy that a drastic decrease in *T*-linear component was observed below $T \approx 1.2$ K, which is robust to magnetic fields up to 9 T. This is suggestive of the existence of the singlet excitation from the quantum disordered ground state. These results show that the ground state of $Sr_2CuTe_{1-x}W_xO_6$ is the valence-bond-glass state with a singlet gap.

B12-03. Dirac and chiral quantum spin liquids on the honeycomb lattice in a magnetic field. *Z. Liu*[1] *1. Department of Physics, Renmin University of China, Beijing, China*

Motivated by recent experimental observations in α-$RuCl_3$, we study the K-Γ model on the honeycomb lattice in an external magnetic field. By a slave-particle representation and Variational Monte Carlo calculations, we reproduce the phase transition from zigzag magnetic order to a field-induced disordered phase. The nature of this state depends crucially on the field orientation. For particular field directions in the honeycomb plane, we find a gapless Dirac spin liquid, in agreement with recent experiments on α-$RuCl_3$. For a range of out-of-plane fields, we predict the existence of a Kalmeyer-Laughlin-type chiral spin liquid, which would show a quantized thermal Hall effect.

[1] arXiv:1709.07990

B12-04. Non-Abelian S = 1 chiral spin liquid on the kagome lattice. *Z. Liu*[1] *1. Department of physics, Renmin University of China, Beijing, China*

We study S = 1 spin liquid states on the kagome lattice constructed by Gutzwiller-projected px+ipy superconductors. We show that the obtained spin liquids are either non-Abelian or Abelian topological phases, depending on the topology of the fermionic mean-field state. By calculating the modular matrices S and T, we confirm that projected topological superconductors are non-Abelian chiral spin liquid (NACSL). The chiral central charge and the spin Hall conductance we obtained agree very well with the SO(3) level 1 field theory predictions. We propose a local Hamiltonian which may stabilize the NACSL. From a variational study we observe a topological phase transition from the NACSL to the Z2 Abelian spin liquid.

B12-05. Spin liquid on the stuffed honeycomb lattice. *J. Sahoo*[1], D. Kochkov[2], B. Clark[2] and R. Flint[1] *1. Physics and Astronomy, Iowa State University, Ames, IA, United States; 2. Physics, University of Illinois at Urbana-Champaign, Champaign, IL, United States*

We introduce the stuffed honeycomb lattice (a honeycomb lattice with a superimposed triangular lattice formed by sites at the center of each hexagon) that interpolates between the triangular and the honeycomb lattice[1]. The triangular lattice limit is particularly interesting as the triangular lattice itself has a clear spin liquid region[2,3,4] whose nature is still unclear. We analyze both the classical and quantum phase diagrams, revealing a novel classical multi-critical point. This multi critical point lies on the triangular limit line and is surrounded by four phases namely the collinear, interpolating and two non-collinear phases (Non-collinear I and Non-collinear II) that compete with each other and eventually gives rise to a large spin liquid region, as seen in exact diagonalization results. Projective symmetry group [5,6] analysis combined with variational Monte Carlo simulations suggest that the region is a novel Dirac spin liquid.

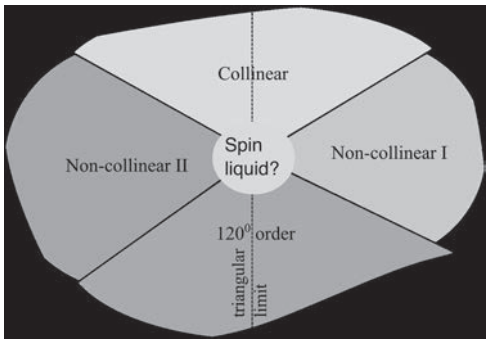

Fig. 1. Multi-critical point hosting the spin liquid phase.

B12-06. NMR Study of Spin-1/2 Square-Lattice Random J_1-J_2 Heisenberg Antiferromagnet $Sr_2CuTe_{1-x}W_xO_6$. *W. Ueno*[1], K. Matsui[1], T. Goto[1], M. Watanabe[2] and H. Tanaka[2] *1. Physics Division, Sophia University, Chiyodaku, Japan; 2. Tokyo Institute of Technology, Meguro-ku, Japan*

The quasi-two-dimensional compounds Sr_2CuMO_6 (M = Te and W) are described as S =1/2 square-lattice J_1-J_2 Heisenberg antiferromagnets with dominant J_1 and J_2 in-plane exchange interactions on nearest neighboring and next nearest neighboring spins, respectively. Both Sr_2CuWO_6 and Sr_2CuTeO_6 show an antiferromagnetic order at T_N = 24 and 29 K with different spin structures, the collinear antiferromagnetic state and the Néel antiferromagnetic state, respectively [1,2]. This difference is interpreted in terms of the ratio of J_1 and J_2. The purpose of this study is to investigate microscopically the ground state of solid-solution system of the two. In partially substituted systems, randomness is introduced both in J_1 and J_2, and the magnetic order is expected to be suppressed. Cu-NMR study was performed on powder samples of $Sr_2CuTe_{0.8}W_{0.2}O_6$ (x = 0.2) and $Sr_2CuTe_{0.9}W_{0.1}O_6$ (x = 0.1) by using 16 T superconducting magnet, in the temperature range between 1.8 and 20 K. NMR spectra, a typical powder pattern for I = 3/2 quadrupolar nuclei, was obtained by plotting the spin-echo amplitude against the magnetic field. From the analysis of spectra for x = 0.2 taken under several different NMR frequencies with 2nd order perturbation, the Knight shift K and the nuclear quadrupolar parameter $^{63}\nu_Q$ at 1.8 K were obtained as 1.3 % and 52 MHz, respectively. As increasing the temperature, K showed a slight decrease to be 1.0 % at 20 K. This smallness in K directly assures that the x = 0.2 system stays paramagnetic at low temperatures. By the scaling of K and uniform susceptibility, the hyperfine coupling constant was determined to be -13 T/μ_B. Its negative sign and magnitude are typical for divalent coppers, and assures that NMR well probes the copper spins. As for x = 0.1, the observed NMR signal was much weaker than that for x = 0.2, possibly because of a short relaxation time T_2, suggesting that the composition x = 0.1 locates in the vicinity of quantum critical point (QCP) between the antiferromagnetism and the paramagnetism.

B12-07. A Phase Diagram for Hole-Doped Lithium Iridates. *M. Vranas*[1], A. Ruiz[1], G. Lopez[1] and J. Analytis[1] *1. Physics, University of California, Berkeley, Berkeley, CA, United States*

Spin systems with anisotropic exchange interactions have been proposed to give rise to quantum spin liquid ground states. In 5d materials, strong spin-orbit coupling causes large anisotropies, which, in the case of the honeycomb iridates, leads to strong magnetic frustration closely described by the Kitaev Hamiltonian. Still, all potential Kitaev materials order at low temperatures, and therefore do not satisfy the QSL ground state. Experiments show, however, that the Kitaev interaction dominates in these systems; studying the nature of the magnetic ordering can therefore lead to a deeper understanding of spin-interactions in these systems. In particular, the beta- and gamma-phases of the lithium iridates, Li_2IrO_3, show an unusual incommensurate antiferromagnetic ordering at low temperatures, Ti ~ 38K. Just as magnetic ordering can be suppressed by the application of weak magnetic fields and isotropic pressure, doping the compound with its nonmagnetic counterpart gives us insight into the nature of its strange magnetic ordering via its suppression. In this work, we report a full phase diagram indicating the transitions present in a hole-doped strain of Li_2IrO_3, indicating the fragility of the incommensurate order.

B12-08. Absence of long-range order in $K_2Ni_2(SO_4)_3$ with a novel modified hyper-kagome lattice. *I. Zivkovic*[1], R.S. Freitas[2], V.Y. Favre[3], C. Mingee[1], P. Baker[4], C. Baines[5], H. Luetkens[6], A. Magrez[1] and H.M. Ronnow[1] *1. Institute of Physics, EPFL, Lausanne, Switzerland; 2. Departamento de Física dos Materiais e Mecânica, Instituto de Física, Universidade de São Paulo, São Paulo, Brazil; 3. Physics, EPFL, Lausanne, Switzerland; 4. ISIS, Oxford, United Kingdom; 5. PSI, Villigen, Switzerland; 6. PSI, Villigen, Switzerland*

In recent years several magnetic compounds have been suggested to have a ground state without long-range order. It is assumed that such a state is characterized by a highly dynamic spectra of entangled spins, i.e. a quantum spin liquid. A necessary requirement is a geometrical frustration imposed by the underlying crystal lattice of magnetic ions, paired with antiferromagnetic interactions. Well-known systems are 2D triangular $NiGa_2S_4$ and $YbMgGaO_4$, 2D kagome $ZnCu_3(OH)_6Cl_2$ and 3D hyper-kagome $Na_4Ir_3O_8$ [1]. Here we present results of our investigation of $K_2Ni_2(SO_4)_3$ which belongs to a family of sulphates of the langbeinite type $K_2M_2(SO_4)_3$, investigated for their ferroelectric behavior [2]. Our susceptibility, μSR, specific heat and neutron diffraction experiments show that no long range order occurs down to lowest temperatures achieved. A linear Curie-Weiss behavior of inverse susceptibility is observed from 350 K down to 50 K, with θ = -17 K, indicating a dominant antiferromagnetic interaction. μSR revealed absence of oscillations or wiggles in a wide temperature range from 300 K down to 20 mK with no sign of frozen moments or any static magnetism emerging from applying a longitudinal field up to 2000 G. Magnetic specific heat (extracted using a non-magnetic analog $K_2Mg_2(SO_4)_3$) exhibits a broad maximum centered around 5 K with $C_P \sim T^2$ for $0.05 < T < 1$ K which points to gapless, linearly dispersive modes in two dimensions. Similar finding has been reported for a two-dimensional triangular lattice compound $NiGa_2S_4$ [3] but for $K_2Ni_2(SO_4)_3$ t represents a surprising discovery since it crystallizes in a chiral cubic $P2_13$ space group without any distinguished low-dimensional features. In fact, it can be described as a modification of a hyper-kagome lattice in $Na_4Ir_3O_8$: there are two crystallographic sites (Ni1 and Ni2), each forming a network of equilateral triangles. Triangles are further connected in a non-coplanar way to form pentagons, raising even further the level of geometrical frustration. With Ni ions having S=1 spin state $K_2Ni_2(SO_4)_3$ represents a new route for testing theories of quantum spin liquids beyond S=1/2.

B12-09. Quantum spin ice under an electric field. *S. Onoda*[1,2] *1. Condensed Matter Theory Laboratory, RIKEN, Wako, Japan; 2. Quantum Matter Theory Research Team, RIKEN CEMS, Wako, Japan*

Quantum spin liquids are novel hypothetical states of magnetic materials where elementary excitations are described by so-called spinons fractionalized from spins and by gauge bosons. Unambiguously detecting the emergent gauge fields and spinons has been called for to establish quantum spin liquids from experiments, although it remains open to date. Here,

we theoretically demonstrate novel ways of detecting analogous quantum electrodynamics and Maxwell laws hosted by bosonic U(1) quantum spin liquids. In particular, we treat quantum spin ice for magnetic rare-earth pyrochlores and possibly *A*-site intercalated spinel iridates. Field-theoretical analyses of quantum spin ice have highlighted several phases around classical spin ice, including a deconfined U(1) quantum spin liquid hosting the analogous compact quantum electrodynamics of magnetic and electric monopoles as well as gapless photons, and charge-1 Higgs phases where magnetic monopoles are Bose-Einstein condensed and their excitations as well as the gauge fields are completely screened. Now two nontrivial phenomena of deconfined magnetic monopoles in quantum spin ice are in order. Both are based on an observation that the symmetry requires a coupling between an external electric field/polarization and a fictitious electric gauge flux directly transmitted to magnetic monopoles [1]. Firstly, we show that an electric field applied to the edges of the U(1) quantum spin liquid creates the fictitious electric gauge flux for deconfined magnetic monopoles in the bulk and bends their orbital motion. This leads to antisymmetric tensor components in transport coefficients of magnetic monopoles and thus a heat carried by them [2], in an analogy to Hall transport phenomena of electrically charged particles under a magnetic field or with a uniform magnetization. Secondly, we show that dissipationless magnetic monopole supercurrent is generated across a tunnel junction of, for instance, two charge-1 Higgs confined ferromagnets weakly linked through the U(1) quantum spin liquid under an applied electric eld parallel to the interface [1]. Finally, we discuss possible experimental setups for the two phenomena using candidate materials $Pr_2Zr_2O_7$ and $Yb_2Ti_2O_7$.

B13-01. Improved structural, magnetic and spectroscopic properties of M-type strontium hexaferrite synthesised by citrate precursor method. *K. Rana*[1], P. Thakur[2] and A. Thakur[2] *1. Department of Physics, IEC University, Baddi, India; 2. Department of Physics, Amity University, Gurgaon, India*

In present investigation Mtype $SrFe_{12}O_{19}$ hexaferrite has been synthesised by conventional citrate precursor method. The magnetic, spectroscopic and structural properties of $SrFe_{12}O_{19}$ ferrite was examined at two different sintering temperature i.e. 800°C and 950°C. After an appropiate heat treatment the powder sample is pressed in pellet form and characterised by using Xray diffraction (XRD) Field emission scaning electron microscopy (FESEM),Transmission electron microscopy (TEM), fourier transform infrared spectroscopy (FTIR), Raman spectroscopy (RS) and Vibrating sample magnetometer (VSM). XRD revealed the fornamtion of M-phase of $SrFe_{12}O_{19}$ with an average crystallite size slightly increased from 36-39 nm. FESEM micrograph confirmed the uniform ferrite grains with an average size of 80 and 95 nm. Average crystallite size found from TEM are in close aggrement with XRD results. FTIR and RS are used to study the spectroscopic properties of SrM ferrites. The position of vibrational bands in the range 460-420 cm^{-1} and 560-540 cm^{-1} confirmed the strong metal oxygen bond streching vibration of hexaferrite. M-H loops of these samples are measured at room temperature upto an applied field of 10,000 Oe. Coericivity of these ferrites are found to be of the order of few hundereds Oesterd, an essential condition for electromagnetic materials. Saturation magnetisation M_s and squareness ratio (M_r/M_s) of the sample sintered at 950°C are found to be 92.58 emu/g and 0.5836 respectively. These properties make this material suitable for recording media as well as high frequency applications.

B13-02. Hard-magnetic properties of (Co, Mn) co-doped $BaFe_{12}O_{19}$ hexaferrites. *N. Tran*[1], H. Kim[1], T. Phan[1] and B. Lee[1] *1. Department of Physics and Oxide Research Center, Hankuk University of Foreign Studies, Yongin-si, The Republic of Korea*

$BaFe_{12}O_{19}$, namely M or BaM ferrite, has been of interest for many years due to its attractive physical properties [1-4]. Its magnetic properties can easily tuned as expected upon fabrication conditions, crystal sizes, and dopants [5, 6] that widens remarkably its application range. For the doping case, Fe in $BaFe_{12}O_{19}$ can be substituted a transition metal. In this work, $BaCo_{1-x}Mn_xFe_{11}O_{19}$ (x = 0-1) nanoparticles (NPs) were prepared by co-precipitation method followed by heat treatment. These NPs were then checked the grain morphology by a scanning electron microscope (SEM). Their crystal structures were studied by using an X-ray diffractometer (XRD). The magnetic properties were studied by using a vibrating sample magnetometer. Results revealed that fabricated $BaCo_{1-x}Mn_xFe_{11}O_{19}$ NPs with average particle sizes of 100~400 nm crystallized in a hexagonal structure. When Mn content (x) increases, the shape as well as the grain size of crystals modify very much. The size increases rapidly from ~100 nm to ~400 nm with increasing of x. In addition, the shape of the samples becomes clearly hexagonal plates which can be observed from SEM images. This agrees with the XRD patterns, shown in Fig. 1. The peaks become shaper for high x value samples. Lattice parameters a and c decrease with increasing of x, in the range of a = 5.970(2)–5.985(7) Å, and c = 23.116(6)–23.239(3) Å. This is ascribed to the difference between Mn^{3+} ionic radius (0.66 Å) and Co^{2+} ionic radius (0.72 Å). Our study on the magnetic properties has indicated the x dependence of magnetic parameters, as seen in Fig. 2. While M_s decreases from 46.1 emu/g for x = 0 to 29.9 emu/g for x = 1, H_c tends to increase from 1630 Oe for x = 0 to ~5010 Oe for x = 1. It is worth noting that M_r/M_s increases from 0.61 for x = 0 to 0.89 for x = 1, revealing the applicability of $BaCo_{1-x}Mn_xFe_{11}O_{19}$ NPs in permanent magnets.

Strontium M-type hexagonal ferrites were synthesized at different calcination temperatures (800 °C, 1000°C and 1100 °C) using sol-gel autocombustion method. Thermogravimetric analysis (TGA), X-ray diffraction (XRD), scanning electron microscopy (SEM), Mössbauer spectroscopy (MS) and superconducting quantum interference device magnetometer (SQUID) techniques were used to characterize crystal structure, phase composition, morphology and magnetic properties. TGA gives T=800 °C as beginning of suitable calcination. Hexaferrite structure of single phase is obtained according to XRD results for all samples with crystallite size between 28 nm and 35 nm. SEM images show the growth of grain size with increasing of annealing temperature. (BH)max is calculated based on SQUID results and shows an enhancement between T=800°C and T= 1000°C of 25%. The magnetic properties observed at low temperature are explained and confirmed by ab-initio calculations.

B13-04. Enhanced Properties of MnBi synthesized via Novel Fabrication Method. *J. Kim*[1], Y. Shin[1], C. Ahn[1], J. Choi[1], G. Hwang[1], Y. Yang[1], J. Park[1], K. Chung[1] and C. Choi[1] *1. Powder and Ceramics Division, Korea Institute of Materials Science, Changwon, The Republic of Korea*

Developments of new permanent magnets, especially rare-earth free candidates for the growing market demands are current emerging issues of industry and academic research as well. Among the rare-earth free permanent magnets MnBi magnets have attracted tremendous attention for its strong magneticcrystalline anisotropy, high energy product and positive temperature coefficient of coercivity. MnBi magnets have been mostly fabricated via so-called top-down process, i.e. starting from ingot casting or arc-melting to micro-sized crushed powder with long-period preparation processes. In this study, a novel *'Bottom-up'* fabrication method for MnBi and its advantages will be discussed. With this bottom-up process, a high content of the low-temperature-phase(LTP) was obtained and an enhanced properties of MnBi were confirmed. The maximum energy product, (BH) max of MnBi synthesized via bottom-up process was about 8.6 MGOe, which is quite remarkable for permanent magnet applications. A detailed optimization process and mass production of MnBi powder via bottom-up process will be emphasized. In addition, structural and magnetic property variations according to the transition metal elements addition for instance Fe, Ni and Ga to enhance MnBi's magnetic property will also be discussed in detail.

B13-05. Magnetovolume Effect Induced Zero Thermal Expansion in $Er_2Fe_{16.5}Cr_{0.5}$. *S. Dan*[1], S. Mukherjee[1], C. Mazumdar[2] and R. Ranganathan[2] *1. Department of Physics, The University of Burdwan, Bankura, India; 2. Condensed Matter Physics Division, Saha Institute of Nuclear Physics, Kolkata, India*

In general, most of the materials expand with increasing temperature due to anharmonic nature of lattice vibrations. However, there exist a few materials exhibiting the rare phenomenon of volume contraction on heating. These are usually called negative thermal expansion (NTE) materials. The even rarer phenomenon of zero thermal expansion (ZTE), *i.e.*, a material that neither expands nor shrinks with temperature, have also been found. Technologically, ZTE materials have immense potential in application-oriented research. In many cases, ZTE is achieved in a composite material by appropriately combining an NTE material with another one that exhibits regular, positive thermal expansion. This, however, often undergoes thermal stability problem due to the nature of such inhomogeneous solid solutions. ZTE could also be achieved by tweaking an NTE material where the strengths of NTE are reduced gradually[1,2]. In this work, we have considered this approach to achieve ZTE in Cr-substituted Er_2Fe_{17}. The binary Er_2Fe_{17} have earlier been reported to show NTE below its Curie temperature (T_C) [3]. We show that only 3 at. % of Cr –doping in Fe-site in polycrystalline $Er_2Fe_{16.5}Cr_{0.5}$ could result in ZTE over a large temperature range of 13–300 K, 13 K being the lower limit of our measurement system (x-ray diffractometer). DC magnetic measurements reveal $Er_2Fe_{16.5}Cr_{0.5}$ to order magnetically below T_C = 367 K (Fig 1). The unit cell volume (v) remains almost temperature independent for $13K \leq T \leq 300K$ (Fig.2). Such a behavior results from the competition between the magnetovolume effect that reduces the unit cell volume with increasing temperature, and the normal phononic contribution to the lattice expansion. Above the room temperature, $Er_2Fe_{16.5}Cr_{0.5}$ exhibit NTE behavior till 390 K above which the ferromagnetic correlation vanishes (Fig 1). The estimated coefficient of thermal expansion in the temperature range 13–300 K is 1.65×10^{-6} K^{-1} and -3.51×10^{-5} K^{-1} in the temperature range 300–390 K. Rare earth free hard magnetic Mn-based alloys, Mn-Ga, MnAl and MnBi, are the most suitable for the next generation permanent magnets, due to the relative abundance of the forming elements and trivial formation of the necessary hard phases. In this study, intrinsic magnetic properties of Mn-Ga micro and nanoparticles have been extensively studied. Mn-Ga owes its hard magnetic properties to tetragonal L10 and $D0_{22}$ phases with magnetic anisotropy energy of 2.6 MJ/m^3 and 2 MJ/m^3, respectively. Considering the ongoing erratic fluctuation in rare earth supply, Mn-Ga could be a rare earth free alternative to the rare-earth magnets (Nd,Dy-Fe-B and Sm-Co). [1, 2] Micro and nanoparticles of Mn-Ga have been successfully produced by surfactant assisted planetary ball milling. Flake like formations (Fig.1) and nanoparticles have been observed in the slurry and the upper solution, respectively. As-cast alloy has been crushed down to below 300 μm followed by ball milling for 4h, 6h and 8h. Annealing under vacuum has been performed between 500K to 800K for 1 to 12 hours. Room temperature coercivity of ~7 kOe has been achieved on flakes milled for 8h. Rietweld analysis of the XRD data showed the presence of L10 and the D022 phases simultaneously. (Fig. 2) Work was supported by Tübitak project: 115C114.

B13-07. Severe Variation of Permanent Magnet Properties in Gas-Atomized MnAl Particles by Controlled Nanostructuration and Phase Transformation. J. Rial[1], E.M. Palmero[1], J. Camarero[1], P. Švec[2], P. Švec Sr.[2] and *A. Bollero*[1] *1. Division of Permanent Magnets and Applications, IMDEA Nanoscience, Madrid, Spain; 2. Institute of Physics, Slovak Academy of Sciences, Bratislava, Slovakia*

Rare earth (RE)-based permanent magnets (REPMs) are used in an increasing number of applications, which combined with the geographical distribution of REs, makes a search for alternatives to RE-PMs necessary [1]. We have explored recently the use of short milling times –by comparison with typically tens of hours– in a variety of RE-free PM materials: Co-ferrite [2,3], Sr-ferrite [4] and MnAl [5]. Controlled nanostructuraction in combination with microstrain and phase transformation dramatically change PM properties. A large coercivity of 4.7 kOe and a record $(BH)_{max}$ for isotropic $CoFe_2O_4$ powder of 18.6 kJm^{-3} (2.34 MGOe) were obtained after milling for 3 and 9 min, respectively [2,3]. Microstructural modification in Sr-ferrite ($SrFe_{12}O_{19}$) allowed improvement of a commercial powder by increasing coercivity in a factor 3.5, with a 25% increase in remanence after milling for 3 min [4]. This study focuses in tuning PM properties in gas-atomized $Mn_{54}Al_{46}$ powder by varying the impact energy (use of different milling media) in short milling times (90-270 s). Most of the studies aim a maximized content of the ferromagnetic τ-MnAl phase, i.e. enhanced

magnetization, with a decreased coercivity, which limits its potential use in PM applications. A combination of τ- and β- phases proves to be beneficial in coercivity development [5]. Milling with tungsten carbide media (270 s) enhances coercivity up to 4.8 kOe, which is above twice the value obtained for the annealed starting powder (Fig. 1), consequence of amorphization followed by controlled recrystallization and phase transformation (Fig. 2). Milling the as-atomized powder with steel (close-to-half density of tungsten carbide) diminishes amorphization and strain, reduces β-phase and enhances τ-phase contents. Consequently remanence of the optimized initial powder is preserved while coercivity still exceeding 2.5 kOe (Fig. 1) [6]. A decreased post-processing temperature (100°C lower), and short processing times, opens a new path for the production of isotropic MnAl powder.

B13-08. In-field Annealing Effects on $L1_0$-(Mn,Zn)-Al and Mn-Al-C.

Y. Mitsui[1], R. Kobayashi[1], *A. Takaki*[1], Y. Takanaga[1], R.Y. Umetsu[2], M. Mizuguchi[3], K. Takahashi[2] and K. Koyama[1] *1. Kagoshima University, Kagoshima, Japan; 2. Tohoku Universty, Sendai, Japan; 3. Tohoku University, Sendai, Japan*

$L1_0$-MnAl (τ-phase) is one of the rare-earth free hard magnetic materials. As τ-phase is metastable, modification or the substitution for Mn-Al were examined for stabilizing t-phase. Among them, it is reported that the substitution of Zn and addition of carbon enhanced the fraction of τ-phase [1,2]. On the other hand, we found that the in-field annealing below T_C accelerated the synthesis of t-phase [3]. Thus, it is expected that high fraction of τ-phase is obtained by in-field annealing for (Mn,Zn)-Al or Mn-Al-C. In this study, in-field annealing effects on (Mn,Zn)-Al and Mn-Al-C is investigated. $Mn_{53}Zn_2Al_{45}$ and $Mn_{55}Al_{45}C_2$ were prepared by reactive sintering and arc-melting, respectively. Each obtained ingots were annealed at 1373 K for 24 h, following quenching into iced water. The each ingot showed single ε-phase with hcp structure. In-field annealing was carried out at 573 K under magnetic fields up to 15 T. The characterization of obtained phases was evaluated by X-ray diffraction measurements at room temperature. The magnetization was evaluated by vibrating sample magnetometer for $\mu_0 H \leq 1.5$ T. Fig.1 shows the saturation magnetization M_s of $Mn_{53}Zn_2Al_{45}$ as the function of annealing time. In a zero field, the magnetization still increased at $t = 48$ h. On the other hand, M_s has a maximum value at $t = 24$ h for in-field annealed samples. It is found that in-field annealing effects exhibit lower tempreature than previous result for $Mn_{55}Al_{45}$[3]. Thus, both the magnetic field and substitution of Zn accelerated e-t transformation. Fig.2 shows the XRD patterns for Mn-Al-C annealed at 573 K for 48 h under 0, 10, and 15 T. ε-τ transformation did not proceed even in 48 h under 15 T. Magnetic field induced acceleration of the transformation was not observed. In the presentation, the magnetic field effect and the difference between Zn substition and the addition of carbon on the synthesis of τ-phase are discussed.

B13-11. Magnetic Hardening and Microstructure in deformed $L1_0$-MnGa Magnet. *Q. Lu*[1], D. Wang[1], H. Zhang[2] and Y. Ming[1] *1. College of Materials Science and Engineering, Beijing University of Technology, Beijing, China; 2. College of Materials Science and Engineering, Beijing University of Technology, Beijing, China*

In the recent search for new rare-earth-free hard magnetic materials, $L1_0$-ordered MnGa alloy has gained particular attention due to its excellent intrinsic magnetic properties. Many researches have reported on the phase transition, intrinsic and extrinsic magnetic properties dependence on the structure and composition of Mn-Ga alloys. As far as we have known, few works have been done on the magnetic hardening and microstructure of $L1_0$-ordered Mn-Ga bulks, and the magnetic properties are far from satisfactory. So it is a significant work to propose novel method to achieve magnetic hardening and if possible magnetic anisotropy in Mn-Ga bulk magnets. In this study, we reported on the unique hot deformation (HD) method using spark plasma sintering (SPS) to prepare $L1_0$-ordered Mn-Ga magnet with small grain size and high coercivity. HD technology via spark plasma sintering effectively realized the magnetic hardening in $L1_0$-MnGa alloy. During the HD process, recrystallization and grain size refinements were achieved without changing the crystal structure, which led to the improvement of the magnetic properties. High deformation rate at low temperature can obtain fine and uniform grains which benefit for the high coercivity of the bulks. Small, homogenous grain size as 1-2μm and maximum height reduction rate up to 90% is obtained in $L1_0$-$Mn_{1.33}Ga$ magnet, and the corresponding remanence of 3.87 kGs, coercivity of 5.65 kOe are achieved, leading to a $(BH)_{max}$ of 2.65 MGOe. Except for the grain refinement, some defects, especially low-density twin boundaries with the {111}-conjugated twin interface are observed from TEM, which are estimated to donate as the pinning sites and also contribute to the improvement of coercivity. The room-temperature initial magnetization and minor hysteresis loops demonstrated that the magnetization reversal of the deformed MnGa magnet is controlled by the weak pinning mechanism.

B14-02. Phase diagram of the J_1-J_2-J_3 transverse Ising antiferromagnet on the honeycomb lattice with frustration: An effective-field study. *A. Bobák*[1], E. Jurčišinová[2], M. Jurčišin[2,1], M. Zukovic[1] and T. Balcerzak[3]
1. Institute of Physics, P. J. Šafárik University, Košice, Slovakia;
2. Institute of Experimental Physics, Slovak Academy of Sciences, Košice, Slovakia; 3. Department of Solid State Physics, University of Lodz, Lodz, Poland

In this work, we investigate the phase transitions and critical behaviors in the frustrated J_1-J_2-J_3 transverse Ising antiferromagnet on the honeycomb lattice using an effective-field theory (EFT). The adopted theory is based on the approximate Ising spin identity introduced in Ref. [1] for the single-spin cluster in a transverse field Ω. In this approach all the single-site kinematic relations are correctly accounted for and only multispin correlation functions between various spins are decoupled. We confine our study to all the interactions being antiferromagnetic (J_1, J_2, $J_3 < 0$). We have found that adding the frustrating second-neighbor antiferromagnetic interaction J_2 and the third-neighbor antiferromagnetic interaction J_3 leads to a complex phase diagram even for zero transverse field. However, for large negative J_3 (< -1/3), we find only one tricritical point (TCP) in the phase diagram at which the phase transition between the Néel antiferromagnetic and the paramagnetic phases changes from second to first order. This behavior is in agreement with the recent EFT results [2] based on larger clusters than the single-spin one for $J_3 = 0$ and Ω = 0. Thus, it is interesting to study effects of Ω on the phase diagram of the frustrated transverse Ising antiferromagnet on the honeycomb lattice along a constant $J_3 < -1/3$ line as a function of the frustration parameter R ($R= J_2/|J_1|$). In particular, the variation of TCP in the three-dimensional space is constructed for $J_3/|J_1| = -0.4$. We also discuss the ground-state energy and the magnetization order parameter calculated within the EFT for $J_3/|J_1| = -0.4$ and selected values of R and Ω. Acknowledgments This work was supported by the Scientific Grant Agency of Ministry of Education of Slovak Republic (VEGA Nos. 1/0331/15 and 2/0065/17) and the scientific grant of Slovak Research and Development Agency provided under Contract No. APVV-16-0186.

The magneto-caloric effect (MCE) represents a phenomenon in which the temperature variation in a magnetic material is caused by the change of external magnetic field. On MCE based magnetic refrigeration has recently attracted considerable attention as an alternative way of cooling. In order to improve the application possibilities of magnetic refrigeration very recently a novel rotating magneto-caloric effect (R-MCE) has been proposed [1], in which the MCE can be obtained by rotating the magnetic refrigerant in constant field instead of changing the applied field. This R-MCE refrigeration can be used in case of strongly anisotropic magnetic materials and has advantages in comparison with its conventional counterpart as it appears to be more simple and compact. In our contribution we present results of R-MCE investigations on geometrically frustrated magnetic tetraboride TmB_4, which exhibits strong Ising-like magnetic anisotropy with magnetic moments of Tm ions oriented along the *c*-axis below its Néel temperature $T_N = 11.7$ K [2, 3]. In the ordered antiferromagnetic state the magnetization M for magnetic fields $B \parallel c$ reaches its saturation M_S at about 4 T accompanied by magnetization plateaus at 1/2 M_S and 1/8 M_S. On the other hand, for fields $B \perp c$ the saturation of M is reached only at fields above 30 T which points to a strong anisotropy. Results of the R-MCE in TmB_4 which have been received based on calculations from detailed heat capacity data in a wide T and B range show rather large entropy ΔS and temperature ΔT changes below and above T_N when the direction of the magnetic field is changed between directions $B \parallel c$ and $B \perp c$ for $B > 1$ T. These results are compared with experimentally carried out angular dependencies of the R-MCE, which moreover, exhibit some additional interesting features. The calculated and experimentally received $\Delta T(T,B)$ distributions are analyzed and discussed. The work was supported by projects VEGA 2-0032-16, APVV 14-0605 and DAAD - SVK. B14-04. A New Constructive Method of the Quantum Dimer Model in Spin-1/2 Heisenberg Antiferromagnets with Frustration on a Diamond-Like-Decorated Square Lattice. *Y. Hirose*[1], A. Oguchi[1], M. Tamura[1] and Y. Fukumoto[1] *1. Tokyo University of Science, Noda, Chiba, Japan*

We study spin-1/2 Heisenberg antiferromagnets on a diamond-like-decorated square lattice [1-4]. The diamond-like-decorated square lattice is a lattice in which the bonds of a square lattice are replaced with diamond units. The diamond unit has two types of antiferromagnetic exchange interactions, and the ratio λ of the strength of the diagonal bond to that of the other four edges controls the strength of frustration [1]. For $0.974<\lambda<2$, the present system has a nontrivial macroscopic degeneracy [1,5], which is called the macroscopically degenerated tetramer-dimer (MDTD) states. The MDTD states are identical to the Hilbert space of the Rokhsar-Kivelson quantum dimer model (QDM) [6], which is a phenomenological Hamiltonian of the resonating valence bond (RVB) theory. By introducing the further neighbor couplings in the MDTD states, we calculate the second-order effective Hamiltonian [2,3]. The effective Hamiltonian is exactly the same as the square-lattice QDM with a finite hopping amplitude t and dimer-dimer interaction v. Furthermore, we calculate v/t as a function of the ratio λ in the Heisenberg model and examine which phases of the square-lattice QDM appear in our obtained states. The present model contains only quadratic Heisenberg-type couplings, and is based on an ordinary two-dimensional lattice periodicity and connectivity. Therefore, our construction of QDMs from Heisenberg models provides a clear pathway to experimental reali-

zation or material design of QDMs. For example, layered compounds of Cu^{2+} ions bridged by bidentate di-radical ligands, or alkali metal atoms on an optical superlattice, is accessible [7,8]. If realized in such a way, it would give a new insight into progress in RVB physics.

B14-05. Magnons in a Strongly Spin-Orbital Coupled Magnet.
P. Maksimov[1], S. Winter[2], K. Riedl[2], S. Chernyshev[1], A. Honecker[3] and R. Valenti[2] *1. University of California, Irvine, Irvine, CA, United States; 2. Theoretical Physics, University of Frankfurt, Frankfurt, Germany; 3. Université de Cergy-Pontoise, Cergy-Pontoise Cedex, France*

We present the non-linear spin-wave theory calculations of the dynamical response of an extended Kitaev-Heisenberg model for the parameters applicable to α-$RuCl_3$. We argue that large anisotropic terms of spin-orbit nature necessarily imply strong anharmonic coupling of magnons. Subsequently, the overlap of one- and two-magnon states must lead to broad spectral features in magnon spectrum. These are accompanied by a significant longitudinal component of the structure factor from the two-magnon states that are also broadened. We calculate magnon decay rates due to anharmonic coupling within a self-consistent approach and find our results for the dynamical structure factor to be in a good agreement with both exact diagonalization results for the same set of parameters and experiment.

B14-06. Hidden Ferromagnetism in the Kitaev Honeycomb Iridates.
A. Ruiz[1]*, A. Frano[2], N. Breznay[4], Z. Islam[3] and J. Analytis[1] *1. University of California, Berkeley, Berkeley, CA, United States; 2. Physics, University of California, San Diego, San Diego, CA, United States; 3. Argonne National Laboratory, Lemont, IL, United States; 4. Physics, Harvey Mudd College, Claremont, CA, United States*

A unique feature of 5d materials is the fact that spin-orbit coupling and Coulomb interactions are of comparable strength. In the honeycomb iridates, this leads to strongly anisotropic, Ising-like exchange between neighboring spin-1/2 moments. Such interactions couple each spin to orthogonal components of the three neighboring spins and, as a consequence, no single exchange direction can be simultaneously satisfied, leading to strong frustration closely approximated by the Kitaev Hamiltonian. So far, all potential Kitaev materials have been found to order at low temperatures, eluding the sought-after QSL state. However, most experiments suggest that Kitaev exchange is the dominant spin interaction in these systems with small contributions from a direct Heisenberg and a symmetric off-diagonal exchange term. The intricate balance of these different energy scales dictates the nature of the observed ground state while external perturbations such as an applied magnetic field, can tilt the balance into a nearby state. In this work, we present thermodynamic evidence for a thus far overlooked ferromagnetic transition in all members of the Kitaev honeycomb iridate family which provides an opportunity to understand the true microscopic Hamiltonian and to construct the correct phase diagram that describes these compounds.

B14-07. Noncollinear magnetic ordering in a frustrated magnet: Metallic regime and the role of frustration.
M. Shahzad[1] *1. School of Physical & Mathematical Sceiences, Nanyang Technological University, Singapore*

We explore the magnetic phases in a Kondo lattice model on the geometrically frustrated Shastry-Sutherland lattice at metallic electron densities, searching for noncollinear and noncoplanar spin textures. Motivated by experimental observations in many rare-earth-based frustrated metallic magnets, we treat the local moments as classical spins and set the coupling between the itinerant electrons and local moments as the largest energy scale in the problem. Our results show that a noncollinear flux state is stabilized over an extended range of Hamiltonian parameters. These spin states can be quenched efficiently by external fields like temperature and magnetic field as well as by varying the degree of frustration in the electronic itinerancy and exchange coupling between local moments[1]. Interestingly, unlike insulating electron densities that we discussed in paper I of this sequence[2], a Dzyaloshinskii-Moriya interaction between the local moments is not essential for the emergence of their noncollinear ordering.

B14-08. Effective model with strong Kitaev interaction for α-$RuCl_3$.
S. Suga[1] and T. Suzuki[2] *1. University of Hyogo, Himeji, Japan; 2. University of Hyodo, Himeji, Japan*

We calculate the dynamical spin structure factors of three *ab-initio* models and one *ab-initio*-guided model for a honeycomb-lattice magnet α-$RuCl_3$ using an exact numerical diagonalization method [1]. We also calculate the temperature dependence of the heat capacity and the nearest-neighbor spin-spin correlation function using thermal pure quantum states [1]. The results show that the four models reproduce the six-pointed star shape observed in the inelastic-neutron-scattering (INS) experiments [2,3], and that the intensity at the Γ point increases with increasing the nearest-neighbor spin correlation. In the four models, when temperature decreases, the heat capacity shows a prominent peak at a high temperature where the nearest-neighbor spin-spin correlation function increases but the zigzag magnetic order does not set in. However, the peak temperature in the heat capacity is too low in comparison with that observed experimentally [3,4]. To address these discrepancies, we propose an effective model that includes strong ferromagnetic Kitaev coupling [1]. We show that this model quantitatively reproduces both the INS experiments and the heat-capacity measurements. To further examine the adequacy of the proposed model, we calculate the field dependence of the polarized terahertz spectra, which reproduces the experimental results [5]: the spin-gapped excitation survives up to an onset field where the magnetic order disappears and the response in the high-field region is almost linear. We also calculate the polarized terahertz spectra using the other *ab-initio* model and compare both results. Based on these numerical results, we argue that the low-energy magnetic excitation in α-$RuCl_3$ is mainly characterized by symmetric off-diagonal interactions and weak Heisenberg interactions between nearest-neighbor pairs.

We studied the critical behavior of $Ni_{1-x}Rh_x$ alloys based on the Arrott-Noakes scaling analysis [1]. The ferromagnetic ordered temperature is continuously suppressed to zero at a critical concentration $x_c \sim 0.39$. For $x = 0.3$, mean-field like exponents $\beta = 0.53$ $\gamma = 1.43$, and $\delta = 3.35$ are observed. With increasing x, critical exponents vary smoothly and reach at $\beta = 0.91$ $\gamma = 0.53$, and $\delta = 1.56$ for $x = 0.38$. The Widom scaling relation $\gamma/\beta = \delta$ holds for $x = 0.3$ - 0.38. The evolution of exponents with x and the exponent values close to the critical concentration cannot be described by any known universality classes for classical models. The possible explanations for the trend of exponents will be discussed.

The chiral itinerant-electron magnet MnSi crystallizes in the non-centrosymmetric $P2_13$ space group. The space group's lack of inversion symmetry enforces a Dzyaloshinskii-Moriya interaction which gives rise to the rich magnetic phase diagram of MnSi [1]: Below a critical magnetic field of $B_{c1} = 0.1$ T and temperatures lower than $T_c = 29.5$ K the manganese spins arrange in a helical pattern. A conical spin phase is found for fields above B_{c1} and below $B_{c2} = 0.55$ T. Helimagnon dynamics in these phases form a band-like dispersion relation due to strong Umklapp scattering in the small magnetic Brillouin zones, which have a helix pitch of $k_h = 0.036$ A^{-1} [2,3]. Above B_{c2}, the spins are completely oriented along the external field, forming the field-polarized phase. Here, the dispersion has been found experimentally to be asymmetric with respect to energy gain or loss [4]. Furthermore, a small region at the border of the conical phase contains the skyrmion phase where the spins form magnetic vortices [1]. Using the instruments TASP (PSI) and MIRA (MLZ), we recently succeeded in fully mapping out and describing theoretically the field-dependent evolution of the non-reciprocal magnon dispersion relations beginning from the conical towards the field-polarized phase [5]. The non-reciprocal nature of the dispersion manifests itself in a full asymmetry of the dynamical structure factor *S(q, E, B)* with respect to flipping either the direction of the external magnetic field *B*, the reduced momentum transfer *q*, or the energy transfer *E*. In order to achieve quantitative results with respect to the dispersion branches and their spectral weights we utilized a four-dimensional instrument resolution deconvolution procedure. With that our theoretical model is in excellent agreement with all of our measurements as depicted in Fig. 1 [5]. An extension of our theory and experiments towards the skyrmion phase is currently underway.

B15-03. High temperature ferromagnetism in $NbCo_2$ nanoparticles – bulk magnetization and hyperfine field measurements. S.K. Mohanta[2], S.M. Davane[3], A. Thamizhavel[4], A. Chandra[5], S.K. Srivastava[6] and *S.N. Mishra*[1] *1. Department of Nuclear and Atomic Physics, Tata Institute of Fundamental Research, Mumbai, India; 2. Physics, Govt. College of Engineering, Bhawanipatana, Odisha, Bhawanipatana, India; 3. Department of Nuclear and Atomic Physics, Tata Institute of Fundamental Research, Mumbai, India; 4. Department of Condensed Matter Physics & Material Science, Tata Institute of Fundamental Research, Mumbai, India; 5. Physics, IIT Kgaragpur, Kharagpur, India; 6. Physics, IIT Kharagpur, Kharagpur, India*

The C-15, Laves phase compound $NbCo_2$ is known to exhibit Pauli paramagnetic behavior. Here, we report the observation of high temperature ferromagnetism in nanoparticles of $NbCo_2$, prepared by high speed ball milling. The magnetic properties of the bulk and nanocrystalline samples have been studied through measurements of bulk magnetization and hyperfine field at ^{100}Rh impurity. Compared to the temperature independent magnetic susceptibility (~10^{-5} emu/mole) observed for bulk $NbCo_2$, the nanoparticle samples exhibit very high value of magnetic susceptibility (~10^{-3} emu/mole), whose temperature dependence indicates possible ferromagnetic ordering near or above room temperature. Low field magnetization studies carried out on the nanoparticles under zero field cooled and field cooled conditions show buildup of hysteresis near 300 K. The field dependence of magnetization, measured up to 60 kOe, shows low saturation moment of ~0.15 mB/f.u., suggesting that ferromagnetism in nanocrystalline $NbCo_2$ may be of itinerant character. To supplement the bulk magnetic properties we carried out hyperfine field measurements for ^{100}Rh nuclear probe using time differential perturbed angular correlation technique. The ^{100}Rh probe nuclei populated during the decay of the parent ^{100}Pd radio isotope, were produced and recoil implanted via nuclear reaction ^{11}B(^{93}Nb,4n)^{100}Pd using 52 MeV ^{11}B beam. From the temperature dependence of the hyperfine field (B^{hf}) at ^{100}Rh, measured in the range 10 – 600 K, we find a clear evidence for bulk ferromagnetic ordering with Curie temperature T_C ~ 310 K. The saturation transferred hyperfine field equal to -23 kG at ^{100}Rh would imply a small localized moment on the surrounding Co atoms, consistent with the itinerant magnetic behavior of the nanocrystalline $NbCo_2$.

B15-04. Magneto-Resistance of $NdBaMn_2O_6$ Single Crystal. *S. Yamada*[1], K. Ogawa[1], N. Abe[2], H. Sagayama[3,4] and T. Arima[2] *1. Department of Materials System Science, Yokohama City University, Yokohama, Japan; 2. Department of Advanced Materials Science, The University of Tokyo, Kashiwa, Japan; 3. Institute of Materials Structure Science, High Energy Accelerator Research Organization, Tsukuba, Japan; 4. Department of Materials Structure Science, The Graduate University for Advanced Studies, Tsukuba, Japan*

Large magneto-resistance effect near room-temperature has been observed in $NdBaMn_2O_6$ single crystal. Figure 1 shows temperature dependence of (a) electric resistivity and (b) magnetic susceptibility in $NdBaMn_2O_6$ single crystal. Near 290 K, the resistivity steeply changes within 1.5 K. The metal-insulator transition is accompanied by magnetic anomaly. The metal-insulator transition temperature shifts from 290 K to 265 K under 70 kOe magnetic field. This result means that the insulating-phase in the temperature range between 265 K and 290 K changes to metallic-phase by a magnetic field which is smaller than 70 kOe. Figure 2 shows magnetic field dependence of (a) resistance and (b) magnetization at 275 K. The large magneto-resistance effect is clearly observed. The transition width for a magnetic field is within 5 kOe. As similar phenomenon, large magneto-resistance of $La_{1-x}Sr_xMnO_3$ is well known.[1] The origin of the magneto-resistance effect is mainly double exchange interaction between manganese ions. Though the magneto-resistance of $La_{1-x}Sr_xMnO_3$ is observed around room temperature, the magnetic field dependence is gradual. The magneto-resistance of $Pr_{1-x}Ca_xMnO_3$,[2] which is caused by melting charge ordering phase, is much steeper and larger than that of $La_{1-x}Sr_xMnO_3$. However, this magneto-resistance effect can be seen only far below room temperature. A much steeper magneto-resistance effect of $NdBaMn_2O_6$ occurs around roomtemperature at a relatively low magnetic field. Our single crystal structure analysis by means of synchrotron x-ray diffraction shows that the insulating phase does not accompany change but orbital order of x^2-y^2 type.[3] The observed magnetoresistance may be attributable to the magnetic-field induced order-disorder transition of the orbital degree of freedom.

In strongly correlated electron systems frustration and quantum fluctuations can destroy long-range magnetic order giving rise to quantum paramagnetic phases such as valence-bond solids with broken lattice symmetry or spin liquids where symmetry is conserved. Such states are sometimes found in proximity to superconductivity. Therefore, understanding them is subject of many theoretical and experimental studies. In this context the spin-1/2 square lattice antiferromagnets are the most interesting to explore as careful inelastic neutron scattering measurements can be readily quantitatively compared to theoretical models. To this end, we have explored two Cu compounds: Sr_2CuTeO_6 and $Ba_2Cu_3O_4Cl_2$. Novel ab initio multi-reference configuration interaction calculations were able to accurately predict the exchange interactions in Sr_2CuTeO_6 and revealed that Sr_2CuTeO_6 is a rare realisation of an almost ideal nearest-neighbour coupled Heisenberg antiferromagnet with a relatively weak coupling of 7.2 meV. We show that (i) our general methodology can be accurately applied to exploring strongly correlated electron systems; and (ii) the low energy scale of the magnetic interactions in Sr_2CuTeO_6 opens up the possibility to explore quantum effects such as spinon deconfinement through magnetic field experiments, etc that are otherwise out of reach for most Cu-O based spin-1/2 systems.

B15-06. Complex magnetic behavior in $RE_8Pd_{24}Ga$ (RE = Gd, Tb and Dy) compounds. *M.B. Tchoula Tchokonte*[1], J.J. Mboukam[1,2], A.K. Bashir[4], B.M. Sondezi[2], R. Kumar[2], A. Strydom[2] and D. Kaczorowski[3] *1. Physics and Astronomy, University of the Western Cape, Bellville, South Africa; 2. Physics, University of Johannesburg, Johanneburg, South Africa; 3. Magnetic, Institute of Low temperature and Structure research, Polish Academy of Sciences, Wroclaw, Poland, Wroclaw, Poland; 4. Physics and Astronomy, University of the Western Cape, Bellville, South Africa*

We report the studies of $RE_8Pd_{24}Ga$ (RE = Ga, Tb and Dy) compounds, by means of electrical resistivity, $\rho(T)$, magnetic susceptibility, $\chi(T)$, magnetization, $M(\mu_0 H)$, heat capacity, $C_p(T)$ and magnetocaloric effect, (MCE), measurements. All three compounds order antiferromagnetically at T_N = 8.15, 5.5 and 3.8 K for RE = Gd, Tb and Dy respectively, and undergo spin reorientation transition below their respective T_N. The ordering temperature was confirmed by $\rho(T)$, $\chi(T)$ and $C_p(T)$ measurements. In the ordering state, $\rho(T)$ data for Tb and Dy compounds, can be represented in terms of antiferromagnetic (AFM) spin – wave dispersion with an energy gap Δ_ρ = 29.6(1) and 15(1) K for Tb and Dy respectively, while $\rho(T)$ data for Gd compound shows a linear behavior with temperature. Above T_N, $\rho(T)$ variation is characteristic of electron – phonon scattering. On the other hand, $C_p(T)$ data well above T_N can be described by the Debye model giving Debye temperature values of Δ_D = 238.8(1), 230.26(4) and 233.20(2) K for RE = Gd, Tb and Dy respectively. At high temperature, the $\chi(T)$ data follows the Curie – Weiss relation giving an effective magnetic moment (μ_{eff}) values close to that expected for the RE^{3+} ion. Except for the Gd compound, $M(\mu_0 H)$ for the Tb and Dy compounds exhibit metamagnetic transition at low field. The magnitude of MCE was estimated from the isothermal magnetization data to be 14.23 J/kg.K and 11.25 J/kg.K for a filed change of 7 T for RE = Tb and Dy respectively. For the Tb compound, MCE shows a sign change below T_N for low field change, which may be attributed to non – collinear AFM structure of the compound.

B15-07. Giant magnetocaloric effect and universal scaling analysis of Er_5Pd_2 superspin glass system. *M.K. Sharma*[1] and K. Mukherjee[1]
1. School of Basic Sciences, Indian institute of Technology Mandi Himachal Pradesh India, Mandi, India

Rare earth intermetallic compounds of the form R_5Pd_2 are extensively investigated as these materials have complex magnetic behavior and exotic magnetic properties [1-4]. A compound Er_5Pd_2 belonging to this family has been investigated using dc and ac magnetic susceptibilities, magnetic memory effect, isothermal magnetization, non-linear dc susceptibility, heat capacity and magnetocaloric effect studies. Interestingly, even though the compound does not show geometrical frustration it undergoes glassy magnetic phase transition below 17.2 K. Investigation of dc magnetisation and heat capacity data divulged absence of long-ranged magnetic ordering. Additionally, this magnetic transition was also characterized by the Arrott plot which confirmed its second order nature. Through magnetic memory effect, time-dependent magnetization and ac susceptibility studies it was revealed that the compound undergoes glass-like freezing below 17.2 K. Analysis of frequency dependence of this transition temperature through scaling and Arrhenius law; along with Mydosh parameter indicate, that the dynamics in Er_5Pd_2 is due to the presence of strongly interacting superspins rather than individual spins. This phase transition was further investigated by non-linear dc susceptibility and was characterized by static critical exponents γ and δ. Our results indicate that this compound show signature of superspin glass at low temperature. Additionally, both conventional and inverse magnetocaloric effect was observed with large value of magnetic entropy change (ΔS_M~19.8 J/kg-K at 70 kOe) and relative cooling power (RCP~870 J/kg). A phenomenological universal curve also constructed for Er_5Pd_2 by normalizing the ΔS_M with rescaled temperature.

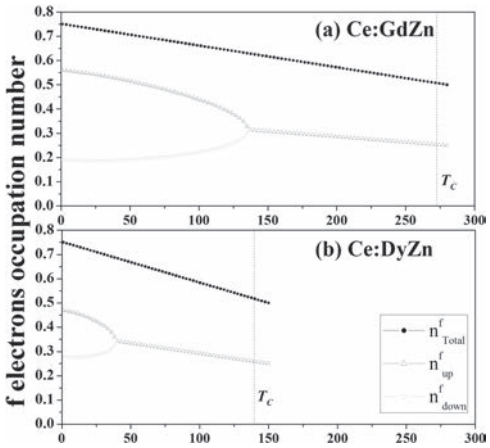
B15-08. Observation of size dependent orbital magnetism of single Fe impuritiy in nanocrystalline Pb hosts. S.K. Mohanta[2], S. Sarkar[3], P. Ayyub[4] and *S.N. Mishra*[1] *1. Department of Nuclear and Atomic Physics, Tata Institute of Fundamental Research, Mumbai, India; 2. Physics, Govt. College of Engineering, Bhawanipatana, Bhawanipatana, India; 3. Department of Condensed Matter Physics & Material Science, Tata Institute of Fundamental Research, Mumbai, India; 4. Department of Condensed Matter Physics & Material Science, Tata Institute of Fundamental Research, Mumbai, India*



Employing the time differential perturbed angular distribution (TDPAD) technique investigated the local magnetism of single Fe impurity in bulk and nanocrystalline Pb matrices, by measuring the local susceptibility and spin relaxtion rate of ^{54}Fe nuclei, produced through heavy-ion fusion evaporation reaction $^{12}C(^{45}Sc, p2n)^{54}Fe$. Compared to the nonmagnetic behavior of Fe in bulk Pb host characterized by independent $c_{loc}(T)$, it's magnetic response in nanocrystalline hosts show size dependent enhancement in the local susceptibility, exhibiting Curie-Weiss like temperature dependence for particle size below 10 nm. The observed slope of the $c_{loc}(T)$ data reflect high positive hyperfine field for Fe, which in turn indicates the presence of large orbital magnetic moment with magnitude $m_{orb}(Fe) \sim 1 m_B$. The high orbital moment observed for Fe in nano-Pb samples indicates enhanced localization of d-electrons, possibly arising from size induced lattice expansion and/or associated change in electronic density of states at Fermi energy which in turn affects the Kondo coupling strength.

B15-09. Temperature dependence of the magnetic hyperfine interaction on a Ce impurity embedded in *R*Zn, (*R* = Gd, Dy). A. de Oliveira[1], C. Chaves[2], N. Oliveira[3] and *A. Troper*[2] *1. Instituto Federal de Educacao Ciencia e Tecnologia do Rio de Janeiro, Nilopolis, Brazil; 2. Exp, Centro Brasileiro de Pesquisas Fisicas, Rio de Janeiro, Brazil; 3. Physics department, UERJ, Rio de Janeiro, Brazil*

In this work we present a theoretical study of the local moment formation and the magnetic hyperfine field at a Ce impurity diluted in *R*Zn, the impurity occupying a *R* site. We use an intermediate valence model [1,2], focusing on the temperature dependence of the magnetic hyperfine fields, thereby extracting the 4f Ce valence at the range of temperature $T \leq T_C$. The temperature dependence of the local magnetic moments and related hyperfine magnetic interaction are calculated adopting a functional integral approach in the static approximation. Our self-consistent calculations are in very good agreement with recent experimental results [3], in particular exhibiting the two regimes of the magnetic hyperfine fields (and local magnetic moments) with temperature, cf. figures 1 and 2. The obtained valence state of Ce impurity for the GdZn compound ranges from 0.75 at $T = 0$ to 0.55 at $T = T_C$, but the up and down 4f occupations of the Ce hump became equal from $T \approx 146$ K to $T = T_C$ (fig.2(a)). For Ce:DyZn the Ce impurity valence also ranges from 0.75 at $T = 0$ to 0.55 at $T = T_C$ whereas the up and down 4f occupation become equal from $T \approx 40$ K to $T = T_C$ (see fig.2(b)).

B16-01. Topological features of the thermal Hall conductivity in a chiral *p*-wave superconductor under strain. *Y. Imai*[1] and M. Sigrist[2]
1. Applied Physics, Okayama University of Science, Okayama, Japan; 2. ETH-Zurich, Zurich, Switzerland

Motivated by the experimental studies on the effect of tensile and compressive strains or uniaxial pressure in the superconducting phase of the transition metal oxide Sr_2RuO_4, the pairing symmetries in the chiral *p*-wave superconducting state and the transport property are studied theoretically. The strain effect particularly leads to the Fermi surface deformation which is strongly connected with the topological aspect. First principles studies of the normal phase of Sr_2RuO_4 suggest that the strain along the [100] direction particularly generates more remarkable modification of the Fermi surface of the γ band than that of [110] direction. By means of a self-consistent Bogoliubov-de Gennes approach, the edge states and the thermal Hall conductivity are investigated for several pairing structures expected for a chiral *p*-wave phase. The superconducting order parameters are affected by the Fermi surface geometry induced by the strain, and the topological aspect clearly switches around the Lifshitz transition in the γ band. In particular, the temperature dependence of the thermal Hall conductivity is associated with the amplitude and the direction of the strain. While the topological number determines the *T*-linear contribution in the low-temperature limit, deviations from this behavior appear with increasing temperature depending on the pairing structure. Our results provide the information on intrinsic structure of the gap function of the chiral *p*-wave phase.

B16-02. Symmetry breaking of spin and valley degree of freedom in a massless-Dirac electron system, α-(BEDT-TTF)$_2$I$_3$ under magnetic fields. *K. Miyagawa*[1], M. Matsuno[1], T. Taniguchi[1], D. Liu[1], M. Hirata[2], M. Tamura[3] and K. Kanoda[1] *1. Department of Applied Physics, The University of Tokyo, Tokyo, Japan; 2. Institute for Materials Research, Tohoku University, Sendai, Japan; 3. Department of Physics, Tokyo University of Science, Chiba, Japan*

Since the discovery of massless-Dirac Fermions (MDF) in graphene, MDF states have found in a range of materials. A quasi-2D organic conductor, α-(BEDT-TTF)$_2$I$_3$, in which a MDF phase appears under pressure. At ambient pressure, this system is a charge-ordered insulator due to intersite Coulomb interactions. This insulating state is suppressed by pressure and a MDF state appears above 12 kbar, providing a stage for investigating the effect of electron correlations on the MDF. In addition, the bulk nature of α-(BEDT-TTF)$_2$I$_3$ enables one to investigate the properties by experimental probes that require sample volume, such as NMR. Indeed, we already found the reshape of Dirac cones [1] and an anomalous enhancement in the spin-lattice relaxation rate, $1/T_1$, at low temperatures [2] due to short and long range Coulomb interactions. In this presentation, we focus on the electronic state of MDF under magnetic fields. When the magnetic field is applied normal to the 2D planes of MDFs, the orbital-quantized Landau levels (LLs) contains the n=0 state (zero mode LL), unlike conventional 2D metals. It is well known that the MDF system has two degrees of freedom, that is, spin and valley. They are degenerated under a zero magnetic field. In case of non-zero fields, there are two possible states, depending on which of spin- or valley-splitting dominates over the other in energy. When the spin splitting energy is larger than the valley splitting one, the system will be spin-polarized (QHF:Quantum Hall Ferromagnetic). In the inverse case, a non-magnetic state (QHI:Quantum Hall Insulator) will be realized. We measured ^{13}C NMR with a magnetic field applied perpendicular to the 2D layers to clarify which state is realized. With decreasing temperature, the shift of spectra decreases, since the thermal-averaged density of state characteristic of Dirac cones decreased. At low temperatures, however, the NMR shift increases because of the formation of the zero-mode LL. Upon further cooling, a large NMR shift is observed, which indicates the generation of local fields. The value of the shift agrees with the value estimated from the Zeeman spin splitting of the zero-mode LL, indicating the QHF state.

B16-03. Distinctly Different Spin Disorder Topological Phases in J1-J2 Heisenberg Model in Honeycomb Lattice. J. Liu[1], Y. Quan[2], H. Lin[3] and *L. Zou*[1] *1. Research Laboratory of Computational Materials Sciences, Institute of Solid State Physics, Chinese Academy of Sciences, Hefei, China; 2. Institute of Solid State Physics, Chinese Academy of Sciences, Hefei, China; 3. Beijing Computational Science Research Center, Beijing, China*

Searching for spin liquid phase remains attracts much attention, especially in honeycomb lattice. In this work we study the topological properties of the J1-J2 Heisenberg model in honeycomb lattice and its finite-temperature thermodynamic properties both by topologically and numercilly. We show that in the generaly recognized spin ordered regime, i.e. 0.2<J2/J1<0.45 [1], there exist in fact two distinct spin ordered phases: one is a “zero-flux” spin liquid which is topological trivial and have a zero gap, another one is a “-flux” spin liquid or chiral spin liquid, which is topological nontrivial and have a finite gap. The quantum phase transition occurs at J2/J1=0.32. Utilizing the recently developped finite-temperature Lanzcos technique, we confirm that the quantum critcal point, and demonstate the existence of quantum cirtical reime in finite temperatures.

ISIS Pulsed Neutron and Muon Source, Didcot, United Kingdom*

Experimental and theoretical investigations on 5d oxides, especially oxides containing Ir^{4+}, have brought into focus a large number of novel magnetic states driven by competition between strong spin-orbit coupling and electronic correlations, include spin-orbit Mott insulators, axion insulators, Weyl semi-metals and other phases with non-trivial (topological) electronic states [1]. The pyrochlore iridates, $R_2Ir_2O_7$ (R = Y, lanthanide) have generated particular interest following predictions of a possible magnetically-induced

Weyl semi-metal phase [1,2]. These iridates exhibit metal–insulator transitions (MIT) at a temperature T_{MI} which decreases with increasing ionic radius of R^{3+} and vanishes for R between Nd and Pr, and become more insulating for the smaller R^{3+} ions, such as Yb and Lu, see Fig. 1. Magnetic order on the Ir sublattice occurs concurrently with the MIT, and various ab initio calculations predict that out of a number of possible magnetic structures, the Weyl semi-metal can occur only for the so-called all-in-all-out (AIAO) structure. A conclusive determination of the Ir magnetic structure is therefore very important. Here we present neutron powder diffraction studies of $R_2Ir_2O_7$ for R = Yb and R=Lu. We find the Ir sublattice in both samples to order in the AIAO structure. We find no evidence of the Yb sublattice ordering down to 1.5 K, in contrast with $Nd_2Ti_2O_7$ [3] in which the Nd lattice orders at low temperatures.

B16-05. Temperature dependent Magneto-transport properties of MnAl Binary Alloy Thin Films. *V. Barwal*[1], S. Husain[1], N. Gupta[1], A. Kumar[2], P. Svedlindh[2] and S. Chaudhary[1] *1. Physics, Indian Institute of Technology Delhi, New Delhi, India; 2. Department of Engineering Sciences, Uppsala University, Uppsala, Sweden*

High perpendicular magnetic anisotropy (PMA) and low damping constant (a) in ferromagnets are one of the few necessary requirements for their potential applications in the field of spintronics [1]. In this regards, ferromagnetic t-phase of MnAl possesses the highest PMA (K_u>10^7 erg/cc) at room temperature, high saturation magnetization (M_s~800emu/cc) and a Curie temperature of ~395K [1-3]. In this work, we have investigated the magnetotransport behaviour of this potentially useful binary system. Thin films of $Mn_{52}Al_{48}$ are grown at different growth temperatures RT-600°C in steps of 100°C on Si (100) substrate by pulsed DC-magnetron sputtering. In-plane and out-of-plane transverse magnetoresistance (MR) measurements on films sputtered under optimized growth conditions revealed non-saturating behavior with MR values ~ 6% and 40% at 9T, respectively at 275 K (Fig.1). Resistivity shows a parabolic dependence on the field H, when the H is weak. At higher H, non-saturating positive MR that increases exponentially with the strength of magnetic field is observed, a typical character of hopping type conduction mechanism. An anomalous decrease in MR is observed on lowering the temperature. These preliminary findings on the MR behavior of MnAl thin films will be presented in detail. The anomalous large MR in mixed phase MnAl system is evidently useful for future spintronic applications.

B16-06. Field-induced Weyl metal phases of non-collinear antiferromagnet: GdB_4. *D. Ryu*[1], K. Kim[1,2] and B. Min[1] *1. Physics, POSTECH, Pohang, The Republic of Korea; 2. Max Planck POSTECH/Korea Research Initiative, Pohang, The Republic of Korea*

Since the combination of inversion (*P*) and time-reversal (*T*) symmetry forbids the emergence of Weyl points, one must break *PT* symmetry to find Weyl metal phase. One of the most common ways for *PT*-breaking is to apply the magnetic B-field. But, depending on its direction, B-field may not preserve some crystal symmetry of the system that is essential to protect Weyl points in the presence of large spin-orbit coupling. Thus the emergence of Weyl points significantly depends on the direction of B-field in this case. Recently, GdB_4 is known to show one of the typical properties of Weyl material in dHvA experiment, in spite of that GdB_4 has non-collinear antiferromagnetic ground state with *PT* symmetry. It means that the Weyl metal phase of GdB_4 must have been induced by the applied B-field. To prove this feature theoretically, we have calculated the density functional theory (DFT) band structures of GdB_4 with/without the B-field along the [001] and [110] directions. We show that (i) doubly degenerate crossing points emerge with applying the B-field and (ii) the position of crossing points depends on the direction of the B-field. Finally, we show that (iii) those crossing points are indeed Weyl points based on the Berry-phase calculation.

B16-07. Effects of doping on the semiconductor $OsGe_2$. *G. Lopez*[1,2], A. Gong[1,2] and J. Analytis[3] *1. Physics, University of California, Berkeley, Berkeley, CA, United States; 2. Materials Science Division, Lawrence Berkeley National Laboratory, Berkeley, CA, United States; 3. University of California, Berkeley, Berkeley, CA, United States*

We investigate the effects of doping on the semiconductor OsGe2, whose resistivity saturates at low temperature. We track the evolution of the 31.5 meV bandgap of the parent compound with chemical pressure. Also, we track the evolution of reisistivity as a function of sample thickness.

B16-08. Formation of a topological spin liquid regime in $Mn_{1-x}Fe_xSi$. *C. Franz*[1,2], J. Kindervater[1], T. Adams[1], A. Bauer[1], F. Haslbeck[1], A. Chacon[1], S. Muehlbauer[3], F. Jonietz[1], A. Neubauer[1], U. Gasser[4], G. Nagy[4], N. Martin[1,2], W. Häußler[1,2], R. Georgii[1,2], M. Garst[5] and C. Pfleiderer[1] *1. Physics Department, Technical University of Munich, Garching, Germany; 2. Heinz Maier-Leibnitz Zentrum, Technical University of Munich, Garching, Germany; 3. Heinz Maier Leibnitz Zentrum (MLZ), Technical University of Munich, Garching, Germany; 4. Laboratory for Neutron Scattering and Imaging, Paul Scherrer Institut, Villingen, Switzerland; 5. TU Dresden, Dresden, Germany*

We have combined magnetisation, ac susceptibility, specific heat and electrical transport measurements with comprehensive small angle neutron scattering and resonant neutron spin echo spectroscopy to determine the evolution of the magnetic and metallic state in $Mn_{1-x}Fe_xSi$ for increasing x [1]. While the onset of helimagnetic order decreases with increasing x, the magnetic phase diagram remains highly reminiscent of the parent compound MnSi for $x \lesssim 0.10$ including, in particular, a well-defined pocket of skyrmion lattice state and a fluctuation-induced first-order transition from paramagnetism to helimagnetism in zero field. For $x > 0.10$ a sphere of intensity is observed down to lowest temperatures characteristic of a fluctuation-disordered regime. Quasi-elastic measurements in the helical phase of neutron spin-echo spectroscopy reveal that the quasi-elastic linewidth Γ remains finite in the full temperature range under study for the samples with $x > 0.10$. While no static magnetic order is observed down to 50 mK, a topological contribution to the Hall effect establishes the formation of a spin liquid state with non-trivial topological character [2].

ELECTRIC FIELD EFFECTS ON MAGNETIC SYSTEMS

Yonggang Zhao, Chair
Tsinghua University, Beijing, China

CONTRIBUTED PAPERS

11:30

C1-01. Electric field effect on exchange interaction in ultra-thin Co films with ionic liquids. *M. Ishibashi*[1], K. Yamada[2], Y. Shiota[1], F. Ando[1], T. Koyama[4], H. Kakizakai[1], H. Mizuno[1], K. Miwa[3], S. Ono[3], T. Moriyama[1], D. Chiba[4] and T. Ono[1] *1. Institute for Chemical Research, Kyoto University, Kyoto, Japan; 2. Institute for Chemical Research, Kyoto University, Uji, Japan; 3. Central Research Institute of Electric Power Industry, Yokosuka, Japan; 4. Department of Applied Physics, The University of Tokyo, Tokyo, Japan*

Electric-field-modulations of magnetic properties have been extensively studied not only for practical applications but also for fundamental interests. Especially, electrical control of Curie temperature in Co ultra-thin film has attracted much attention [1]. Recently, *ab* initio calculation showed electric field effect on exchange interaction as the origin of electric-field-change in Curie temperature [2]. Previously, we experimentally demonstrated electric-field modulation of exchange stiffness [3]. However, the exchange stiffness reflects not only exchange interaction but also temperature effect. Therefore, the electric-field-modulation of exchange stiffness does not give essential evidence of modulation of exchange interaction by electric field. In this study, we investigate electric field effect on the exchange coupling J characterized from the direct measurement of magnetization as a function of temperature in GaAs sub./ Ta(2.3 nm)/Pt(2.0 nm)/Co(0.25 nm)/ MgO(2.0 nm) films by a superconducting quantum interference device. The gate voltage V_G was applied using capacitor structure with ionic liquids which enable to apply large electric field to Co layer. In our definition, the positive V_G increases the electron density at the Co/MgO interface. As shown in Fig. 1 where ΔN represents change in the electron number per Co atom, a clear change in J by applying V_G is observed. From linear fitting in Fig. 1, we found that J increases by 7.2 % as the electron number per Co atom increase by 0.010. According to the theoretical prediction, J increases by 5.2 % as 0.010 electrons increase per Co atom [2]. The trend and the efficiency of electric field effect on J are in good agreement with that of the theoretical prediction. In the presentation, we will also discuss the electric field effect on J in Pd/Co ultra-thin film.

C1-02. Magneto-electricity in Van der Waals Magnetic Bilayers. *C. Lei*[1], K. Nomura[2] and A.H. MacDonald[1] *1. Physics, University of Texas at Austin, Austin, TX, United States; 2. Institute for Materials Research, Tohoku University, Sendai, Japan*

We consider the magneto-electric response of antiferromagnetic van der Walls bilayers to gate electric fields. Because the gate field changes the relative strength of magnetic exchange interactions in the two layers, a net magnetic response is achieved. We identify two different microscopic mechanisms that lead to a magneto-electric response and explain how they can be distinguished by their temperature dependence. Finally we address the possibility of identify two-dimensional magnetic materials systems that have a potentially useful magneto-electric response at room temperature.

C1-03. Solid state magneto-ionic proton pump. *A. Tan*[1], M. Huang[1], C. Avci[1] and M. Mann[1] *1. Materials Science and Engineering, MIT, Cambridge, MA, United States*

In a thin film ferromagnet/oxide heterostructure, the chemical structure at the interface can substantially influence the magnetic properties. This interface can be electrochemically tuned using a gate voltage to produce large changes in the properties. The approach, dubbed magneto-ionic control of interfacial magnetism, has demonstrated modulation of magnetic anisotropy on the order of ~1erg/cm^2, >10x larger than any other voltage-induced effect[1,2]. However, all current magneto-ionic devices are oxygen-based devices; they rely on the redox of the ferromagnet layer to toggle the anisotropy. As a result, they have poor cyclability due to irreversible structural damage to the magnetic layer[3]. In this work[4], we demonstrate the first hydrogen-based magneto-ionic devices where interfacial magnetism is modulated by

hydrogen loading in an adjacent storage layer. This novel approach presents an enormous advantage in protection of the magnetic layer, and we were able to toggle the magnetic anisotropy for >2000 cycles, two orders of magnitude larger than the state-of-the-art magneto-ionic device reported in literature. Besides the cyclability, the device exhibits the fastest room temperature switching. By then engineering an appropriately designed heterostructure, we demonstrate for the first time large modulation of magnetic anisotropy at a metal/metal interface which cannot be achieved by any other known mechanisms due to vanishing electric field.

C1-04. Strain-induced magnetization control at the $La_{0.65}Sr_{0.35}MnO_3/BaTiO_3$ interface. F. Motti[1,2], G. Vinai[1], A. Petrov[1], B. Davidson[1], B. Gobaut[3], A. Filippetti[1], G. Rossi[2,1], G. Panaccione[1] and *P. Torelli*[1] *1. CNR-IOM, Trieste, Italy; 2. Universita di Milano, Milano, Italy; 3. Synchrotron Soleil, Saint Aubain, France*

The possibility of control the magnetic properties of a device by an electric impulse has attracted a great attention in the last years due to the important application that such a possibility will find in electronics. The absence of a bulk material displaying a sufficient large magnetoelectric coupling coefficient [1] has pushed toward the control of magntoelectric coupling in suitable nanostructures [2], however the current research is mainly based on transport measurements and magnetic measurements such as SQUID and MOKE which, despite the sensitivity to the magnetization, lack of chemical sensitivity and do not provide information on the electronic structure of the materials. For these reasons the investigation of interfaces and heterostructures in which artificial magnetoelectric coupling is realized are increasingly studied by operando XMCD experiments. At the APE-HE beamline at Elettra the Italian synchrotron radiation facility [3] we developed a set-up for performing XMCD while applying electric bias. With this set-up we investigated the magnetic properties of the LSMO/BTO interface as a function of temperature and of the ferroelectric polarization [4]. In this experiment we were able to separate the effect of strain and of the electric charge of the substrate ferroelectric polarization on the magnetic properties of the FM overlayer. In fact, the BTO substrate as a function of temperature change the crystallographic structure inducing different strain on the overlayer, at the same time switching the FE polarization of the substrate while recording XMCD we were able to observe the changes induced by the strain or the charge separately. In this experiment we demonstrated that ferromagnetism, absent in the pristine condition at room temperature, can be established by electrically switching the BTO ferroelectric domains in the out-of-plane direction. The present results confirm that electrically induced strain can be exploited to control magnetism in multiferroic.

C2-01. Development of Organic Quantum Magnets. *Y. Hosokoshi*[1]
1. Department of Physical Science, Osaka Prefecture University, Sakai, Japan

Purely organic magnets with π-electron spins have essentially negligible spin–orbit couplings and are attractive materials because they are archetypical S =1/2 Heisenberg spin systems in which quantum fluctuations play an important role. The antiferromagnetic frameworks of isotropic S =1/2 spins connected by the small number of the nearest neighbors (z) are the key factors of the novel magnetic states arising from quantum fluctuations. Most extensive study has been done on one-dimensional (1D) Heisenberg antiferromagnets. Our recent study on a quasi-1D Heisenberg antiferromagnet, F_5PNN, has established the direct 3D long-range order without the development of 1D short-range order near the saturation magnetic field [1]. Besides the study on 1D Heisenberg antiferromagnets, growing attention is being paid to the effect of quantum fluctuations in 2D or 3D Heisenberg antiferromagnets with the small number of z, but the experimental realization is still rare. The molecular designing toward high-dimensional magnets is presented. The key is the multidirectional magnetic exchange pathways by the twist of π-conjugated planes and polyradicals. By the usage of twisted monoradicals, 2D and 3D magnetic networks are realized. 3D network of pentagonal lattice and its novel state near the saturation field induced by frustration is described [2]. Planar or non-planar biradicals forming 2D and 3D lattices are also presented. A new organic biradical with twisted π-planes, F_4BIPBNN, forms a new 3D honeycomb lattice with z = 4 [3]. The effect of the quantum fluctuation appears in the concave shaped magnetization curve and the field dependence of T_N. The quantum fluctuation was evaluated as the shrinkage factor of spin to 28 % with respect to its classical value. This is the first observation of the quantum fluctuations among 3D magnetic lattice without spin frustration. The development of 2D honeycomb lattice and its quantum properties are also described.

Orbital angular momentum is a prerequisite for magnetic anisotropy, although for transition metal complexes it is typically quenched by the ligand field. While maximal orbital angular momentum has been observed in cobalt adatoms,[1] achieving the same electronic structure in a molecule has remained a challenge. Previous work in our lab has shown the effectiveness of linear coordination environments in isolating iron complexes with unquenched orbital angular momentum.[2-5] For example, $[Fe(C(SiMe_3)_3)_2]^-$ has a ground state electron configuration of $(d_{z2})^2(d_{x2-y2}, d_{xy})^3(d_{xz}, d_{yz})^2$ which has L = 2 and, as a result, very large magnetic anisotropy.[3] Calculations on the hypothetical complex $Co(C(SiMe_3)_3)_2$ predicted an increase in orbital angular momentum (L = 3) and a concomitant rise in magnetic anisotropy,[6] however, attempts to synthesize this molecule were unsuccessful. By reducing the basicity of the carbon donor atom, we synthesized the cobalt(II) dialkyl complex $Co(C(SiMe_2OPh)_3)_2$. Long-range Co···O interactions led to a significantly bent C–Co–C axis, and the magnetic properties indicate quenched orbital angular momentum with weak magnetic anisotropy. After synthesizing a number of similar ligands, we found that the naphthol (R = Naph = $C_{10}H_7$) derivative yielded the requisite linear geometry. Atypical of transition metal complexes, $Co(C(SiMe_2ONaph)_3)_2$ has a sufficiently weak ligand field that interelectron repulsion and spin-orbit coupling play a dominant role in determining the electronic ground state. Using dc magnetic susceptibility data, experimental charge density maps, and *ab initio* calculations, we assign a $(d_{x2-y2}, d_{xy})^3(d_{xz}, d_{yz})^3(d_{z2})^1$ electron configuration—a non-Aufau electronic structure that is unprecedented for a transition metal complex. Further, far-IR spectroscopy and ac magnetic susceptometry reveal a 450 cm^{-1} spin reversal barrier, a record for any transition metal containing complex.

C2-03. XMCD Studies of 5d Transition Metal Complexes - Building Blocks for Molecular Magnets. *A. Rogalev*[1], K. Pedersen[2], F. Wilhelm[1] and R. Clerac[3] *1. ESRF, Grenoble, France; 2. Department of Chemistry, Technical University of Denmark, Lyngby, Denmark; 3. CNRS-Univ. Bordeaux, CRPP, UMR 5031, Pessac, France*

The study of paramagnetic complexes based on heavier transition metals (TMs) is an emerging research topic in the field of molecular magnetism. The diffuse nature of their d orbitals, their strong magnetic anisotropy in consequence of large spin–orbit coupling, and their diverse structural and redox properties are driving forces for the interest in this subject. Modelling of magnetic behaviour of such systems is challenging and requires state-of-the-art experimental techniques that can probe locally the electronic states, the spin and the orbital atomic magnetic moments. These could be directly determined from X-ray magnetic circular dichroism (XMCD) measurements at the $L_{2,3}$ absorbing edges of 5d elements. Herein, we present recent XMCD measurements on a series of nearly octahedral TM^{5d}-ion fluoride complexes, where TM^{5d} are Os, Re and Ir [1,2]. Analysis of experimental data taken at magnetic field up to 17 Tesla and at temperatures from 2 to 300 K allowed us to obtain unprecedented insight into the electronic and magnetic structure of the 5d states. The isolation of TM^{5d}-ion fluoride unit, e.g. the $[IrF_6]^{2-}$ complex, by means of large organic cations, thereby making any TM^{5d} – TM^{5d} magnetic interactions negligible, allowed the determination of the intrinsic 5d spin and orbital momentum as well as the anisotropy of the 5d spin-orbit interaction. Moreover, to make sure that the obtained results reflect the magnetic properties of isolated unit, we have repeated XMCD measurements on liquid solutions at room temperature and in frozen solutions at 2 K. The deduced spin and orbital moments are found to be in perfect agreement with those obtained on powdered solid samples. These results help to understand the overall magnetic behaviour of 5d based building blocks for molecular magnets and to orient future syntheses toward improved single-molecule magnets incorporating heavy transition elements.

Magnetic hard disk drives (HDDs) store over 90% of the world's digital data enabling the internet and economical access to data to power everything from social media to self-driving cars. Heat assisted magnetic recording (HAMR) is being developed as the next recording technology for HDDs. HAMR will bring profound changes to the HDD components and architecture. Critical components of this technology, such as the plasmonic near field transducer and high anisotropy granular FePt media [1], as well as recording demonstrations [2] and fully integrated drives have been reported [3]. One of the ongoing challenges of magnetic recording in general and HAMR in particular has been the demonstration of high linear density recording approaching the grain-size limit of the recording media, and a clear pathway to smaller grain sizes while maintaining good magnetic properties and distributions. This paper will demonstrate the extensibility of FePt-based media, and using a head with high thermal gradient we will show a high linear recording density approaching the grain size limit of the media. Assuming continued progress in growth, microstructure and architecture of the media stack and the head architecture, and based on simplistic geometrical scaling, these demonstrations provide visibility out to the 3-4 Tb/in^2 areal density range, enabling high capacity HAMR HDDs that will serve the demand for future economical storage solutions for the world's ever growing data. As announced in a recent blog, Seagate is now shipping HAMR units to select customers for integration tests, and will start shipping commercial HAMR products to key customers by the end of 2018 [4].

C3-02. Ultrafast Non-dissipative Photo-magnetic Recording. *A. Stupakiewicz*[1] *1. Faculty of Physics, University of Bialystok, Bialystok, Poland*

All-optical control of spins with ultrashort laser pulses is an intriguing and rapidly growing fundamental research area [1] as well as an increasingly important issue in modern data storage technology. The minor improvements in the memory speed and the efficiency, along with the growing CPU-memory gap, have significantly limited the developments in computing during the last decades. The large power consumption in the global scale, the generation of massive amounts of waste heat and the difficulties in managing the thermal dissipation within both the single chips and huge IT data centers are growing issues. Recent discovery of all-optical switching demonstrates that it is possible to switch magnetization exclusively in metals by femtosecond circularly polarized pulses [2,3]. Here, we focused on low-dissipative control of magnetization states in magneto-optical garnet dielectrics by ultrafast light pulses. In such garnets were observed the excitations of nonthermal photo-magnetic effect based on spin-orbital modifications by laser light in both quasi-statics regime and dynamics of magnetization precession. We demonstrate ultrafast non-dissipative photo-magnetic recording in ferrimagnetic garnet thin films using time-resolved magneto-optical imaging [4]. In garnet a single linearly polarized 50 fs laser pulse promote switching of the magnetization at room temperature without external magnetic field. Changing the linear polarization of this laser pulse we deterministically steer the net magnetization in the garnet, write "0" and "1" magnetic bits at will. The mechanism of this switching allows ever fastest write-read magnetic recording accompanied by lowest dissipation. The process of recording is based on magnetization precession due to photo-induced magnetic anisotropy in a garnet film. We anticipate that the non-dissipative magnetic switching open up a plethora of opportunities for a novel design of cold photo-magnetic recording.

Session C4
DOMAIN WALL DYNAMICS I
Roberto Lo Conte, Chair
University of California, Berkeley, Berkeley, CA, United States

INVITED PAPER

11:30

C4-01. Dramatic Effect Of Curvature On Velocity Of Chiral Domain Walls. *C. Garg*[1,2], S. Yang[1], T. Phung[1], A. Pushp[1] and S.S.P. Parkin[1,2]
1. IBM Almaden Research Center, San Jose, CA, United States; 2. Max Planck Institute for Microstructure Physics, Halle (Saale), Germany

The current-driven motion of domain walls (DWs) [1] in magnetic nanowires has been an area of considerable research for more than a decade. One of its promising applications is the racetrack memory[1] in which the current-driven synchronous motion of DWs allows information in the form of magnetic domains to travel back and forth without the need of any mechanically moving components. Recently, the use of spin-orbit torques and exchange-coupling torques to move chiral Néel domain walls[2,3] has led to much faster DW velocities (~750m/s)[4] thus further increasing the attractiveness of such a device. Much of the past work on the current-driven motion of the DWs has been limited to straight wires. Yet the true promise of a racetrack memory device lies in the two-dimensional or three-dimensional extension of this concept, potentially leading to a many-fold increase in the storage capacity. In our recent work, we study the motion of DWs in curved wires[5] made out of a perpendicularly magnetized system such as Pt/Co/Ni/Co. We find that depending on the sign of curvature - which we define with respect to the direction of motion of DW - a DW can travel faster or slower with a speed that can differ by a factor of 10. This speeding up or slowing down of DWs depends on the configuration of the DW (up|down vs down|up) and the sign of the curvature, but does not depend on the sign of either the effective spin Hall angle or the chirality of the DW. As adjacent DWs no longer move in lock-step along a bend in the wire, the information encoded in the bit-spacing is no longer preserved. This serious problem can be solved in a magnetic nanowire formed out of a synthetic antiferromagnetic system[4] in which we demonstrate that DWs no longer move with different velocities.

Física Aplicada, Universidad de Salamanca, Salamanca, Spain*

The elastic deformation of a magnetic material has been proposed as an alternative source of energy to control the magnetization states and switching in nanoelements. [1], [2] [3]. In this work we fabricated a Surface Acoustic Wave (SAW) resonator [4] in close proximity to a 10 μm long Ni nanostripe of cross section 400 nm x 35 nm deposited by sputtering. The interdigital transducer (IDT) was fabricated by e-beam lithography on a 2 μm thick ScAlN piezoelectric film which was synthesized by reactive sputtering on a Si/SiO_2 substrate. The Ni nanostripe was placed 45 μm away from the end of the IDT, with its axis in the direction of the traveling acoustic waves. Figure 1 shows the Anisotropic Magnetoresistance (AMR) response of the

nanostripe for both no excitation in the IDT (black curve) and a power of +15 dBm (red curve). Although the field and the current are both in the direction of the nanostripe axis, there is significant AMR signal. Without any SAW excitation, after saturation with a positive field, the magnetization begins to rotate away from the stripe axis at about 70 Oe and the AMR signal drops gradual and reversibly. This reflects the polycrystalline nature of the sputtered Ni and the random orientation of the anisotropy axis. After reversing the external field at -20 Oe, there is an irreversible transition and the switching of the magnetization is completed at -42 Oe. When the IDT is powered with +15 dBm at its resonant frequency (1.25 GHz), the coercivity decreases noticeably. This can be expected as the movement of the domain walls is activated by the magnetolastic energy delivered by the SAWs [5] [6]. Strikingly, the return from saturation becomes irreversible. The inset to figure 1, shows a minor loop taken after the sudden drop of AMR at +8 Oe. This jump is irreversible, suggesting that a domain wall is injected in the nanostripe before reversing the external magnetic field, triggered by the magnetoelastic energy delivered by the SAW. These interesting results will be discussed in the light of additional micromagnetic simulations coupled to the magnetoelastic response of the system.

C4-03. Eavesdropping on spin waves inside the domain-wall nanochannel via three-magnon processes. B. Zhang[1], Z. Wang[1], Y. Cao[1], *P. Yan*[1] and X. Wang[2] *1. Electronic Science and Engineering, University of Electronic Science and Technology of China, Chengdu, China; 2. Physics, The Hong Kong University of Science and Technology, Kowloon, Hong Kong*

One recent breakthrough in the field of magnonics is the experimental realization of reconfigurable spin wave nanochannels formed by magnetic domain wall with a width of 10~100 nm [Wagner et al., Nat. Nano. 11, 432 (2016)]. This remarkable progress enables an energy-effcient spin-wave propagation with a well-defined wave vector along its propagating path inside the wall. In the mentioned experiment, a micro-focus Brillouin light scattering spectroscopy was taken in a line-scans manner to measure the frequency of the bounded spin wave. Due to their localization nature, the confined spin waves can hardly be detected outside the wall channel, which guarantees the information security to some extent. In this work, we theoretically propose a scheme to detect/eavesdrop on the spin waves inside the domain-wall nanochannel via nonlinear three-magnon processes. We send a spin wave in one magnetic domain to interact with the bounded mode in the wall. Two kinds of three-magnon processes, i.e., confluence and splitting, are expected to occur. The confluence process is conventional: conservation of energy and momentum parallel with the wall indicates a transmitted wave in the opposite domain, while the momentum perpendicular to the domain wall is not necessary to be conserved due to the non-uniform internal field near the wall. We predict a stimulated three-magnon splitting (or "magnon laser") effect: the presence of a bound magnon propagating along the domain wall channel assists the splitting of the incident wave into two modes, one is identical to the bound mode in the channel, and the other one is propagating in the opposite magnetic domain. Micromagnetic simulations confirm our theoretical analysis. These results demonstrate that one is able to uniquely infer the spectrum of the spin-wave in the domain-wall nanochannel once we know both the injection and the transmitted waves.

The magnetocaloric effect (MCE) is the temperature or entropy change of a material subject to a variation of magnetic field and is the basic principle of magnetic refrigeration. This technique is considered as promising for a more environmentally friendly and efficient use of energy. However, the microscopic mechanisms at play are to be revealed and the key ingredients are to be identified in order to design new materials. $Mn_{(5-x)}Fe_xSi_3$ ($0 \leqq x \leqq 5$) based systems exhibit moderate MCE at low magnetic fields and at different temperatures depending on x. The materials $MnFe_4Si_3$ and Mn_5Si_3 show direct and inverse MCE, respectively. To get insight into the microscopic mechanisms of the MCE inelastic neutron scattering single crystal studies under different temperatures and magnetic fields have been employed using polarized and unpolarized neutron beams. Magnetic excitation spectra of $MnFe_4Si_3$ were collected in the ferromagnetic phase (T_c = 305K), as well as in the paramagnetic state, in order to understand the nature of the magnetism in $MnFe_4Si_3$. We found isotropic dynamical spin susceptibilities in the PM state and strong anisotropy between in- and out-of-plane magnetic exchange interactions. The correlation lengths indicate a short-range order, while the average linewidth is of the order of k_BT_C pointing to a behavior typical of many ferromagnets. In addition the critical fluctuations in the PM state show a strong response to a magnetic field of 2T [1]. Mn_5Si_3 shows two stable antiferromagnetic phases (T_C = 100K and 66K) where the high temperature one has an unusual magnetic excitation spectrum with coexisting propagative spin waves and diffuse spin fluctuations [2]. It is evidenced that the inverse MCE of Mn_5Si_3, the cooling by adiabatic magnetization, is associated with field induced spin-fluctuations, contrary to the usual suppression of fluctuations by a magnetic field that is observed in the direct MCE of $MnFe_4Si_3$ [1].

Data is the fuel of the new digital economy that has stimulated a whole new class of innovative technologies and businesses. While data has become an indispensable part of modern society, the rate at which data is generated is exploding. This is pushing not only our current storage and processing technologies to their limits, but also that of our energy production: our ICT and data centers already consume around 5% of the world electricity production, and with an annual increase of 7%, this is rapidly becoming unsustainable. In stark contrast, the human brain, with its intricate architecture combining both processing and storing of information, only consumes about 10 Watt of energy while having a similar capacity as a supercomputer consuming around 10 Megawatt. We try to develop materials and concepts that mimic the efficiency of the brain by combining local processing and storage, using adaptable physical interactions that can implement learning algorithms. We demonstrate, by modelling, that a reconfigurable and self-learning structure can be achieved, which implements the prototype perceptron model of a neural network based on magneto-optical interactions. Importantly, we show that optimization of synaptic weights is achieved by a global feedback mechanism, such that learning does not rely on external storage or additional optimization schemes. For the experimental realization of adaptive synaptic structures, we choose to use optically controllable magnetization in a thin Co/Pt film[1], using circularly polarized picosecond[2] pulse trains. The combined stochastic/deterministic nature of all-optical switching in this material[2] offers the possibility to continuously vary the magneto-optical Faraday rotation with the number of pulses (see Figure), yielding the necessary ingredient to realize a perceptron-like structure. First results of such a learning structure will be demonstrated.

C6-01. Synthesis and Characterization of Multifunctional Fe_3O_4-ZnO Colloidal Nanocrystal Clusters for Ultra-sensitive *in vitro* Diagnosis.
M. Ko[1], B. Park[1], L. Pan[1] and Y. Kim[1] *1. Department of Materials Science & Engineering, Korea University, Seoul, The Republic of Korea*

Magnetic nanoparticles (MNPs) have attracted huge interest owing to their wide field of potential applications in drug delivery system, medical imaging, therapeutics, and diagnostics [1]. Among above applications, point-of-care testing (POCT) field using superparamagnetic iron oxide nanoparticle have been researched actively. However, several technological barriers still exist, such as limit-of-detection, lack of quantitative analysis, taking long time for testing. In this study, we report ferrimagnetic Fe_3O_4-ZnO colloidal nanocrystal clusters for ultra-sensitive *in vitro* diagnostic agents and their magnetic, and photonic properties. The Fe_3O_4 colloidal nanocrystal clusters were synthesized by a modified polyol method [2]. After that, in order to nucleate zinc oxide on the Fe_3O_4 colloidal nanocrystal clusters zinc acetate solution was added in the pot, and heated to 180°C for 2 hours [3]. The final products were purified by centrifugation and magnetic separation for several times. The structure of multifunctional colloidal nanoclusters was analyzed by XRD, TEM, and EDX. Magnetic properties were measured by VSM, and optical properties were confirmed by PL. Figure 1 represents the morphology and structural analysis of Fe_3O_4-ZnO colloidal nanocrystal clusters. In figure 1(a), CNCs are constituted by well-defined sperical shape crystals. Elemental mapping suggests that ZnO crystals cover Fe_3O_4 clusters. Also, figure 1(b) exhibits the co-existence of Fe_3O_4 and ZnO phase, respectively. On the other hands, figure 2 shows the clusters have both ferrimagnetic and photoluminescent behaviors. They have relatively higher M_s than other core-shell nanoparticles, while having dual emission area, UV-light originating from band-gap of ZnO and green light coming out from surface defects. As a consequence, Fe_3O_4-ZnO clusters have a great potential for ultrasensitive *in vitro* diagnostic agents owing to magnetic separation and optical detection at once.

Recently, we reported the use of magnetic particles as temperature indicators in magnetic resonance imaging thermometry (tMRI) [1,2]. In this method, the brightness of the MR image changes with temperature due to a temperature-dependent magnetic field inhomogeneity caused by the dipolar field of the magnetic particles. Ferrites are a promising class of materials for tMRI applications because of their biocompatibility and because their magnetic properties can be easily varied by changing composition. Earlier studies used micrometer sized ferrite particles in a proof-of-concept demonstration. However, such large particles cannot be administered intravenously for *in-vivo* use. In this presentation, we report the use of nanoscale $Co_{0.3}Zn_{0.7}Fe_2O_4$ ferrite particles as temperature sensors for tMRI. Measurements of the temperature-dependent magnetization demonstrated a Curie temperature around 275 K (see Figure 1). We conducted nuclear magnetic resonance (NMR) and MRI studies of samples with different concentrations of ferrite nanoparticles suspended in agar gel. We observed inhomogeneous NMR line broadening as a function of temperature from nanoparticles dipolar field (see Figure 2). As a result, the relative MR image intensity shows a near-linear temperature dependence. These ferrite nanoparticles in the form of aggregates (250 nm in diameter) at low concentration (0.12 g/L), provide image contrast corresponding to a temperature resolution of ±1.5 K at 310 K. The decrease of the agglomerates size to 50 nm resulted in similar NMR linewidth broadenings, bolstering the potential viability of this material for clinical applications.

C6-03. White Blood Cell Tracking with Magnetic Particle Imaging Towards Sensitive and Radiation-Free Diagnosis of Infection and Inflammation. *X.Y. Zhou*[1,2], P. Chandrasekharan[2], K. Jeffris[2], D. Mai[2], E.Y. Yu[1,2], B. Zheng[2] and S. Conolly[2,3] *1. Bioengineering, UC Berkeley - UCSF Graduate Program in Bioengineering, Berkeley, CA, United States; 2. Bioengineering, UC Berkeley, Berkeley, CA, United States; 3. Electrical Engineering and Computer Science, University of California, Berkeley, Berkeley, CA, United States*

White blood cell (WBC) scintigraphy has significant impact on clinical care for suspected osteomyelitis [1,2]. To create a clinically useful image, clinicians wait 24+ h for WBCs to clear from areas of nonspecific uptake to areas of infection, by which time image quality has degraded due to radioactive decay [3]. Magnetic particle imaging (MPI) is a sensitive medical imaging technique with zero ionizing radiation and long persistence for SPIO tracers [4]. We show time course MPI images of SPIO-labeled cultured macrophages in mice and of SPIO-labeled neutrophils isolated from mouse blood. Images were taken with the UCB home-built 6.3 T/m field free line scanner (Fig. 2a) [6]. The MPI time course (Fig. 1c) shows that cultured macrophages were localized to mouse lungs and cleared slowly over time. 300,000 neutrophils were isolated from mouse blood and confirmed for CD11b and Ly6G surface marker via flow cytometry (Fig. 2b). MPI imaging of neutrophils is shown in Fig. 2c. The MPI signal was linear with cell number (R2 = 0.967). Time course MPI imaging of cultured macrophages and initial work on SPIO tracer labeling of neutrophils isolated from mouse blood demonstrates that MPI WBC imaging has potential to provide a radiation-free diagnostic complement to Indium-111 WBC scans. Because there is no decay in magnetic signal over time, there is no tradeoff between radioactive half-life, SNR and time constant for optimal pathophysiologic contrast.

C6-04. Isolation of Bacteria from Water Samples Using Spin-Vortex Magnetic Microdiscs. *K.Y. Castillo-Torres*[1], E. McLamore[2] and D.P. Arnold[1] *1. Electrical and Computer Engineering, University of Florida, Gainesville, FL, United States; 2. Agricultural and Biological Engineering, University of Florida, Gainesville, FL, United States*

Pathogenic bacteria in water systems present a threat that may cause widespread illness and even death. This work presents a method for the rapid capture, concentration, and fluorescence-based assay of bacterial targets from water samples of up to 100 mL. Surface-functionalized, micrometer-sized (1.5-μm Ø, 80-nm thick) gold-coated ferromagnetic ($Ni_{80}Fe_{20}$) spin-vortex microdiscs [1-4] are used to bind to target bacteria. These microdiscs are microfabricated using photolithography, sputter deposition, and lift-off techniques. Their "bacteria" size (1-2 μm) and their larger magnetic moment when compared to commonly used "magnetic beads," which typically use only 1-5% volume-fraction loads of iron-oxide nanoparticles, make them more effective to capture bacterial targets. Also, the closed magnetic spin arrangement of the discs results in near-zero stray field preventing disc agglomeration when in free suspension while still exhibiting a large magnetic response to applied magnetic fields (fig. 1). Discs are bio-functionalized with DNA aptamers for capture of *E. coli* and with Concavalin A (ConA) lectins for capture of general coliforms. We have demonstrated selective capture of *E. coli* and coliforms (*E. coli, P. mirabilis, and K. varicola)* on aptamer-functionalized and ConA-functionalized discs, respectively. Here, 100-mL lab-prepared bacterial water samples are enriched with Lysogeny broth (LB) for 6 hr, and then disc/cell conjugate recovery is achieved using a magnet capture apparatus. Capture efficacy is assessed via epifluorescent and confocal microscopy using commercial cell viability stains (propidium iodide/SYTO9). For 1-10-mL samples, we have shown capture of *E. coli* K12 at levels as low as 1 CFU/mL within 10 minutes (fig. 2). For 100-mL samples, we have demonstrated capture of *E. coli* at levels of 1-10 CFU/100 mL, and coliforms at levels of 2-10 CFU/100 mL within 8 hr (including enrichment). These bacterial concentrations are representative of the requirements for water quality monitoring.

Departamento de Física, Universidad de Santiago Chile, Santiago, Chile*

Magnetic films of magnetite (Fe_3O_4) with controlled defects, usually called antidots arrays, where synthesized by a new technique called AFIR, that considers the deposition of a thin film by atomic layer deposition, the generation of holes using focused ion beam milling in the case of squared and hexagonal lattices, and the subsequent thermal reduction process of antidots arrays. Magnetic characterizations were carried out by magneto optic Kerr effect, showing the enhancement of the coercivity for the antidots arrays. The presence of the ordered non-magnetic holes induces a demagnetization field distribution that change the magnetization switching mechanism. This technique opens a new route of manufacture ordered antidots arrays of magnetic oxides with variable lattice parameters. The authors acknowledge financial support from Fondequip (refs. EQM120045 and EQM140092), from Fondecyt (ref. 1150952 and 11150671), from DICYT, from the Spanish MINECO (ref. MAT2014-59772-C2-1-P) and from the Basal Proyect (ref. FB0807).

C7-03. Exploration of Fe_2O_3/Cu nanocomposite metaconductors formed by electro-infiltration. *C.S. Smith*[1], T. Clingenpeel[1], Y. Yoon[1] and D.P. Arnold[1] *1. Electrical and Computer Engineering, University of Florida, Gainesville, FL, United States*

This study explores the potential metaconductor behavior exhibited by fabricating transmission lines made from nanocomposite material comprised of commercially purchased Fe_2O_3 ferro-magnetic nanoparticles (primarily of the gamma phase and with diameters less than 50 nm) embedded in a non-ferromagnetic copper matrix using the electro-infiltration technique. Metaconductors are conductive materials that have been engineered to overcome the various limitations posed by traditional conductors at high frequencies, such as the skin effect and the resulting low conductivity. Past metaconductors have been made using alternating layers of ferro-magnetic and non-ferromagnetic materials, and have shown a higher conductivity at frequencies above 10 GHz [1]. Electro-infiltration is a fabrication method where nanoparticles are deposited onto a metal seed layer and into a photoresist mold. The nanoparticle film is then infiltrated by electroplating metal upward from the seed layer and between the particles, forming one solid structure [2]. Removal of the surrounding seed layer results in an electrically isolated and patterned nanocomposite film. The resulting 1.5 mm and 3.5 mm long metaconductor transmission lines formed using electro-infiltration were measured to have thicknesses of 2.5 μm, and were characterized using a network analyzer from 300 kHz to 20 GHz (inset of Fig. 1). S-parameters were gathered and plotted, showing a 0.4 dB insertion loss and a -0.5 return loss at 20 GHz (Fig. 1). Further, VSM data was collected for the

metaconductor transmission lines and plotted, showing an out-of-plane hysteresis loop that indicates the presence of ferro-magnetic particles in the nanocomposite material with a saturation magnetization of 0.52 kA/m (Fig. 2). Future experiments will derive the frequency response of the resistance for these devices and compare it to that of a plain copper conductor transmission line to identify the existence of metaconductor behavior for the nanocomposite [3].

C8-01. Ultrafast Manipulation of Topological Properties using Shear Strain in a Weyl Semimetal. *E. Sie*[1] *1. Stanford University, Stanford, CA, United States*

Manipulation of topological invariants in quantum materials plays a key role in topological switching applications. Prior studies have proposed lattice strain as a means of tuning these topological invariants, as it directly modifies the electron-ion interactions and potentially alters the underlying crystalline symmetry on which the topological properties depend. However, conventional means of applying strain through heteroepitaxial lattice mismatch and dislocations are not extendable to controllable time-varying protocols. Here, we perform a femtosecond-resolution crystallographic measurement using relativistic electron diffraction on the Weyl semimetal WTe2. We demonstrate that terahertz (THz) light pulses can be used to induce interlayer shear oscillations at 0.24 THz with ~1% large strain amplitudes, identified by measuring structure factor modulations of many Bragg reflections. We show that such shear strain serves as an ultrafast, energy-efficient means to induce more robust, well separated Weyl points or to annihilate all Weyl points of opposite chirality. This defines new possibilities for ultrafast manipulation of the topological properties in solids and for a topological switch operating at THz frequencies.

C8-02. Ultrafast electronic dynamics in a strongly correlated insulator SmB_6. *K. Xu*[1], A. Gauthier[1,2], J. Sobota[1,2], H. Pfau[1,2], J. Xia[3], P. Kirchmann[1,2] and Z. Shen[1,2] *1. Stanford University, Stanford, CA, United States; 2. SLAC National Accelerator Laboratory, Menlo Park, CA, United States; 3. University of California, Irvine, Irvine, CA, United States*

SmB_6 is a strongly correlated Kondo insulator that forms a gap at the Fermi level due to hybridization between Sm 4f and 5d states. Such a gap can support interaction-driven excitons protected by strongly renormalized bands as discussed in inelastic neutron scattering and Raman spectroscopy studies. We excite SmB_6 with an ultrafast laser pulse, and study the resulting dynamics using time- and angle-resolved photoemission spectroscopy. We discover a coherent oscillatory response of the electronic states near the Gamma point, which we characterize as function of excitation density and temperature. We discuss possible origins for the observed mode.

C8-03. Pulse-induced η-pairing correlation in a Mott-Hubbard system. *T. Kaneko*[1], T. Shirakawa[2], S. Sorella[3] and S. Yunoki[1,2] *1. Computational Condensed Matter Physics Laboratory, RIKEN, Wako, Japan; 2. Center for Emergent Matter Science (CEMS), RIKEN, Wako, Japan; 3. SISSA-International School for Advanced Studies, Trieste, Italy*

Light-induced states have been attractive topics in recent condensed matter physics [1]. In particular, recent ultrafast time-resolved experiments provide new insights in strongly correlated electron systems [2]. In the case of Mott insulator (MI), the photoinduced insulator-to-metal transition is a fundamental phenomenon, which has been reported in time-resolved experiments for several transition-metal and organic-molecular compounds [3]. Photoinduced metallic states in those systems are recognized as a results of photo-carrier doping to MIs, where carriers are doublons (doubly occupied sites) and holons (empty sites) created simultaneously by pulse irradiation [4]. Here, we consider the photodoped MI by the interpretation of η-pairing. The η-pairing state was originally proposed by C. N. Yang [5], where the exact eigenstate which possesses the off-diagonal long-range order (ODLRO) was introduced in the Hubbard model [5]. At half-filling, since the ground state of the Hubbard model is the MI state, a η-pairing state is not realized as the ground state. η-pairing eigenstates are thus hidden in the excited states in the Hubbard model. We investigate the superconducting pair correlations in the Hubbard model with a pulse field. In the one-dimensional (1D) Hubbard chain, we show that the superconducting pair correlation is enhanced at momentum $q = \pi$ by pulse irradiation. In order to explain the enhancement of the pair correlation at $q = \pi$, we consider the η-pairing eigenstates which possess pair-density-wave like off-diagonal long-range correlation in the Hubbard model. Here, we estimate the weights of the eigenstates in the pulse-induced state, which clarify that the enhancement of the pair correlation is caused by the η-pairing eigenstates. We also verify the signatures of η-pairing even in a large size 1D chain as well as in the two-dimensional square lattice, suggesting that the pulse-induced enhancement of the η-pairing correlation is a phenomenon generally found in the Hubbard model.

C9-01. Learning Quantum Emergence with AI. *E. Kim*[1] *1. Physics, Cornell University, Ithaca, NY, United States*

The application of artificial neural network to central questions in the theory of quantum matter is a rapidly developing field. The driving insight here is that the problems of theoretical interests are primarily those of regression in which an exponentially large volume of data must be condensed into a more accessible or meaningful form, e.g., labeled with phases. In this talk, I will review the state of this rapidly developing field. I will then showcase how my group built and taught neural networks to recognize topological phases, different non-equilibrium phases and universal features from scanning tunneling microscopy data. I will then discuss new insights from the synergy between human intelligence and artificial intelligence: the key to our success.

C9-02. Evolution of Electronic Non-Fermi Liquid Excitations in $YbRh_2Si_2$. *L. Jiao*[1], S. Seiro[1], S. Kirchner[2], S. Hartmann[3], S. Friedemann[4], C. Geibel[1], Q. Si[5], F. Steglich[1] and S. Wirth[1] *1. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 2. Zhejiang University, Hangzhou, China; 3. Fraunhofer Institute for Photonic Microsystems, Dresden, Germany; 4. School of Physics, University of Bristol, Bristol, United Kingdom; 5. Rice University, Houston, TX, United States*

Quantum entanglement is a fascinating effect which can strongly shape the low temperature properties of matter. $YbRh_2Si_2$ serves as a prototypical correlated metal to investigate the intricate interplay of localized spin states and itinerant electronic states, which is manipulated by the quantum entanglement [1]. The formation of Kondo lattice coherence and quasiparticle destruction related to a field-induced quantum critical point was proposed in $YbRh_2Si_2$ at very low temperature and around 0.66 T, where quantum entanglement is pronouncedly enhanced. In this talk, I would like to show how, upon lowering the temperature, the Kondo lattice coherence first develops and finally gives way to non-Fermi liquid electronic excitations. By measuring the single-particle excitations through scanning tunneling spectroscopy on $YbRh_2Si_2$, we observe the Kondo lattice peak emerging below the Kondo temperature T_K ~25 K [2]. At even lower temperature, the Kondo lattice peak displays a non-trivial temperature dependence with a strong increase below around 3.3 K [3]. At the lowest measurable temperature and as a function of an external magnetic field, the width of this peak is minimized in the quantum critical regime. The suppression of the Kondo lattice peak together with the non-Fermi liquid electronic excitations in quantum critical metals elucidates a microscopic picture for the strange-metal phenomena that have been ubiquitously observed in strongly correlated electron materials, and the interplay between quantum entanglement, Kondo lattice behavior and quantum criticality could be traced.

C10-01. Universal thermal Hall conductivity of a kagomé antiferromagnet. *M. Yamashita*[1], H. Doki[1], M. Akazawa[1], H. Lee[1], J. Han[2], K. Sugii[1], M. Shimozawa[1], N. Kawashima[1], M. Oda[3] and H. Yoshida[3] *1. The Institute for the Solid State Physics, The University of Tokyo, Kashiwa, Japan; 2. Department of Physics, Sungkyunkwan University, Suwon, The Republic of Korea; 3. Department of Physics, Faculty of Science, Hokkaido University, Sapporo, Japan*

Searching for the ground state of a kagomé Heisenberg antiferromagnet (KHA) has been one of the central issues of condensed-matter physics, because the KHA is expected to host many unknown spin-liquid phases with exotic elementary excitations. To study the elementary excitations, we investigate the longitudinal (κ_{xx}) and transverse (κ_{xy}) thermal conductivities of a new candidate of $S = 1/2$ kagomé insulator Ca kapellasite ($CaCu_3(OH)_6Cl_2 \bullet 0.6H_2O$) of which the spin Hamiltonian is suggested to be well approximated to be an ideal KHA [1]. We find a clear thermal Hall signal in the spin liquid phase of $T^* < T < J / k_B$ ($T^* \sim 7$ K is the magnetic transition temperature and $J / k_B \sim 66$ K is the effective spin interaction energy). The temperature dependence of κ_{xy}/T shows a peak at $T \sim J/(3\ k_B)$, which is followed by a rapid decrease below T^*. We find that κ_{xy} is well reproduced, both qualitatively and quantitatively, by the Schwinger-boson mean-field theory with the Dzyaloshinskii-Moriya interaction of $D/J = 0.1$-0.3 [2]. Most remarkably, both κ_{xy} of Ca kapellasite and that of another kagomé antiferromagnet volborthite [3] are found to converge to one single curve of our Schwinger-boson calculation only by choosing J and D as fitting parameters. This excellent agreement demonstrates not only that the thermal Hall effect in these kagomé antiferromagnets is caused by spins in the spin liquid phase, but also that κ_{xy} is given by a simple scaling function $f(k_BT/J)$, unveiling the universal $\kappa_{xy}(T)$ of KHA.

C10-02. Topography and mimicry of spin liquids on a triangular lattice. *S. Chernyshev*[1] *1. University of California, Irvine, Irvine, CA, United States*

There is a significant recent interest in spin systems with strongly-anisotropic frustrating spin interactions due to possible exotic ground states. We have explored an extended 3D phase diagram of a class of such models on an ideal triangular lattice using density-matrix renormalization group (DMRG) and quasiclassical approaches [1,2] and have mapped out the topography of the region that can harbor a spin liquid state. A 4D extension of this phase diagram naturally connects to a different spin liquid phase of the isotropic J_1-J_2 model. We find that spin-spin correlations are nearly identical between these two limits [2], making a strong case that their respective spin liquids are isomorphic to each other. For $YbMgGaO_4$, a rare-earth-based triangular-lattice antiferromagnet with anisotropic spin-spin interactions, our analysis finds no transitions to a spin liquid near experimentally relevant range of parameters [1,2]. We have proposed that a randomization of the subleading pseudo-dipolar interactions due to spatially-fluctuating charge environment of the magnetic ions can successfully mimic a spin liquid by forming short-range stripe-ordered domains, producing the structure factor that is in agreement with experiment. This spin-liquid mimicry scenario is relevant to other quantum magnets with fragile ground states selected by an order-by-disorder fluctuations and random environments.

C10-03. Field-Induced Spinon Pairing in a Gapless Fermi-Surface Spin Liquid on the Kagome Lattice. *A. Zorko*[1], M. Gomilsek[1], M. Klanjsek[1], R. Zitko[1], M. Pregelj[1], Y. Li[2], Q. Zhang[2,3], F. Bert[4] and P. Mendels[4] *1. Jozef Stefan Institute, Ljubljana, Slovenia; 2. Department of Physics, Renmin University of China, Beijing, China; 3. Shanghai Jiao Tong University, Shanghai, China; 4. Laboratoire Physique des Solides, Université Paris-Sud, Orsay, France*

Quantum kagome antiferromagnets (QKA's) are spin systems in which strong geometrical frustration, coupled with quantum fluctuations, suppresses any long-range magnetic order. Instead, quantum-entangled spin-liquid states are promoted. The true nature of the spin-liquid ground state of the QKA remains an unresolved issue [1]. One possibility to unveil this mystery is to study the response of QKA representatives to external perturbations, like the applied magnetic field. We will present our in-depth experimental study of Zn-brochantite, $ZnCu_3(OH)_6SO_4$, one of the few realizations of the QKA lacking long-range magnetic order at any experimentally accessible temperature [2]. In this compound, several instabilities of a correlated spin state [3] occur below the temperature set by the strongest exchange interaction of ~65 K and a gapless spin-liquid ground state with a spinon Fermi surface is realized below ~1 K [4]. Based on recent nuclear magnetic resonance results, we show that this spin-liquid state is prone to an intrinsic field-induced instability, resulting in another spin liquid, this time with a full or a partial spin gap (see figure) [5]. The instability is ascribed to pairing of spinons - fractional excitations characteristic of spin liquids – and is a magnetic analogue to Cooper pairing in superconductors. The implications of our discovery for other known cases of field-induced instabilities in gapless spin liquids will be discussed.

C10-04. Stability of the spiral spin liquid in $MnSc_2S_4$. Y. Iqbal[1], *T. Müller*[2], H. Jeschke[3], R. Thomale[2] and J. Reuther[4,5] *1. Department of Physics, Indian Institute of Technology Madras, Chennai, India; 2. Institute for Theoretical Physics and Astrophysics, Julius-Maximilian's University of Würzburg, Würzburg, Germany; 3. Research Institute for Interdisciplinary Science, Okayama University, Okayama, Japan; 4. Dahlem Center for Complex Quantum Systems and Institut für Theoretische Physik, Freie Universität Berlin, Berlin, Germany; 5. Helmholtz-Zentrum für Materialien und Energie, Berlin, Germany*

We investigate the stability of the spiral spin-liquid phase in $MnSc_2S_4$ against thermal and quantum fluctuations as well as against perturbing effects of longer-range interactions. Employing *ab initio* DFT calculations we propose a realistic Hamiltonian for $MnSc_2S_4$, featuring second (J_2) and third (J_3) neighbor Heisenberg interactions on the diamond lattice that are considerably larger than previously assumed. We argue that the combination of strong J_2 and J_3 couplings reproduces the correct magnetic Bragg peak position measured experimentally. Calculating the spin-structure factor within the pseudofermion functional-renormalization group technique we find that close to the magnetic phase transition the sizeable J_3 couplings induce a strong spiral selection effect, in agreement with experiments. With increasing temperature the spiral selection becomes weaker such that around three times the ordering temperature an approximate spiral spin-liquid is realized in $MnSc_2S_4$.

Physics and Astronomy, University of California Riverside, Riverside, CA, United States; 2. Physics and Astronomy, University of California, Irvine, Irvine, CA, United States; 3. Helmholtz-Zentrum Dresden - Rossendorf, Dresden, Germany; 4. Department of Physics, Colorado State University, Fort Collins, CO, United States; 5. Physics and Astronomy, UCLA, Los Angeles, CA, United States*

Injection of a pure spin current into magnetic insulator modifies the chemical potential of magnons, as demonstrated by recent experiments [1], and leads to intriguing phenomena such as long-range spin transport [2] and magnon condensation [3]. A pure spin current can be injected into magnetic insulator via spin Seebeck effect [4]. A temperature gradient at the interface of magnetic insulator and normal metal generates a non-equilibrium population of incoherent magnons. Nonlinear magnon interaction transfers the angular momentum from incoherent magnon cloud to a low-energy magnon state, thereby reducing its effective damping [3,5]. Above the critical magnitude of such thermal spin current, magnonic system undergoes a phase transition establishing a coherent low-energy magnonic state [3]. This process corresponds to bosonic condensation of non-equilibrium magnons, generated by incoherent heat transport process, into a coherent magnon condensate. Such magnon condensate driven by thermal spin current has been recently realized in nanowires fabricated from bilayers of Yttrium Iron Garnet (YIG) and Platinum [5]. Via ohmic heating of the Pt layer, a temperature gradient is established across the YIG/Pt interface. The thermal spin current compensates the damping of YIG and creates a magnonic condensate that manifests through auto-oscillations of the lowest spin wave mode of the nanowire. The auto-oscillations generate a microwave signal by means of magnetoresistive effects in Pt that is measured spectroscopically. The experimental results demonstrate that magnon condensates can be created via incoherent drives and present a route for technological implementation. Energy loss due to ohmic heating is the major bottleneck for the performance of nanoelectronics devices. Thermally generated spin currents can be employed to harvest the waste heat and to operate spintronic devices, such as tunable microwave oscillators and spin wave emitters. This work was supported by Spins and Heat in Nanoscale Electronic Systems (SHINES), an Energy Frontier Research Center funded by the US Department of Energy.

D1-02. Supercurrent in a room-temperature Bose-Einstein magnon condensate.
B. Hillebrands[1] *1. Physics, TU Kaiserslautern, Kaiserslautern, Germany*

A room-temperature magnon Bose-Einstein condensate (BEC) observed in magnetic insulators (single-crystal films of yttrium iron garnet, YIG) [1, 2] has a large potential in high-speed and low-power information processing and data transfer. Recently, we have succeeded to create magnon supercurrents by introducing a spatial phase gradient into a BEC wave function [3]. It has been found that *local* heating of a magnetic sample leads to the excessive BEC decay caused by outflow of condensed magnons from the hot sample spot. Here, I show that *non-local* probing of the magnon BEC provides direct evidence of long-distance supercurrent transport. By utilizing space-, time- and wavevector-resolved Brillouin light scattering (BLS) spectroscopy the propagation of a supercurrent pulse is detected on an undisturbed background of the slowly decaying magnon BEC. This pulse can be understood as a (nonlinear) second sound of magnon BEC travelling with a constant velocity over a millimeter-long distance. The discovery of the room-temperature magnon supercurrent transport opens door to studies of magnonic macroscopic quantum transport phenomena as a novel approach in the field of information processing. At the same time, the miniaturization of supercurrent-based magnonic devices constitutes an extraordinary challenge for their future applications. Conventionally, the conditions for the formation of the BEC are created in macroscopic YIG samples by powerful microwave parametric pumping. Here, a fundamentally new approach is presented. Fast DC-current pulses applied to YIG/Pt microstructures result in a strong heating. Consequently, this leads to an increased number of magnons, distributed over the whole spectrum. Once the current is switched off the system cools down rapidly. This results in a strong increase of the magnon density at the bottom of the spectrum, leading to the formation of magnon BEC observed by BLS microscopy. Our experiment shows, that the BEC formation depends on the magnon temperature and the timescale of the cooling process. The work is supported by ERC Starting Grant 678309 MagnonCircuits, ERC Advanced Grant 694709 SuperMagnonics, EU-FET Grant 612759 InSpin, and DFG Grant DU 1427/2-1.

2:30

D1-03. Magnonic condensates and superfluids.
S. Kim[1] *1. Physics and Astronomy, UCLA, Los Angeles, CA, United States*

Recent advancements in spintronic techniques originally developed for spin-based devices now enable us to study fundamental spin physics of insulating materials with unprecedented spin-current control and measurement, opening a new area of theoretical and experimental investigation. One concept of emerging interest in the aforementioned direction is spin superfluidity in magnetic insulators, a magnetic analog of mass superfluidity, which has been envisioned about a half century ago and can now be realized with the aid of spin-current sources and detectors developed in spintronics. This talk will provide a theoretical understanding of two spin-superfluid phenomena that have been recently investigated experimentally in magnetic insulators: thermoelectrically-pumped magnon condensation and superfluid spin transport via the collective spin dynamics.

Session D2
MAGNETIC SKYRMIONS AND SPIN TEXTURES

Christian Rüegg, Chair
Paul Scherrer Institut, Villigen, Switzerland

INVITED PAPER

1:30

D2-01. Vortices And Skyrmions In Itinerant Magnets. *Y. Motome*[1]
1. The University of Tokyo, Tokyo, Japan

Swirling noncoplanar spin textures have attracted great interest owing to not only their topological aspect but also an emergent electromagnetic field for itinerant electrons associated with the spin Berry phase. Several mechanisms have been discussed for stabilizing such spin textures: for instance, long-ranged dipole interactions, the relativistic spin-orbit coupling, and frustrated magnetic exchange interactions. We here discuss yet another mechanism arising from the coupling of localized spins to itinerant electrons. In the the spin-charge coupled systems, effective interactions between the localized spins are generated by the kinetic motion of itinerant electrons. A well-known interaction is the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction in the weak coupling limit. Although the RKKY interaction often stabilizes a simple helical order, extensive researches in the past decades have unveiled that the spin-charge coupling can induce a variety of spin textures, including noncoplanar vortices and skyrmions. In this talk, we will give an overview of our recent theoretical studies for the effect of spin-charge coupling on exotic spin textures. We have investigated this problem by adopting complementary methods, such as analytical perturbation theories, variational calculations for the ground state, and numerical simulations at finite temperatures. We will discuss the microscopic origin of swirling spin textures: effective multiple-spin interactions with particular wave numbers dictated by the Fermi surface [1-3]. The discovery of new spin textures will also be presented, including a vortex crystal with a chiral stripe as a generic ground state in the weak coupling regime [4] (Fig. 1) and a skyrmion crystal with a high topological number [5] (Fig. 2). We will also show that the spin-orbit coupling in itinerant electrons can generate further exotic spin textures [6]. This work has been done in collaboration with Y. Akagi, C. D. Batista, K. Barros, G.-W. Chern, S. Hayami, R. Ozawa, and M. Udagawa. This research was supported by KAKENHI (Grant No. 21340090, 24340076, 16H06590), the Strategic Programs for Innovative Research (SPIRE), MEXT, and the Computational Materials Science Initiative (CMSI), Japan. Parts of the computation in this work were carried out at the Supercomputer Center, Institute for Solid State Physics, the University of Tokyo.

D2-02. Signatures of Skyrmion Lattice Order in Antiferromagnetic $EuPtSi_3$. *W. Simeth*[1], A. Bauer[1], A. Senyshyn[2], C. Franz[2], T. Schrader[3], R. Bozhanova[1], S. Gottlieb-Schönmeyer[1] and C. Pfleiderer[1] *1. Physics, Technical University of Munich, Garching, Germany; 2. Heinz Maier-Leibnitz Zentrum, Garching, Germany; 3. Jülich Centre for Neutron Science, Garching, Germany*

An abundance of systems has been reported in which skyrmion lattice order emerges in a nearly ferromagnetic host. We report the observation of key signatures suggesting skyrmion lattice order in the antiferromagnetic state of $EuPtSi_3$, which crystallizes in the non-centrosymmetric space group *I4mm*. The magnetic properties of high-quality single crystals, grown by means of the optical float-zoning, were determined by means of measurements of the magnetization, ac susceptibility, specific heat and electrical transport properties. In addition, powder and single crystal neutron diffraction have been performed. At temperatures below 17 K antiferromagnetic order of the local f-moments emerges featuring a complex magnetic phase diagram comprising two and four different magnetic phases for field applied parallel and perpendicular to the c-axis, respectively. An additional contribution to the Hall effect shares all the characteristics expected of topological spin textures akin the skyrmion lattice in ferromagnetic host materials. Neutron diffraction provides evidence of a long-wavelength Néel-type modulation of the magnetic structure in zero field. In combination with a symmetry analysis our data suggest the formation of skyrmion lattice order in an antiferromagnetic host material.

D2-03. Magnetoelectric effect and orbital magnetization in skyrmion crystals: New ways for detection and characterization of skyrmions. *B. Göbel*[1], A. Mook[2,1], J. Henk[2] and I. Mertig[2,1] *1. Max Planck Institute for Microstructure Physics, Halle (Saale), Germany; 2. Martin-Luther University, Halle, Germany*

Skyrmions are small magnetic quasiparticles, which are uniquely characterized by their topological charge and their helicity [1]. We present theoretically how both properties can be determined without relying on real-space imaging [2]. The topological Hall effect of electrons allows to distinguish

skyrmions from antiskyrmions by sign of the topological Hall conductivity [3,4] and the orbital magnetization [2,5]; cf. Fig. 1(a,b). Here, we predict a magnetoelectric effect in skyrmion crystals [2], which is the generation of a magnetization (polarization) by application of an electric (magnetic) field. Its dependence on the skyrmion helicity fits that of the classical toroidal moment of the spin texture and allows to differentiate skyrmion helicities: it is largest for Bloch skyrmions and zero for Neel skyrmions [Fig. 1(c)]. We predict distinct features in the magnetoelectric polarizability that can be used to detect and characterize skyrmions in experiments.

Physics, UC Davis, Davis, CA, United States; 6. Physics, University of Miami, Coral Gabels, FL, United States*

Magnetic skyrmions are a focus of intense research due to their application to ultra-low power data storage and logic technologies as well as their fundamental qualities as topological pseudo-particles. In this work we use small angle neutron scattering (SANS) to demonstrate a method to precipitate ordered and oriented skyrmion lattices from an initial domain configuration consisting of mutli-q helices and randomly oriented skyrmion arrays. This approach uses a symmetry-breaking magnetic field sequence to define a preferred orientation of the skyrmion lattice. We demonstrate this approach on single-crystals of (Fe, Co)Si. Interestingly, the efficacy of this technique is independent of the orientation of the crystal, suggesting a similar approach could be applied to a randomly oriented powdered sample. Indeed, we are able to precipitate ordered and oriented skyrmion lattices in a powdered sample of Cu_2OSeO_3. Simulations (OOMMF) reveal the underlying mechanics responsible for the ordering and also suggest that the resultant orientation of the skyrmion lattices arrises due to symmetry breaking in the sample (e.g. magnetocrystalline anisotropy and microstructure) and also skyrmion-skyrmion interactions. This approach means that candidate skyrmion materials can be tested as powders using SANS, significantly improving accessibility to skyrmion research.

D2-05. Electronic properties of chiral spin textures from non-commutative quantum mechanics. *F.R. Lux*[1], F. Freimuth[1], S. Blügel[1] and Y. Mokrousov[1] *1. Peter Grünberg Institut and Institute for Advanced Simulation, Forschungszentrum Jülich, Jülich, Germany*

Non-collinear magnetism has a profound impact on the electronic transport. Its hallmarks are the large anomalous Hall effect in strongly frustrated non-collinear antiferromagnets [1] and the topological Hall effect in magnetic skyrmions [2, 3]. While these effects are readily studied from *ab initio* for atomic scale structures, they are notoriously difficult to treat theoretically when the scale of the problem exceeds beyond the nanometer regime, as it is the case with the vast majority of chiral skyrmions considered these days. They require the treatment of thousands of atoms per unit cell. Here, we pursue a different approach which is based on a semiclassical expansion of the single-particle's Green's function in the Keldysh formalism [4]. It allows us to treat the deviations from the collinear magnetic state diagrammatically – order by order – in the gradients of the texture. This systematic formalism is especially suited to analyze transport and magnetic properties of the electronic system as it incorporates external fields in a gauge covariant way right from the start. The developed framework can find important applications in the field of spin-orbitronics, where the orbital physics of electrons plays a central role and orbital magnetization represents a key concept. By employing the above procedure, we demonstrate how the orbital magnetization in extended chiral magnetic systems can be understood as the electronic response to emergent electromagnetic fields [5]. We also discover that in such systems the spin-orbit interaction can be used to great advantage in that it promotes a complex interplay of real-space and k-space topology resulting in enhanced response to external electric and magnetic fields in interfacial chiral magnets.

D3-01. Biomedical and Electronic Applications of Magnetoelectric Nanofibers. *J. Andrew*[1] *1. Materials Science & Engineering, University of Florida, Gainesville, FL, United States*

In many single-phase materials certain properties are mutually exclusive. Examples of this property dichotomy include strength and toughness, high electric permittivity and high magnetic permeability, and soft and hard magnetic properties. Nanostructured composite materials have the potential to overcome some of these limitations of single-phase materials. For example, magnetic and ferroelectric materials can be combined on a single particle or fiber, yielding new nanostructured multiferroic composites with enhanced properties, opening up new applications including tunable microelectronics, sensors and dual-state memory. Here, we present the first example of composite nanostructured building block with a Janus-type morphology for multiferroic applications. By fabricating composites on a single particle or fiber in an anisotropic manner (e.g. Janus-type) the surface and bulk properties of each phase remain accessible, providing additional degrees of freedom in composite design. Applications of these materials in biomedical and electronic applications will be presented.

D3-02. Micro-magnetic circuit for logical operation of multiplex cell tweezers. B. Lim[1], X. Hu[1], K. Kim[1], J. Yoon[1] and *C. Kim*[1] *1. Emerging Materials Science, DGIST, Daegu, The Republic of Korea*

The remotely controllable cells manipulation in a lab on a chip systems promises to play a key role towards multiplex cell tweezers for single cell analysis, cell separation and inter-cellar interaction. Particularly, most existing single cell platforms are unable to achieve large scale operation with flexibility on cells and digital manipulation, and thus there is urgent need of innovative techniques to accomplish the automation of single cells. Recently, the flexibility of magnetic shuttling technology using nano/micro scale magnets for the manipulation of particles has gained significant advances and has been used for a wide variety of single cells manipulation tasks. Drawing inspiration from general circuit theory and magnetic bubble technology, here we demonstrate a class of integrated circuits for executing sequential and parallel, timed operations on an ensemble of collected cells [1,2]. The integrated circuits are constructed from lithographically defined, overlaid patterns of magnetic film and current lines. The magnetic patterns passively control particles similar to electrical conductors, diodes, and capacitors. The current lines actively switch particles between different tracks similar to gated electrical transistors. When combined into arrays and driven by a rotating 3D-magnetic field clock, these integrated circuits can implement general multiplexing properties and enable the precise control of arbitrary objects with magnetization contrast relative to its surroundings. In this talk, I will present the magnetic domains of different micro-magnetic tracks, the governing magnetic force and energy of transporting superparamagnetic carriers [3], as well as a completed Spintrophoretic platform for multiplexed cell tweezers.

D3-03. Magnetic Particle Imaging (MPI) for Highly Sensitive, Quantitative, and Safe *in Vivo* Gut Bleed Detection in a Murine Model. *P. Chandrasekharan*[1], E.Y. Yu[1], Z. Tay[1], X.Y. Zhou[4] and S. Conolly[5] *1. BioEngineering, University of California, Berkeley, Berkeley, CA, United States; 4. Bioengineering, UC Berkeley - UCSF Graduate Program in Bioengineering, Berkeley, CA, United States; 5. University of California, Berkeley, Berkeley, CA, United States*

Aim: Gastrointestinal (GI) bleeds can occur spontaneously, after physical trauma or as a result of surgical complications, and are responsible for many hospitalizations in the US [1]. We present to you a novel imaging modality called Magnetic Particle Imaging (MPI), for highly sensitive, safe and robust detection of GI bleed in a murine model using long-circulating magnetic nanoparticles [2,3]. *Materials & Methods*: Mice [4] with a genetic mutation that results in intestinal polyps (that spontaneously bleed, with wild-type for control) was scanned using MPI. MPI was carried out with a home built vertical bore field-free line (FFL) MPI scanner with a gradient strength of 6.3 T/m. Dynamic projection MPI scans were acquired with respiratory gating. SPIOs (Long-circulating) was injected through a lateral tail vein. MPI data were obtained as 2D projection over 80 minutes. Region-Of-Interest (ROI) based flow quantification was performed after converting the MPI signal to iron concentration. *Results & Discussion*: GI related major and minor bleed events are critical in surgical planning. 2D MPI projection image of 10 min and 86 minutes post-SPIO injection are shown (Fig(left)). MPI signal was observed to accumulate in the mouse colon of the APC model, whereas the wild type showed signal from the vascular compartment. The tracer accumulation of the gut lumen was linear with time (Fig(right)) and had a flow rate of 1-5 μL/min. Ex vivo MPI data confirmed the SNR in the gut to be ~1.2 times that of the liver. In the current work, we were able to detect gut bleed with high sensitivity and of extremely slow flow rates using MPI and was comparable to the nuclear medicine techniques, but by using a blood-pool, non-radioactive SPIO tracer.

D3-04. Recent achievments for ultrasensitive gas sensing and biophysic detection. *F. Terki*[1] and Q. Tran[1] *1. Université de Montpellier, Montpellier, France*

Promising generation of room temperature micro/nano-sensor «sensor 3.0» based on micromagnetometry devices for indirect detection of hysteresis switching loops in addressable nanoparticle[1] named Spin Cross-Over Materials (SCO) will be presented. Bistable $[Fe(hptrz)_3](OTs)_2$ nanoparticles with a volume of *ca*. 3×10^{-3} mm^3 has been investigated and given rise to 100 nV detection signal[1,2]. Further improvements to the device have been achieved for the enhancement of the sensitivity, reducing noise, and the implementation of a new concept based on a differential method[3] for a more accurate detection. These advances permit the increase of the sensitivity by 4 order magnitude of the magnetization detection[2,3] (10^{-14} emu) in comparison to the SQUID (10^{-10} emu). This optimization provide us an original microdevice, portable, flexible and easily integrated in electronics for detecting at room-temperature very few amount of nanoparticles. The ultimate target will be the study of a single object. In order to understand the mechanism of the magnetic behaviour at nanoscale. The goals are: What is the interplay between the volumes to surface due to the minimisation of the nanoparticle size? What are the relative impact of inter-particle interactions in the ligand matrix? This original and ultrasensitive experimental developments represent significant breakthroughs within the field of molecular magnetism and bio detection (femtomole) [4,5]. Efforts towards detecting SCO in single objects at room temperature using this powerful method are really promising to answer to the still open questions. Keywords: Micromagnetometry; spin crossover; molecular magnetism. We acknowledge the financial supports from Occitanie region & SATT_AxLR and ANR Nanohybrid 2017

D4-01. Magnetic nanoparticle assembly in extreme force gradients.

T.M. Crawford[1,2] *1. Smart State Center for Experimental Nanoscale Physics, University of South Carolina, Columbia, SC, United States; 2. Physics and Astronomy, University of South Carolina, Columbia, SC, United States*

We employ perpendicular recording media as a programmable source of nanoscale resolution patterned magnetic field gradients that reach ~ 25 MT/m near the surface (Figure 1) [1-2]. By combining nanoparticle self-assembly with magnetic-field-gradient driven assembly, we can create 2-dimensional features as small as 75 nm, i.e. resolution comparable to Electron Beam Lithography, using single nanoparticles as blocks (Figure 2). Critical to this patterning technology is a magnetization perpendicular to the surface, which allows arbitrary in-plane features to be assembled (Figure 2 D-E). The extreme magnetic field gradients found within nanometers of the medium surface decrease rapidly with height (large gradient of the gradient), meaning the magnetic force on a nanoparticle increases rapidly as it approaches the surface, overcoming thermal energy and propelling the nanoparticle toward the surface and the boundary between magnetized regions. Balancing such attractive force gradients is the repulsive short-range colloidal force that keeps the nanoparticles from aggregating in fluid. By tuning this balance between magnetic and colloidal stabilizing forces, for example by modifying the suspending fluid, we can trigger self-assembly of magnetic nanoparticles [3]. We have developed a real-time measurement based on optical diffraction to monitor this triggering as the nanoparticles assemble into parallel lines on a magnetic recording medium [3]. Triggered self-assembly depends strongly on the ionic properties of the colloidal fluid, but at a level that is too weak to cause aggregation in the bulk colloid far from the medium surface, i.e. it happens specifically in this region of rapidly changing field gradient near the medium surface. To date simulations are able to predict the triggering, but not the dynamics observed as a function of ionic strength. Beyond driving self-assembly via tuning nanoscale forces, this approach offers a metrology with sufficient sensitivity to measure subtle effects that could affect nanoparticle behavior in a clinical setting. Future efforts will include improved control of feature size, in part by using smaller diameter nanoparticles, and increasing functionality by adding photoluminescent or semiconducting shells to the magnetic nanoparticle blocks to create precision 2D patterned materials with novel optical and/or semiconducting properties.

D4-02. Nanomagnetic Writing via Dynamic Magnetic Charge: Magnonic Horizons & Developments Beyond Surface Probe Lithography. *J.C. Gartside*[1], D.M. Arroo[1], S. Jung[1], S. Yoo[1], D.M. Burn[2], L.F. Cohen[1] and W.R. Branford[1] *1. Physics, Imperial College London, Harwell, United Kingdom; 2. Diamond Light Source Ltd, Didcot, United Kingdom*

Much of the intrigue and utility of nanomagnetic systems arises from the properties of specific system-wide magnetic configurations, or microstates. From practical applications such as data storage to microstates of fundamental physical and statistical interest such as ground states[1,2] or metastable excitations[3,4], the ability to prepare systems in any given microstate is of crucial importance. Historically, microstate preparation methods have been somewhat limited – relying on globally-applied or stripline-generated fields and thermalisation protocols to access a limited range of states. Groups have recently demonstrated that the dynamic magnetic charge of a scanning MFM tip may be used to write all conceivable microstates[5,6], but requires that the sample is situated within expensive and cumbersome SPM hardware. We present developments and applications of the dynamic magnetic-charge writing method 'Topological Defect-Driven Magnetic Writing' (TMW)[6], outlining a fully solid-state and current-addressable SPM-free solution replacing the MFM tip with alternative magnetic charge sources. This improved technique is leveraged to realise novel reconfigurable magnonic circuit elements, implemented within strongly-interacting nanomagnetic networks.

D4-03. FORC based interaction strength investigations in permalloy micro arrays. F. Groß[2], S.E. Ilse[2], *J. Gräfe*[1] and E.J. Goering[3] *1. Max Planck Institute for Intelligent Systems, Stuttgart, Germany; 2. Modern Magnetic Systems, Max Planck Institute for Intelligent Systems, Stuttgart, Germany; 3. Schuetz, Max-Planck-Institute for Intelligent Systems, Stuttgart, Germany*

First-order reversal-curves (FORCs) are a powerful tool to distinguish between microscopic interaction and coercivity contributions without the need for lateral resolution. However, most real systems violate Mayergoyz' criteria [1] which hinders the interpretation of the FORC density as Preisach distribution [2], thus, limiting FORC to a 'fingerprint' of this specific material. Hence, understanding additional features in such complex FORC diagrams is crucial for the applicability of the method. Here, we extend the interpretability of FORCs diagrams. We artificially design permalloy stripe systems of alternating width which violate the before mentioned criteria in order to systematically investigate resulting features in the FORC density [3] [4][5] and link them to their micromagnetic origin. Using a NanoMOKE3 we directly measure the low field spatially resolved switching field distribution (SFD) (fig. 1, upper illustration, inset) and the FORC density (fig. 1, upper illustration),. Comparing two independent approaches for the SFD with the FORC density, we can decode additional features and assign them to be a consequence of interaction between hard and soft magnetic components. We find this interaction peak intensity to be a quantitative measure for the interaction strength in the system and can correlate its volume to the actual interactions within the system (fig. 1, lower illustration). This is a thorough step into a more quantitative interpretation of FORC diagrams.

Graz Centre for Electron Microscopy, Graz, Austria; 4. Institute of Electron Microscopy and Nanoanalysis, Graz University of Technology, Graz, Austria; 5. Bielefeld Institute for Applied Materials Research, Bielefeld University of Applied Sciences, Bielefeld, Germany*

Driven by the quest for novel magnetic phenomena, there is an ongoing effort dedicated to expand 2D nanomagnetism to the third dimension where spin textures extend into the vertical direction of the substrate plane, thereby creating more complex ferromagnetic properties and opening the door for a fascinating new research area. This idea recently became viable by the advent of advanced fabrication methods such as the direct-write process FEBID (focused electron beam induced deposition) and the possibility of high-resolution detection of small magnetic signals, e.g. using a home-built micro-Hall sensor. In a recent work [1,2], and in this presentation, we discuss first insights into the magnetic properties of nano-engineered 3D CoFe structures, which have been deposited using FEBID directly on the sensor's surface. *Firstly*, we report systematic measurements of the magnetic stray fields of nano-cube (see Figure 1: a and b) and tetrahedral nano-tree structures as a function of temperature and magnetic field angle. We compare the experimental findings to both macro-spin and micro-magnetic simulations in order to unveil the complex switching behaviour and mechanism of magnetization reversal. This combination of methods reveals a reversal of the edge spin textures proceeding via complex vortex configurations. *Secondly*, in order to gain further insights in the hysteresis loops, (irreversible) magnetic interaction effects and coercivity distributions, we present first-order-reversal curves (FORC) of these 3D nanomagnets supported by simulations of a simple macro-spin model. We give an outlook to the future design of such structures towards the realization of 3D artificial spin ice architectures.

D4-05. Ferromagnetic resonance in three-fold nano-ellipse clusters.
W. Bang[1,2], F. Montoncello[3], M. Jungfleisch[2], A. Hoffmann[2], L. Giovannini[3] and J.B. Ketterson[1,4] *1. Physics and Astronomy, Northwestern University, Evanston, IL, United States; 2. Materials Science Division, Argonne National Laboratory, Argonne, IL, United States; 3. Physics, University of Ferrara, Ferrara, Italy; 4. Electrical and Computer Engineering, Northwestern University, Evanston, IL, United States*

We have experimentally and theoretically characterized ferromagnetic resonance (FMR) in 120°-symmetric clusters formed from three closely-spaced but non-contacting permalloy nano-ellipses together with the angular and thickness dependence. To achieve maximum sensitivity and coupling, we fabricate well separated arrays of such clusters on a coplanar waveguide. The arrays were patterned using electron-beam lithography, and deposited using electron-beam evaporation. Theoretical simulations were performed using the dynamical matrix method and show excellent agreement with the experimental results [1]. We find that the overall response of the clusters is dominated by, and can be represented as a superposition of, the spectra arising from the individual macrospins. This finding has important implications for using FMR to unravel the spectra of more complex structures, such as spin ice lattices formed by assembling elemental building blocks into arrays. *Work at Northwestern was supported under NSF grant DMR 1507058; work at Argonne was supported by the U.S. Department of Energy, Office of Science, Materials Science and Engineering Division.

D5-01. Synthesis of single-phase $L1_0$-FeNi magnet powder by nitrogen insertion and topotactic extraction. *H. Kura*[1], S. Goto[1], E. Watanabe[1], H. Yanagihara[2], Y. Shimada[3], M. Mizuguchi[3], K. Takanashi[3] and E. Kita[2,4] *1. Advanced Research and Innovation Center, DENSO Corporation, Nisshin, Japan; 2. Institute of Applied Physics, University of Tsukuba, Tsukuba, Japan; 3. Institute for Materials Research, Tohoku University, Sendai, Japan; 4. National Institute of Technology, Ibaraki College, Hitachinaka, Japan*

In recent year, a demand for strong magnets mounted on high performance motor is rapidly increasing. $L1_0$-FeNi, which is composed of only base metals, is attracting much attention because it has high saturation magnetization, large uniaxial magnetic anisotropy, and high Curie temperature. To realize an $L1_0$-FeNi magnet, single phase $L1_0$-FeNi with high long range order parameter, S, is essential, because the magnetic properties strongly depend on the volume fraction and S of the $L1_0$ phase. $L1_0$-FeNi is generally synthesized through disorder-order transition from FeNi disordered alloy. The temperature of heat treatment to promote the phase transition should not exceed 320 °C, because $L1_0$-FeNi is stable below this temperature[1]. Since atomic diffusion is extremely slow at such low temperatures, an astronomical length of time would be required to synthesize $L1_0$-FeNi. Various approaches such as neutron/ion irradiation, melt-spinning, etc., were attempted to promote atomic diffusion and accelerate the formation rate of $L1_0$-FeNi. However the synthesized $L1_0$-FeNi reported so far showed only a low S and/or low volume fraction. From above, it seems difficult to obtain single phase $L1_0$-FeNi with a high S through a thermally activated process. Therefore we tried to develop an ordering method with a different scheme from conventional methods using thermal activation. In this study, we have successfully developed an ordering method called "nitrogen insertion and topotactic extraction (NITE)" in which $L1_0$-FeNi is fabricated via a stable ordered intermediate material[2]. A schematic for synthesizing ordered alloys using the NITE method is shown in Figure 1. In this method, FeNiN is adopted as a stable intermediate material, which has the same ordered arrangement of Fe and Ni as that of $L1_0$-FeNi. FeNiN is formed by nitriding FeNi disordered alloy powder with ammonia gas. Subsequently, single-phase $L1_0$-FeNi is derived by topotactic denitriding reaction of FeNiN with hydrogen gas. The proposed method has realized single-phase $L1_0$-FeNi with a high S of 0.71. The transition of disordered FeNi into the $L1_0$ phase has increased the coercivity from 14.5 kA/m to 142 kA/m. The NITE method is suitable for industrialization because this method involves only simple processes and is applicable to powder form material. It is expected that the NITE method significantly accelerates the development of $L1_0$-FeNi magnets. This work is based on results obtained from the Future Pioneering Program "Development of magnetic material technology for high-efficiency motors" commissioned by the New Energy and Industrial Technology Development Organization(NEDO).

D5-02. Rare-earth-free permanent magnets based on transition-metal nanowires: how far can we go?. *P. Liu*[1] *1. University of Texas-Arlington, Arlington, TX, United States*

It is of a grand challenge to develop rare-earth-free permanent magnets with high energy density based on transition metals and their intermetallic alloys, because those elements and alloys lack strong magnetic anisotropy. However, it has been found possible to develop high coercivity in nanoscale transition-metal particles with high aspect ratio. Recently, we have worked on bottom-up approaches to produce high-aspect-ratio nanorod/nanowire assemblies with high coercivity. The approaches start from synthesis of ferromagnetic nanowires and nanorods with modified solvothermal synthesis techniques. We have successfully synthesized monodisperse nanorods, nanowires and submicron chips of ferromagnetic FeCo, FePt, CoNi, CoCx and Co based materials [1-8]. Randomly oriented nanorod/nanowire assemblies show decent room temperature coercivity for their shape anisotropy, while alignment of the rods/wires significantly enhances the magnetic hardening. The aligned Co nanowires have their coercivity values exceeding 12 kOe, comparable to rare-earth permanent magnets. In view of the conventional AlNiCo permanent magnets that have been used for decade long, these types of nanorod/wire assemblies may be used as building blocks for advanced bulk and thin film permanent magnets with reduced materials cost and improved thermal stability in the future.

D5-03. Development of hard magnetic $L1_0$ FeNi phase in amorphous FeNiZr thin films deposited on MgO. *P. Sharma*[1], K. Sato[2], M. Nishijima[3], S. Okamoto[4], H. Yasuda[2], O. Kitakami[4] and A. Makino[1]
1. New Industry Creation Hatchery Center (NICHe), Tohoku University, Sendai, Japan; 2. Research Center for UHVEM, Osaka University, Ibaraki, Japan; 3. Hard magnetic $L1_0$ FeNi phase found in Fe-based meteorites is promising based on its high magnetocrystalline anisotropy (K_u ~1.3 x 10^7 erg cm^{-3}) and saturation magnetization (M_s~1270 emu cm^{-3}). However, artificial production of this phase is extremely difficult.[1-3] Recently, we have demonstrated the possibility of $L1_0$ FeNi phase formation through annealing of an amorphous $Fe_{42}Ni_{41.3}Si_8B_4P_4Cu_{0.7}$ alloy[1-3]. Necessary requirements for formation of this phase are amorphous alloy containing high concentration of Fe-Ni, and low crystallization temperature (T_x) close to order-disorder transition temperature (~320 ^{0}C) of FeNi. The T_x of $Fe_{42}Ni_{41.3}Si_8B_4P_4Cu_{0.7}$ alloy is ~ 390 ^{0}C, which is obtained by increasing metal contents in alloy. Further increase in metal concentration results in crystallization of as-quenched ribbon due to decrease in amorphous forming ability. It can be enhanced further in thin film deposition. For Fe based alloys, Fe-Zr thin films[4] can be made into amorphous state up to Fe concentration as high as 92 at.%. Therefore, possibilities exist to make amorphous thin films with high concentration of FeNi in FeNiZr system. We deposited FeNiZr thin films (thickness ~ 40 to 500 nm) on MgO substrate by co-sputtering of pure Fe, Ni and Zr targets. Ratio of Fe to Ni in film was adjusted to ~ 50:50, and Zr concentration was varied. We could obtain amorphous films (T_x ~360 ^{0}C) with Zr concentration as low as ~ 5 at.%. Films were annealed *in-situ* for 5 minutes to 24 hours. Films were characterized with techniques such as XRD, DSC, TEM, VSM (H_{max} ~ 33 kOe) with magnetic field applied at different angles etc. The M_s of the films is ~ 900 emu/cc (Fig. 1). Slightly lower M_s is due to minor precipitation of other phases in addition to FeNi (observed with TEM). A maximum coercivity (H_c) of ~ 1800 Oe in out of plane direction was obtained. In some of the films (shown in Fig. 1), we could clearly notice two phase like hysteresis, which is typical for composite magnets made from hard and soft magnetic phases. Details of magnetic properties and TEM observations will be presented.

D5-04. Micromagnetic Simulation of Partially Ordered $L1_0$ FeNi Permanent Magnets. *J. Fischbacher*[1], A. Kovacs[1], H. Oezelt[1], T. Schrefl[1], D. Niarchos[2] and M. Gjoka[2] *1. Department for Integrated Sensor Systems, Danube University Krems, Wiener Neustadt, Austria; 2. INN, NCSR Demokritos, Athens, Greece*

Tetragonal $L1_0$ FeNi is a promising rare-earth-free permanent magnet material with a reasonably large magnetocrystalline anisotropy and saturation magnetization. However, synthesis of bulk $L1_0$ FeNi remains challenging [1]. Often chemical ordering of such samples is imperfect which means that a fraction of the atoms resides on the wrong atomic sublattice. This disorder is described by the long-range chemical order parameter S and is known to have a negative effect on the magnetic anisotropy energy and Curie temperature of FeNi [2]. Using first-principles studies Kota et al. [3] have shown that the magnetocrystalline anisotropy energy of $L1_0$ FeNi is proportional to $S^{1.95}$. We use finite element micromagnetism to compute the influence of partial ordering on the coercivity of $L1_0$ FeNi magnets. Fig. 1 shows a granular structure used as a model system for our simulations. Each grain is split into 100 patches. For S = 1 (fully ordered) we set K_1 = 1.3 MJ/m^3 [4,5]. For S = 0 (disordered) we set K_1 = 3.6 kJ/m^3 (A1 FeNi). Saturation magnetization and exchange constant are 1.59 T and 10 pJ/m, respectively. We assume a Gaussian distribution of S to simulate partial order within a grain. This translates to a variation of the local anisotropy constant K_1 from patch to patch. Fig. 2 shows the coercive field as a function of the mean anisotropy constant. For a mean S = 0.7 and standard deviation σ_S = 0.2, the coercive field and the energy density product are 0.24 T/μ_0 and 262 kJ/m^3, respectively. To get similar specs for grains twice as large the required order is S = 0.9 and σ_S = 0.07. Work supported by the NOVAMAG project (EU H2020, Grant Agreement No. 686056) 2020.

D6-01. Magnetization Dynamics Driven By Surface Acoustic Waves.
L. Thevenard[1], I. Camara[1], P. Kuszewski[1], L. Becerra[1], A. Lemaître[2], J. Duquesne[1] and C. Gourdon[1] *1. Institut des Nanosciences de Paris, Sorbonne Universités, CNRS, Paris, France; 2. Centre de Nanosciences et de Nanotechnologies, CNRS, Univ. Paris-Sud, Université Paris-Saclay, Marcoussis, France*

In the spin-valves constituting magnetic random access memory data bits, a pulsed field or current triggers the precession of the magnetization. Switching off the excitation at the right moment can lead to a final opposite magnetization - a data-writing route routinely called "precessional switching" - potentially only fractions of nanoseconds long, and deterministic. The difficulty lies in obtaining the large angle, highly non-linear magnetization dynamics. Here we show how this can be done using the effective field generated by inverse magnetostriction upon the passage of a surface acoustic wave (SAW) on a magnetic layer. These SAWs are excited electrically by interdigitated transducers. They are 100MHz-5GHz surface-confined lattice excitations, well suited to interact resonantly with the magnetization. They are very weakly damped, which could enable an action remote from their generation, with the added possibility to use wave-front shaping or focusing to address a given area. We will show an ensemble of results starting from the theoretical predictions of optimum conditions for SAW-driven irreversible resonant switching [1], to its experimental demonstration using static Kerr microscopy on in-plane [2] and out-of-plane magnetized (Ga,Mn)As and (Ga,Mn)(As,P) layers [3]. In the former, we evidenced that SAWs are equally efficient to switch magnetization when propagating along the hard or easy axis, creating filamentary multi-domain configurations which are well reproduced by micromagnetic simulations. The resonant nature of the switching mechanism reflects blatantly on its increased efficiency when increasing f_{saw}. Exciting stationary SAWs of varying f_{saw} can moreover pattern magnetic stripes of tunable width and position. Complementing this static magnetic domain data, we probe the time-resolved polarization rotation induced on femtosecond laser pulses by the travelling SAW. A careful polarization analysis distangles the 3 components of the magnetization precession and the strain dynamics. We confirm that the precession amplitude resonates for a field such that $f_{prec}(B) \sim f_{saw}$, concomitantly with the resonant absorption of the acoustic wave amplitude [4]. This work is to our knowledge the first unambiguous time-domain observation of magneto-acoustics relying triggered by traveling surface acoustic waves.

D6-02. Zero-field Magnetic Response Functions in Landau Levels.
Y. Gao[1] and *Q. Niu*[2] *1. Physics, Carnegie Mellon Univ, Pittsburgh, PA, United States; 2. Physics, University of Texas at Austin, Austin, TX, United States*

We present a fresh perspective on the Landau level quantization rule; that is, by successively including zero-field magnetic response functions at zero temperature, such as zero-field magnetization and susceptibility, the Onsager's rule can be corrected order by order. Such a perspective is further reinterpreted as a quantization of the semiclassical electron density in solids. Our theory not only reproduces Onsager's rule at zeroth order and the Berry phase and magnetic moment correction at first order, but also explains the nature of higher-order corrections in a universal way. In applications, those higher-order corrections are expected to curve the linear relation between the level index and the inverse of the magnetic field, as already observed in experiments. Our theory then provides a way to extract the correct value of Berry phase as well as the magnetic susceptibility at zero temperature from Landau level fan diagrams in experiments. Moreover, it can be used theoretically to calculate Landau levels up to second-order accuracy for realistic models.

D6-03. Spin wave resonances in GaMnAsP films with perpendicular anisotropy.
X. Liu[2], S. Bac[1,2], S. Dong[2], S. Lee[1], M. Dobrowolska[2] and J.K. Furdyna[2] *1. Physics, Korea University, Seoul, The Republic of Korea; 2. Department of Physics, University of Notre Dame, Notre Dame, IN, United States*

We study spin dynamics in the GaMnAsP with perpendicular anisotropy by GHz microwave absorption techniques, such as ferromagnetic resonance (FMR) and spin wave resonance (SWR)[1]. In particular, we focus on the dependence of SWR in GaMnAsP films on P concentration and on film

thickness. An example of multi-mode SWR spectra observed in GaMnAsP are shown in Fig. 1. Analysis of such results provides new information on magnetic anisotropy (including surface anisotropy), dynamic surface spin pinning (derived from the surface anisotropy), and values of exchange stiffness constant. The dependence of SW modes on orientation of the applied magnetic field H, including the so-called "critical angle" phenomenon, are analyzed in terms of the surface inhomogeneity (SI) model[2]. Due to differences between the surface and the bulk exchange lengths, such non-uniformities can either occur at the surfaces of the film (where they will be decisive in determining surface anisotropy and spin pinning conditions in the [1-10] crystallographic direction), or throughout the bulk of the film (in the form of a magnetization gradient film along the [001] direction)[3]. In the latter case, fields H_n corresponding to successive n-th SWR modes are seen to progress as $n^{2/3}$, indicating a linear progression of the magnetic properties with sample thickness[4]. In addition, we will discuss the dependence of the surface pinning parameter A on polar and azimuthal angles of both field and magnetization as a function of P concentration[5]. The observed phenomena suggest that the surface anisotropy and surface spin pinning on the boundaries of the film are of key importance for understanding spin dynamics in GaMnAsP films with perpendicular anisotropy. To achieve a complete picture of SWR modes in this material, including their dependence on both film composition and its geometrical parameters, further investigations is required.

Diluted magnetic semiconductors combine the benefits of magnetic and semiconducting materials and are thus considered promising candidates for future spintronics applications. Despite extensive studies on the prototypic compounds (Ga,Mn)As and (Ga,Mn)P, the precise electronic structure and the exact mechanism of the carrier-mediated long-range ferromagnetic order are still under debate. Theoretical approaches range from the assumption of free charge carriers (*p-d* Zener model) to the opposite case of strongly localized carriers (impurity-band model). In the latter case, an intriguing concept for the origin of spontaneous magnetization is the percolation of bound magnetic polarons [1]. As has been shown in a previous work on the ferromagnetic semimetal EuB_6, the investigation of low-frequency resistance fluctuations is a powerful tool to demonstrate the existence of percolating nanoscale magnetic clusters and a concomitant electronic phase separation [2]. In analogy, the present study focuses on a systematic analysis of the charge carrier dynamics in a series of metallic and insulating thin films in order to detect possible signatures of electronic inhomogeneities in (Ga,Mn)As and (Ga,Mn)P. For compounds with localized charge carriers we find clear evidence for an electronic phase separation manifesting itself in a strongly enhanced noise magnitude near the corresponding Curie temperature. By contrast, for metallic samples with stronger Mn doping the resistance fluctuations are dominated by switching processes related to defects and thus no prominent features occur around T_C [3]. We put our results into the context of the central debate on the development of spontaneous magnetization and infer that the impurity-band picture appears to be more appropriate for (Ga,Mn)P and insulating (Ga,Mn)As, whereas the well-established *p-d* Zener model can be applied to metallic (Ga,Mn)As. Finally, by means of careful analysis of the obtained noise spectra, we compare the defect landscape of various samples and discuss the effects of the utilized thin-film fabrication methods and post-growth treatments.

D6-05. Giant manipulation of magnetic properties in magnetic semiconductor (Ga,Mn)As. H. Wang[1] and *J. Zhao*[1] *1. State Key Laboratory of Superlattices andMicrostructures, Institute of Semiconductors, Chinese Academy of Sciences, Beijing, China*

Magnetic semiconductor is an ideal material system for manipulating the spin degree of freedom of charge carriers in semiconductors to merge functionalities of information storage, computation logic and optical communications into one chip. III-V group (Ga,Mn)As with a well-accepted intrinsic ferromagnetism is a presentative material in the family of magnetic semiconductors. Through modulation of the hole density, electrical gating has been shown to alter the magnetic properties of (Ga,Mn)As films, but with limited electric-field effects on the Curie temperature about 10 K[1-3]. Here we present our recent work on modulation of magnetism in (Ga,Mn)As. We have realized a giant manipulation of the magnetism in (Ga,Mn)As ultra-thin films via electric field with the assistance of a special dielectric, ionic liquid or solid state ionic gel. The maximum modulation of the Curie temperature is up to 100 K.

D7-01. Synthesis of spinel tunnel barriers for advanced spintronics devices. *H. Sukegawa*[1] *1. Research Center for Magnetic and Spintronic Materials, National Institute for Materials Science (NIMS), Tsukuba, Japan*

A magnetic tunnel junction (MTJ) consisting of a ferromagnet (FM)/tunnel barrier/FM structure is one of the most widely used spintronics devices, which have been implemented as read sensors in hard disk drives, memory cells of magnetoresistive random access memories (MRAMs), and highly sensitive magnetic sensors. In the MTJ applications, a crystalline MgO is dominantly used for the barrier since the large tunnel magnetoresistance (TMR) ratios more than 100% by the coherent tunneling mechanism can be easily obtained using a polycrystalline CoFeB/MgO/CoFeB structure [1]. However, MgO shows a large lattice-mismatch with various FM layers such as CoFe (mismatch 3~4%) and Co-based Heusler alloys (3~7%). Therefore, degraded FM/barrier interfaces due to misfit dislocations are generally formed, which may limit MTJ performance. To broaden the application for MTJs further, it is necessary to improve TMR ratios as well as to reduce resistance area (*RA*) products through developing new barrier materials. Recently, it has been demonstrated that the lattice mismatch is effectively reduced by the use of an $MgAl_2O_4$ spinel-based oxide barrier [2]. Therefore, spinel oxide barriers are promising for creating defect-free FM/barrier interfaces toward high performance MTJs. In this talk, I will outline recent progress of spinel barrier technology. Similar to MgO, large TMR ratios over 300% at room temperature (RT) were observed in epitaxial MTJs with an $MgAl_2O_4$ barrier prepared by post-oxidation of an Mg-Al layer [2,3]. Recently, as shown in Fig. 1, an atomically flat and perfectly lattice-matched $MgAl_2O_4$ barrier was demonstrated by introducing a direct sputtering method using a sinter $MgAl_2O_4$ target [4]. A TMR ratio of the epitaxial Fe/$MgAl_2O_4$/Fe(001) MTJ reached 245% at RT, which is very large as an MTJ using Fe electrodes. Additionally, polycrystalline CoFeB/$MgAl_2O_4$/CoFeB MTJs with TMR > 240% at RT were successfully fabricated using an ultrathin MgO insertion at one CoFeB/$MgAl_2O_4$ interface [5]. These results demonstrate the industrial viability of spinel-based MTJs. In addition to $MgAl_2O_4$, a magnesium-gallium spinel ($MgGa_2O_4$) barrier, which is known as a transparent semiconductor oxide, has been synthesized by direct sputtering [6]. An epitaxial Fe/$MgGa_2O_4$/Fe(001) MTJ showed a relatively large TMR ratio of 121% at RT, indicating the Δ_1-band preferential coherent tunneling through the $MgGa_2O_4$(001) barrier. Furthermore, *RA* of the $MgGa_2O_4$ MTJ was much smaller than that of an Fe/$MgAl_2O_4$/Fe MTJ (~1/50 at a given barrier thickness) owing to a low band gap of $MgGa_2O_4$. Therefore, a barrier height of an MTJ barrier can be reduced through composition control of a spinel oxide. In the near future, spinel based MTJs are expected to be designed for specific applications by precise compositional tuning. I would like to thank Y. Kato, T. Daibou, N. Shimomura, Y. Kamiguchi, J. D7-02. Tunneling magnetoresistance effect with an equiatomic CoFeMnSi Heusler alloy electrode. *L. Bainsla*[1], K. Suzuki[1,2], M. Tsujikawa[3,2], H. Tsuchiura[4,2], M. Shirai[3,2] and S. Mizukami[1,2] *1. WPI Advanced Institute for Materials Research, Tohoku University, Sendai, Japan; 2. Center for Spintronics Research Network, Tohoku University, Sendai, Japan; 3. Research Institute of Electrical Communication, Tohoku University, Sendai, Japan; 4. Department of Applied Physics, Tohoku University, Sendai, Japan*

Highly spin-polarized current sources are an essential requirement for spintronic devices, which are expected to provide non-volatile, reconfigurable logic functions and ultralow power consumption. Half-metallic ferromagnets feature complete spin polarization P at the Fermi level E_F and are suitable

candidates for spin-polarized current sources. Among the various half-metallic materials, Co_2-based ternary Co_2YZ and pseudo-quaternary $Co_2Y_{1-x}Y'_xZ$ full Heusler alloys have a special place due to their tunable electronic structure, a Curie temperature T_C that is well above room temperature, and P that is close to unity. As a different class of materials, there is increasing interest in equiatomic quaternary XX'YZ Heusler alloys since these materials can exhibit various functional properties resulting from their crystal structures differing in symmetry from the original Heusler $L2_1$ structure [1]. Here, we focus on CoFeMnSi (CFMS) from among the numerous elemental combinations suggested. Quite recently, we succeeded in growing single-crystalline CFMS films that have full $B2$ and partial $L2_1$ ordering, which were still expected to show a half-metallicity even though the pseudo gap in the majority spin band could be lost due to the non-ideal Y-type structure [2]. In this work, we study on TMR for CFMS/MgO/CoFe MTJs to gain an insight into the half-metallicity of CFMS. A relatively high TMR ratio of about 521% and 101% were observed at 10 and 300 K, respectively, as shown in Fig. 1 [3]. This suggested the high spin polarization of CFMS with a full $B2$ and partial $L2_1$ ordered structure even though the obtained TMR ratio was smaller than the past record in the MgO-MTJs with CoFe and Mn-enriched Co_2MnSi Heusler alloy electrodes [4]. The large bias voltage dependence of the TMR ratio was also observed at low temperature, as similarly observed in Co_2MnSi Heusler alloys-based MTJs in the past. L. Bainsla is a JSPS fellow. This work was partially supported by the ImPACT program and KAKNHI (No. 17F17063).

D7-03. Modulation and detection of single neuron activity using Spin Transfer Nano-Oscillators. *E. Waks[1] 1. University of Maryland, College Park, MD, United States*

The brain is a complex network of interconnected circuits that exchange electrical signals with each other. These electrical signals provide insight on how neural circuits code information, and give rise to sensations, thoughts, emotions and actions. Currents methods to detect and modulate these electrical signals use implanted electrodes or optical fields with light sensitive dyes in the brain. These techniques require complex surgeries or suffer low resolution. In this talk we explore a new method to both image and stimulate single neurons using spintronics. We propose using a Spin Transfer Nano-Oscillators (STNOs) as a nanoscale sensor that converts neuronal action potentials to microwave field oscillations that can be detected wirelessly by magnetic induction. We will describe our recent proof-of- concept demonstration of both detection and wireless modulation of neuronal activity using STNOs [1,2]. For detection we use electrodes to connect a STNO to a lateral giant crayfish neuron. When we stimulate the neuron, the STNO responds to the neuronal activity with a corresponding microwave signal. For modulation, we stimulate the STNOs wirelessly using an inductively coupled solenoid. The STNO rectifies the induced microwave signal to produce a direct voltage. This direct voltage from the STNO, when applied in the vicinity of a mammalian neuron, changes the frequency of electrical signals produced by the neuron. These results pave the way towards developing spintronics based biological sensors that can report and stimulate biological signals wirelessly in vivo.

Energy harvesting technologies offer a promising approach to capture energy from ambient sources, such as vibration, heat, and electromagnetic waves. Among them, the ambient radio-frequency (RF) electromagnetic signals provide an attractive energy source for applications in self-powered portable electronics in the "internet of things" era. However, currently available microwave detectors based on semiconductors do not meet the practical requirements for energy harvesting applications. In fact semiconductor devices, such as Schottky diodes, fail to provide a satisfactory conversion efficiency specifically for micro-Watt power-harvesting. Here we show the development of a *bias-field-free* nanoscale spintronic diode (NSD) based on a magnetic tunnel junction (MTJ) having a *canted magnetization* in the free layer, and demonstrate that this NSD could be an efficient harvester of broadband ambient RF radiation, capable to efficiently harvest microwave powers of microWatt and below. We have measured the rectified voltage with an RF current in the absence of an applied magnetic field by applying an RF current to the device through a bias tee using a signal generator, while the rectification voltage V_{DC} across the MTJ is recorded with a nanovoltmeter. The frequency response of the NSD shows that a novel type of frequency behaviour, i.e. broadband response, is achieved. Figure 1 displays an example with a RF input power of P_{RF} = 10 μW, showing that the NSD rectifies a nearly constant voltage across a 100 to 550 MHz range[1]. Our results [1] also demonstrate that the power generated by NSDs is sufficient to drive active devices, such as BP nano-sized photo sensors, for use in low-power electronic systems, showing their potential as building blocks of self-powering devices for applications in wireless sensing and portable electronics in the emerging era of the "internet of things".

D8-01. Sr_2RuO_4: Challenges and Opportunities. *C. Kallin[1] 1. Physics & Astronomy, McMaster University, Hamilton, ON, Canada*

Much of the interest in Sr_2RuO_4 is due to the theoretical and experimental studies that point to chiral p-wave superconducting order in this material -- a type of order that can support chiral edge modes, Majorana fermions and half quantum vortices. The metallic state of Sr_2RuO_4 is strongly correlated but forms a well-defined Fermi liquid below about 30K, still well above the superconducting transition at 1.5K. The Fermi surfaces are well characterized and relatively simple compared to other superconductors that are considered to be candidates for chiral order, such as UPt_3 and URu_2Si_2, making Sr_2RuO_4 a promising candidate for detailed comparisons between theory and experiment. Numerous experiments point to odd-parity or (pseudo) spin triplet pairing with broken time-reversal symmetry, the key signatures of chiral p-wave order.[1,2] However, even after more than two decades of study, a number of challenges remain in clearly identifying the superconducting state of Sr_2RuO_4 with chiral p-wave order. A striking prediction of chiral p-wave superconductivity is the presence of edge currents, but multiple experimental searches for these in Sr_2RuO_4 have returned null results.[3] However, recent theoretical studies have shown that these currents can be substantially suppressed, particularly in highly anisotropic models of chiral p-wave,[4] although more work is needed to fully resolve this issue. A number of other challenges remain in reconciling experiments on Sr2RuO4 with predictions for chiral p-wave order. These challenges include (i) developing a quantitative understanding of Knight shift data, which sees no suppression of the spin susceptibility in the superconducting state for any field orientation, (ii) reconciling chiral p-wave order with the absence of any observable splitting of the superconducting transition with uniaxial strain, [5] (iii) understanding low temperature thermal conductivity data that appear much more consistent with d-wave than with chiral p-wave order,[6] and (iv) upper critical field measurements that suggest Pauli limiting behavior as expected for spin singlet superconductivity. These and other open issues, together with recent work and promising future directions, will be discussed.

Sr_2RuO_4 is a candidate for chiral odd-parity superconductivity with T_c~1.5 K, an interpretation supported by unchanged ^{17}O and ^{101}Ru hyperfine shifts [1] upon cooling through the superconducting transition accompanied by evidence for time reversal symmetry breaking [2,3]. In-plane symmetry-breaking fields, such as uniaxial strain, present another opportunity to confirm the proposed chiral order. Recent compressive strain experiments uncovered a sharp increase in the critical temperature to T_c^{max}~3.5 K (at a strain e_c), which was associated to a Van Hove Singularity (VHS) of the so-called γ band, considered primarily of Ru d_{xy} character [4]. Normal state ^{17}O NMR spectra, recorded at low temperature and in samples subject to compressive strain, exhibit an evolution of the electric field gradients (EFG) qualitatively consistent with DFT calculations, and strong singularities in hyperfine shifts at e_c, coincident with the maximum critical temperature. The results deviate significantly relative to expectations for the VHS, in that impacted susceptibilities are inferred to originate not just with d_{xy} orbitals, but also d_{yz}, d_{xz}. While spin-orbit coupling can lead to mixing, it is not clear in this case how it accounts for the observations. At e_c, there is evidence for enhanced low energy spin fluctuations relative to the low strain case. Strains exceeding e_c result in a rapid drop of the hyperfine shifts and spin lattice relaxation rates consistent with a metallic phase. Measurements in the superconducting state of strained samples are in progress.

Strontiumruthenate Sr_2RuO_4 is one of the best studied unconventional superconductors. Nevertheless, the pairing symmetry, most likely of spin-triplet type, and the pairing mechanism remain a subject of very intense debate. Strong magnetic fluctuations are known to exist at incommensurate antiferromagnetic vectors in reciprocal space. These, however, do not favor a chiral p-wave state, making the explanation of superconductivity in Sr_2RuO_4 a major experimental and theoretical challenge. We have performed

a thorough characterization of magnetic fluctuations by polarized inelastic neutron scattering. We have identified, in addition to the known excitations, a second component that carries significant weight but has been overlooked so far due to its broad extension and slowly varying shape. It is centered at the ferromagnetic wavevector and covers a large part of the Brillouin zone. This newly discovered component allows to account quantitatively for the observed macroscopic properties (susceptibility, specific heat, nuclear magnetic resonance). With the currently available parameters it may be not sufficient as the only ingredient, but simple model calculations show that it strongly tends to stabilize the equal spin pairing state. We also report on measurements of the magnetic excitations in the superconducting state. The antiferromagnetic fluctuations of the one-dimensional bands (α,β) persist even at energies below 2Δ, while they become partially suppressed only at energies below 0.3meV. This strongly suggests that the one-dimensional bands with the associated nesting fluctuations do not form the active, highly gapped bands in the superconducting pairing in Sr_2RuO_4.

A layered-perovskite superconductor Sr_2RuO_4 with T_c=1.5 K has attracted intensive interest because it has been a good candidate for a chiral-*p*-wave spin-triplet superconductor [1]. Recently, however, a first-order superconducting transition was discovered under an in-plane magnetic field [2-5], which is reminiscent of the Pauli-paramagnetic effect for spin-singlet pairing. Thus, the pairing symmetry of Sr_2RuO_4 remains controversial. To solve this issue, we have investigated the gap structure from the field-angle dependence of quasiparticle excitations, which is a powerful tool for determining the position of gap zeros [6]. In the present work [7], we have revealed that the low-field specific heat increases in proportion to $H^{1/2}$ with no multigap structure at 0.06 K, in sharp contrast to the previous reports [8, 9]. This suggests that multiple gaps on the three bands (α, β, and γ) equivalently survive up to relatively high fields and possess lines of deep minima in some directions. In addition, we have revealed that the fourfold oscillation in the specific heat that appears under an in-plane rotating field [9, 10] does not change sign down to the lowest temperature of $0.04T_c$ in the low-field region. Such behavior cannot be explained in the currently-favored chiral-*p*-wave scenario. On the basis of microscopic theoretical calculations, we show that field and temperature variations of the specific-heat oscillation match well with the presence of horizontal line nodes on cylindrical bands whose Fermi velocity is highly anisotropic within the plane. The agreement between the experimental and the calculated results becomes even better by taking into account the Pauli-paramagnetic effect. The present results challenge the historical view of Sr_2RuO_4 and call for reconsideration of its order parameter.

D9-01. The Utility of Band Theory in Strongly Correlated Electron Systems. *G. Zwicknagl*[1] *1. Institut fuer Mathematische Physik, TU Braunschweig, Braunschweig, Germany*

Understanding the collective electronic properties of emergent materials with strong correlations remains a great challenge to condensed-matter theory. The complex behavior and the high sensitivity with respect to external fields result from the fact that the quantum mechanical (ground) states are determined by subtle compromises between various interactions. It is not surprising that standard band structure calculations assuming independent electrons have difficulties to capture these effects. In the present talk I shall demonstrate that the Renormalized Band method provides an effective single-particle description which may be successfully applied to interpret observations and even predict results in materials with strongly correlated electrons. The central focus will be the low-temperature properties of materials with heavy fermions. Of particular interest are the topologies of the Fermi surfaces and the role of critical points. Consequences for superconductivity and magnetic order will be discussed. Magnetic-field-induced Lifshitz transitions are reflected in anomalies in transport properties. The analysis of the Seebeck coefficient allows for detailed transport spectroscopy of the strongly renormalized quasiparticle bands in the vicinity of critical points.

D9-03. Arrested Kondo hybridization and incommensurate wave vector locking at the hidden order transition in URu_2Si_2. *J. Denlinger*[1], J. Kang[2], J. Allen[3] and M.B. Maple[4] *1. Advanced Light Source, Lawrence Berkeley National Laboratory, Kensington, CA, United States; 2. Physics, The Catholic University of Korea, Bucheon, The Republic of Korea; 3. U. of Michigan, Ann Arbor, CA, United States; 4. Physics, UC San Diego, San Diego, CA, United States*

Previous high-resolution angle-resolved photoemission (ARPES) studies of URu_2Si_2 have attempted to characterize the temperature (T) dependent behavior of *f*-states close to the Fermi level mostly in a narrow *k*-space range around the surface zone center at low photon energy, where the states being probed are generally absent from bulk-sensitive soft x-ray ARPES measurements [1]. In this ARPES study we report a significant T-evolution in a non-high symmetry k-space cut through a large Z-point hole Fermi surface, consistent in size with SX-ARPES. Upon cooling below the resistivity coherence temperature T*~70K, a gradual change of the near-E_F electronic structure occurs down to the hidden order transition (T_{HO}), ending with the development of sharp quasiparticle bands at k_F values corresponding to the incommensurate *q*-vector (0.6,0,0)a* observed by inelastic neutron scattering (INS), as shown in Fig. 1. Such behavior is consistent with tunneling and optical spectroscopy evidence for the development of *f*-hybridization below 70K, and is suggestive of the theoretical model of an 'arrested Kondo effect' [2] arising from the interplay between the two lowest energy quasi-localized crystal field states [2,3]. Also in accordance with INS, small gapping of these QP peaks is evident. The observed wavevector nesting within a single large paramagnetic Z-hole pocket differs markedly from nesting scenarios derived from zone-folded *f*-itinerant LDA calculations [4].

While the Kondo effect is well understood for single Kondo impurity systems, for Kondo lattice systems containing rare-earth elements (for which the Kondo impurities are realized by local *f* electron orbitals), it remains more puzzling and exhibits surprising phenomena [1, 2]. For instance, anisotropic orbital-dependent hybridization may have significant

consequences for the entire phase diagram of these systems [3]. The heavy fermion URu_2Si_2 that exhibits one of the most mysterious quantum states of matter below 17.5 K, the so-called ''hidden order'' (HO) state, is a relevant example of metallic Kondo lattice systems for which exotic Kondo effects may play a significant role in the appearance of the HO. Despite over three decades of intensive research, no consensus has yet been found regarding the microscopic nature of the HO. Recent efforts have revealed important information on this problem, including the A_{2g} signatures of the HO state as seen by Raman spectroscopy [4, 5]. While the URu_2Si_2 ''story'' appears close to being resolved, some key issues remain, such as the inter-relation between Kondo coherent regime and the HO state. Here, we present a Raman study of the Kondo physics of single crystalline URu_2Si_2 [6]. We observe a symmetry dependence of the electronic Raman response through the Kondo crossover (100K), with a Kondo pseudo-gap developing mainly in the E_g symmetry, highlighting the presence of strong anisotropy. Through Raman vertex calculations within the effective mass approximation, we obtain the *k*-space dependence of the observed Kondo pseudo-gap. Moreover, we show that this E_g Kondo pseudo-gap survives deep into the HO, indicating a possible relationship between the Kondo physics and the well-established A_{2g} Raman signatures of the HO. Finally, we will also present what happens to one of the Raman signatures of the HO - the A_{2g} sharp excitation at 1.7 meV - under high magnetic fields (up to 25T).

The correlated *f*-electron compound URu_2Si_2 has an effective mass of ~25 m_e, where m_e is the free electron mass, undergoes a second order transition into a "hidden order" (HO) phase at T_o = 17.5 K, and exhibits unconventional superconductivity (SC) that coexists with HO below $T_c \approx 1.5$ K [1]. Remarkably, the order parameter (OP) of the HO phase has not been identified after more than three decades of research. Experiments have revealed that competing interactions in URu_2Si_2 can be "tuned" by varying the composition (x) of atomic substituents, pressure (P) and magnetic field (H), yielding complex temperature (T) vs x, P and H phase diagrams. These $T(x, P, H)$ phase diagrams contain a rich variety of electronic phases and phenomena, including unconventional SC, antiferromagnetism, ferromagnetism, HO, exotic phases in the vicinity of quantum critical points (QCP's), and non-Fermi liquid behavior. Several years ago, we reported that substitution of isoelectronic Fe for Ru suppresses SC and induces a transition from the HO phase to a large moment antiferromagnetic (LMAFM) phase, similar to the behavior of pure URu_2Si_2 under pressure [2]. Experiments on $URu_{2-x}Fe_xSi_2$ single crystals reveal that the $T(x)$ phase diagram and variation of the U magnetic moment with x in the $URu_{2-x}Fe_xSi_2$ system are consistent with the $T(P)$ phase diagram and evolution of the U magnetic moment with P in URu_2Si_2 [3]. Single crystals of $URu_{2-x}Fe_xSi_2$ provide an opportunity to study the transition from the HO to the LMAFM phase at atmospheric pressure with techniques that cannot be readily performed on URu_2Si_2 under high pressure (e.g., ARPES, STM, neutron scattering, measurements in high magnetic fields, etc.). Such studies will yield information about the electronic structure of URu_2Si_2 in the HO and AFM phases and, hopefully, clues to the identity of the OP of the elusive HO phase. Recent experiments on $URu_{2-x}Fe_xSi_2$ single crystals as a function of x, P, and H by our group demonstrate that the physical properties depend additively on P and x [4] and establish the 3D phase diagram of T vs x and H that reveals the relationship between HO, LMAFM and several exotic phases that emerge near the QCP at high magnetic fields [5].

Since the seminal ideas of Berezinskii, Kosterlitz and Thouless [1, 2], topological excitations are at the heart of our understanding of a whole novel class of phase transitions. In most of the cases, those transitions are controlled by a single type of topological objects. There are however some situations, still poorly understood, where two dual topological excitations fight to control the phase diagram and the transition. Finding experimental realization of such cases is thus of considerable interest. I will show in this presentation that this situation occurs in $BaCo_2V_2O_8$, a spin-1/2 Ising-like quasi-one dimensional antiferromagnet [3], when subjected to a uniform magnetic field transverse to the Ising axis [4]. In zero-field, the excitations of the Néel phase of this interesting compound consist in confined two-spinon excitations stabilized by weak interchain interactions. This yields two series of discrete modes with transverse and longitudinal character [5] regarding the direction of the ordered magnetic moments (the chain Ising *c*-axis) [6], the latter series of modes having no classical analogue. The application of a transverse magnetic field along the *b* direction, because of the non-diagonal anisotropic *g*-tensor of $BaCo_2V_2O_8$, induces a staggered field along the *a*-direction [7], that is perpendicular to both the Ising-axis and the uniform field. As a result, a quantum phase transition occurs at about 10 T between two different antiferromagnetic phases: the low-field Néel phase, stabilized by the Ising anisotropy and the weak interchain couplings, and a high field novel phase, stabilized by this induced staggered field, which actually competes with the interchain interaction and the single-ion anisotropy, as determined from single-crystal neutron diffraction [4]. Using inelastic neutron scattering experiments combined with theoretical calculations, a drastic modification of the quantum excitations is evidenced beyond this phase transition: the spinon excitations of the low field phase, each carrying a spin ½ along the Ising axis, give way to their dual topological excitations in the high field phase, solitons carrying a spin 1 along the staggered magnetic field [4]. $BaCo_2V_2O_8$ thus provides a remarkable experimental system in which a novel kind of topological quantum phase transition occurs, which is described through a dual-field double sine-Gordon model in effective field theory.

D10-02. Experimental observation of Bethe strings. *Z. Wang*[1] *1. Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany*

Almost one century ago, string states - complex bound states (Wellenkomplexe) of magnetic excitations - have been predicted to exist in one-dimensional quantum magnets [1] and since then become a subject of intensive theoretical studies [2-7]. However, experimental realization and identification of string states in a condensed-matter system remain an unsolved challenge up to date. Here we use high-resolution terahertz spectroscopy to resolve string states in the antiferromagnetic Heisenberg-Ising chain $SrCo_2V_2O_8$ in strong longitudinal magnetic fields [8]. In the field-induced quantum critical regime, we identify strings and fractional magnetic excitations, which are precisely described by the Bethe ansatz [7]. Close to the quantum criticality, the string excitations govern the quantum spin dynamics, while the fractional excitations, dominant at low energies, reflect the antiferromagnetic quantum fluctuations. Today, Bethe's result is important not only in the field of quantum magnetism but also more broadly, including in the study of cold atoms and in string theory; hence, we anticipate that our work will shed light on the study of complex many-body systems in general. in collaboration with Jianda Wu, Wang Yang, Anup Kumar Bera, Dmytro Kamenskyi, A. D10-03. Magnetic excitations in the One Dimensional Ising chain $CoCl_2$*$2D_2O$. *U.B. Hansen*[1,2], J. Rodriguez-Rivera[4], O.F. Syljuaasen[3], J. Jensen[2] and K. Lefmann[2] *1. The Insitute Laue Langevin, Grenoble, France; 2. The Niels Bohr Institute, The University of Copenhagen, Copenhagen, Denmark; 3. Depertment of Physics, University of Oslo, Oslo, Norway; 4. NIST Center for Neutron Research, Gaithersburg, MD, United States*

$CoCl_2$*$2D_2O$ has been considered as a model system for a 1-dimensional Ising chain. The dominant interactions are ferromagnetic and couple nearest neighbour spins, into chains. Weaker inter-chain interactions gives rise to an antiferromagnetic ordering of the chains below T_N = 17.2 K. When a magnetic field is applied along the easy axis, $CoCl_2$*$2D_2O$ has two meta-magnetic transitions at H_{c1} = 3.1 T and at H_{c2} = 4.5 T. The transition at H_{c1} is from the antiferromagnetic state (AF) to a ferrimagnetic state (FI) and the transition at H_{c2} is to a ferromagnetic state (FE) [1,2,3]. Here we will present inelastic neutron scattering results and theoretical modelling of the spin wave spectrum of $CoCl_2$*$2D_2O$ in the AF-, FI- and FE-phases and analysed the data within the randomphase approximation. The conventional one spin flip spin waves are modified by a hybridisation with higher order spin flip excitations. In general excitations involving more than one spin-flip are normally to weak to be observed, but here we have the unique situation that they fall in the same energy range as the normal spin waves, which allows for the hybridisation to occur. In Fig. 1, one example of a neutron scattering intensity ma is shown, which can be compared to our model calculations shown in Fig. 2. Futhermore, we have also studied the magnetic excitations of $CoCl_2$*$2D_2O$ at higher temperatures, where the strong one-dimensionality of the system gives rise to unconventional signatures in the observed signal.

Fractional magnetic excitations, such as one dimensional spinons[1,2], are incontrovertible evidence for the quantum nature of a system, and it is widely believed that small magnetic moments are required, such as those originating from a transition metal ion with *d*-electrons. Our neutron scattering experiments unambiguously reveal exactly these exotic quantum states is a much different sort of system, Yb_2Pt_2Pb [3]. Our observation of spinons in this material is novel, because the magnetic moments hosting these excitations are very large, orbitally dominated *f*-electron states of Yb^{3+}. In 3*d* electron materials with spins-1/2 the orbital angular momentum is quenched and spinons are typically associated with the separation of the charge and spin degrees of freedom. In Yb_2Pt_2Pb, magnetic moments have predominantly orbital origin, and spinons bring about the separation of the charge and orbital degrees of freedom.

E1-01. Magnetic Switching with Topological Insulator and Compensated Ferrimagnet. *L. Liu*[1] *1. EECS, MIT, Cambridge, MA, United States*
2017 IUPAP Young Scientist Prize in Magnetism

New materials and physics mechanisms are required to further lower down the power consumption and increase the switching speed of spintronic devices. In this talk, I will focus on two novel material systems which can provide superior performances for magnetic switching. First of all, it is known that under the application of surface charge current, topological insulators with strong spin orbit interaction can lead to spin accumulation at the surface, which can be utilized to manipulate magnetic moments via the spin-orbit torques. In our experiment, we observe magnetic switchings in a topological insulator/magnet bilayer at room temperature [1]. This represents a major advance compared with previous works where flipping of magnetic moments was only realized at liquid helium temperature. The low switching current density and large effective spin Hall angle provide a definitive proof on the high spin-orbit torque efficiency from topological insulators. The large energy gain makes topological insulators outstanding candidates to realize high-efficiency magnetic switching devices compared with commonly used spin-orbit metals. Secondly, antiferromagnetically coupled material can exhibit fast dynamics as well as robust protection against external magnetic fields, which can enable spintronic devices with fast speed and high density. In this talk, I will discuss our recent study on rare earth based ferrimagnetic alloys which has antiferromagnetically coupled sublattices, net zero magnetic moment and electrically controllable magnetic state. Particularly, I will show that the inequality of the two sub-lattices provides finite electrical signals for convenient electrical reading, and the spin orbit torque allows for efficient writing [2]. Moreover, to illustrate the speed advantage of these compensated magnetic material, we further carry out current induced domain wall motion experiment, where highest domain wall mobility is obtained in samples with compensated angular momentum.

E1-02. Planar Hall torque. *C.J. Safranski*[1], E.A. Montoya[2] and I. Krivorotov[2] *1. Physics, University of California Irvine, Trabuco Canyon, CA, United States; 2. Physics & Astronomy, University of California, Irvine, Irvine, CA, United States*

Spin-orbit torques (SOTs) in bilayers of ferromagnetic (FM) and nonmagnetic (NM) materials enable energy efficient manipulation of magnetization by current. Previously studied spin Hall [1] and Rashba [2] torques originate from spin-orbit interactions within the NM layer and at the FM/NM bilayer interface, respectively. In this talk, we report a SOT arising from planar Hall current in the FM material of the bilayer [3]. This antidamping planar Hall torque (PHT) exhibits biaxial symmetry in the plane defined by the bilayer normal and the charge current direction (xz plane in Fig. 1). The unusual symmetry of PHT can be deduced from the angular dependence of the planar Hall current in the FM layer and is distinctly different from the uniaxial symmetry of the spin Hall torque (SHT) as illustrated in Fig. 1. We measure SOTs by spin-torque ferromagnetic resonance in FM/NM nanowires, where FM is a Co/Ni superlattice and NM = Au, Pd, and Pt. The antidamping component of the SOTs is deduced from the dependence of the ferromagnetic resonance linewidth ΔH on direct current density J_{dc} applied to the nanowire. Fig. 2 shows angular dependence of the slope of $\Delta H(J_{dc})$ for three different NM materials. This figure shows that the magnitude of SHT depends on the NM material while the magnitude of the PHT is nearly the same for all three NM materials, lending further support to the planar Hall effect in the FM layer being the origin of the novel SOT. Fig. 2 demonstrates that the magnitude of PHT is similar to that of the giant SHT of Pt and that strong PHT can be present in a system with negligibly small SHT (e.g. FM/Au). We also show that PHT is large enough to cancel magnetic damping of the FM layer and excite auto-oscillations of the FM magnetization [4,5]. The discovery of PHT [6] expands the class of materials for energy efficient manipulation of magnetization by giant SOTs.

E1-03. Effects of spin-orbit torque on the magnon gas. *V.E. Demidov*[1], S. Urazhdin[2], B. Divinskiy[1] and S. Demokritov[1] *1. Institute for Applied Physics, University of Muenster, Muenster, Germany; 2. Emory University, Atlanta, GA, United States*

Recent theoretical studies suggest that spin orbit torque (SOT) can drive the magnon gas into a quasi-equilibrium state described by the Bose-Einstein statistics with non-zero chemical potential, suggesting the possibility of electrically-driven Bose-Einstein condensation (BEC) of magnons. Variations of the chemical potential of the magnon gas were recently detected in measurements of spin relaxation rates of a nitrogen-vacancy center in diamond coupled to spin waves in a magnetic insulator. However, there was no direct experimental evidence that the magnon gas driven by SOT forms a quasi-equilibrium distribution, and the dependence of the effective thermodynamic characteristics has not been established. We have studied the effects of SOT on the magnon distribution in Permalloy (Py) over a broad spectral range, by utilizing the micro-focus Brillouin light scattering (BLS) spectroscopy. Pure spin current was injected into Py due to the spin-Hall effect in the adjacent Pt layer. The BLS spectra, reflecting the current-dependent spectral density of magnons, allowed us to analyze the spectral magnon population function and determine the thermodynamic characteristics of the magnon gas. Our analysis clearly indicates that the magnon distribution can be described by the Bose-Einstein statistics expected for the quasi-equilibrium state. We determined the current-dependent chemical potential and effective temperature of the magnon gas (Fig. 1), and showed that, for one polarization of the spin current, the effective temperature of the magnon gas becomes significantly reduced, while the chemical potential stays almost constant (Fig. 1a). In contrast, for the opposite polarization, the effective temperature remains nearly unaffected, while the chemical potential linearly increases with current, until it closely approaches the lowest-energy magnon state (Fig. 1b), indicating the possibility of spin current-driven Bose-Einstein condensation.

E1-04. Spin Currents and Spin-Orbit Torques in Ferromagnetic Trilayers. S.C. Baek[2], V.P. Amin[3], Y. Oh[2], G. Go[1], S. Lee[1], G. Lee[2], K. Kim[2], M.D. Stiles[3], B. Park[2] and *K. Lee*[1] *1. Korea University, Seoul, The Republic of Korea; 2. KAIST, Daejeon, The Republic of Korea; 3. National Institute of Standards and Technology, Gaithersburg, MD, United States*

Magnetic torques generated through spin-orbit coupling promise energy-efficient spintronic devices. It is important for applications to control these torques so that they switch films with perpendicular magnetizations without an external magnetic field[1]. One suggested approach[2] uses magnetic trilayers in which the torque on the top magnetic layer can be manipulated by changing the magnetization of the bottom layer. Spin currents generated in the bottom magnetic layer or its interfaces transit the spacer layer and exert a torque on the top magnetization. Here we demonstrate field-free switching in such structures[3] and show that its dependence on the bottom layer magnetization is not consistent with the anticipated bulk effects[2]. We describe a mechanism for spin current generation[4] at the interface between the bottom layer and the spacer layer, which gives torques that are consistent with the measured magnetization dependence. This other-layer-generated spin-orbit torque is relevant to energy-efficient control of spintronic devices.

E1-05. Tailoring the spin-orbit torques in $Pd_{1-x}Pt_x$/ferromagnet bilayers. *L. Zhu*[1], D. Ralph[1,2] and R. Buhrman[1] *1. Cornell University, Ithaca, NY, United States; 2. Kavli Institute at Cornell, Ithaca, NY, United States*

Current-induced spin-orbit torques (SOTs) in heavy metal/ferromagnet bilayers have attracted considerable attention due to the potential for magnetization manipulation at the nanoscale. The damping-like SOT has been shown to be sufficiently large to switch a magnetic layer, excite magnetization dynamics and skyrmions, or induce chiral domain wall motion [1-3]. Exploration of new, more efficient spin Hall materials continues to be of significant scientific and technologic interest. Meanwhile, micromagnetic simulations suggest that there can be an important role of the field-like SOT in determining the speed and reliability of SOT switching of magnetization via sub-nanosecond scale micromagnetic processes [4,5]. However, an experimental investigation of such effects has remained a big challenge due to the lack of control over the strength of the field-like SOT. Here, we report very efficient charge-conversion and tunable field-like SOTs due to the giant spin Hall effect in the $Pd_{1-x}Pt_x$ alloy from direct spin torque measurements using perpendicularly magnetized Co, in-plane magnetized Co and FeCoB as three independent spin current detectors. Similar to the case of $Au_{1-x}Pt_x$ alloy [7], $Pd_{1-x}Pt_x$ shows a maximum ξ_{DL} of 0.26 at $x = 0.75$ (resistivity of ~57 μΩ cm), which is 25% higher than that of pure Pt, ξ_{DL} of 0.2, (~51 μΩ cm), for 4 nm thick films. This work establishes an efficient spin current generator $Pd_{0.25}Pt_{0.75}$ with giant damping-like spin torque efficiency and relatively low resistivity for the SOT-based fundamental research and technological applications such as efficient SOT-driven magnetic memories, chiral spin texture devices, and terahertz emitters. Moreover, by simply varying the Pt concentration inside the $Pd_{1-x}Pt_x$ spin Hall generator, the field-like SOT efficiency can be continuously tuned from a significant positive value to a significant negative value while maintaining a high damping-like spin torque efficiency. The ability to tune the field-like spin torque (ξ_{FL}) while maintain a high damping-like torque provides experimental access to controllable studies of the roles of field-like SOT in various spin-orbitronic phenomena.

E2-01. Revealing Magnetic Configurations With X-ray Magnetic Nanotomography. *V. Scagnoli*[1,2] *1. Laboratory for Mesoscopic Systems, Department of Materials, ETH Zurich, Zurich, Switzerland; 2. Laboratory for Multiscale Materials Experiments, Paul Scherrer Institut, Villigen, Switzerland*

Three dimensional magnetic systems hold the promise to provide higher density devices and new functionality associated with greater degrees of freedom. Over the last years we have worked towards developing methods to fabricate and characterise three dimensional magnetic structures. Specifically, we have fabricated an artificial magnetic buckyball and performed a high spatial resolution tomographic characterisation of the structural and elemental properties [1]. In order to determine the magnetic configuration in such three dimensional systems, we have combined X-ray magnetic imaging with a new iterative reconstruction algorithm to achieve X-ray magnetic tomography [2,3]. In a first demonstration, we determine the three dimensional magnetic nanostructure within the bulk of a soft $GdCo_2$ magnetic micropillar, observing a complex magnetic configuration consisting of vortices and antivortices that form cross-tie and vortex walls. By determining the magnetic structure surrounding singularity points found at the intersections of these magnetic structures we have identified the presence of Bloch points of different types [3]. X-ray magnetic nanotomography will enable to unravel complex three dimensional magnetic structures for a range of magnetic systems with high spatial resolution.

E2-02. Modulated Valley and Spin Polarizations in $BiFeO_3/BiIrO_3$ Multiferroic Superlattices. L. Yin[1] and *W. Mi*[1] *1. Department of Applied Physics, Tianjin University, Tianjin, China*

The generation and modulation on valley and spin degrees of freedom are essential to multifunctional electronic devices[1]. Herewith, the electronic structures in $BiFeO_3/BiIrO_3$ multiferroic superlattices are studied by first-principles calculations with spin-orbital coupling. Different from previous $BiAlO_3/BiIrO_3$ system, both valley and spin polarizations in bilayered $BiIrO_3$ are achieved in $BiFeO_3/BiIrO_3$ superlattices, where the spin polarization in the valley can be engineered by the spin orientation of Fe owing to the *xy*-plane orbitals. Especially, the relatively parallel and antiparallel directions of ferroelectric polarization in $BiFeO_3$ and $BiIrO_3$ can switch the valley injection in $BiFeO_3/BiIrO_3$ superlattices. The tunable valley and spin polarizations in $BiFeO_3/BiIrO_3$ multiferroic superlattices pave a way for developing the nonvolatile data memories and valley-spin devices. This work is supported by National Natural Science Foundation of China (51671142 and U1632152), Key Project of Natural Science Foundation of Tianjin (16JCZDJC37300).

E2-03. Van der Waals spin valves. *C. Cardoso*[1], D. Soriano[1], N. Garcia-Martinez[1] and J. Fernandez-Rossier[1,2] *1. Quantum Materials, Science & Technology, International Iberian Nanotechnology Laboratory, Braga, Portugal; 2. Departamento de Fisica Aplicada, Universidad de Alicante, Alicante, Spain*

The so called Van der Waals (VdW) heterostructures [1, 2] can combine a variety of 2D materials, including insulators (h-BN), semiconductors (MoS_2), conductors (graphene) and superconductors ($NbSe_2$). The recent discovery of 2D crystals with magnetic order [3, 4, 5, 6] adds both ferromagnetic and antiferromagnetic insulators to this list. Recently, VdW devices consisting of CrI_3 thin layers, a ferromagnetic insulator, have been reported [7, 8, 9]. Here we propose a new class of spin valve that takes advantage of the strong influence that spin proximity effect can have in a 2D conducting crystal

placed between two insulating ferromagnetic layers. We consider a simple model for a graphene bilayer put between two ferromagnetic insulators. Spin proximity effect is considered by including a spin dependent potential whose sign can be different in the top and bottom graphene layers. We find that the relative orientation of the magnetization of the magnets, have a strong impact in the electronic structure and in the in-plane conductivity. We have also considered a possible physical realization of a VdW spin valve, based on graphene bilayer, that is feasible within the experimental state of the art. For that matter, we choose CrI_3 monolayers as the insulating ferromagnet. It was recently shown that CrI_3 monolayers remain ferromagnetic up to 45K [10]. In addition CrI_3 preserves its magnetic properties even when deposited on graphite [6] or encapsulated between graphite electrodes [11]. We have considered two configurations in which the relative orientation of the CrI_3 monolayers magnetization is either parallel (FM) or antiparallel (AF). We find that the states around the Dirac energy, where the conduction and valence parabolic bands of freestanding graphene bilayer meet, are very different for the two configurations. While for the AF configuration a gap opens in the graphene bilayer bands at the Dirac point, for the FM case the bands spin split and bilayer graphene remains metallic.

E2-04. Magnetism and Magneto-Electric Transport in Amorphous Thin Films of Iron-Silicon and Iron-Germanium. *D. Bouma*[1,2], J. Karel[3], F. Bruni[1], T. Chen[4] and F. Hellman[1,2] *1. Department of Physics, University of California, Berkeley, Berkeley, CA, United States; 2. Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, United States; 3. Materials Science and Engineering, Monash University, Clayton, VIC, Australia; 4. Physics, Arizona State University, Tempe, AZ, United States*

In thin films of amorphous iron-germanium (a-Fe_xGe_{1-x}) and amorphous iron-silicon (a-Fe_xSi_{1-x}), broken local inversion symmetry and local spin-orbit coupling yield a local Dzyaloshinskii-Moriya (DM) interaction, which manifests itself in distinctly non-square hysteresis loops. The amorphous structure also leads to enhanced magnetization, anomalous Hall effect, and spin polarization compared to crystalline counterparts. We discuss the composition dependence of the magnetization, Hall effect, and electrical resistivity of thin films (50-80nm in thickness) of a-Fe_xGe_{1-x} and a-Fe_xSi_{1-x} with $0.43 < x < 0.71$. The films are magnetic over the entire composition range investigated. Furthermore, the magnetic moment on the Fe atoms in a-Fe_xGe_{1-x} is augmented compared to that in a-Fe_xSi_{1-x} due to the increased size of the Ge atom relative to Si, indicating a potentially enhanced spin polarization. We ascribe the large anomalous Hall effect, and its dependence on composition and resistivity to an increased importance of the orbital magnetism in amorphous materials, which is equivalent to a localized Berry phase curvature.

E2-05. Transport properties through multi-barrier magnetic system containing a non-coplanar defect. A.S. Sahakyan[2], A.V. Pogosyan[2], R.M. Movsesyan[2] and *A.N. Kocharian*[1] *1. Physics and Astronomy, California State University. Los Angeles, Los Angeles, CA, United States; 2. Physics, National Polytechnic University of Armenia, Yerevan, Armenia*

The studies of the transport properties in films containing magnetic nanolayers and nanostructures are important in connection with the problems existing in synthronics. Here we consider the one-dimensional nanoscale structures with a potential relief containing magnetic barriers separated by nonmagnetic quantum wells with a enough width by implying that there is no exchange interaction between the magnetic moments of adjacent barriers. An example of such a structure is the sequence of N barriers divided into two ‘ferromagnetic domains’ of the length n and N-n-1 both having parallel internal fields. In contrast, the internal field of the n-th barrier is not coplanar with respect to the internal fields of the left and/or right ‘domains’. The degree of spin polarization of an electron wave transmitted through this system is calculated with assumption that the incident wave is unpolarized with the degree of its polarization equal zero. It is shown that the degree of polarization of the transmitted wave as a function of the impulse presents a sequence of sufficiently wide plateaus which are close to unity. These regions alternate with rather narrow ranges of momentum values, where the degree of polarization is zero. The degree of polarization of the transmitted wave turns out to be weakly dependent on the coordinate of the ‘non-coplanar defect’, but it essentially depends on the degrees of freedom that describe the noncoplanarity of the system. In particular, there are significant deviations from the known synthronous phenomena found earlier in this system such as the gate and the giant magnetoresistance effects. This circumstance creates opportunities for managing the transport properties by varying the non-coplanar degrees of freedom of the system. E3-01. Imaging chiral spin textures with a scanning-NV magnetometer.
V. Jacques[1] 1. Laboratoire Charles Coulomb, CNRS, Montpellier, France

Experimental methods allowing for the detection of single spins in the solid-state, which were initially developed for quantum information science, open new avenues for the development of highly sensitive quantum sensors. In that context, it was shown that the electronic spin of a single nitrogen-vacancy (NV) defect in diamond can be used as an atomic-sized magnetometer, providing an unprecedented combination of spatial resolution and magnetic sensitivity under ambient conditions [1]. In this talk, I will illustrate how scanning-NV magnetometry can be used as a powerful tool for exploring condensed-matter physics, focusing on chiral spin textures in ultrathin ferromagnets [2,3] and antiferromagnetic order in multiferroic materials [4].

Magnetic force microscopy (MFM) is a high resolution, 2-pass scanning probe technique which maps of the stray magnetic fields emanating from a sample[1]. The 2nd pass is conducted at a fixed tip-sample distance (TSD), however 3D-MFM collects data at many TSDs successively, generating MFM data extending along 3 dimensions (Fig. 1a–b). Thus no assumptions of the sample's stray magnetic field decay are required and, by relating the sample's stray fields as a function of TSD[2], misinterpretation of tip-sample interactions can be excluded from further analysis. Quantitative-MFM (qMFM) was used to demonstrate the influence of these inherent errors, and minimise their effects with 3D-MFM. qMFM extracts the probe's magnetic profile as the tip transfer function (TTF), which requires controlled measurement of a reference sample[2,3] (Fig. 1b). The calibrated probe is used to measure a sample's magnetisation by deconvolving its MFM response with the TTF (Fig. 1c). New procedures for 3D data-handling, prior to analysis are demonstrated and we exhibit the volumetric TTF, signifying its advantages with calibrated measurement of a test sample. The test sample is an artificial spin ice (ASI) array (1000 μm^2) of frustrated permalloy nanoislands (NIs) (380×100×25 nm^3) (Fig. 1d), where each NI's magnetisation collapses into two opposing out-of-plane Ising-spins[4,5]. The novel ASI design here produces macro-ordered mono- and multimodal states (Fig. 1e), allowing for unique study of magnetic frustration. In summary, a new approach to data-handling and analyses from a combination of 3D-MFM and qMFM allows for comprehensive understanding of magnetic properties on the nanoscale; free from common errors and assumptions in 2-pass MFM. 3D-MFM shows improved accuracy of quantitative values obtained by qMFM; and from analysing the probe magnetisation volume, the test sample's field is quantified experimentally as a function of TSD.

The promising and potential applications of spintronic devices in the development of green and more sustainable technologies attract great research interest. Novel devices and structures such as 3D nanomagnets can present high level of complexity [1]. Their study, and most importantly, their understanding needs the development of novel characterization and visualization techniques. In this framework, the present work introduces a new method to obtain 3D magnetic reconstructions of arbitrary systems by using dichroism and conventional soft X-ray tomography [2]. Recently, the volume resolved magnetic reconstruction has been experimentally demonstrated by C. Donnelly *et al.* [3] by using hard X-rays showing the great potential of

the technique. Our approach exploits the natural high dichroic contrast of magnetic elements in the soft X-ray energy range to acquire high quality data from reduced number of images without compromising reconstruction accuracy compared with the hard X-rays approach. The proposed method uses two orthogonal tilt series (Fig. 1) acquired with both positive and negative dichroism, to gather information about the three magnetization components. These tomograms are jointly processed using a modified Algebraic Reconstruction Technique for obtaining the 3D magnetization configuration of the sample. The method has been applied to two simulated magnetic particles: a nanodisc and a thick heterostructure. The obtained 3D magnetization configurations have been compared with the original ones testing the accuracy of the method. The results are qualitatively in agreement with the ground truth and can be quantitative (Fig. 2). This suggests that our method has great potential to characterize highly complex magnetic systems, and can be an extremely powerful tool to study 3D nanomagnets and novel spintronic devices.

4. IFW Dresden, Dresden, Germany

Magnetic force microscopy (MFM) is used to detect and visualise the stray magnetic fields that emanate from the surface of magnetic materials [1]. Typically, MFM is used only in a qualitative capacity to gain physical insight into the morphology of magnetic domains, however, there are established calibration methods that can be employed to make quantitative measurements [2,3,4]. Here we use current carrying coils of micrometric dimension, in particular, we focus on the role of electrostatic compensation on the measured values of the effective monopole and dipole contributions of an MFM probe. The effect of electrostatic compensation switched off and on is shown in Fig. 1a and b, respectively. Without the use of compensation, there is an electrostatic influence on the measured MFM signal, which is observed at the coil edges as well as charging effects on the surrounding SiO_2 substrate. Conversely, the addition of electrostatic compensation is shown to significantly reduce these parasitic effects Fig. 1b phase. The electrostatic nulling signal is shown in Fig. 1b SKPM. The experimental setup displaying the coil topography is shown in Fig. 2a. Finally, average line profiles of the MFM signals with/without electrostatic compensation are presented in Fig. 2b. Qualitatively these line profiles vary significantly, this dramatically impacts quantitative solutions, making the measurements taken without compensation unreliable. In this work we demonstrate a combination of the standard MFM approach with electrostatic compensation to image the magnetic field distribution in µ-coils. This approach is a significant step towards a correct calibration of MFM probes for quantitative MFM.

E3-05. *In-situ* imaging of magnetic tunnel junctions using a scanning electron microscope to improve their yield. *E. Jackson*[1], J. Kim[1], M. Samiepour[1], M. Sun[2], T. Kubota[2], K. Takanashi[2] and A. Hirohata[1]
1. University of York, York, United Kingdom; 2. Institute for Materials Research, Tohoku University, Sendai, Japan

A series of magnetic tunnel junctions (MTJs), structure shown in fig. 1, were produced on a single wafer. These MTJs could be split into two distinctive groups, High or low tunnelling magnetoresistance (TMR). This corresponds with the effective yield of the process, which was 21%. To improve the total yield the devices were investigated using a recently developed imaging technique [1]. This technique utilises CASINO [2], an electron scattering in solids simulator, to find a controlled voltage which will penetrate the sample down to a chosen interface. This investigation focused on the CoFe, MgO and CFMS layers and interfaces. The technique found the main difference between the two groups was a build-up of material around the low TMR MTJs, an example is shown in fig. 2. Energy-dispersive X-ray spectroscopy

was utilised to identify the material around the pillar, with both spectra and chemical maps obtained. These two techniques led to the conclusion that the material was most likely to be an aluminium carbide, such as Al_4C_3, formed during the deposition of the insulator, AlO, and carbon from the resist used during the etching stage. When steps were taken to reduce the probability of this occurring the yield went up to 36%. Therefore the technique has proved, alongside previously established techniques, that it can be used to identify faults that arise during the production of magnetic devices. Due to the ability of this technique to non-destructively study interfaces it has also proved essential in an in-situ study of spintronic devices that is being performed. The technique has already identified key faults in devices, by imaging them as they are powered. We thank JEOL UK for their support and acknowledge the funded provided through EPSRC EP/M02458X/1 and the JSPS Core-to-Core grant.

E4-01. Spin Wave Circuits Using Forward Volume Mode in Yttrium Iron Garnet. *T. Goto*[1,2], K. Sekiguchi[3], A. Granovsky[4], C. Ross[5], Y. Nakamura[1], H. Uchida[1] and M. Inoue[6] *1. Department of Electrical and Electronic Information Engineering, Toyohashi University of Technology, Toyohashi, Japan; 2. JST-PRESTO, Kawaguchi, Japan; 3. Yokohama National University, Yokohama, Japan; 4. Moscow State University, Moscow, Russian Federation; 5. Dept.of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, MA, United States; 6. Toyohashi University of Technology, Toyohashi, Japan*

Spin waves (SWs) are attracting considerable interest as new information carriers because of their low Joule heating during propagation. In particular, the forward volume spin wave (FV SW) is the most suitable mode for SW integrated circuits (SW ICs). However, functionalities using phase interference of FV SWs have not been shown because FV SWs suffer from noise generated by edge reflection and/or scattering. To suppress such noise, we introduced SW absorbers consisting of ~10 nm thick gold film deposited onto the edges of a yttrium iron garnet (YIG) waveguide. As a result, SW reflection was reduced drastically, and stable SW interference was demonstrated in the YIG waveguide [1]. This suppression effect for SW was analyzed by the finite element method, showing that the positions of the SW absorbers were quite important for reducing noise. This was manifest in the reduced spectral fringes in the SW transmission spectra. This SW absorbing technique was applied to the design of SW devices, and we recently demonstrated logic gates using FV SW propagating in both 10 μm thick and 50 nm thick YIG films. AND and OR gates were demonstrated in devices made using 10 μm thick YIG [2]. The function of the gate was selected by the phase of one of three input signals. In addition, the phase of the input signal was continuously changed, showing a multi-level logic gate. In this device, the propagation direction and wavenumber of the SW were unfavorably modulated by the spatially-dependent demagnetization field of the YIG waveguide. To reduce this, we proposed a new waveguide geometry in an un-patterned film of YIG, in which the demagnetization field is constant within the waveguide. We can describe this structure as a core-cladding waveguide, and it showed better results than a patterned ridge-waveguide. In the all demonstrations, the antennas used for excitation of SWs were microstrip lines with 50 μm width and short terminations. These needed to be separated by about >5 mm from each other, hence the device size approached 1 cm. To miniaturize the devices, we used 50 nm thick YIG films with 2.5 μm wide coplanar waveguides. The YIG films were epitaxially grown on garnet substrates using pulsed laser deposition, showing clear reflection fringes in x-ray diffractions. In addition, to suppress SW noise, SW absorbers were introduced at the edge of SW waveguide. The wavelength of the SWs was about 63 μm. Successfully, interference of SW was demonstrated, and a simple logic gate was shown. SW spectroscopy was obtained and theoretically analyzed. The device size was 1000 times smaller than our previous work, but the isolation ratio was almost the same. Therefore, several functions of FV SW have been demonstrated using YIG films with micrometer and 10s of nanometer thickness. These illustrate the significant advantage of FV SW propagating in YIG films for development of SW ICs.

E4-02. Protected Chiral Spin-Wave Modes for Backscattering-Immune Magnonic Transport. M. Mohseni[1], Q. Wang[1], *T. Brächer*[1], D.A. Bozhko[1], B. Hillebrands[1] and P. Pirro[1] *1. Physics, TU Kaiserslautern, Kaiserslautern, Germany*

Protected transport of energy and information as an emerging realm of research and technology has gained a tremendous amount of interest during the last decade [1-2]. Indeed, one of the biggest challenges in reducing the level of energy consumption and increasing the efficiency of information technology devices arises from various mechanisms of energy loss and signal distortion. Among them, defects, disorders and inhomogeneities inside or at the surfaces play an important role. This motivated, inter alia, many contributions to the field of topological states of matter because topology opens the possibility to create protected and unidirectional transport [1-4]. In this contribution, we study the protection of spin waves, which are the low energy excitations of the spin ensemble of a magnetically ordered system. They are considered as a promising counterpart of electrons, photons and phonons to serve as information carriers in future wave-based data processing devices [5,6]. This stimulated a lot of theoretical works on the potential topological protection of spin waves in different systems like, e.g., magnonic crystals, which have been proposed to host topological spin wave bands [7-9]. Nevertheless, protected transport is still a great challenge since most of the proposed systems obtain their protection from Dzyaloshinskii-Moriya interaction or strongly inhomogeneous magnetic ground states which are properties that are hard to realize experimentally. Here, we demonstrate that backscattering-immune spin-wave modes exist even in simple thin film systems which have homogeneous magnetic parameters and feature no DMI. By micromagnetic simulations, we investigate the transmission of different spin-wave modes in YIG films after scattering of the waves by different kinds of defects and inhomogeneities. In particular, we show that chiral

waves known as Magneto Static Surface Waves, whose reciprocity is broken because of the symmetry-breaking part of the dynamic dipole-dipole interaction with respect to the inversion of the propagation direction [7, 10], can be robust against even large inhomogeneities and defects.

SSRL, SLAC National Accelerator Laboratory, Menlo Park, CA, United States*

For the in depth understanding of magnetization dynamics on the micro- and nano-scale it is of utmost importance to be able to measure single objects inside an ensemble. Until recently it was only possible to measure an average signal of many different nano- or micro-sized objects. Due to the development of lithography fabricated micro-resonators [1] it is now possible to measure nano-sized objects with a detection sensitivity of down to 10^6 spins [2]. By combining these micro-resonators with scanning X-ray transmission microscopy (STXM), it is possible to measure the ferromagnetic resonance (FMR) with a space resolution of 35 nm and a time resolution of 17.4 ps due to the synchronization of the microwave excitation and the X-ray pulses generated by the synchrotron [3,4]. In the frame of this work we selected two different sample geometries for a STXM-FMR measurement. Both consist of two perpendicular micro-stripes in the form of a T with dimensions of 5x1x0,03 μm^3 and a distance between the stripes of 1 μm. The orientation of the T of the two samples is rotated by 90 degrees in order to investigate the influence of the stray field of one stripe on the resonance of the second one. For an in-depth understanding of the contrast mechanism in STXM-FMR the influence of the circular polarization on the dynamic magnetic contrast at ferromagnetic resonance was systematically investigated. Additionally, the influence of the polarization on the X-ray absorption in the samples during resonance was investigated by switching the polarization between measurements. Moreover the absorption on different absorption edges for the same element was investigated (Ni-L_3 compared to Ni-L_2). The STXM-FMR measurements complement previously measured thermally modulated FMR measurements [4]. The combination of these allow to identify the influence of the stray-field on the respective ferromagnetic resonances and linewidths.

Spin waves based devices are promising for next generation analog signal processing systems as they display small wavelength (μm) and easily tunable frequencies in the radiofrequency regime. For instance, by propagating spin waves through a periodic magnetic structure, i.e., a magnonic crystal (MC), one can achieve filtering in the GHz regime at the micro-scale [1]. In the last few years, the advent of nanometer-thick YIG films of high quality either grown using pulsed laser deposition (PLD [2]), sputtering ([3] or LPE [4]) has open new perspective to adapt the knowledge that has been developed for metallic magnonic crystals [5] to YIG. Recently, using phase resolved μ-BLS microscopy on a width-modulated YIG waveguide, frequency filtering has been reported [6]. Here we report on S-parameter characterization of a series of ultrathin YIG MC waveguides using Propagating Spin Wave Spectroscopy (PSWS). The MC obtained by etching 150 nm wide, periodically spaced grooves. The studied system is composed of 50 parallel wave-guides that are each 2.5μm-wide. These guides are designed using e-beam lithography and laser lithography and etched off 20nm thick YIG film PLD grown film with a Gilbert damping of $4x10^{-4}$ [7] (see figure 1). The MC Bragg k-vector is 1μm^{-1}. The spectrum of mutual inductance due to the propagation of the spin waves is recorded over a frequency range between 0.5 and 2.5GHz, at various magnetic fields. A 20MHz transmission gap is observed corresponding to a decrease by a factor of 4 of the spin wave intensity at 30μm from the antenna when compared to the reference waveguide. Importantly, we also find that the transmission outside the frequency gap is unaffected by the presence of the periodic grooves. Furthermore, the attenuation length of our films being of the order of 150μm at 1GHz, we expect to obtain much higher frequency selectivity by increasing the distance between our antennas up to 100μm.

E4-05. Dipole-exchange spin-wave spectrum in ferromagnetic films calculated using the method of geometrical optics. *I. Lisenkov*[1], V. Tyberkevych[2] and A.N. Slavin[2] *1. School of Electrical Engineering and Computer Science, Oregon State Univeristy, Corvallis, OR, United States; 2. Department of Physics, Oakland University, Rochester, MI, United States*

The dispersion of spin-waves in ferromagnetic films is determined by a short-range exchange interaction and a long-range dipolar interaction. The operators describing these interactions do not commute, so it is impossible to find a set eigenfunctions satisfying both operators simultaneously. It is natural to use a complete set of eigenfunctions of one of the operators as the expansion basis to find a spin wave dispersion law [1]. Although this approach leads to a correct formal solution for the spin wave dispersion, it remains practical only when the eigenfunction expansion can be truncated to a few first terms. To resolve this problem, we propose to calculate dispersion in films using the approach which was used to calculate waveguide modes in geometrical optics [2]. There, we consider a spin-wave mode inside a ferromagnetic film as a result of interference of eigenmodes (propagating and evanescent) of a bulk ferromagnet without any boundaries. When a spin-wave reflects from a boundary (Fig. 1), In contrast with the isotropic optics, the incident and reflected spin waves can have different values of a transverse wavenumber. It turns out, that for relatively long wavelength spin waves the incident (κ_0) and reflected (κ_r) transverse wavenumbers are related as κ_r=-k tan(2θ+arctan(κ_0/k), where k is the in-plane wavenumber, and θ is the angle between the equilibrium magnetization and the film normal. Fig. 2 shows the dependence of the κ_r on the κ_0 calculated numerically and using the analytical expression for θ=3π/8. The transverse wavenumber κ_r can be negative or positive, thus the incident and reflected waves do not always form a standing wave in the transverse direction, but may form a traveling wave instead [3]. The boundary conditions determine the amplitude of the reflected wave, and, in the case of an in-plane static magnetization, the transverse profiles of the spin wave modes demonstrate "pinning" of a dipolar nature, which is increasing with the increase of the in-plane (longitudinal) spin wave wavenumber.

E5-01. Quantitative analysis of hysteretic magnetocaloric materials. *V. Franco*[1], J. Law[1] and A. Conde[1] *1. Condensed Matter Physics Department, Sevilla University, Sevilla, Spain*

The use of magnetocaloric materials for energy efficient applications like magnetic refrigeration or thermomagnetic energy generation requires a deep understanding of their hysteretic response upon periodical variation of field and temperature. In the case of magnetic refrigeration, the ideal refrigerant material would exhibit characteristics that lay in the separation between first order (FOPT) and second order phase transitions (SOPT). In the former case, the magnetic entropy change and the adiabatic temperature change are larger than for SOPT, but at the price of thermal hysteresis and slower kinetics of the transition due to phase coexistence, which are detrimental for potential applications. Therefore, three main questions should be considered in the characterization of magnetocaloric materials: 1) which is the order of the phase transition that it undergoes?; 2) which is the composition of that particular series of alloys or compounds that will provide us with the desired properties at the borderline between FOPT and SOPT? (i.e. the critical point of the first order phase transition, also denoted as the tricritical point); and 3) which are the characteristics of the thermal hysteresis loops that the sample undergo during its operation? In this talk we will give an overview of magnetocaloric materials that exhibit both FOPT and SOPT characteristics [1] that could be potential candidates for technological applications. The determination of the order of the phase transition will be made using a new quantitative method based on the field dependence of the magnetic entropy change [2] that is even applicable to cases in which the conventional methods give erroneous results. A detailed study of this field dependence will also allow us to predict the composition of the tricritical point of a series of alloys [3]. Finally, we will show that first order reversal curves (FORC) and, in particular, temperature-FORC (T-FORC) experiments can be used to characterize the hysteresis of magnetocaloric materials [4]. Even if T-FORC experiments are time consuming, we will show that the use of an effective temperature axis in the T-FORC diagrams allows us to characterize thermal hysteresis of magnetocaloric materials in a much more efficient way in terms of time and resources than simply sweeping temperature. This work was supported by AEI/FEDER-UE (project MAT-2016-77265-R) and the PAI of the Regional Government of Andalucía.

E5-02. Magneto-caloric effect in $NdCo_2$ and $Nd_{0.4}Gd_{0.6}Co_2$. *S. Pandya*[1,2], L. Sharath Chandra[2,3] and V. Ganesan[1] *1. UGC-DAE Consortium for Scientific Research, Indore, India; 2. Department of Physics, Sardar Patel University, Anand, India; 3. Magnetic and Superconducting Materials Section, Raja Ramanna Center for Advanced Technology, Indore, India*

The first order phase transitions show thermal and magnetic irreversibility and this irreversibility leads to hysteretic loss of relative cooling power. Hence, it is necessary to search good magneto-caloric material accompanied by second order transitions [1]. It is noticed that, even though the magnetic transitions in $NdCo_2$ are accompanied by the structural transitions, these transitions are shown to be not hysteretic and appears to be more of second order in nature [2, 3]. Hence, the magneto caloric effect (MCE) in the present family of compounds is worth studying. Our results suggest that the MCE parameters such as entropy change (ΔS) and adiabatic temperature change (ΔT) at curie transition ($T_c \sim 100$ K) and spin reorientation transition ($T_{sr} \sim 42$ K) are noticeably large. Active region over which this system may be useful is also very large, which leads large relative cooling power (RCP). Doping of Gd at the site of Nd increases the internal molecular field of system, consequently the Curie transition of the system can be tuned near to room temperature. Here we present detail magneto-heat capacity studies of $NdCo_2$ and $Nd0.4Gd_{0.6}Co_2$ in search of MCE near room temperature. Outcomes point out functionality of $Nd0.4Gd_{0.6}Co_2$ near room temperature.

The search and study of new functional materials for solid-state cooling remains one of the promising energy efficient and environmentally safely alternatives to current methods of cooling. As known, the multiferroics are the materials, which can demonstrate the two or more known types of ordering (ferroelectric, magnetic and elastic). In this consideration, theoretically multiferroics can exhibits the magnetocaloric (MCE), electrocaloric (ECE) and elastocaloric (ElCE) effects. Recently, the idea based on using multiferroics with couple caloric effects are considered as one of the promising for solid-state refrigeration. The recent theoretical works confirms these suggestions about possibility of application couple caloric effects, but experimentally the multicaloric effect with values suitable for practical application have not yet been observed. Natural single-phase multiferroics demonstrate the small values of ECE and MCE and the temperatures of ferroelectric and magnetic phase transitions are far away from each other. In present work the caloric effects in ceramic magnetoelectric (ME) composites with room temperature MCE and ECE effects were studied. In generally, the connectivity schemes of ME composites divides to 0-3–type for particulate composites of piezoelectric and magnetic grains; 2-2–type for layered composites consiating of magnetic and piezoelectric layers; and 1-3–type for composites with fiber of the one phase embedded in the matrix of another phase. The 0-3 and 2-2 types of ME composites on base of magnetic and ferroelectric components with room temperature phase transitions were fabricated and characterized. The magnetic, ferroelectric, multicaloric and magnetoelectric properties around phase transition temperatures were studied. In ceramic ME composites MCE and ECE at room temperature, anomalies of magnetoelectric effect around phase transition temperatures and influence of FE phase on MCE were observed. The double anomalies of entropy changes and correlation with magnetoelectric effect around temperatures of FM and FE phase transitions were observed. The role of magnetoelectric coupling on caloric effects in volume multiferroic composites also was considered.

E5-04. Rotating Magnetocaloric Effect in the Region of Spin-Reorientation Transition in the Fe_7Se_8 Single Crystal. *I. Radelytskyi*[1,2], Y. Konopelnyk[2] and A. Schneidewind[1] *1. Jülich Centre for Neutron Science (JCNS) at MLZ, Garching, Germany; 2. Institute of Physics PAS, Warsaw, Poland*

Trigonal Fe_7Se_8 (3c type) shows in constant magnetic fields a spin-reorientation transition from the easy *c*-axis to the easy *c*-plane near the temperature T_R = 125 K, as a first-order phase transition [1]. This transition is induced by temperature and/or by an applied magnetic field. We investigated a Fe_7Se_8 single crystal by magnetization measurements above and below T_R and obsered first order metamagnetic field induced transitions. The rotating entropy change was evaluated from magnetization data using the Maxwell equation to be about 1.7 J kg/K for H = 2 T which is twice that one of the conventional magnetocaloric effect at spin reorientation region. A one-ion model of the rotating magnetocaloric effect has been developed and its predictions have been compared with experimental data. This study was partly financed by the National Centre for Research and Development, Research Project no. PBS2/A5/36/2013

E5-05. On the optimization of Magneto-volume coupling for practical applied field magnetic refrigeration. A. Davarpanah[1], *J.H. da Silva*[1], V.S. Amaral[1] and J.S. Amaral[1] *1. CICECO & Physics dept., Universidade de Aveiro, Aveiro, Portugal*

High performance, magnetocaloric refrigerants usually present high magneto-volume coupling. When sufficiently strong, this coupling can lead to a coupled first-order magnetic and structural transition, and a giant magnetocaloric effect. The trade-off of the resulting increased entropy change is hysteresis, and, when the applied field is <2 T the transition may not be complete, implying that the full cooling capacity of the refrigerant is not harnessed [1]. In this study the magnetocaloric properties of a second-order phase transition system were investigated as a function of the magneto-volume coupling via the parameter (in the [0,1] range), magnetic field change (ΔH in the [0.1, 2] T range) and individual spin moment (*S* of 0.5, 1, 1.5, and 3.5). The focus was given to the magnetocaloric effect at small magnetic field changes (up to 2 T), as feasible commercial applications will have to work with magnetic fields generated by permanent magnets. This theoretical simulation is performed in the framework of the molecular mean-field model and Bean-Rodbell magnetovolume coupling [2]. Increasing η value leads to higher maximum entropy change together with less broad entropy change curve. This results in a surprising non-monotonous dependency of cooling capacity with a peak value away from tricritical point. By tuning these effects, the cooling capacity can be considerably larger than the uncoupled system (15-40% for applied field between 0.5 and 0.1 Tesla and $0.4 < \eta < 0.9$). Our results demonstrate how magneto-volume coupling can be optimized for second-order phase transition materials, enhancing the magnetic refrigerant performance, especially at low applied fields. Achieving maximum cooling capacity value for weakly magneto-volume coupled systems underlines that the search for optimized magnetocaloric materials can focus on second-order materials with fine-tuned magneto-volume coupling, rather than the tri-critical region. With proper chemical substitution, the materials can be tuned towards optimized cooling performance.

EECS, UC Berkeley EECS, Berkeley, CA, United States*

Magnetic Particle Imaging (MPI) [1] shows great promise for clinical biomedical Imaging. MPI relies on completely different physics from MRI and nuclear medicine. MPI offers extraordinary contrast, because human tissues produce zero MPI signal and are magnetically transparent. MPI detects superparamagnetic iron oxide (SPIO) nanoparticle tracers. Our homebuilt Berkeley scanner shows 200-cell sensitivity (1 micromolar) with quantitative, positive contrast at any depth, better than all other cell tracking methods. Moreover, we have tracked cells for 90 days *in vivo*, because the magnetic "half life" is essentially infinite, a distinct advantage over nuclear medicine reporters Tc99m (6-hour half life) and In111 (2.8-day half life). SPIO tracers are considered safe for human use, and some are already FDA or EU safety approved. My lab has researched many aspects of MPI, including high-resolution and high-sensitivity 3D scanner hardware, advanced image reconstruction software algorithms, high-spatial-resolution MPI tracers. In the last three years, we have explored several promising applications where MPI could serve as a noninvasive complement to nuclear medicine (see Figure 1) including stem cell tracking, early-stage noninvasive cancer detection, rapid and safe gut bleed detection, rapid pulmonary embolism detection, and immunotherapy tracking without radiation. The MPI field needs experts in nanoscale physics, chemistry and pathophysiologic targeting. We believe that MPI tailored nanoparticles will be crucial for improving the spatial resolution of MPI, now about 1 mm, to 100 microns.

The combination of different strategies into one single therapeutic platform is the next step for efficient, safer and less invasive anticancer treatments, a field in which nanomaterials are playing an important role.[1-3] Iron nanowires (NWs) have exhibited good biocompatibility and cellular internalization with a low cytotoxic effect even at high concentrations with long incubation periods.[4,5] Here, a novel method for bimodal cancer cell destruction by combining the optical and chemotherapeutic properties of doxorubicin (DOX) functionalized iron (Fe) NWs was developed. Fe NWs were coated with bovine serum albumin (BSA-NWs) and functionalized with DOX (BSA-NWS_DOX) through a pH sensitive linker. Cellular internalization was qualitatively and quantitatively assessed by confocal reflection microscopy and inductively coupled plasma-mass spectrometry. The capability of Fe NWs to transduce optical energy from a NIR laser into heat in physiological conditions was evaluated with a NIR thermal camera reaching an average value of 83±7% that was translated into a temperature increase of 20 °C in breast cancer cells incubated with BSA-NWs. The ability of BSA-NWS_DOX to induce cancer cell death by combining the selective drug release with the photothermal therapy (PTT) upon irradiation with a NIR laser was evaluated on MDA-MB 231 cells by a cell viability assay that resulted in high level of cancer cell death, up to 76%, that was more effective than individual therapeutic strategies, BSA-NWs+DOX: ~40% and BSA-NWs+PTT: ~28% at the same concentration, and comparable to previously reported bimodal strategy that combined chemotherapy and magneto-mechanical actuation at similar concentration.[6]

E6-03. Nanofabrication process, magnetic response and cellular uptake of nanostructures for biomedical applications. *P. Tiberto*[1], F. Celegato[1], G. Barrera[1], M. Coisson[2], C. Divieto[1] and M. Sassi[1] *1. INRIM, Torino, Italy; 2. Electromagnetics, INRIM, Torino, Italy*

Magnetic nanostructures in the last decade raised interest for biomedical applications, such as contrast agents in magnetic resonance imaging, drug delivery systems and hyperthermia. Among the open issues preventing their full exploitation as therapeutic agents, reliable and reproducible methods of synthesis and functional capability have to be established. Recently, self-assembling of polystyrene nanospheres was used to obtain $Ni_{80}Fe_{20}$ free-standing nanodisks [1]. Transmitted electrons image (STEM) of nanodisks (diameter and thickness of about 630 and 30 nm) are reported in Fig. 1. An alternative process to produce magnetic nanoparticles based on the solid-state dewetting of a $Fe_{80}Pd_{20}$ thin film is here presented. STEM image of $Fe_{80}Pd_{20}$ nanoparticles obtained by such a process performed at 870°C for 300 s (diameter 300 nm and thickness 30 nm) is shown. An adequate choice of the initial thin film thickness, annealing parameters allows to finely tune the final size (up to 30 nm) and shape of free-standing magnetic nanoparticles. Room-temperature hysteresis loops and first-order reversal curves were measured to investigate the evolution of magnetic properties as a function of synthesis process. The curves are shown in Fig. 1: the nanodisks display an hysteresis loop having the typical shape of magnetisation vortex nucleation with a high coercive field (black curve in Fig. 1). Conversely, the dewetted nanoparticles are characterised by a soft magnetic behavior with a lower initial susceptibility (red curve). To study the cellular uptake, a STEM image of pancreatic cancer cells after exposure to the $Ni_{80}Fe_{20}$ nanodisks is shown in Fig. 2. The cells have been fixed on a TEM copper grid after a washing procedure: remaining nanodisks have adhered to cell membrane or have being internalised.

E6-04. A Combined Magnetic-Acoustic Device For Simultaneous, Co-aligned Application Of Magnetic And Ultrasonic Fields. *L. Barnsley*[2,1], M. Gray[1], E. Beguin[1], D. Carugo[3,1] and E. Stride[1] *1. Institute of Biomedical Engineering, University of Oxford, Oxford, United Kingdom; 2. Jülich Centre for Neutron Science, Forschungszentrum Julich, Garching, Germany; 3. Faculty of Engineering and the Environment, University of Southampton, Southampton, United Kingdom*

Recently, there has been considerable interest in magnetically functionalised microbubbles as multi-modality imaging agents and carriers for magnetically targeted drug delivery [1]. The latter application in particular requires simultaneous application of magnetic and acoustic fields to a target region. This can present a significant practical challenge, especially *in vivo* where access is typically limited. In this paper, we present a design for an integrated device capable of generating co-aligned magnetic and acoustic fields in order to accumulate microbubbles at a specific location and then to activate them acoustically. For the purposes of this proof of concept study, the magnetic component of the device was designed to concentrate microbubbles at a distance of 10 mm from the probe's surface [2], commensurate with relevant tissue depths in preclinical small animal models. The ultrasound transducer was designed to maximise the acoustic intensity in the same region. Previous studies have indicated that both microbubble concentration and duration of cavitation activity are positively correlated with therapeutic effect [3]. The ability of the device to trap and activate microbubbles was therefore assessed by a series of *in vitro* tests in a tissue mimicking phantom containing a single

vessel of 1.2 mm diameter. At a flow rate of 4.2 mm/s magnetic trapping produced an increase in intensity under B-mode ultrasound imaging consistent with the predicted accumulation profile [4]. When the microbubbles were exposed to the ultrasound field from the probe, the resulting cavitation activity was sustained for a period more than 4 times longer than that achieved with an identical acoustic field but in the absence of a magnet. The feasibility of developing a larger scale device for human applications is discussed.

E6-05. Chemical synthesis and theranostic applications of magnetic nanoparticles. *Y. Hou*[1], Y. Ju[1], H. Zhang[1] and J. Hou[1] *1. Peking University, Beijing, China*

With unique magnetic properties and feasible synthesis, magnetic nanoparticles (MNPs) have been widely used in cancer theranostics[1-4]. They can migrate to and accumulate in desired sites due to their response to external magnetic fields. They can serve as magnetic resonance imaging (MRI) contrast agents since they can decrease the transversal relaxation time of protons. They can generate heat when exposed to alternating magnetic fields, leading to cell apoptosis. Additionally, by regulating the morphology and surface modification of MNPs, they can also be used to construct drug delivery system. Among all MNPs, iron carbides are emerging as promising theranostic agents for cancer treatment. The affiliation of carbon endows iron carbides with good absorption in near-infrared (NIR) and conversion into heat and ultrasound signals for photothermal therapy (PTT) and photoacoustic tomography (PAT), respectively. Herein, we first introduce general protocle to produce monodisperse magnetic nanoparticles, and then highlight multifunctional Fe_5C_2 and Au-Fe_2C nanoparticles (NPs) with their synthetic process and theranostic applications included. Owing that Fe_5C_2 and Au-Fe_2C NPs possess magnetic features and additive photothermal characteristics, they are consequently developed as multifunctional probes for imaging-guided cancer therapy. Through modification of affinity proteins (ZHER2:342), Fe_5C_2 NPs can selectively bind to HER2 overexpressing cancer cells. T2-weighted MRI and PAT signals are readily observed, and tumors are effectively ablated by PTT under NIR irradiation [5-8]. Likewise, the ZHER2:342-binding Au-Fe_2C NPs are capable of MRI/multispectral photoacoustic tomography/computed tomography tri-modal imaging-guided PTT. To enhance cancer therapeutic efficiency, anticancer drug doxorubicin is loaded into bovine serum albumin coated Fe_5C_2 NPs, combining PTT with chemotherapy. Such nanoplatform can respond to NIR and acidic environments, and exhibit burst drug release.

E7-01. Magneto-plasmonic nanostructures and crystals: principles and applications. *P. Vavassori*[1,2], M. Pancaldi[1] and A. Lopez-Ortega[1] *1. CIC nanoGUNE Consolider, San Sebastian, Spain; 2. IKERBASQUE, Basque Foundation for Science, Bilbao, Spain*

Plasmons play a large role in the optical properties of metals. The rapidly developing field of magnetoplasmonics merges the concepts from plasmonics and magnetism to realize novel and unexpected phenomena and functionalities for the manipulation of light at the nanoscale. Owing to the intertwined optical and magneto-optical properties, magnetoplasmonics may offer a smart toolbox for magnetically tuneable optical ultrathin surfaces and metasurfaces. Here we review recent advances in the research on magnetoplasmonic nanoantennas and two-dimensional magnetoplasmonic crystals. From the one side, they contributed to broaden the understanding and control of optics at the nanoscale. From the other side, magnetoplasmonic nanoantennas and surfaces have already shown a clear path towards applications to variety of emerging technologies as, e.g., ultrasensitive molecular sensing and ultrathin optical devices. The fundamentals aspects of the physics underlying the optical behavior of magnetoplasmonic metamaterials are first briefly introduced [1-3]. A survey of applications to a variety of emerging technologies is presented as an example of their broad scientific and technological perspectives, namely: - magnetoplasmonic nanoantennas based surfaces allowing for ultra-sensitive and label-free molecular detection, which are expected to have a prominent impact on biochemistry and biomedicine [4-8]; - ultra-thin 2D surfaces, built on magnetoplasmonic bimetallic meta-atoms, where the chiral light transmission is modulated by the externally applied magnetic field [9-10]; - 2D magnetoplasmonic crystals, namely plasmonic crystals made of a periodic array of nanoatennas or holes in a ferromagnetic layer, which support collective modes (surface lattice resonances) or surface plasmon polariton modes and display a two-dimensional photonic band structure that can be engineered to obtain tailored and enhanced magneto-optical response [11-14]. - thermoplasmonics using magnetoplasmonic nanoantennas, for harvesting electromagnetic radiation energy and convert it in heat, which can be used to tune the magnetization reversal of the nanostructures [15].

E7-02. Resonant magneto-optically active structures: external control and enhancement. *A. García-Martín*[1] *1. Instituto de Micro y Nanotecnologia - IMN (CNM-CSIC), Madrid, Spain*

The possibility to create and manipulate nanostructured materials encouraged the exploration of new strategies to control the electromagnetic properties without the need to modify its physical structure, i.e. by means of an external agent. An approach is the combination of magneto-opticaly active and resonant materials (e.g. plasmonic modes), where it is feasible to control the optical properties with magnetic fields in connection to the excitation of resonances [1] (magnetoplasmonics). Here I will review the fundamental aspects behind magneto-optically active resonant nanostructures and then show that they can be employed in a wide variety of systems and ranges of the electromagnetic spectrum. I will specifically show that these structures: (i) modulate the propagation wavevector of SPPs [2], which allows the development of label free sensors with enhanced capabilities [3-5] (ii) enhance the magneto-optical response in isolated entities as well as films, in connection with a strong localization of the electromagnetic field [6-8] (iii) actively control thermal emission and the radiative heat transfer between objects in the near and far field [9-11] (iv) enable the appearance of novel, magnetic-field driven phenomena in the field of optical forces and nanoparticle maniputlation [12]

E7-03. Enhanced magneto-optical response of 0-D magneto-plasmonic nanostructures. S.D. Pappas[1], P. Lang[1], M. Aeschlimann[1] and *E. Papaioannou*[1] *1. Physics, TU Kaiserslautern, Kaiserslautern, Germany*

Plasmonic resonances can enhance the magneto-optical effects exhibited by adjacent ferromagnetic materials [1,2]. In this work, we reveal the anomalous enhancement of the magneto-optical Kerr response (MOKE) exhibited by thin films of the ferrimagnetic dielectric bismuth substituted yttrium iron garnet (Bi-YIG), induced by localized surface plasmons (LSPs) in gold nanoparticles (AuNPs). The resonant frequency of the LSPs has been revealed with the aid of optical UV-VIS spectrophotometry. A Bi-YIG sample containing no nanoparticles was also used as a reference.

The magneto-plasmonic response was studied with the aid of a spectroscopic MOKE setup. The experimental results reveal an anomalous magneto-optical response for the sample containing Au nanoparticles close to the LSP resonances. In order to gain insight into the mechanism of the exhibited anomalous Kerr effect, the Near Field enhancement has been simulated and correlated to the corresponding Far Field results.

E7-04. Geometric frustration in a hexagonal array of plasmonic nanoelements. A. Conde-Rubio[1,2], A. Fraile Rodríguez[1,2], F. Perez-Murano[3], X. Batlle[1,2] and *A. Labarta*[1,2] *1. Departament de Física de la Matèria Condensada, University of Barcelona, Barcelona, Spain; 2. Institut de Nanociència i Nanotecnologia (IN2UB), University of Barcelona, Barcelona, Spain; 3. Institut de Microelectrónica de Barcelona (IMB-CNM, CSIC), Bellaterra, Spain*

Inspired by frustrated magnetic systems, the effect of geometric frustration in the optical response of plasmonic arrays of nanoelements is studied. We present the case of a hexagonal lattice of Au nanoasterisks arranged such that the gaps between neighboring elements are small and lead to strong near-field coupling. This is associated with low energy modes in the near infrared. Besides, far-field interactions yield higher-order collective modes in the visible that follow the translational symmetry of the lattice and show enhancements of the electric field over large areas of the array. However, the dipolar excitations of the gaps in the hexagonal array are geometrically frustrated for interactions beyond nearest neighbors, resulting in the destabilization of the low energy modes. This gives rise to a complex interplay between the two kinds of modes resulting in a slow decaying response in which the system fluctuates through a wide range of excitations combining the localized and collective modes, sharing features with geometrically frustrated magnetic systems. Moreover, the use of a metal-insulator-metal configuration increases the absorption of the system reaching values above 90% for the peaks corresponding to both modes. In short, we observe an almost perfect absorption around the visible and near-infrared regions and an extended time response as compared to the excitation pulse, both as a result of the geometrical frustration of localized dipolar excitations in the hexagonal lattice. Hence, this system could be of interest for enhanced spectroscopies such as Raman or photoluminescence or other applications related to light absorption. This work was supported by Spanish MINECO (MAT2015-68772- P project and ACR Ph.D. contract BES-2013-065377), the Spanish ICTS Network MICRONANOFABS, partially supported by MINECO, and European Union FEDER funds.

E8-01. Odd-Frequemcy Superconductivity in Sr_2RuO_4 Measured by Kerr Rotation. *A. Black-Schaffer[1] 1. Physics and Astronomy, Uppsala University, Uppsala, Sweden*

In this talk I will show that essentially all multi-band superconductors host bulk odd-frequency superconductivity. Applying these results to the chiral topological superconductor Sr_2RuO_4, we find that an intrinsic Kerr effect is direct evidence for this odd-frequency state [1]. We use both general two- and three-orbital models, as well as a realistic tight-binding description of Sr_2RuO_4 to demonstrate that odd-frequency pairing arises due to finite hybridization between different orbitals in the normal state, and is further enhanced by finite inter-orbital pairing. I will also demonstrate that a very similar relationship is present between odd-frequency pairing and Kerr effect in the heavy-fermion superconductor UPt_3 [2]. If time permits, I will show how an analogous bulk odd-frequency superconducting state also appears in a buckled quantum spin Hall insulator, such as silicene, proximity-coupled to a conventional superconductor [3].

E8-02. Skyrme Insulators: Insulators at the Brink of Superconductivity. *O. Erten[1,2], P. Chang[3], P. Coleman[4] and A. Tsvelik[5] 1. Arizona State University, Tempe, AZ, United States; 2. Max Planck Institute for the Physics of Complex Systems, Dresden, Germany; 3. Rutgers University, Piscataway, NJ, United States; 4. Physics and Astronomy, Rutgers University, Piscataway, NJ, United States; 5. Brookhaven National Laboratory, Upton, NY, United States*

Current theories of superfluidity are based on the idea of a coherent quantum state with topologically protected quantized circulation. When this topological protection is absent, as in the case of 3He-A, the coherent quantum state no longer supports persistent superflow. Here, we argue that the loss of topological protection in a superconductor gives rise to an insulating ground state. We specifically introduce the concept of a Skyrme insulator to describe the coherent dielectric state that results from the topological failure of superflow carried by a complex-vector order parameter. We apply this idea to the case of SmB_6, arguing that the observation of a diamagnetic Fermi surface within an insulating bulk can be understood as a realization of this state. Our theory enables us to understand the linear specific heat of SmB_6 in terms of a neutral Majorana Fermi sea and leads us to predict that in low fields of order a Gauss, SmB_6 will develop a Meissner effect.

E8-03. Fluctuation Effects at the Onset of $2k_F$ Density Wave Order with One Pair of Hot Spots in Two-Dimensional Metals. *J. Sykora[1], T. Holder[2] and W. Metzner[1] 1. Max Planck Institute for Solid State Research, Stuttgart, Germany; 2. Weizmann Institute of Science, Rehovot, Israel*

We analyze quantum fluctuation effects at the onset of charge or spin density wave order in two-dimensional metals with an incommensurate $2k_F$ wave vector connecting a single pair of hot spots on the Fermi surface. We compute the momentum and frequency dependence of the fermion self-energy near the hot spots to leading order in a fluctuation expansion (one loop). Non-Fermi liquid behavior with anomalous frequency scaling and a vanishing quasi-particle weight is obtained. The momentum dependence yields a divergent renormalization of the Fermi velocity and a flattening of the Fermi surface near the hot spots. Going beyond the leading order calculation we find that the one-loop result is not self-consistent. We show that any momentum-independent self-energy with a non-Fermi liquid frequency exponent wipes out the peak of the polarization function at the $2k_F$ wave vector, and thus destroys the mechanism favoring $2k_F$ density waves over those with generic wave vectors. However, a $2k_F$ density wave QCP might survive in presence of a sufficiently flat renormalized Fermi surface.

E8-04. Exact Solution to Interacting Kitaev Chain at Symmetric Point. *F. Zhang[1], J. Miao[1], H. Jin[2] and Y. Zhou[2] 1. Kavli Institute for Theoretical Sciecnes, Univ of Chinese Academy of Sciences, Beijing, China; 2. Physics Department, Zhejiang University, Hangzhou, China*

Kitaev chain model with nearest neighbor interaction U is solved exactly at the symmetry point $\Delta=t$ and chemical potential $\mu=0$ in open boundary condition. By applying two Jordan-Wigner transformations and a spin-rotation, such a symmetric interacting model is mapped to a non-interacting fermion model, which can be diagonalized exactly. The solutions include topologically non-trivial phase at $|U|<t$ and topologically trivial phase at $|U|>t$. The two phases are related by dualities. Quantum phase transitions in the model are studied with the help of the exact solution.

E9-02. Quantum Oscillation Studies of $YbNi_4P_2$ with prototypical Ferromagnetic Quantum Critical Point. *S. Friedemann[1], K. Kliemt[2], P. Ross[2], E. Eljaouhari[3], G. Zwicknagl[3], A. McCollam[4] and C. Krellner[2] 1. HH Wills Laboratory, University of Bristol, Bristol, United Kingdom; 2. Physics, Goethe-University Frankfurt, Frankfurt, Germany; 3. Institut für Mathematische Physik, TU Braunschweig, Braunschweig, Germany; 4. High Field Magnet Laboratory, University of Radboud, Nijmegen, Netherlands*

$YbNi_4P_2$ is a rare example of a heavy-fermion compound with ferromagnetic (FM) order. Moreover, a FM quantum critical point (QCP) can be accessed if phosphorous is partially substituted by arsenic [1]. The presence of a FM QCP makes $YbNi_4P_2$ unique as FM QCPs are avoided in most metallic systems through a change of the transition to 1st order or through an intervening antiferromagnetic phase. The preservation of the FM QCP is theoretically suggested to be due to an effective one-dimensional electronic structure. Here, we present quantum oscillation measurements performed at high magnetic fields and low temperatures. We compare the angular dependency of the observed frequencies with both predictions from band structure calculations treating the 4*f* electrons as core electrons and predictions from fully renormalized band structure calculations. Finally, we analyse the evolution of quantum oscillations through the Lifshitz transitions inferred from transport and thermodynamic measurements [2]. Whilst the measurements detect closed orbits, they provide valuable information into the electronic structure in the absence of other probes of the Fermi surface.

E9-03. Disorder as an Electronic Transport Tuning Parameter in the Strange Metal Normal State of $CeCoIn_5$. *N. Maksimovic[1,2], I. Hayes[1,2], S. Jang[3] and J. Analytis[4,2] 1. Physics, University of California Berkeley, Berkeley, CA, United States; 2. Lawrence Berkeley National Laboratory, Berkeley, CA, United States; 3. Lawrence Berkeley National Lab, San Ramon, CA, United States; 4. University of California, Berkeley, Berkeley, CA, United States*

$CeCoIn_5$ displays similar normal state transport phenomenology to other unconventional superconductors near a putative quantum critical point, most notably a resistivity linear in temperature above the superconducting transition, a hallmark of the strange metal. Pure $CeCoIn_5$ is believed to exist near a field-tuned quantum critical point, with signatures in magnetoresistance at finite temperature. We show that cadmium, a non-magnetic dopant of the indium site, at low concentration acts as an electronic transport tuning parameter identically to magnetic field over a wide range of temperature in the strange metal in $CeCoIn_5$. This result has an interpretation in the context of the global phase diagram of $CeCoIn_5$.

E10-01. Magnetic properties of geometrically frustrated $SrLn_2O_4$ compounds. *S. Riberolles*[1,3], G. Balakrishnan[1], M. Ciomaga Hatnean[1], O. Petrenko[1], P. Manuel[2], C. Ritter[3] and N. Qureshi[3] *1. Physics, The University of Warwick, Coventry, United Kingdom; 2. STFC, Didcot, United Kingdom; 3. Institut Laue-Langevin, Grenoble, France*

We present a series of neutron scattering studies on the geometrically frustrated compounds $SrLn_2O_4$ (Ln = Nd, Gd, Er). The crystal structure of these materials consists of a succession of hexagons and triangles inducing a high degree of magnetic frustration arising from incompatibilities between lattice and magnetic interaction geometries [1]. The strong influence of magnetic frustration in different members of the $SrLn_2O_4$ family is evident from the complex magnetic structures they exhibit at temperature well below θ_{CW} [2-4]. Magnetic anisotropy often plays as important a role in these magnets as the competing exchange and dipolar interactions. Powder neutron diffraction (PND) techniques were employed to determine the magnetic structures of $SrNd_2O_4$ and $SrGd_2O_4$. We report the onset of a magnetic order modulated by a k=(0,1/2,1/2) propagation vector for $SrNd_2O_4$ below 2.3 K. For $SrGd_2O_4$, two different structures are subsequently stabilised at 2.73 and 0.47 K (see Fig). Magnetic diffuse scattering was also investigated by PND techniques revealing the presence of strong magnetic correlations in these systems well above T_N. For $SrEr_2O_4$, we focused on the field-induced behaviour and studied the magnetisation process [2,3] using single crystal neutron diffraction. We have produced maps of the neutron scattering intensity at dilution fridge temperatures for two orientations of the field. For H//c, a magnetic field of only 0.3 T is sufficient to replace the zero-field low-temperature long range order by a state governed by much shorter correlations, while in fields above 0.7 T, long range ferromagnetic order is stabilised. For H//a, a short range *two up one down* magnetic structure is stabilised in intermediate fields, prior to a complete field polarisation of the system.

Institut Laue Langevin, Grenoble, France*

In the modelling of magnetic insulators, one often assumes only the interactions between dipolar moments. However, in *f*-electron systems, multipolar interactions can be of importance [1]. The multipoles correspond to magnetic dipoles, electric quadrupoles, magnetic octupoles, etc. Recent examples of multipolar interactions in frustrated magnets are found in the rare-earth pyrochlores. The effects of electric quadrupole interactions have been enlighten in Pr-based pyrochlores [2,3]. The presence of a quadrupolar order has also been reported in off-stoichiometric $Tb_2Ti_2O_7$ [4]. We here report the effects of electric quadrupole interactions in another family of frustrated magnets, the SrR_2O_4 compounds. Their magnetic properties are dominated by rare-earth magnetic ions *R* that form frustrated zigzag chains [5,6]. Neutron scattering measurements on $SrDy_2O_4$ and $SrHo_2O_4$ reveal diffuse scattering patterns that can be related to the correlations between the dipolar magnetic moments. For these two compounds, the effects of electric quadrupolar interactions appear in the excitation spectrum measured by inelastic neutron scattering. Specifically, in $SrDy_2O_4$, a crystal-electric field level exhibits a dispersion with an energy scale that is an order of magnitude larger than the energy scale of the dipolar magnetic correlations. This observation can be explained by a large quadrupole-quadrupole coupling. This 'hidden' energy scale can exist because the Kramers ground state doublet is

insensitive to quadrupolar interactions. In $SrHo_2O_4$, a complete description of the excitation spectrum also requires to consider quadrupole-quadrupole coupling. Furthermore, a direct coupling between the quadrupolar degrees of freedom and the lattice appears in the Ho analogue. This is observed by hybrid magnetoelastic modes formed from crystal-electric field levels and acoustic phonons. These results indicate the importance to consider multipolar interactions in *f*-electron systems, where competing multipolar interactions could lead to novel phenomena.

E10-03. When Three is a Crowd: Entanglement of Quantum Spins on Tripartite Lattices. *A. Thomasen*[1], J. Romhanyi[1] and N. Shannon[1]
1. Theory of Quantum Matter Unit, Okinawa Institute of Science and Technology, Onna-son, Japan

There are a number of interesting materials, which are built up of strongly coupled triangular plaquettes that form a breathing lattice. One example is the quantum spin liquid $Ca_{10}Cr_7O_{28}$ which has been observed experimentally to suppress magnetic order down to 19 mK, despite its predominantly ferromagnetic exchange interactions. This particular material has now been studied using classical monte-carlo methods, but a question that arises is whether there are fundamentally quantum excitations and how they arise. In our work we approach a simpler version of this problem, namely the breathing monolayer kagome, by investigating the effects of local entanglement. We start by diagonalizing the Hamiltonian of a single triangle of interacting spins exactly. The full wavefunction of the lattice can then be expanded as a combination of all possible trimer eigenstates. Then we decompose the system into a multiboson basis of excitations on top of an ordered ground state [1]. We show that this reproduces results of linear spin-wave theory on the same lattice, whilst at the same time including the dispersion of higher spin excitations. Whereas the effects of entangled excitations are normally not accounted for in spin-wave theory, multiboson theory gives a natural way to explore them at a local level in a basis that may be expanded by inclusion of more spins. As has been seen before this can serve to explain unconventional magnetic excitations in frustrated magnetism [2]. Having seen that this method works for the simple cases we can now apply it to more interesting geometries. It is as if we are exploring the social life of an infinite number of spins by viewing them not as individuals, but as groups of three who are regarded as a clique by the rest of the lattice. That is when their quantum nature emerges, because in physics three's a crowd.

The hexagonal swedenborgite, $CaBaCo_2Fe_2O_7$, is a chiral frustrated antiferromagnet, in which magnetic ions form alternating Kagome and triangular layers.[1] We observe a long range $\sqrt{3}\times\sqrt{3}$ antiferromagnetic order setting in below T_N=160K by single crystal neutron diffraction (see Fig. 1a).[2] Both magnetization and polarized neutron single crystal diffraction show that close to T_N spins lie predominantly in the *ab*-plane, while upon cooling the spin structure becomes increasingly canted due to Dzyaloshinskii-Moriya interactions.[3] The ordered structure can be described and refined within the magnetic space group $P31m$'. Diffuse scattering between the magnetic peaks reveals that the spin order is partial. Monte Carlo simulations based on a Heisenberg model with two nearest-neighbor exchange interactions [4,5] show a similar diffuse scattering and coexistence of the $\sqrt{3}\times\sqrt{3}$ order with disorder. The coexistence can be explained by geometrical frustration resulting in a manifold of degenerate ground states, which gives spins the freedom to vary within the long-range ordered ground state. Polarization analysis [6] of the magnetic peaks indicates the presence of long-period cycloidal spin correlations (see Fig. 1b) resulting from the broken inversion symmetry of the lattice, in agreement with our symmetry analysis.

E10-05. The Numerical Study of Quantum Phase Transitions of the Heisenberg Antiferromagnet on a Frustrated Two-Dimensional Lattice. *A. Shimada*[1], H. Nakano[2], T. Sakai[2,3] and K. Yoshimura[1] *1. Graduate School of Science, Kyoto University, Kyoto, Japan; 2. Graduate School of Material Science, University of Hyogo, Kamigori, Japan; 3. National institutes for Quantum and Radiological Science and Technology, Spring-8, Sayo, Japan*

The ground state of the spin-1/2 Heisenberg antiferromagnet on a distorted triangular lattice is studied using numerical-diagonalization method. The network of interactions is of √3 × √3-type, in which the interactions are continuously controlled among the undistorted triangular lattice, the dice lattice and the honeycomb lattice accompanied by isolated spins. The undistorted triangular lattice is a frustrated system, on the other hand the dice lattice and the honeycomb lattice accompanied by isolated spins are not frustrated. We revealed the ground state of the spin-1/2 Heisenberg antiferromagnet on a √3 × √3-type distorted triangular lattice shows interesting intermediate phases of spontaneously magnetized states, of which magnitude varying continuously with the √3 × √3-type distortion (1). The purpose of this study is to present novel information on the phase transitions at the boundaries of these nontrivial intermediate phases from several points as follows: [1] the position of the boundaries at zero temperature [2] the temperature dependence of the specific heat of this system [3] the temperature dependence of the magnetic susceptibility of this system. We obtained the following results (2-4) using both the Lanczos method and the Householder method. We draw the distortion dependence of the spontaneous magnetization for various system sizes by using Lanczos method. Moreover, we can get the temperature dependence of physical quantities for 12 sites system by the Householder method. Then, we focus on the temperature dependences of specific heat capacity and magnetic susceptibility of the 12 sites systems. The behavior of the temperature dependability of the specific heat capacity and magnetic susceptibility seem to be seriously related to the appearance of the intermediate phases at zero temperature.

E10-06. Magnetic ground states of manganese vanadate systems with 2D striped triangular lattices. *O. Garlea*[1], L.D. Sanjeewa[2], D. Pajerowski[1], M. McGuire[3], F. Ye[1] and J. Kolis[2] *1. Neutron Scattering Division, Oak Ridge National Laboratory, Oak Ridge, TN, United States; 2. Department of Chemistry, Clemson University, Clemson, SC, United States; 3. Oak Ridge National Laboratory, Oak Ridge, TN, United States*

The roles played by frustration, thermal and quantum fluctuations on the ordering properties of honeycomb and triangular-lattice systems continue to be the subject of intense research. In the layered honeycomb lattices, which are derived from the edge-sharing triangular planar lattice by removing 1/3 of the magnetic sites in an ordered fashion, the frustration arises from competing interactions rather than geometric constraints. This frustration is further enhanced by strong quantum fluctuations due to the low coordination number z = 3. Competition between first, second and third neighbor magnetic exchange interactions results in rich magnetic phase diagrams that include Néel, zigzag, stripy, and spiral orders. An increase in complexity of magnetic phase diagram may be expected for lattices with mixed hexagonal honeycomb and triangular motifs, where the spins local coordination number becomes z = 4 or 5. Such magnetic lattices have recently been found in three newly synthesized manganese vanadate materials with spins residing on two-dimensional strip-like triangular lattices [1]. We will discuss the results of recent elastic and inelastic neutron scattering measurements carried out on these magnetic systems. While the inelastic data confirmed the strong two-dimensionality of the magnetic interactions, the elastic measurements revealed the onset of very complex antiferromagnetic orderings. We found evidence of coexisting short-range and long-range orders, ground-states characterized by multiple ordering vectors, or incommensurate spin structures.

F1-01. Inverse spin Hall effect in Mn-Sn amorphous alloy thin film. *D. Qu*[1], T. Higo[1,2], T. Nishikawa[1], K. Matsumoto[1], K. Kondou[3], D. Hamane[1], R. Ishii[1], P. Muduli[1], Y. Otani[1,3] and S. Nakatsuji[1,2] *1. ISSP, The University of Tokyo, Kashiwa, Japan; 2. JST-CREST, Tokyo, Japan; 3. RIKEN-CEMS, Wako, Japan*

Very recently, the non-collinear Kagome lattice antiferromagnets Mn_3X (*X=Sn, Ge, Ga*) have attracted a lot of attention because of their large anomalous Hall and Nernst effects (AHE and ANE) while being antiferromagnets with negligible magnetic moment [1-4]. These properties are not only scientifically interesting but also could lead to technological advances. The large AHE and ANE in Mn_3X are caused by the large fictitious field due to the Berry phase curvature in the momentum space. Since the AHE and the inverse spin Hall effect (ISHE) share the same origin, the injection of pure spin current into these materials could potentially engender large ISHE, bring on exciting physics and possible applications. In this work, we studied the ISHE in the α-Mn and the Mn-Sn amorphous alloys. The spin current is generated in the ferromagnetic insulator Yttrium Iron Garnet (YIG) by the longitudinal spin Seebeck effect and is then injected into the attached metal layer (α-Mn or Mn-Sn). By systematic study in a series of samples with different thicknesses, we obtained the spin Hall angle (θ_{SH}) and spin diffusion length (λ_{sd}) of both Mn and Mn-Sn alloy. Interestingly, we found that by doping Mn with 18% Sn, the θ_{SH} of the amorphous non-magnetic Mn-Sn alloy is increased by as large as 20 times while the resistivity (ρ) is reduced by about 10 times. Most importantly, the spin Hall conductivity (σ_{SH}) of the Mn-Sn alloy is nearly 200 times larger than pure Mn. The large enhancement of the spin Hall angle is further corroborated by the spin pumping measurement. These results not only serve as essential references for studying the pure spin current phenomena in Mn-based alloys, but also offer a promising method for exploring high energy efficient spin Hall materials.

F1-02. Symmetry analysis of electrical switching of antiferromagnet. *H. Watanabe*[1] and Y. Yanase[1] *1. Department of Physics, Kyoto University, Kyoto, Japan*

Antiferromagnetic states are insensitive to electric or magnetic perturbations, since it has no net electric or magnetic polarizations. Several approaches have been proposed to operate the antiferromagnetic states [1, 2]. Especially, the switching scheme of current-induced antiferroic spin-orbit torque recently attracted much attention in the field of antiferromagnetic spintronics [3]. This scheme has been proposed by the theoretical investigation and conducted by the celebrated experiment of Wadley *et. al* [4]. In the presentation, we conduct the symmetry analysis of current-induced AFM switching. The antiferroic (Neel) spin-orbit torque is derived from the local non-centrosymmetric property of crystal structure as the previous theoretical studies clarified [4, 5, 6]. With the use of representation theory and magnetic point group, we identify what "antiferromagnetic order" can be switched by applying electric current. Although previous studies have focused on the simple antiferromagnets [6], our symmetry analysis can be applied to the systems with complex magnetic configurations. Following the symmetry analysis, we propose the candidates for the switchable antiferromagnets and also discuss the relation with the ferro-toroidic order and the possibility to observe it.

F1-03. Generation of Néel field in anti-ferromagnetic nanowire by a sloped electric field. K. Kubota[1], K. Yamada[2] and *Y. Nakatani*[1] *1. University of Electro-communications, Tokyo, Japan; 2. Gifu University, Gifu, Japan*

Since a proposal of a racetrack memory, a magnetic domain wall (DW) motion in a magnetic nanowire has attracted attention as a novel technique for memory development [1]. Recently, it has reported that the DW motion velocity in Anti-ferromagnets (AFM) is much faster than that in ferromagnets [2-6] and, the DW motion in AFM has been gathering attentions. The DW in AFM with Dzyaloshinskii-Moriya interaction (DMI) can be moved by a spin-orbit transfer torque [4-5]. Whereas the DW in AFM without DMI can be moved by Néel field generated by Néel Spin Orbit Torque (NSOT) [7, 8]. In this study, we propose a method to generate Néel field by using a sloped electric field (SEF) and demonstrate the DW motion in AFM by micromagnetic simulations. In the simulation, we assumed that K_u is decreased by the electric field, therefore K_u is decreased linearly from left edge to the right edge in the wire by SEF (Fig. 1) [9]. The reduction rate of K_u is defined as ΔKu (erg/cm^4) [9]. Because K_u changes by SEF, the DW energy (where A is the homogeneous exchange stiffness constant) [10] changes with the position in the nanowire. The DW moves in the direction of decreasing DW energy (K_u) even in AFM wire. An effective magnetic field should be applied to the moving DW. The directions of the effective field to M_1 and M_2 sublattices in moving DW in AFM should be opposite (Néel field) (see Fig.1). In this way, the Néel field is generated by SEF. To confirm the generation of the Néel field by SEF, we simulated the DW

motion in AFM by SFE. Fig.2 shows the effect of the ΔK_u on the DW motion velocity (v). The Néel field (H_k) generated by the SEF can be obtained in the same method as [9]; , (1) where M_s is the saturation magnetization. Fig.2 also shows the effective Néel field (H^{eff}_k) generated by the SEF and the DW motion velocity obtained by (where g, D and are the gyromagnetic ratio, DW width and the Gilbert damping constant respectively). The simulation results agree very well with the DW velocity of v_{Anlay} obtained by Eq. (1). It shows that Néel Field can be generated in AFM by SEF.

The magneto-optical Kerr effect (MOKE) has been intensively studied in a variety of ferro- and ferrimagnetic materials because it provides a powerful probe for electronic and magnetic properties as well as for various applications including magneto-optical recording. Recently, there has been a surge of interest in antiferromagnets (AFMs) as prospective spintronic materials owing to their vanishingly small stray field and faster spin dynamics compared to their ferromagnetic counterparts [1]. In fact, the MOKE has proven useful for the study and application of the antiferromagnetic (AF) state. Although limited to insulators, certain types of AFMs are known to exhibit a large MOKE, as they are weak ferromagnets due to canting of the otherwise collinear spin structure. In the fully compensated collinear AFMs, the MOKE has been believed to be absent. However, recent theoretical and experimental progress has revealed that certain non-collinear AFMs can exhibit a large anomalous Hall effect (AHE) in zero magnetic field despite a vanishing magnetization [2-5]. Because the AHE has the same symmetry requirements as the MOKE, it is possible that the same class of AFMs may exhibit a Kerr rotation. Thus, the recent experimental discovery of a large AHE in the non-collinear AFM Mn_3Sn [3], which is recently reported to be a Weyl magnet [6], as well as its soft response to a magnetic field give promise for a potentially large MOKE character. Here we report the first observation of a large MOKE signal in an AF metal at room temperature [7]. In particular, we find that despite a vanishingly small magnetization of $M \sim 0.002\ \mu_B$/Mn, the non-collinear AF metal Mn_3Sn exhibits a large zero-field MOKE with a polar Kerr angle of 20 mdeg, comparable to ferromagnetic metals. Our first-principles calculations have clarified that ferroic ordering of magnetic octupoles in the non-collinear Néel state may cause a large MOKE even in its fully compensated AF state without spin magnetization. This large MOKE further allows imaging of the magnetic octupole domains and their reversal induced by magnetic field. The observation of a large MOKE in an AF metal shall open new avenues for the study of domain dynamics as well as spintronics using AFMs.

Non-collinear hexagonal antiferromagnets Mn_3Z (Z = Ge and Sn) have received much attention in recent years, since they exhibit remarkable structural, magnetic and magnetotransport properties. These compounds show giant anomalous Hall effect (AHE) [1,2], although their net magnetization is almost zero, driven by non-vanishing Berry curvature arising from their chiral spin structure. Until now, the only reports on these materials study bulk polycrystalline or single crystal samples. Here, we demonstrate the growth of the Mn_3Sn compound in thin film form. Mn_3Sn films with different thicknesses were heteroepitaxially grown on ZrO_2 substrates with a Ru underlayer. We find that the films crystallize in the hexagonal $D0_{19}$ structure with (0001) preferred orientation and the c-axis normal to the film plane [Fig. 1(a)]. TEM analysis confirms the crystal structure of the films, while at the same time reveals a nearly perfect heteroepitaxy of the epilayers. Furthermore, chemical mapping shows that the films are homogeneous and there is no intermixing between the film and the underlayer. The Mn_3Sn films exhibit a small net magnetization with in-plane anisotropy [Fig. 1(a)]. Additionally, we have studied the exchange bias effect in a Mn_3Sn/Py bilayer. Exchange bias fields of H_{EB}=14 mT can be achieved, with a blocking temperature very close to room temperature. The exchange bias not only confirms the antiferromagnetic nature of the Mn_3Sn films, but can also be used to investigate spin transfer phenomena applicable to the developing field of antiferromagnetic spintronics.

School of Physics, International Center for Quantum Materials (ICQM), Beijing, China*

Despite intense research studies on spin current transport though antiferromagnetic (AFM) insulators, the mechanism remains obscure [1]. The recent development of synchrotron-based x-ray pump-probe measurement offers an element- and time-resolved spin pumping and precession measurement [2]. Here we report an experimental study of the ac spin current transmission through CoO layer in Py($Fe_{20}Ni_{80}$)/Ag/CoO/Ag/$Fe_{75}Co_{25}$/MgO(001) system. With ferromagnetic resonance (FMR) of the Py layer pumping spins current into the CoO layer, we measured the spin processions of the FeCo layer. The result shows that the FeCo spin precession amplitude exhibits a peak around the CoO's Neel temperature (T_N), showing the existence of an ac spin current transported through the CoO layer around T_N, similar to the behavior of dc spin current reported in the literature [3,4,5]. Then we prepared Py/Ag/CoO/MgO(001) system with rotatable CoO AFM spin to directly study the CoO spin processions using X-ray Magnetic Linear Dichroism (XMLD). The CoO AFM spins show non-detectable precession of the AFM spin axis at the Py FMR frequency at both 220 K and 280 K with an estimated up-limit at least one order of magnitude smaller than the FeCo spin precession, suggesting that the ac spin-current in the CoO is carried by thermal magnons rather than by a coherent precession of the AFM equilibrium spin axis. Using X-ray Magnetic Circular Dichroism (XMCD), we identified submonolayer uncompensated Co ferromagnetic spins at the Ag/CoO interface which process with the Py spins. The combined result of spin dynamics of the uncompensated CoO FM moment (before spin current entering the CoO layer) and the FeCo spins (after spin current transport through CoO layer) reveals a temperature-dependent spin current attenuation in the CoO layer.

F1-07. Imaging Domains in a Zero-moment Half-metal. *M. Coey*[1], K. Siewierska[1] and R. Schaefer[2] *1. Trinity College, Dublin, Dublin, Ireland; 2. IFW Dresden, Dresden, Germany*

We have a good choice of methods of imaging domains or domain walls in a ferromagnet, at least at the surface of a specimen, by imaging the stray field distribution (atomic force microscopy, colloid methods), the magnetic induction *B* in very thin specimens (Lorentz transmission electron microscopy), or the polarization of transmitted or reflected light (magneto-optic Faraday or Kerr effect). None of these methods works in an antiferromagnet, where we have to resort to polarized neutron beam tomography or X-ray linear magnetic dichroism at synchrotron light sources [1]. However the discovery of perfectly- compensated half metallic ferrimagnetic films of Mn_2Ru_xGa (MRG)) with perpendicular magnetization [2] opens up new imaging possibilities for domains in magnetically-ordered materials with no net moment. There are two, inequivalent but oppositely-aligned Mn sublattices with equal and opposite sublattice moments, but only one of them contributes spin polarized conduction electrons at the Fermi energy. MRG looks like an antiferromagnet from the outside, but from the point of view of electronic structure it resembles a highly spin polarized ferromagnetic metal. Since magnetic anisotropy axis is perpendicular to the MRG film, it is possible to image the domains *directly* by magneto-optic Kerr effect (MOKE). The domains are seen to have irregular outlines, with dimensions of order 20 microns. The irregular outlines suggest that the domain wall energy per square metre is significantly smaller than in typical ferromagnets. The hysteresis loop of a sample at room temperature, well above the compensation temperature deduced from the MOKE images, is shown in Fig. 1 (the magnetic axis lies perpendicular to the film plane). The evolution of the domain patterns around the positive and negative switching fields are shown in Fig. 2. In some cases, a topological Hall effect may be inferred from a direct comparison of the Kerr and anomalous Hall loops.

F1-08. Probing Interface Magnetism in $Ir_{20}Mn_{80}$\Pt Bilayers.
M. Ribeiro[2], T. Pham[2,1], J. Park[2] and T. Kim[2,1] *1. Department of Physics, Ewha Womans University, Seoul, The Republic of Korea; 2. Center for Quantum Nanoscience, Institute for Basic Science (IBS), Ewha Womans University, Seoul, The Republic of Korea*

Based on unique properties of antiferromagnetic materials (AFMs) such as zero net magnetization, non-collinear magnetic structure, and considerable spin-orbit coupling, the AFM-based spintronics has attracted great attention to develop future spintronic devices with low-power assumption, fast operation speed, and high-integration [1]. Demonstration of large spin Hall effect (SHE) and inverse spin Hall effect (ISHE) signals in AFM-based spintronic devices is of current interest in exploring spin current phenomena. Antiferromagnetic (AF) alloys such as Cu-Au-I-type AFMs with both heavy elements and magnetic atoms are known as ideal systems to generate and detect spin current. Polycrystalline IrMn is a prototypical Cu-Au-I-type antiferromagnet commonly used as an exchange layer in spin-valve devices. To build an effective AFM-based device, investigation of the effect of AF ordering on SHE or ISHE in IrMn-based simple heterostructures is required, which is even more challenging at the interface (or surface). Here, we focus on $Ir_{20}Mn_{80}$\Pt bilayers to explore their interface effects on the magnetic properties and ISHE as well. Using UHV-MBE technique, the 3-nm-thick Pt was deposited *in situ* through a meal shadow mask onto $Ir_{20}Mn_{80}$ films with thickness ranging from 1.5 to 40 nm. The shadow mask was used to define 50-μm-wide and 400-μm-long Hall bars. Prior to a systematic investigation of the spin Hall magnetoresistance (SMR) properties for IrMn\Pt devices, the interface microstructure of IrMn thin films was investigated by Atomic Force Microscopy (AFM). For IrMn-film\Pt-Hall-bar samples zero field cooled (ZFC) and field cooled (FC) resistivity measurements as a function of temperature in different directions of magnetic field revealed clearly the existence of AF order at the interfaces below 79 K, which is confirmed by the Neel temperature observed in the M-T curves using SQUID. Moreover, we observed that MR and magnetic properties strongly depend on the interface properties of IrMn\Pt thin films. Our results provide further understanding of magneto-transport in metallic AFMs.

F1-09. Study of Resistive switching on $La_{0.3}Ca_{0.7}MnO_3/YBa_2Cu_3O_7$ Bilayers Deposited by Sputtering DC.
J.S. Betancourt[1], *J.E. Ordoñez*[1], C.W. Sanchez[1], M.E. Gomez[1] and W. Lopera[1] *1. Thin films group, Universidad del Valle, Cali, Colombia*

Devices based on phenomenon of resistive random access memory (RRAM) have been studied on different transition metal oxides. In this materials the favorable properties as low power consumption, simplicity, long retention time and even multilevel switching are very important in the eld of resistive switching. A basic device is generally a capacitor like structure with an insulating oxide sandwiched between two conducting electrodes [1], [2]. Different mechanism is associated to explain resistive switching such as the formation and rupture of local conducting laments formed by oxygen vacancies and/or di used metallic ions from the electrode [3] and the interface type attributed to oxygen vacancy related redox processes at the metal/oxide interface. We have deposited $La_{0.3}Ca_{0.7}MnO_3$ (LCMO) films on $YBa_2Cu_3O_7$(YBCO)/$SrTiO_3$(STO) and Nb doped $SrTiO_3$ (STO:Nb) like a possible route to study the resistive swithiching on complex oxide. In this case, LCMO (t_{LCMO}= 250 nm) was used like insulator material in contact with YBCO (t_{YBCO}=40 nm) and STO:Nb like bottom electrode. From XRD we found that the LCMO and YBCO layers growth textured aligned with substrate with c_{LCMO} =3.87 Å and c_{YBCO} =3.855 Å, respectively. The LCMO surface was analyzed by Atomic force microscopy to study the influence on roughness and grain size associated to YBCO like a bottom electrode. The electrical properties with temperature using Au like top electrode, and the I vs V curves allow us investigate the implications of the stacking an oxide as a YBCO like a botton electrode and a complex oxide like LCMO as an insulator layer with the phenomena of resistive switching. The movement of the oxygen vacancies, conducting mechanisms like space charge limited conduction (SCLC) and a structure deformations were taken in count for this study. This work has been supported by the CENM and the intern research project CI 7999 - the Universidad Del Valle, Cali, Colombia.

Department of Mathematical and Computer Science, Physical Sciences and Earth Sciences, University of Messina, Messina, Italy*

Antiferromagnetic (AFM) materials are suitable for spintronic devices working in the THz range [1-2]. The theoretical approach for studying them is generally based on the analysis of the magnetizations of the two AFM sublattices. Our micromagnetic code performs numerical simulations of an AFM layer by solving the Landau-Lifshitz equations of motion for the magnetizations M_1 and M_2 of the two sublattices. In particular, here we propose an AFM spin-Hall oscillator, consisting of an AFM layer coupled to a heavy metallic layer (Fig.1). The AFM layer is square-shaped, with in-plane dimensions 40x40 nm^2, and is modeled with in-plane anisotropy (along x). The heavy metal is designed with 4 terminals that can be used to apply a charge current, and/or to read the device resistance. The direction of the spin-Hall polarization p can be modified by applying the current differently at the terminals [3]. Simulations highlight that, whatever the direction of p, the magnetizations of the sublattices precess around that direction, as sketched in the inset of Fig.2, with uniform magnetic configurations. Excitation, moreover, shows a hysteretic behavior, since the current to switch off the dynamics is lower than the ignition current. Frequency of dynamics is in the range of THz, and, in particular, the component of the magnetization along the spin polarization has a double frequency with respect to the other components. Such properties, highlighted within a systematic study performed by varying the exchange constant A, the damping α, and the thickness d of the AFM, are in agreement with theoretical predictions [2]. Also the obtained blue-shift of the frequency with the applied current (see an example for a particular set of parameters in Fig.2) was expected by theory. By means of simulations, we have also predicted that dynamics in presence of Dzyaloshinskii–Moriya interaction are characterized by a translation of non-uniform domain walls along the AFM layer.

F1-11. Interfacial magnetic-phase transition mediated large perpendicular magnetic anisotropy in FeRh/MgO by a heavy transition-metal capping. *O. Dorj*[1] *1. Department of Physics, Incheon National University, Incheon, The Republic of Korea*

Stacking a magnetic memory junction in spintronic devices necessarily involves making contacts with a transitional-metal capping electrode. In this talk, we will present results of our recent first-principles calculations on a cruicial role of heavy transition-metal (HTM) capping on magnetic-phase transition from antiferromagnetic to ferromagnetic order and large perpendicular magnetic anisotropy (PMA) found in Ta- and Os-capped FeRh films on MgO substrate. While magnetization of FeRh films reorients from in-plane to PMA when in contact with MgO, the presence of HTM capping further enhances PMA up to an order of magnitude in energy, which is associated with the occurrence of ferromagnetism at the interface. Such a large PMA is mainly driven by the interplay between the out-of-plane Fe 3*d*–O 2*p* and Ta (Os) 5*d*–Fe 3*d* hybridized orbital states at both interfaces. Furthermore, the magnetic-phase transition at the interface is the results of the mutual mechanisms of the capping-induced volume/tetragonal expansion in the interfacial FeRh layers and the competition between the direct and indirect exchange interactions mediated by the hybridization with the spin-polarized Ta (Os) 5*d* orbitals. These findings suggest that HTM/FeRh/MgO multilayers may represent the highly favorable memory materials with net interfacial ferromagnetism and large PMA in antiferromagnet spintronics.

F2-01. Cooling Characteristics of Magnetoconvection in Vegetable Insulating Oil-Based Ferrofluid with Different Volume Fractions.
H. Lee[1] *1. Changshin University, Changwon-si, The Republic of Korea*

This paper presents on the cooling performance of a vegetable insulating oil based magnetic nanofluid with different volume fractions of magnetic nanoparticles resulting from magnetoconvection effects in presence of an external magnetic field. Recently, the environment issues have been raised in electric apparatus areas, and new technologies with nanotechnology are promising for resolving these engineering problems [1]. Mineral-based oils are typically used in power transformers because of their high dielectric strength and good cooling performance under operating conditions. Owing to their environmental impact, the eco-friendly vegetable transformer oils have been lately replacing the mineral-based insulating oils [2]-[3]. Until now, several studies reported only the dielectric breakdown characteristics of vegetable oil based magnetic nanofluids without considering any real electromagnetic system [4]. Besides, the thermal characteristics of vegetable oil based magnetic nanofluids have not been fully discussed yet. The aim of our study, therefore, is to examine the cooling performance by adding magnetic nanoparticles to the vegetable transformer oil. To quantitatively analyze this effect, a multiphysics technique coupled with magnetic-thermal-fluidic fields was developed by using the quasi-static magnetic field approximation and conjugate heat transfer. To validate our numerical setup, some experiments were successfully conducted in a simple electromagnetic system with different insulating liquids. The results indicate that the cooling performance in a simple solenoid system is suitable to verify the numerical setup. In a future extended paper, we will investigate quantitatively this phenomenon in detail.

F2-02. Magnetic PolyHIPE Composites with Activated carbon and Iron oxide Nanoparticles.
P. Seeharaj[1], E. Thasirisap[1], C. Tridech[2] and S. Jindasuwan[3] *1. Advanced Materials Research Unit, Department of Chemistry, Faculty of Science, King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand; 2. Science Park Promotion Agency, Ministry of Science and Technology, Bangkok, Thailand; 3. Department of Industrial Chemistry, Faculty of Applied Science, King Mongkut's University of Technology North Bangkok, Bangkok, Thailand*

Poly high internal phase emulsions (polyHIPEs) are low density, high open porosity, high degree of interconnectivity and high surface area porous polymer foams that can be used in many fields such as filtration, water purification, chromatography, tissue engineering and sensor technology [1]. Incorporation of inorganic particles as additives into the polymers matrices to form polyHIPE composites was reported to improve and modify the properties of polyHIPEs which make them suitable for particular practical applications. Therefore, the effects of incorporation of co-additives including activated carbon (ATC, 1 wt%) and iron oxide (Fe_3O_4) nanoparticles (5, 10 and 15 wt%) on physical, mechanical, magnetic and heavy ion adsorption properties of the polyHIPE composites were investigated in this study. The polyHIPE composites were prepared via water in oil emulsion system which its organic phase consisted of styrene and divinylbenzene (DVB) as monomers, 2,2'-azobisisobutyronitrile (AIBN) as an initiator and Span 80 as a surfactant in an aqueous phase, a solution of 0.34 M calcium chloride dihydrate ($CaCl_2.2H_2O$). The ratio of the organic phase to the aqueous phase was 20 to 80 vol%. The incorporation of the co-additives, 1 wt% ATC and 5 to 15 wt% Fe_3O_4, was found to enhance the physical and mechanical properties by increasing the specific surface area to 34.9-767.9 m^2/g, Young's modulus and crushing strength to 5.31-7.75 MPa and 0.49-0.70 MPa, respectively. The magnetic property of the polyHIPEs composites increased with increasing the Fe_3O_4 contents from 5 to 15 wt% as presented in Figure 1. The polyHIPE composites with 1 wt% ATC and 15 wt% Fe_3O_4 showed the highest saturated magnetization at 11.89 emu/g and had high iron(III) ions (Fe^{3+}) adsorption efficiency at 89.11 % in the equilibrium condition. These results suggest that the magnetic polyHIPE composites with ATC and Fe_3O_4 nanoparticles possess good physical and mechanical properties and have potential to be developed for heavy ion adsorption applications.

F2-03. Probing the Dynamics of Magnetic Nanoparticles in Freeze-Concentrated Solutions.
G. Sitbon[1] and *W. Schwarzacher*[1] *1. H H Wills Physics Laboratory, University of Bristol, Bristol, United Kingdom*

When an aqueous solution is cooled below its freezing point, its concentration is increased as water is removed in the form of ice. This process is known as freeze concentration and has numerous applications, ranging from food processing to cryobiology. As the solution concentration and temperature change, the viscosity of the freeze-concentrated solution also changes, which in turn affects the characteristic time for any nanoparticles suspended in the solution to relax by Brownian rotation. For the specific case of magnetic nanoparticles suspended in a freeze-concentrated solution, this Brownian relaxation can be detected magnetically. We showed previously that for a field-cooled and freeze-concentrated solution of magnetoferritin (a quasi-spherical protein encasing a synthetic cobalt-doped magnetite nanoparticle) a step is observed in the magnetic susceptibility starting at the temperature where the Brownian relaxation time becomes comparable to the timescale of the magnetic measurements (~100s) [1]. The position and magnitude of this step provides information about both the

freeze-concentration process and the interactions of the nanoparticles with ice. For example, denaturing of the ferritin during a freeze-thawing process could be detected by a shift of the step to higher temperatures [2]. Here we apply a similar approach to study commercially available 15 nm diameter iron oxide nanoparticles (supplied by Ocean Nanotech). To transfer the nanoparticles to a water-based solvent, we performed a ligand exchange using 3,4-dihydroxybenzoic acid to replace the initial oleic acid functionalization with hydrophilic ligands. The figure shows magnetic susceptibility data (arbitrary units) for these nanoparticles in a freeze-concentrated aqueous glycerol solution on warming following field cooling in a 5T applied field. A step that we attribute to Brownian relaxation is clearly observed between 175 K and 200 K, independent of the initial cooling rate (30 K/min or 5 K/min).

F2-04. Remarkable magnetic anisotropy of nickel nanoparticles embedded in porous coir fiber. *M.A. Macedo*[1], N.d. Ferreira[1] and J.C. Menezes[1] *1. Physics, Federal University of Sergipe, Sao Cristovao, Brazil*

The synthesis of magnetic nanoparticles in biodegradable matrix from renewable resources has attracted considerable interest because of its possibility of environmental applications to the detection and removal of pollutants from contaminated waters. In this work, nickel nanoparticles grown inside the coir fibers were synthesized by the aquolif process [1]. X-ray diffraction measurements showed that nickel nanoparticles present a single phase and preferential growth in the [111] direction. Scanning electron microscopy images reveals that nanoparticles grew on the walls of the microtubes, along the length of the coconut fiber. For magnetic field applied along the c-axis of the coir fiber, a very weak ferromagnetic behavior is observed with high noise signal and low values of $\mu_0 H_c$=7x10^{-3} T, Mr=5x10^{-6} μ_B/Ni and low saturated moment of per Ni atom (Ms=3x10^{-5} μ_B/Ni) (Figure 1(a)). In contrast, for field applied perpendicular the c-axis, the magnetization is higher, and the hysteresis curve was well defined with low coercivity ($\mu_0 H_c$= 2x10^{-2} T) and remanence (Mr = 0.15 μ_B/Ni) which is characteristic of a soft ferromagnetic behavior. Moreover, magnetization is constant for $\mu_0 H > 1$ *T* with a large saturated moment of 0.6 μ_B/Ni (Figure 1(b)). This value match well with that one previously reported magnetic moment for bulk fcc nickel (0.57 - 0.60 μ_B/Ni)[2]. The magnetization measurements as a function of the magnetic field exhibited a very high anisotropy in the saturation magnetization value, with a factor of 10^4 between the field applied perpendicular to and along the fiber length. The technique used in this work enables the synthesis of long-length (> 0.15 m) magnetic fibers with the easy axis perpendicular to their length. In this manner, such fibers can be a suitable material to act as a metal absorber for effective removal of heavy metals in water due to the large surface area of contact with the capture system, which could be an electromagnet.

F2-05. X-ray Magnetic Circular Dichroism Study of Ni-Cu Thermoseeds for Self-Controlled Magnetic Hyperthermia. *S. Pandey*[1], A.T. N'Diaye[2], A. Aryal[1], I. Dubenko[1], D. Mazumdar[1], S. Roy[2], S. Stadler[3] and N. Ali[1] *1. Physics, Southern Illinois University Carbondale, Carbondale, IL, United States; 2. Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA, United States; 3. Louisiana State University, Baton Rouge, LA, United States*

Ni-Cu alloys are the possible magnetocaloric thermoseeds for self-controlled magnetic hyperthermia methods. The magnetic ordering temperature and magnetic properties of Ni-Cu alloys were perfectly controlled to a range suitable for hyperthermia applications. To understand the details of electronic and magnetic structure of these alloys, X-ray absorption spectroscopy (XAS) and X-ray magnetic circular dichroism (XMCD) measurements were done at the $L_{2,3}$ edges of ferromagnetic Ni. XMCD shed the valuable information on how doping affects relative magnetic moment at the Ni site. The influence of small compositional through the substitution of Ni by Cu on electronic and crystal structure, and thermomagnetic properties were studied to determine the functional magnetic hyperthermia. F2-06. Effect of Ni-doping on the Magnetic Property and Biomedical Application of Zinc Oxide Nanoparticles. *R. Srinivasan*[2], J. Mayekar[2,1] and V.S. Dhar[1] *1. Physics, Jai Hind College, Mumbai, India; 2. Physics, University of Mumbai, Mumbai, India*

Zinc oxide nanoparticles are known to show potential applications in spintronics. The magnetic properties of ZnO are enhanced by doping with transition or rare earth elements. Zinc ferrite finds applications in the electronics industry as well as biomedical fields and its nanoparticle formulations show excellent chemical stability. Our earlier work reported the antibacterial effect of ZnO nanoparticles on some skin pathogens[1]. This work compares the magnetic properties of Ni-doped ZnO nanoparticles with those of Zn ferrite nanoparticles, both synthesized by optimized wet chemical routes. Nickel doped zinc oxide nanoparticles were synthesized in two steps: in first step, precipitate was obtained by reduction of a mixture of zinc nitrate, nickel nitrate and starch by sodium hydroxide solution while in second step, the given precipitate was thermally decomposed at high temperatures of 400^{0}C. The crystallinity of the synthesized nanoparticles was confirmed by X-ray diffraction (XRD). The elemental composition of the powder was analyzed by Energy Dispersive X-ray spectroscopy (EDAX). The Scanning Electron Microscopy (SEM) study showed a flower like morphology for the pure ZnO and spherical one for the doped ZnO. Magnetization measurements on QD-PPMS upto fields of 6T of the Ni-doped ZnO nanoparticles showed a paramagnetic behavior at room temperature and a weak magnetic behavior (0.28 emu/g) at low temperature (2K). The Zn ferrite nanoparticles synthesized by a similar route showed a saturation magnetization of 28 emu/g and a near zero coercivity at room temperature. These nanoparticles also showed

a spherical morphology and this structure-property relation is analyzed for various batches of synthesized samples. The study is further extended to investigate the antibacterial activity of the synthesized nanoparticles on common skin pathogens by standard microbiological assays, in order to understand the effect of doping and ensuing structures of ZnO nanoparticles on the desired end application.

F2-08. Research on Intervention effect of Magnetic Nanoparticles in Magnetic Field on Lung Tumor. N. Zhang[1], S. Ning[2], *S. Wang*[1], C. Zhang[3] and S. Wang[1] *1. State Key Laboratory of Electrical Insulation and Power Equipment, Faculty of Electrical Engineering, Xi'an Jiaotong University, Xi'an, China; 2. College of Electrical and Information Engineering, Shaanxi University of Science and Technology, Xi'an, China; 3. Department of Oncology, Johns Hopkins University School of Medicine, Baltimore, MD, United States*

The intervention of cell multiplication by magnetic nanoparticles (MNPs) in the magnetic field, an international research hotspot, has preoccupied a growing number of scientists in recent years. Currently, the inhibition of the non-thermal effect on tumor cells has been confirmed [1]. The non-thermal effect of MNPs with magnetic field has many advantages. It can avoid the negative impact to the normal cells caused by hyperthermia and make the tumor cell breakdown [2]. However, the frequency and magnetic flux density of the magnetic field limit the inhibitory effect of MNPs on tumor cells. The mechanism of intervention for lung tumor based non-thermal effect of MNPs in the magnetic field is also not been fully determined. In the present study, the magnetic field distribution of MNPs was simulated by FDTD method. The MNPs based on ferroferric oxide was synergized with magnetic field to intervene the proliferation and migration of lung tumor A549 cell line. The tumor cells were checked by the electron microscope. The proliferation of tumor cell was examined by MTT assay. The level of cell migration was checked by wound healing assay. According to our previous work [3], the cells were divided into the Group A (magnetic field), the Group B (MNPs synergized with the magnetic field) and the Group C (control group). The frequency of magnetic stimulation of Group A and B was 2 kHz. Group C was not stimulated by magnetic field. The numerical calculation showed that the magnetic flux density at the location of MNPs in the cell was enhanced. After 24 hours, the MTT assay and the wound healing assay were conducted. The experiment results showed that a small amount of MNPs were endocytosed by A549 cells in Fig.1. The ratio of cell proliferation in Group A was suppressed by the magnetic field. The ratio of cell proliferation of Group B was 21.2% lower than Group A. As shown in Fig. 2, the level of cell migration of Group B was 16.6% lower than Group A. The cell experiments showed that the MNPs synergized with the magnetic field not only suppress the tumor cell proliferation but also cell migration.

Disc-shaped particles are a new generation of magnetic nanoparticles that can face important biomedical challenges as the search for new cancer therapies. Indeed, their ability to vibrate under external magnetic fields can be exploited to damage cancer cells integrity and/or deliver antitumor drugs. Moreover, thanks to their magnetic vortex configuration [1], they possess zero magnetization at remanence eliminating the problem of agglomeration. When an AC field as small as 10 Hz and 100 Oe is applied, the discs vibrate exerting forces capable of triggering cancer cells apoptosis. This capability has been demonstrated using micrometric discs (1-2 micrometers in diameter) [2, 3]. The scaling down of the size could favor the internalization by the cells, opening up new possibilities of actuation from the inside, and reduce the magnetic material injected in the body. Nevertheless, no work has been reported on nanosized discs. We previously fabricated vortex state $Ni_{80}Fe_{20}$ discs down to 30 nm in radius using a cost-effective lithography

technique [4]. We now have performed the first *in vitro* experiments using nanodiscs with cancer cells. Although not biofunctionalized, almost 20% of the cells uptake nanodiscs and accumulate them in lysosomes. The nanodiscs show no cytotoxicity effects by themselves but cause dramatic damages to 30% of the cells after magnetic stimulus, probably due to the rupture of lysosomal membrane and release of hydrolytic enzymes into the cytoplasm. In light of these preliminary results, the intracellular actuation of nanodiscs could become a new pathway to selectively kill cancer cells.

F2-10. Different magnetic behaviors and free radical contents of "DPPH reagents". *N. Matsumoto*[1] and N. Itoh[1] *1. National Metrology Institute of Japan (NMIJ), National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan*

A stable nitrogen radical, di(phenyl)-(2,4,6-trinitrophenyl)iminoazanium [DPPH] had been investigated by many researchers[1] and is nowdays well-used as a standard for number of free radicals in the researches of redox and electronspin sciences, or, as a standard sample for magnetic field in high-frequency EPR measurement. Here, we evaluated 'DPPH' reagents from three manufacturers by measuring their free radical content using a equation combining Curie-Weiss law and the EPR fundamental equation (We call it as "effective magnetic moment method".). Interestingly, the reagents from different manufacturers had varying temperature dependences for both magnetic moment and g-value at low temperatures.[2] As shown in fig. 1, the reagent A and the reagent C show monotonous temperature dependence of magnetic moment under a magnetic field. On the other hand, the reagent B shows singlet-state near liquid He temperature. From the rigorous fitting of each reagent's data to the equation, the maximum relative difference among the three reagents on the number of free radicals per unit mass was 20%, as shown in Table 1. Carbon hydrogen nitrogen (CHN) analyses, high-resolution(Q-band and W-band) EPR measurements, FT-IR measurement, and NMR measurement confirmed that a major component of only the reagent B among the three reagents was 'pure' DPPH. The other two reagents were found to be contaminated by several mol% of benzene in the DPPH crystal structure. On the Q-band and W-band EPR spectra, isotropic peak was detected for the reagent B, while aisotropic peaks were detected for the regent A and C. Only the reagent B may be advisable to use as standard sample for sweeping field at high-frequency EPR measurements.

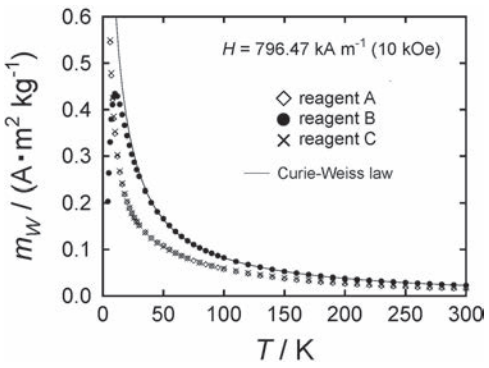

Fig.1 Temperature dependence of magnetic moment per unit mass, m_w, under a magnetic field, H, of 796.38 kA m^{-1}. The m_w equivalent to m divided by W, where the m is magnetic moment measurement from SQUID and the W is the mass of the sample measured with an electronic balance. The solid line represents the theoretical curve according to the Curie-Weiss law and is observably fitted to the data of reagent B of 55 K to 300 K.

Reagent	Temp. range obeying Curie-Weiss law	Number of free radicals per unit mass, n_W † kg^{-1}	Weiss temp., K	Peak shape in Q- and W-EPR	Major component
A	50 to 300 K [monotonous increase more than 4.2 K]	$(1.23\pm0.04)\times10^{24}$ ††	-15±2	anisotropic	DPPH contaminated by several mol% of C_6H_6
B	55 to 300 K [singlet-state below around 10 K]	$(1.524\pm0.056)\times10^{24}$ [Purity as free radical, x_{rad} is 0.998 ± 0.036.]	-4.8±2.5	isotropic	DPPH
C	same as A	$(1.28\pm0.04)\times10^{24}$ ††	-20±2	same as A	same as A

†Each value of n_W and x_{rad} is accompanied by its expanded uncertainty (with a coverage factor of 2)
††These n_W values are significantly dependent on the analytical temperature range (T_1 to T_2) of the data set of m and T. In this table, the results are shown when T_1 is 50 K and T_2 is 300 K. Both T_1 and T_2 were regarded as appropriate analytical temperature boundaries, based on the residual sum of the weighted squared deviation.
†††The x_{rad} is defined as the following formula;
$x_{rad} = n_W$ (Molar mass of major component)/[(number of radical per molecule)(Avogadro's number)]

F3-02. Probing strong electronic correlations in the Heavy Fermion Kondo-Lattice $YbFe_2Zn_{20}$. *M. Cabrera Baez*[1], M. de Abreu Avila[2] and C. Rettori[1,2] *1. DEQ, Universidade Estadual de Campinas, Santo André, Brazil; 2. CCNH, Universidade Federal do ABC, Santo André, Brazil*

We report on the magnetic, thermodynamic and electronic properties of the Gd doped Kondo-lattice compound $YbFe_2Zn_{20}$ ($T_K \approx 32$ K) by means of magnetization measurements and *T*-dependent Electron Spin Resonance (ESR). As Gd is incorporated in this Kondo-lattice system ($Yb_{1-x}Gd_xFe_2Zn_{20}$) the Yb contribution to the Sommerfeld coefficient remains almost unaltered [1] for $x = 0.005$ and 0.01 at $\gamma_{eff} \approx 500$ mJ/mol.K^2, however, for $x = 0.05$ it is reduced to $\gamma_{eff} \approx 450$ mJ/mol.K^2. In the Kondo condensate state ($T_K \approx 32$ K) the Gd^{3+} ESR experiments show, as expected for a Heavy Fermion system, an enhanced Korringa relaxation rate, $b = d(\Delta H)/(dT)$, due to the exchange interaction between the Gd^{3+} localized magnetic moment and the high density of states of 4*f*-conduction electrons (*ce*) at the Fermi level. Moreover, for $x = 0.01$, the Gd^{3+} ESR *g*-shift presents a peculiar *T*-dependence which we associate to an AFM itinerant internal molecular field due to the *ce* that compensate the Yb^{3+} magnetic moments in the Kondo condensate with a value of $\lambda = -2.80(1)$ mol.Oe/emu. The negative value found for this parameter would lead to a singlet non magnetic ground state formation, as expected for a Kondo-lattice system. Still below T_K, but for $x = 0.05$, the Gd^{3+} ESR *g*-shift presents a positive *T*-dependence which we now associate to FM internal molecular field due to a Gd^{3+}-Gd^{3+} superexchange-like [2] interaction via extended 3*d* Fe *ce* with a value of $\lambda_{Gd\text{-}Gd} = 0.03(1)$ mol.Oe/emu. The microscopic coupling between Gd^{3+} and 4*f*-*ce* found for $x = 0.01$ is stronger than that between Gd^{3+}-Gd^{3+} for $x = 0.05$, indicating a subtle *T* and Gd-concentration competition at low-*T* between AFM and FM couplings in $Yb_{1-x}Gd_xFe_2Zn_{20}$. We thank the financial support of FAPESP (Grant No. 2016/15780-0), CNPq and UFABC.

Today there is a critical shortage of ^{3}He due to an increasing demand and to a reduced supply [1]. Therefore it is necessary to find good alternatives to the use of this isotope. Since for cooling below 1K ^{3}He is currently used, this crisis affects also solid state physicists. Refrigeration by adiabatic demagnetization of paramagnetic salts is a ^{3}He-free alternative method to reach temperatures significantly below 1K. However, the utilization of these insulating materials as refrigerants suffers from substantial drawbacks such as poor thermal conductance (which makes it difficult to achieve thermal equilibrium within the salt) and deterioration of the salt due to dehydration [2]. For this reason, very recently metallic compounds have been proposed as good alternative materials to paramagnetic salts in adiabatic demagnetization [3,4]. In this work we report experimental results on crystal structure, magnetic, thermodynamic and transport properties of the new cubic Heusler indide $YbPd_2In$. From the fitting of the magnetic susceptibility a stable trivalent Yb^{3+} ($\mu_{eff} = 4.5\ \mu_B$) state is deduced [5]. The compound is characterized by very weak magnetic interactions and by the absence of a significant Kondo effect as suggested by the very low value of $\Theta_p = -9$ K and by the thermal dependence of the resistivity [5]. At low temperatures, for temperature decreasing the magnetic specific heat divided by temperature C_m/T first increases steeply with a $\sim 1/T^2$ dependence within more than one decade of temperature, and then a maximum occurs at around $T_m = 250$ mK reaching the record value of about 30 J/mol K^2. By applying magnetic field, the kink at T_m transforms into a Schottky-like anomaly peak resulting from the Zeeman splitting of the doublet ground state. The resulting associated thermomagnetic effect, which drastically shifts the entropy to higher temperatures by the application of magnetic field, makes $YbPd_2In$ a promising candidate for adiabatic demagnetization cooling.

F3-05. Vibron Quasi-bound States in Ce-based Intermetallic Compounds. *M. Klicpera*[1] and P. Javorsky[1] *1. Department of Condensed Matter Physics, Charles University, Prague, Czechia*

The tetragonal CeTX_3 and CeT_2X_2 compounds, $T = d$-metal and $X = p$-metal, have been investigated for a variety of exotic ground state properties. Recently, inelastic neutron scattering experiments on $CeCuAl_3$ and $CePd_2Al_2$ powder samples revealed energy spectra containing three magnetic (crystal-electric-field-like) peaks [1,2] although only two CEF excitations are expected for a Kramer's Ce^{3+} ion in a tetragonal point symmetry. The energy spectrum has been interpreted as evidence of a vibron quasi-bound state originating from a strong interaction between CEF excitations and phonons. Such has been proposed for the cubic $CeAl_2$ earlier [3]. Our recent studies on mainly single crystals confirmed the presence of three excitations in the energy spectrum of $CeCuAl_3$. The polarized neutron scattering experiment showed that all three peaks are of magnetic origin and the collected data allowed separating the individual components of the magnetization [4]. Moreover, we investigated the effect of Cu-Al and Al-Ga substitutions on the energy schemes of $CeCuAl_3$ and $CePd_2Al_2$ [5,6], respectively. Results of our studies will be discussed and compared to investigations conducted by other groups.

F3-06. Hill plot and magnetic properties of Ce_2AuP_3. *J. Kitagawa*[1], J. Miyahara[1], N. Shirakawa[2], Y. Setoguchi[1], M. Tsubota[3] and K. Kuroiwa[1] *1. Electrical Engineering, Fukuoka Institute of Technology, Fukuoka, Japan; 2. Flexible Electronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; 3. Physonit Inc., Kaita Aki, Japan*

A Ce compound with no other magnetic elements rarely has a magnetic ordering temperature that is higher than 20 K. We have reinvestigated the Hill plot of approximately 730 Ce-compounds, focusing on a relationship between the Ce-Ce distance and the magnetic ordering temperature [1]. The obtained Hill plots are shown in Figs. 1(a) and 1(b) for ferromagnets and antiferromagnets, respectively, with the vertical dashed line indicating the average Ce-Ce distance 4.161 Å determined by the histogram. As indicated by the reported Hill plot[2,3], Ce compounds tend to show intermediate valence (IV) states with decreasing Ce-Ce distance. Nonetheless, the region of Ce-Ce distance for compounds that show high magnetic ordering temperatures above 20 K overlaps that of IV compounds. This study has revealed that a Ce compound, particularly a ferromagnet, showing a high magnetic ordering temperature would require a short Ce-Ce distance with a suppression of valence instability of the Ce ion. From the study, we had interest in Ce_2AuP_3 with a Curie temperature T_C of 31 K[4]. The doping effect has been examined by ac magnetic susceptibility. We have found that the spin reorientation would occur at approximately 15 K in the parent compound. The ac magnetic susceptibility of $Ce_2AuP_{2.7}Si_{0.3}$ or $Ce_2Au_{0.9}Pt_{0.1}P_3$ shows a depression of the spin reorientation and a sharper peak at T_C compared to that of the parent compound. These results imply the possible increased magnetic anisotropy energy by the hole doping.

F3-07. Systematic study of the $UNiX_2$ ternary compounds (X=C, Si, Ge). K. Maeta[1], *M. Ohashi*[1], S. Hirokawa[1] and T. Yamamura[2] *1. Kanazawa University, Kanazawa, Japan; 2. IMR, Tohoku University, Sendai, Japan*

We attempted to grow $UNiX_2$ ternary compounds by the arc melting method. $UNiC_2$ and $UNiGe_2$ may not melt congruently because both compounds contain impurity phases. $UNiC_2$ crystallizes into the tetragonal $UCoC_2$-type structure with space group *P4/nmm* [1], the annealed sample consists of $UNiC_2$ and U_2NiC_3 as the main and secondary phases, respectively. The lattice constants were obtained to be a = 3.512 Å, c = 7.339 Å. $UNiC_2$ may be a paramagnet because the magnetic susceptibility shows one maximum at T_N = 57 K where the antiferromagnetic transition occurs in U_2NiC_3 secondary phase [2]. $UNiGe_2$ also contains two phases. We assumed that primary phase is isostructural to $UNiSi_2$ that crystallizes into the orthorhombic $CeNiSi_2$-type structure with the space group of *Cmcm* [3]. On the other hand, it is reasonable to assume that UNi_2Ge_2 exists in the compound as secondary phase. The unit cell volume tends to increase as increasing the anomic number of X (C, Si, Ge). It comes from the fact that the atomic radius of X becomes larger as the atomic number becomes larger. The temperature dependence of the magnetic susceptibility of $UNiGe_2$ shows two peaks at T_N=45 K and T_N' = 65 K. Taking an account that UNi_2Ge_2 secondary phase exists in the compound, $UNiGe_2$ is an antiferromagnet below T_N while T_N' may come from the antiferomagnetic order of UNi_2Ge_2 [4]. At 5 K, the slope of the magnetization curve increases as increasing the magnetic field up to 5 T, indicating the presence of a metamagnetic transition. The residual magnetization remains on the magnetization curve at 5 K, which may come from a week ferromagnetism of UNi_2Ge_2 at low temperature.

F3-08. Effects of Cd and Sb Substitution in $CeCuBi_2$ Single Crystals. *G.S. Freitas*[1], M.M. Piva[1], C.B. Jesus[2], J.C. Souza[1], C. Adriano[1] and P. Pagliuso[1] *1. DEQ, Instituto de Física Gleb Wataghin - Unicamp, Campinas, Brazil; 2. Departamento de Física, Universidade Federal de Sergipe, Campinas, Brazil*

The series of Ce-based intermetallic compounds are known to present an interesting competition between the Ruderman-Kittel-Kasuva-Yoshida (RKKY) magnetic interactions, crystalline electrical field (CEF) and Kondo effects. Furthermore, these series commonly show tunable ground states and in, some cases, heavy fermion superconductivity. Previous studies performed on the $CeCuBi_2$ compound have shown an antiferromagnetic behavior below T_N = 16 K and a spin-flop transition at T = 5 K when a magnetic field of $H_{S\text{-}F} \sim 5.7$ T is applied parallel to the c-axis [1]. The analogue $CeCd_{0.7}Sb_2$ compound, however, presents a ferromagnetic behavior below T_C = 3 K [2]. Furthermore, the magnetic order of both compounds is strongly affected by changes on the CEF parameters. In this regard, it is interesting to understand how the magnetic interaction and the CEF effects are tuned along these different series of compounds. Therefore, we have synthesized $Ce(Cu_{1-x}Cd_x)Bi_2$ ($0.1 < x < 0.2$) and $CeCu(Bi_{2-y}Sb_y)$ ($0.35 < y < 1.3$) single crystals by the metallic flux technique. We have performed x-ray powder diffraction, electrical resistivity, specific heat and magnetic susceptibility experiments to fully characterize these materials. The Cd-doped samples showed similar properties to $CeCuBi_2$, with a nearly constant T_N and a slight increase of $H_{S\text{-}F}$ was a function of concentration. Interestingly, the Sb-doped samples displayed more significant changes in their physical properties comparing with the undoped compound, such as a change in the magnetization easy axis, a decrease in T_N and the suppression of the spin-flop transition, indicating a strong effect of Sb substitution in the CEF parameters and exchange interaction in these systems.

F3-09. Crystalline electric field calculations for Rhombhohedral $CeIr_3Ge_7$. *J. Banda*[1], B.K. Rai[2], E. Morosan[2], C. Geibel[1] and M. Brando[1] *1. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 2. Physics and Astronomy, Rice University, Houston, TX, United States*

$CeIr_3Ge_7$ is an antiferromagnetic metal with an extremely low Néel temperature of 0.63K despite the absence of Kondo effect and geometrical frustration. We have solved the crystalline electric field (CEF) scheme for the well

localized Ce^{3+} moment which has a trigonal point symmetry. Our calculations matches perfectly with the experimental data measured on single crystalline samples and found an excellent agreement with one possible solution of CEF ground state wave function with our proposed CEF level schematic. We have evaluated CEF parameters along with the seperation energies of first and second excited energy levels. Comparison with other compounds suggest that such large CEF splitting observed in a Ce system might be connected with the presence of 5d ligands.

F3-10. Transport and thermodynamic properties of Nd_5CuSn_3. *K. Matsumoto*[1], N. Morioka[1] and K. Hiraoka[1] *1. Ehime University, Matsuyama, Japan*

Rare-earth-based R_5TX_3 (R=rare earth, T=Cu, Ag, X=Sn, Pb, Bi) compounds crystallize in the hexagonal Hf_5CuSn_3-type structure [1]. R ions occupy two nonequivalent sites. Ce_5CuX_3 (X=Sn, Bi, Pb) show a magnetic order at low temperatures [2]. Dy_5CuPb_3 have also investigated the magnetic properties [3]. However, the physical properties of R_5CuSn_3 except for R=La and Ce were not explored yet. In this work, we study the transport and thermodynamic properties of Nd counterpart. The polycrystalline sample of Nd_5CuSn_3 was prepared by the arc-melting with high purity elements and annealed at 1173 K for 6 days in an evacuated quartz tube. The X-ray diffraction pattern of Nd_5CuSn_3 was indexed on the basis of the Hf_5CuSn_3-type structure. The electrical resistance, R, as a function of temperature decreased with decreasing temperature. R increased below 65 K and showed a cusp-like anomaly, indicating the magnetic transition. This cusp-like behavior may be due to scattering from critical fluctuations above the phase transition temperature. Figure 1 shows the temperature dependence of specific heat, C, at zero field. At 53.5 K, the values of C showed a peak arising from the magnetic transition. The temperatures which the peak occurred increased with increasing magnetic field. This result suggests that this transition is derived from the ferromagnetic order. Magnetization measurements are now in progress and the analysis of the crystalline electric field effect will be presented.

$SrAl_4$ crystallizes in the $BaAl_4$ type structure. Sr atoms occupy the corners and the center of the body-centered tetragonal lattice. Al atoms have two sites: X(I) and X(II) [1]. From the electrical resistivity and magnetic susceptibility, it was clarified that $SrAl_4$ has a CDW transition at T_{CDW} = 243 K and a structural phase (SP) transition at T_{SP} = 100 K [2]. The ^{27}Al NMR was carried out by using a single crystal of $SrAl_4$. The Al(I) and Al(II) NMR spectra in the case of the external magnetic field $H_0 \perp c$-axis and $H_0 \| c$-axis have been measured between 4.2 and 300 K. The well resolved sharp spectra for $H_0 \perp c$-axis and $H_0 \| c$-axis are obtained at 300 K. Each spectrum splits into five resonance lines composed of a main resonance-line with four satellite-lines in all on both sides because of the nuclear quadrupole interaction by I = 5/2. In the case of $H_0 \perp c$-axis, the each single satellite resonance-line splits into a double-horned shape below T_{CDW}. The line width of the satellite resonance-line below T_{CDW} is modulated by an electrical quadruple interaction between ^{27}Al nuclei and the incommensurate (IC) CDW charge modulation. The IC-CDW amplitude develops rapidly below T_{CDW} and it is getting to be constant around 140 K. However, below 140 K, new resonance-lines appear in the vicinity of the center of the double-horned spectra. This means the emergence of the commensurate (C) CDW state. Below T_{sp}, the IC-CDW states reduce with decreasing temperature, and are changing to the C-CDW states. The most of the CDW states turn into the C-CDW states at 4.2 K. Meanwhile, in the case of $H_0 \| c$-axis, the each single satellite resonance-line does not split into the double-horned shape below T_{CDW} and only becomes the wider line width as the temperature decreases. This behavior is different from that for $H_0 \perp c$-axis. The satellite resonance-lines for both sites show asymmetric line-shapes below 180 K. At T_{SP}, each satellite resonance-line becomes an asymmetric line-shape with a wide envelope like a skirt on the upper frequency side for the Al(II) site and an symmetric line-shape with two peaks for the Al(I) site. The most of the CDW states in the case of $H_0 \| c$-axis become in the C-CDW state below T_{SP}.

F3-03. Growth Routes for Synthesizing the $YbCd_{1-x}Sb_2$ Intermetallic Compounds. *D.S. Christovam*[1], C.B. Jesus[2], J.C. Souza[1], M.M. Piva[1], C. Adriano[3] and P. Pagliuso[1] *1. DEQ, Instituto de Física Gleb Wataghin - Unicamp, Campinas, Brazil; 2. Departamento de Física, Universidade Federal de Sergipe, Campinas, Brazil; 3. Physics, University of Campinas, Campinas, Brazil*

Previous results in the family of heavy-fermion intermetallics $RTBi_2$ (R = Ce, Pr, Nd, Sm, Gd; T = Cu, Au) and $CeCd_{0.7}Sb_2$ compounds show that the crystalline electrical field (CEF) effects play a crucial role in the strong competition between ferromagnetic (FM) and antiferromagnetic (AFM) interactions [1,2]. Moreover, the magnetic phases of these compounds appear to be highly influenced by the dimensionality of the system [1,2]. These Ce-based compounds display highly localized Ce^{3+} ions, which have one electron in their ground state ($^2F_{5/2}$). The strong localization of Ce 4f electrons in those systems may reduce the chance of tuning their ground states towards unconventional superconductivity. As such, perhaps a more reliable path to search for superconductivity in these families would be trying to find analogues with stronger hybridization between the 4f and conduction electrons, possibly the less explored Yb- based analogues. In this work we report the growth and characterization of single crystals of the intermetallic compound $YbCd_{1-x}Sb_2$. This compound was synthesized with different Cd concentrations, using the Sb self-flux technique. Magnetic susceptibility as a function of temperature and applied field, electrical resistivity, specific heat and x-ray powder diffraction measurements were performed to characterize the physical properties of our single crystals. The results suggest an AFM phase with $T_N \sim 3$ K and heavy-fermion behavior. In order to understand the role of the CEF effects in the properties of this system, we have also performed preliminary studies of CEF effects. Finally, we discuss the magnetism and other physical properties of the $YbCd_{1-x}Sb_2$ compound based in the Cd stoichiometry dependency and CEF effects.

F3-12. DISTorX Program for Analysis of Structural Distortions Affecting on X-ray Diffraction Patterns. *L.S. Kalinowski*[1], J. Goraus[1] and A. Slebarski[1] *1. Institute of Physics, University of Silesia, Chorzów, Poland*

For the purposes of research on strongly correlated electronic systems (SCES), the computer program DISTorX [1] was created. The program is an interactive Jupyter notebook [2] which allows to simulate structural distortion caused by the Charge-Density-Wave (CDW) and many different structural distortions; directly visible on X-ray diffraction patterns. Generally the created program is universal enough that it can be successfully applied to a variety of structures. Program can visualize structural data as an interactive 3D model directly in Jupyter web-app. Program is a open-source Python script, which can be a base for further modifications allowing to study many of physical deformations and structural properties observed in X-ray diffraction experiments. In previous reports a structural transition from a cubic phase of $Yb_3Rh_4Sn_{13}$ – type to the superlattice variant has been observed at 160 K for a series of skutterudite-related $Ce_3M_4Sn_{13}$ compounds, where M = Co, Ru or Rh [3]. We have simulated the low-temperature X-ray diffraction patterns of the distorted unit cell using written for that purpose DISTorX program. The method proposed here for x-ray diffraction analysis obtains the simulated XRD patterns from the atomic positions and allows to investigate crystal structure without imposed symmetry operations. We have indicated crystallographic plane where distortion occurs and explained possible origin of CDW in these materials.

F4-01. Magnetic Bragg dip and Bragg edge in neutron transmission spectra of a typical spin order. *H. Mamiya*[1], Y. Oba[2], N. Terada[3], N. Watanabe[4], K. Hiroi[2], T. Shinohara[2] and K. Oikawa[2] *1. National Institute for Materials Science, Tsukuba, Japan; 2. Japan Atomic Energy Agency, Tokai, Japan; 3. Neutron Scattering Group, National Institute for Materials Science (NIMS), Tsukuba, Japan; 4. Kanagawa University, Yokohama, Japan*

Novel magnetic phenomena have been discovered in unprecedented environmental conditions or in newly found magnetic materials, where neutron diffractometry measuring neutrons scattered by the spins at various angles has been a unique tool for clarifying the spin arrangements directly. However, it is not easy to measure neutrons scattered at the sample under extreme environmental conditions such as ultra-high pressure, ultra-high magnetic field, and ultra-low temperatures, because the generations of such conditions are possible in smaller, narrower, or thinner sample space in the sample environment equipment; consequently, the equipment covers almost the whole aspects of the scattered neutrons. Also, it is difficult to promptly measure neutrons scattering of daily synthesized samples in magnetic material search, because large neutron facilities are unavailable without acceptance of experimental proposals and compact neutron sources available inside a laboratory are too weak to measure magnetic scatterings. To eliminate the bottleneck in magnetism, we note the plain fact that the neutrons transmitted through the material attenuate in proportion to the extent to which they are scattered. In this paper, we report the first observation of a magnetic Bragg dip and Bragg edge in the neutron transmission spectra of a typical spin order; clear antiferromagnetic Bragg dips and Bragg edges are found for a single crystal and powder of nickel oxide, respectively. The obtained results show that the neutron transmission spectroscopy is a promising tool both for advanced measurements under multi-extreme conditions and for daily analyses of spin structures using compact neutron sources.

H. Mamiya et al. Scientific Reports 7. 15516 (2017).

F4-03. Magnetic imaging with high spatial and temporal resolution at the PolLux endstation of the Swiss Light Source. *S. Finizio*[1], S. Wintz[1,2], K. Witte[1], B. Watts[1] and J. Raabe[1] *1. SYN, Paul Scherrer Institut, Villigen PSI, Switzerland; 2. Helmholtz Zentrum Dresden Rossendorf, Dresden, Germany*

Scanning transmission x-ray microscopy (STXM) is an x-ray microscopy technique that relies on the use of diffractive optics (Fresnel zone plates) to focus a monochromatic x-ray beam onto a spot of an x-ray transparent sample, and record the transmitted x-ray intensity with a suitable detector. By raster scanning the sample with a piezoelectric stage and recording the transmitted intensity at each point of the scan, a STXM image is then formed. STXM imaging combines the elemental sensitivity of monochromatic x-rays with the x-ray magnetic circular dichroism (XMCD) effect, allowing for the imaging of e.g. micro- and nanostructured magnetic materials, and multilayered magnetic systems. Depending on the employed zone plate, spatial resolutions on the order of 10 to 30 nm can be achieved with STXM imaging in the soft x-ray region. Time-resolved STXM imaging in the pump-probe regime is also possible. This is made possible by the use of avalanche photodiodes to detect the x-rays, and allows the achievement of temporal resolutions on the order of 50-100 ps. In this contribution, we present the current status and operation performances of the X07DA PolLux STXM endstation of the Swiss Light Source [1]. In particular, the performance of the endstation in imaging magnetic systems at high spatial and temporal resolutions will be presented. Furthermore, thanks to its modular design, the PolLux endstation allows for the implementation of specific setups aimed at the imaging of magnetic systems under special configurations. An example of such specific setups, which will be presented in this contribution, is the combination of STXM imaging with electrical transport measurements (e.g. aimed at the measurement of topological contributions of magnetic skyrmions to the anomalous Hall effect [2]).

F4-04. Novel magnetic field imaging technique using pulsed polarized neutrons. *T. Shinohara*[1], K. Hiroi[1], J.D. Parker[2], T. Kai[1], K. Oikawa[1], H. Hayashida[2] and Y. Kiyanagi[3] *1. J-PARC Center, Japan Atomic Energy Agency, Tokai, Japan; 2. Neutron Science and Technology Center, CROSS, Tokai, Japan; 3. Nagoya University, Nagoya, Japan*

Visualization of magnetic field/magnetization distribution in materials or a surrounding space is one of the important techniques to understand magnetic properties of objects. Since the neutron has a magnetic moment, it is possible to sense the magnetic field directly. As a result, the neutron spin state changes depending on the magnetic field strength and direction in the passage along which neutron travelling, or its trajectory changes. Especially because the neutron spin rotation around the magnetic field vector can be measured by means of the polarization analysis, visualizing magnetic field distribution becomes possible by the position dependent neutron polarization measurements. Moreover, as this rotation angle is proportional to the accumulated field strength along the neutron beam pass, it is also possible to

evaluate the magnetic field quantitatively. Recently the authors have developed a neutron imaging facility, named RADEN [1], at the Materials and Life Science Experimental Facility (MLF) in the J-PARC, and have installed a polarimetry apparatus for the three-dimensional neutron polarization analysis to conduct pulsed polarized neutron imaging experiments[2]. In this article, we will introduce about the novel magnetic field imaging technique using the pulsed polarized neutron beam and present recent results of the studies of magnetic domain structure in an electric steel and spatial magnetic fields around an electric motor and a transformer. And also we will discuss about the future prospect of this imaging technique.

F4-05. Subpixel-resolution Kerr Microscopy. V. Kletečka[1], *L. Ohnoutek*[1], L. Beran[1] and M. Veis[1] *1. Institute of Physics, Charles University, Prague, Czechia*

As the development of devices utilizing magnetic properties of various materials is constantly moving forward there is also an increasing need to characterize and further examine these properties. There exists many methods of measuring the magnetic field in materials (e.g. transmission electron microscopy, magnetic force microscopy) and one of the possible ways to do this is by utilizing the magneto-optical Kerr effect. This method is particularly attractive due to its non-invasiveness, so in our laboratory, we have devised a Kerr microscope setup which uses analyzer rotation technique. This setup has undeniable advantages as it is multi-purpose and able to obtain Kerr rotation directly from captured images. We present new progress in characterization of samples, mainly achievements in sub-pixel resolution which is important for small-scale devices characterization and incorporation of many state-of-the-art image processing algorithms during data post-processing phase. The post-processing incorporates noise inhibition, image registration, and sub-pixel domain wall detection. This will enable acquisition of more accurate results and will lead to better analysis of interesting properties of materials and devices. To demonstrate the setup capabilities we have measured and characterized NiFe permalloy gratings and domain structure of Bi:YIG garnets.

F4-06. Feature Extraction from Magnetic Domain Structure by Persistent Homology. *M. Kotsugi*[1,4], T. Yamada[1], S. Suzuki[1], Y. Suzuki[1], T. Ueno[5], C. Mitsumata[2], K. Ono[3], I. Obayashi[6], K. Akagi[6,4] and Y. Hiraoka[6,4] *1. Tokyo University of Science, Tokyo, Japan; 2. NIMS, Tsukuba, Japan; 3. KEK, Tsukuba, Japan; 4. MI2I, Tsukuba, Japan; 5. QST, Hyogo, Japan; 6. AIMR Tohoku Univ., Sendai, Japan*

Recently, Material Informatics is now one of central scientific and engineering subjects, and is rapidly enlarging its applications. Coercivity is an important magnetic property determining power generation efficiency of dynamo; however, its detailed mechanism has not been perfectly understood. One fundamental issue is the difference in data dimension, the correlation between 0-dimensional coercivity and multidimensional magnetic domain structure have not been established so far. In this study, we applied "Persistent Homology" to the magnetic domain structure and demonstrated the feature extraction describing macroscopic magnetic properties. Persistent Homology is a powerful methodology for quantitative evaluation of topological feature in structural data, and reduces the dimension. Moreover, it provides us the inverse analysis from magnetic property to original structural data in the combination with machine learning. We here demonstrate Persistent Homology analysis on magnetic domain structure and examine the validity and usefulness as a descriptor. Magnetic domain observation was performed on YIG garnet single crystal thin film by Kerr microscope, and clear maze pattern was obtained. Persistent Homology was applied to construct persistence diagram (PD). Horizontal and vertical axes in PD represent birth and death of space, respectively. The vertical spread of the data points is the topological feature reflecting the non-uniform of magnetic domain width. In order to examine the validity of PD, we analyzed a number of magnetic domain structures with the same brightness and different domain structures. The output PD showed a statistically common behavior. Next, we investigated magnetic field dependence of PD. The output PD continuously changes as the domain structure changes. PD also pinned particularly in correspondence with the pinning of the magnetic domain. These results indicate the excellent usefulness of PD as a descriptor of magnetic domains. Furthermore, we attempted inverse analysis to visualize dominant contributor of coercivity in the combination with PCA.

F4-07. An Ultrasensitive Differential Capacitance Dilatometer. *M. Williamsen*[1], D. Martien[1], R. Black[1], T. DaPron[1], D. Snow[1], B. Colvin[1] and S. Spagna[1] *1. Quantum Design Inc., San Diego, CA, United States*

In this paper, we describe an ultrasensitive differential capacitance dilatometer ($\Delta L/L \sim 10^{-9}$) and novel ratio metric measurement method in the temperature range between $1.9\ K < T < 400\ K$ for investigation of thermal expansion and magnetostriction of single crystal samples. The dilatometer provides a direct readout of the change in sample length using a balanced dilatometer cell design and nulling bridge. In this regard, an absolute capacity bridge is not required, and even more advantageously, the effects of adsorbed gas on the capacitor plates is greatly reduced compared to conventional dilatometers. The differential capacitance dilatometer provides a symmetrical configuration, which reduces the effects of temperature gradients. The capabilities of the dilatometer are demonstrated by measurements of the magnetic ordering of an URuSi2 sample and the de Hass Van Alphen oscillations in an Aluminum sample.

F4-08. Characterization of bulk magnetic domain structures using small-angle neutron scattering. *K. Ono*[1], M. Yano[2], K. Saito[3], T. Ueno[4], T. Shoji[5], V. Pipich[6], Z. Fu[7] and J. Kohlbrecher[8] *1. KEK, Tsukuba, Japan; 2. Advanced Materials Engineering Div., Toyota Motor Corporation, Susono, Japan; 3. Paul Scherrer Institut, Villigen, Swaziland; 4. Forschungszentrum Julich, Garching, Germany; 7. Department of Nuclear Physics, China Institute of Atomic Energy, Beijing, China; 8. Paul Scherrer Institut, Villigen, Switzerland*

Due to the rapid shift to electric vehicles is in progress on a global scale, high-performance magnetic materials are strongly demanded. Characterization of magnetic domains is the most fundamental characterization techniques for developing magnetic materials, as the magnetic domain structure indicates the link between macroscopic magnetic properties and the intrinsic magnetic properties of materials. Magnetic domains structure is usually observed by microscopy techniques such as Kerr microscopy, magnetic force microscopy, scanning transmission X-ray microscopy, and so on. However, these methods only yield magnetic domains of surface or thin samples. Characterization of bulk magnetic domain structure is demanded since the magnetic properties of magnetic materials are affected by the magnetic domain structure. Recent developments of neutron tomography enabled the direct imaging three-dimensional magnetic domain structures. However, the length scale for domain observation is limited. As a complementary method, small-angle neutron scattering (SANS) can probe bulk magnetic properties by magnetic sensitivity and high transmissivity in a matter of neutrons. Nuclear scattering includes information on microstructures of a sample such as grain size, interface morphology. On the other hand, magnetic scattering contains information of magnetic domains. An advantage of SANS is their multiscale capability, and this non-destructive method has high penetration and provides information with high statistical accuracy by averaging over a macroscopic sample volume [1-6]. Standard SANS technique covers the length scale from 1 to 100 nm in size and very small (VSANS) and ultra-small-angle neutron scattering (USANS) extend the length scale to a few 10 micrometers. We have applied SANS technique to characterize Nd-Fe-B permanent magnet. Sintered magnet and hot-deformed magnet samples with the average grain size of 2 micrometers and 160 nm were observed during magnetization reversal process. We have successfully estimated the average grain size and grain shape as well as the domain size and the shape of domain walls with SANS techniques.

F4-09. Electromagnetic influence of CRDM operating coils on rod position indication system. *G. Lee*[1], J. Lee[1], Y. Park[1] and J. Kim[1] *1. SMART Development, Korea Atomic Energy Research Institute, Daejeon, The Republic of Korea*

The control rod drive mechanism (CRDM) is an electromagnetic equipment that controls the reactivity by moving a control rod assembly (CRA). The position information of the CRA is provided by the Rod Position Indication System (RPIS) of the CRDM. The RPIS is an electric circuit consisting of reed switches and precision electric resistances. Not only the permanent magnet assembly but also the operating coils can affect the electromagnetic field around the reed switches, and reed switch activation due to the coils may cause a malfunction of the RPIS. This phenomenon was proved to be possible through a CRDM performance verification test when the supply current to the coils was increased. In this study, the electromagnetic influence from the coils is analyzed to establish the design criteria to arrange the RPISs without disturbing the operability. The analytical approach is based on previous studies as shown in References 1 and 2. The attraction between the reed blades is estimated using the electromagnetic FE analysis tool, ANSYS Electromagnetic Suite, when the lift and latching current are supplied. When the attraction is produced above the threshold level, it is assumed that the reed switch is activated because of the coils. The 3D analysis model is shown in Figure 1. It is assumed that the latching current is fixed as 25 A and the lift current is variable. It was easily found that the reed blade attraction increases along with the supply current increment as shown in Figure 2. Because the postulated threshold attraction level was 11 mN (the red dashed line), the reed switch may be activated at this position by the lift coil current of over 28 A. This estimation confirms that the current CRDM design for the RPISs and the coil arrangement are satisfactory without a malfunction of the RPIS because of the coil operation. These results shall be confirmed through the CRDM performance verification tests. Acknowledgement This study was supported by the National Research Foundation (NRF) grant funded by the Korea government (Ministry of Science and ICT) (2016M2C6A1930040).

F5-01. Colossal dielectric permittivity of diamagnetic $CdMoO_4:Eu^{3+}$ single crystal. B. Sawicki[1], E. Tomaszewicz[2], *T. Gron*[1], M. Berkowski[3], M. Glowacki[3], M. Oboz[1], J. Kusz[1] and H. Duda[1] *1. Institute of Physics, University of Silesia, Katowice, Poland; 2. Department of Inorganic and Analytical Chemistry, West Pomeranian University of Technology, Szczecin, Poland; 3. Institute of Physics, Polish Academy of Sciences, Warszawa, Poland*

Within the last decade, phosphor-converted white light-emitting diodes are a subject of increasing interest due to their significant advantages over conventional light sources, which include high stability, energy-saving, safety of work, and environment friendlyness. Very good candidates as red phosphors in WLEDs are microcrystalline undoped as well as Eu-doped metal molybdates or tungstates, e.g. Eu_2WO_6, $Cd_{0.25}Gd_{0.50}[]_{0.25}WO_4:Eu^{3+}$, and $Cd_{1-3x}Eu_{2x}[]_xMoO_4$ [1,2]. In the case of Eu_2WO_6 narrower multiplet widths comparable to the thermal energy cause a weak temperature dependence of the magnetic susceptibility without the Curie-Weiss region as well as a low conduction [3]. Our studies showed that single crystals of RE-doped cadmium molybdates i.e. $CdMoO_4:Dy^{3+}$, $CdMoO_4:Nd^{3+}$ with different concentration of dopant showed unique dielectric and magnetic properties [4,5]. Single crystal of $Cd_{0.9856}Eu_{0.0096}[]_{0.0048}MoO_4$ (later labeled as $CdMoO_4:Eu^{3+}$, where denotes cationic vacancies) were successfully grown by the Czochralski method. The X-ray diffraction analysis confirmed that this single crystal crystallizes in the scheelite-type structure (s.g. $I4_1/a$, No. 88). The electrical conductivity was measured by the DC method using a KEITHLEY 6517B Electrometer/High Resistance Meter. Broadband dielectric spectroscopy measurements were carried out using pellets, polished and sputtered with (~80 nm) Ag electrodes in the frequency range from 200 Hz to 2 MHz with a Novocontrol Alpha Impedance Analyzer and in the temperature range 76–400 K. Magnetic properties were measured using a Quantum Design MPMS-XL-7AC SQUID magnetometer in the temperature range 2–300 K in magnetic fields up to 70 kOe. The results of electrical and magnetic measurements showed diamagnetic and semiconducting properties with the activation energy of 0.08 eV regardless of the crystallographic axes. Unexpectedly, in the single crystal under study, the relative permittivity above room temperature reached values of 8,000 and 12,000 along axes [001] and [100], respectively. Such great relative permittivity can be associated with a strong charge accumulation when the width of Eu^{3+}-multiplet becomes comparable to the thermal energy *kT*.

F5-02. Spin frustration in semiconducting $ZnCr_2Se_4$ nanoparticles. *T. Gron*[1], E. Malicka[2], A. Gudwanski[2], A. Slebarski[1], J. Goraus[1], M. Fijalkowski[1], M. Oboz[1], M. Karolus[3] and Z. Stoklosa[3] *1. Institute of Physics, University of Silesia, Katowice, Poland; 2. Instytute of Chemistry, University of Silesia, Katowice, Poland; 3. Institute of Material Science, University of Silesia, Chorzow, Poland*

Commercial applications of thermoelectric devices entailed interest in new materials. Seleno-spinels are promising compounds for this purpose [1] due to rather large cubic unit cell of 10 Å. Pure $ZnCr_2Se_4$, both in mono and polycrystalline form combines *p*-type semiconducting conductivity and a helical antiferromagnetic (AFM) order below the Néel temperature T_N = 20 K with a strong ferromagnetic (FM) component evidenced by a large positive Curie-Weiss temperature (θ) of 115 K [2,3]. The magnetic order is accompanied by structural transformation from cubic *Fd*-3*m* to tetragonal $I4_1/amd$ symmetry with a small contraction along the *c* axis [4]. The nanosized crystallites of $ZnCr_2Se_4$ spinel were made using the High-Energy Ball-Milling (HEBM) method. The starting materials for the HEBM method were monocrystalline samples to avoid impurity phases whose lack was confirmed by the powder X-ray diffraction studies. After 5 h of milling, the crystallite size reached 2 nm, as calculated basing on the Hall–Williamson theory. Static dc and dynamic ac magnetic susceptibility as well as specific heat were carried out in the temperature range 2-300 K using a Quantum Design PPMS platform. The results of magnetic measurements showed that the zero field-cooling (ZFC) and field-cooling (FC) susceptibility (χ) start diverging at the freezing temperature of 17.5 K, suggesting the spin frustration strengthened by the fact that the short-range superexchange interaction is antiferromagnetic (θ = -200 K) and the long-range one is ferrimagnetic (the curve of $1/\chi(T)$ deviates downward from its linear part). The studied nanoparticles are difficult to magnetize, which can be seen on magnetic isotherms, which are far from saturation at 2 K and in the magnetic field of 75 kOe. Electrical conductivity measurements showed the semiconducting properties of $ZnCr_2Se_4$ nanoparticles in the temperature range of 76-400 K. No peak was observed on the specific heat curve, which may suggest a lack of both magnetic and structural transition below the freezing temperature of 17.5 K. This work was supported by Ministry of Scientific Research and Information Technology (Poland) and funded from science resources: No. 1S-0300-500-1-05-06.

$ZnCr_2Se_4$ spinel is a matrix of various diluted systems where effects of site disorder, lattice frustration and random distribution of spin interactions

create novel potential applications in spin-based electronic technology. $ZnCr_2Se_4$ semiconductor reveals a spectacular transition to an antiferromagnetic (AFM) state at the Néel temperature T_N = 20 K with the dominating ferromagnetic (FM) interactions evidenced by large positive Curie–Weiss temperature θ = 115 K [1,2] and accompanied by a structural transformation from cubic *Fd*-3*m* to tetragonal $I4_1/amd$ symmetry with a small contraction along the *c* axis [3], although, the structural investigations using synchrotron radiation defined the latter symmetry as orthorhombic *Fddd* [4]. The compounds belonging to $Zn_{1-x}Mn_xCr_2Se_4$ system were prepared by ceramic method in the concentration range x = 0.1–0.5. Chemical compositions of the samples under study were determined using ICP-AES method. XRD and Rietveld analysis were used in order to obtain anion and lattice parameters. The magnetic isotherms were measured in high magnetic stationary fields (up to 14 T) within a temperature range of 4.2–300 K using an induction magnetometer. The magnetic susceptibility was determined in the temperature range of 1.8–300 K using a Quantum Design SQUID-based MPMSXL–5-type magnetometer. The results of magnetic measurements showed that the compounds under study are antiferromagnets with the Néel temperature of 18-25 K and the Curie–Weiss temperature increasing from θ = 84 K for x = 0.1 to θ = 105 K for x = 0.5. Below T_N the magnetic field dependence of magnetization shows two peaks at critical fields H_{c1} connected with metamagnetic threshold accompanied with transition from helical to conical phase and H_{c2} where the conical magnetic structure transforms into ferromagnetic phase. The values of H_{c1} remain almost constant while the values of H_{c2} shift into higher magnetic fields as the Mn-content increases. Low-dimensional compounds of transition-metal elements continue to be the focus of diverse scientific studies because of a multitude of interesting electrical and magnetic properties, such as high-temperature superconductivity [1], colossal magnetoresistance [2] and thermoelectricity [3]. Effecting and controlling ferromagnetic-like properties in semiconductors has proven to be a complex problem, especially when approaching room temperature. Here we demonstrate the important role of defects in the magnetic properties of semiconductors by reporting the structure and properties of the iron chalcogenides $(BaF)_2Fe_{2-x}Q_3$ (Q = S, Se), which exhibit anomalous magnetic properties that are correlated with defects in the Fe-sublattice. The compounds form in both long-range ordered and disordered polytypes of a new structure typified by the alternate stacking of fluorite $(BaF)_2^{2+}$ and $(Fe_{2-x}Q_3)^{2-}$ layers. The latter layers exhibit an ordered array of strong Fe-Fe dimers in edge-sharing tetrahedral dimers. Given the strong Fe-Fe interaction, it is expected that the Fe-Fe dimer is antiferromagnetically coupled, yet crystals exhibit a weak ferromagnetic moment that orders at relatively high temperature: below 280 – 315 K and 240 - 275 K for the sulfide and selenide analogs, respectively. This transition temperature positively correlates with the concentration of defects in the Fe-sublattice as determined by single crystal x-ray crystallography. Our results indicate that internal defects in $(Fe_{2-x}Q_3)$ layers play an important role in dictating the magnetic properties of newly discovered $(BaF)_2Fe_{2-x}Q_3$ (Q = S, Se), which can yield switchable ferromagnetically ordered moments at or above room temperature.

Dilute magnetic semiconductors (DMS) have in recent decades been extensively studied as potential materials for spintronic devices. Transition metal doped ZnO DMS were suggested to be promising hosts for room temperature ferromagnetism in Mn-doped ZnO [from experimental studies 1] and a theoretical phase diagram predicting a transition to ferromagnetism at moderate dopings in a range of magnetic oxides and nitrides [2]. However, through polarised neutron scattering experiment, we established in [3] that the ferromagnetic behaviour of (Mn,Zn)O appearing in magnetisation measurements is strongly linked to the formation of MnO nanoparticles and concluded that ferromagnetic correlations in Mn:ZnO do not come from a substitution of the zinc by manganese in the ZnO matrix, but from the presence of non-compensated spins at the surface of segregated MnO nanoparticles. Following our (Mn,Zn)O results, we expanded the study to the (Co,Zn)O, another desirable candidate for spintronics showing a large ferromagnetic moment at room temperature. Contradicting views exist on the origin of ferromagnetism in (Co,Zn)O, with a strong dependence on the fabrication method [4,5]. We have carried out polarised neutron scattering experiments on moderately doped (Co,Zn)O powder samples in order to establish the spin correlations, which were then combined with magnetisation measurements. In our cluster-free (Co,Zn)O samples, we found paramagnetic behaviour at high temperatures and short-ranged antiferromagnetic correlations a 5K, consistent with our magnetisation results. We will discuss the implications of our results on the origin of ferromagnetism in ZnO dilute magnetic semi-conductors.

University of Silesia, Katowice, Poland*

Multicomponent oxide systems are widely studied in the last few decades as they are a search area for new materials of interesting magnetic, electric or catalytic properties. It is known from literature data that a series of $M_2FeV_3O_{11}$ (M = Mg, Zn, Pb, Co, Ni) and $M_2InV_3O_{11}$ (M = Mg, Zn, Co, Pb, Ba, Sr) [1–6] compounds are good candidate, which can be used for example as components of effective catalysts for the oxidation processes of light hydrocarbons or as cathode materials in high-energy cells. Preliminary studies of the reactions occurring in the $Zn(Mg)O\text{-}V_2O_5\text{-}In_2O_3$ system allowed to synthesize a series of solid solution of the formula $Zn_{2-x}Mg_xInV_3O_{11}$ (x = 0.0, 0.4, 1.0, 1.6, 2.0) [6]. The X-ray diffraction analysis confirmed that these solid solutions crystallize in the triclinic system. The sample morphology observed on the scanning electron microscopy images showed that the crystals of the phases are irregular polyhedra and their average size is about 1–5 μm. The *I-V* characteristics and the electrical conductivity were measured by the DC method using a KEITHLEY 6517B Electrometer/High Resistance Meter. Magnetic properties were measured using a Quantum Design MPMS-XL-7AC SQUID magnetometer in the temperature range 2–300 K in magnetic fields up to 70 kOe. The results of magnetic measurements of $Zn_{2-x}Mg_xInV_3O_{11}$ showed diamagnetic behavior above room temperature and a weakening paramagnetism with an increase in the content of magnesium ions in the sample at low temperatures. All solid solutions showed semiconducting properties with activation energy of 0.2-0.3 eV in the temperature range of 250-400 K. The *I-V* characteristics, measured at 300 and 400 K, showed a symmetric and linear behavior with more carrier emission for the matrix, and much less for the remaining samples. The latter case may be caused by vacancy trapping centers [7] on the one hand or with the oxidative and passive properties of magnesium ions on the other. Both these mechanisms corroborate the carrier emission. F5-07. Magnetic Semiconducting Heusler Compound $Fe_2Ti_{0.5}Co_{0.5}Si$. *Y. Jin*[1,2], Y. Yang[1,2], s. Valloppilly[2], S. Liou[1,2] and D.J. Sellmyer[1,2] *1. Physics and Astronomy, University of Nebraska-Lincoln, Lincoln, NE, United States; 2. Nebraska Center for Materials and Nanoscience, University of Nebraska-Lincoln, Lincoln, NE, United States*

In spintronics, magnetic semiconductors (MSs), have attracted much attention because in principle they can produce completely (100 %) spin-polarized currents. In addition, the Curie temperature of a MS must be above room temperature (RT) for device applications. In recent years, there has been an upsurge of research on new materials with desired properties, especially in the family of Heusler compounds [1]. Fe_2TiSi with a band gap of about 0.4 eV is a paramagnetic material [2, 3] and is one of the rare full-Heusler structure semiconductors. The Heusler compound Fe_2CoSi was found to be ferromagnetic with a magnetic moment of 4.92 μ_B/f.u. at 5 K and DFT calculations show a zero-gap half-metallic valence-band spectrum close to the Fermi energy [4]. In order to obtain a ferromagnet with high saturation magnetization while conserving the semiconducting properties, we investigate here replacing half of the Ti atoms with Co atoms, i.e., $Fe_2Ti_{0.5}Co_{0.5}Si$. In this work, the structural, magnetic and electron-transport properties of $Fe_2Ti_{0.5}Co_{0.5}Si$ are investigated. The rapidly quenched $Fe_2Ti_{0.5}Co_{0.5}Si$ ribbons crystallized in the cubic $L2_1$ structure. Due to Co substitution, $Fe_2Ti_{0.5}Co_{0.5}Si$ exhibits ferromagnetism with a high Curie temperature of about 790 K. $Fe_2Ti_{0.5}Co_{0.5}Si$ has a RT resistivity ρ(T) of about 6.5 mΩcm and shows a negative temperature coefficient of resistivity. ρ(T) below 100 K has a ρ_0 -A*ln(T) dependence similar to the Kondo effect which might be attributed to a disorder induced materials-specific spin scattering effect. The carrier concentration *n* is 1.15×10^{20} cm^{-3} at 5 K. The high Curie temperatures and magnetic semiconducting behavior make this material promising for RT spintronic and magnetic applications. This research is supported by NSF-DMREF: SusChEM (1436385), NSF-NNCI (1542182), NCMN.

F5-08. Epitaxial thin films of EuS on InAs (100) for future spintronic applications. *A. Goschew*[1], N. Blümel[1] and P. Fumagalli[1] *1. Physics, Freie Universität Berlin, Berlin, Germany*

A major part in spintronics is the efficient spin-injection and detection of spin-polarized currents within the frame of current modern day semiconductor electronics. However, a direct combination of a ferromagnet with a semiconductor for efficient spin-injection is impeded by the impedance mismatch between metals and semiconductors [1]. One way to overcome the impedance mismatch is using a ferromagnetic semiconductor like europium sulfide (EuS). It has a bandgap of 1.6 eV, and a magnetic moment of 7 μ_B per atom with a Curie Temperature (T_C) of just 16.5 K. The low T_C is a drawback for possible direct integrations of EuS in room temperature (RT) spintronics. However, recent combinations of EuS with 3d-metals like Co or Ni have shown an increase of T_C up to RT in multilayer structures [2,3]. More recently EuS/Co bilayers on top of GaAs-based spin-LEDs have shown first results of efficient spin injection at low temperature as well as RT [4]. While the EuS in these multilayers was polycrystalline, for possible future applications EuS would need to be integrated into existing semiconductor electronics epitaxially. We present results of a growth study of thin EuS on the semiconductor InAs in (100) direction. The grown films were deposited by electron-beam-evaporation. Their thickness varies in the range between 2 nm and 20 nm, while the growth temperature was varied between RT and 400° C. Film quality analysis was carried out by RHEED, SPA-LEED, XRD and AFM. The atomic composition was analyzed by Auger electron spectroscopy and XPS. All films show that we succeeded in growing EuS epitaxially (Fig. 1) with the best film quality being achieved at substrate temperatures around 150° C (Fig. 2). The controlled evaporation of thin epitaxial films of EuS on a III-V semiconductor opens up new possibilities for future use of EuS-based spintronic devices. Logically, the next steps will include magnetic measurements of these thin films and the combination with Co to further study the nature of the Curie Temperature enhancement

F6-01. Magnetization reversal mechanism of shape-anisotropy magnetic tunnel junctions. *K. Watanabe*[1], B. Jinnai[2], S. Fukami[1,2], H. Sato[1,2] and H. Ohno[1,2] *1. RIEC, Tohoku University, Sendai, Japan; 2. CSIS, Tohoku University, Sendai, Japan*

Perpendicular-easy-axis (Co)FeB/MgO [1] with a double-interface structure [2] is a *de-facto* system for magnetic tunnel junctions (MTJs) in spin-transfer torque magnetoresistive random access memory (STT-MRAM). This structure allows to miniaturize the MTJ while keeping high performance down to around 20 nm [3], below which a new approach needs to be explored to achieve high enough thermal stability. Recently, we showed a shape-anisotropy MTJ that can overcome this issue, where the free layer diameter D is reduced and the thickness t increased so that the shape anisotropy positively contributes to the perpendicular anisotropy. High thermal stability and STT-induced switching are demonstrated for MTJs even below 10 nm, or the single-digit-nanometer scale [4]. An important question for the shape-anisotropy approach is the coherency/incoherency along the vertical direction of magnetization reversal, because the benefit of this approach presupposes a single-domain model. Here we elaborate the physics of the shape-anisotropy MTJ, in particular the magnetization reversal mechanism and upper limit of the thickness. We firstly measure the magnetic field angle θ_H dependence of the switching field [5] for fabricated MTJs and show that the result is well described by an astroid-like curve derived from the single-domain model(Fig. 1), suggesting coherent reversal of the MTJ. We then discuss the thickness dependence of reversal mode during current-induced switching from micromagnetic simulations of shape-anisotropy MTJs with various t. The simulation results indicate that single-domain switching occurs until an upper limit of $t \sim 30$nm (the domain wall width). These results indicate that our concept of shape-anisotropy MTJs drawn from predictions of the single-domain analytical model [4] is valid, allowing high performance STT-MRAM to be realized in a single-digit-nanometer scale. This work was partially supported by JST-OPERA and ImPACT Program of CSTI. K.W. acknowledges GP-Spin, Tohoku Univ.

F6-02. Experimental and theoretical evidence of band gap and spin injection devices. *P. Kumar*[1], R. Singh[1], F. Ahmed[1], N. Kumar[2], A. Ojha[2], S. Kushvaha[3] and R. Kumar[3] *1. Applied Sciences, IIIT Allahabad, Allahabad, India; 2. Department of Physics, Motilal Nehru National Institute of Technology Allahabad-211004, India, Allahabad, India; 3. National Physical Laboratory, CSIR, New Delhi-110012, India, Delhi, India*

During the last decade there has been a growing interest in complementary metal oxide semiconductor (CMOS) integrable spin based electronics (spintronic) devices, owing to the scaling limit of such devices.[1] Spins in semiconductors are held up to quite high standards when it comes to information processing in CMOS electronics. In order to fulfil the requirement of a high (~100%) spin polarization, the prospect of Heusler alloys as a spin injector layer has been explored. Heusler alloy possess half metallicity i.e. all the carriers at the Fermi level are spin polarized and only spin band is occupied. Band gap studies for thin films of Co_2CrAl deposited on Silicon and glass by DC sputtering were carried out employing Tauc plot. The procedures lead to a discovery of a forbidden transition in the band gap with an indirect forbidden band gap value of 0.5252 eV. The magnetic measurement observations revealed the $L2_1$ structural[2] ordering and ferromagnetic nature of the film. The partial density of states (PDOS) as shon in fig.1 of the electrons having up and down spins in the crystal lattice is calculated employing density functional theory (DFT) calculations using VASP code. We have also observed the spin injection from Co_2CrAl layer into an n-type Silicon (100) substrate. Upon obtaining structural and magnetic characteristics we obtained I-V characteristics of the device so as to ascertain the existence of a Co_2CrAl/Si Schottky [Fig.2] contact which lead us to infer spin injection phenomenon from Co_2CrAl into Silicon due to tunnelling through the lowered Schottky barrier. Figure 2 (a) represents the schematic diagram of the device fabricated by depositing Co_2CrAl film on Si substrate. The devices on which the I-V characterization has been performed consist of multiple films with varying electrode distances, as shown in Figure 2 (b). The reverse bias characteristics are explained on the basis of formation of a Schottky contact and its lowering.

F6-04. Ferromagnet/Semiconductor/Ferromagnet Hybrid Trilayers grown using Solid-phase Epitaxy. S. Gaucher[1], B. Jenichen[1] and *J. Herfort*[1] *1. Paul-Drude-Institute, Berlin, Germany*

The development of multilayer tunnel devices combining ferromagnetic metals (FM) like Heusler alloy Co_2FeSi or Fe_3Si with semiconductors (SC) like Ge or GaAs is limited by the difficulty of growing epitaxial SC *on top of* metals due to large differences in crystallization energies. This causes undesirable interfacial reactions. This is problematic because spin-injection from the FM into the SC requires sharp interfaces with well-defined Schottky tunnel barriers. We recently developed a solid-phase expitaxy approach to create lattice-matched crystalline FM/SC/FM thin film stacks while preventing interfacial reactions [1]. A thin amorphous layer of Ge is deposited on Fe_3Si and then crystallized slowly by annealing. Capping FM layers could then be grown on top of this crystalline layer with high perfection as seen in Fig. 1. The structural analysis reveals that the Ge layer incorporates Fe and Si atoms to spontaneously form an ordered superlattice, with 2D planes of Fe atoms interposed between tetragonal Ge formations. This crystal structure is identified as $FeGe_2$ (where Si atoms replace some Ge lattice sites), a compound that in this structure is not energetically stable as a bulk material [2]. To investigate its electrical and magnetic properties, we prepared also pure $FeGe_2$ on semi-insulating GaAs(001) substrates. $FeGe_2$ thin films are ferromagnetic below 150 K, show a strong magnetocrystalline anisotropy and have a room temperature resistivity $\rho \approx 8 \times 10^{-6}$ Ω m. Alike other thin Fe-Ge compounds [3], $FeGe_2$ in itself is an interesting material and is expected to host topological magnetic skyrmions, among other micromagnetic phenomena. Fig. 2 demonstrates the possibility to control individually the magnetization of the trilayers (parallel or anti-parallel). In addition, the electrical tunnel characteristics were studied. The realization of the $Fe_3Si/FeGe_2/Co_2FeSi$ trilayers is an important step to realize fully crystalline vertical-type semiconductor spintronic devices.

F6-05. Quantum Transport based study of Scaling Effects on Magnetic Tunnel Junctions. *D. Das*[1], A. Tulapurkar[2] and B. Muralidharan[2] *1. Electrical Engineering, Indian Institute of Technology Bombay, Mumbai, India; 2. Electrical Engineering, Indian Institute of Technology, Bombay, Mumbai, India*

Here we present the scaling effect on trilayer magnetic tunnel junctions (MTJs) and pentalayer resonant tunneling MTJs (RTMTJs) by exploring the effect of the cross-sectional areas varied from 25 nm^2 to 10000 nm^2 along the transverse direction. In a trilayer MTJ, a thin MgO layer is sandwiched between a fixed and a free ferromagnetic (FM) layer, whereas in a RTMTJ, a MgO–Semiconductor(SC)–MgO heterostructure is sandwiched between the fixed and the free FM layers. We simulate both structures using the non-equilibrium Green's function (NEGF) spin transport formalism[1,2]. Our findings[3] show that both devices show constant tunnel magnetoresistance (TMR) at larger areas while shooting up rapidly to an ultra-high TMR as the transverse area is reduced to smaller values. For MTJs (RTMTJs), the TMR is 330% (2579%) for larger areas and shoots up to 786% (7374%) at 25 nm^2. The TMR profile for MTJ and RTMTJ are shown in Fig. 1 (a) and (b) respectively. For PC or APC the charge current is calculated as the sum over all the transverse mode currents as shown in Fig. 1 (c)-(f). Both devices show low resistance-area (RA) product of about 2.36 Ω-μm^2 for MTJ and 1 Ω-μm^2

for RTMTJ. The devices considered here, i.e., MTJ and RTMTJ, show high TMR, high resistance, and low RA product at smaller areas. Except for this high resistance, this high TMR, and low RA product satisfy the condition for high-density hard disk drives (HDDs). We thus also propose a device configuration that comprises MTJs with a smaller area connected with each other in a PC so that every MTJ has a common contact on both sides as shown in Fig. 2. With our proposed device, we show that one can lower the resistance while keeping high TMR and low RA product obtained at a small area.

F6-06. Tunneling anisotropic magnetoresistance in an antiferromagnet-based perpendicular tunnel junction with $L1_0$-MnGa/FeMn/AlO_x/Pt structure. *X. Zhao*[1], D. Wei[1], J. Lu[1] and J. Zhao[1] *1. State Key Laboratory of Superlattices and Microstructures, Institute of Semiconductors, Beijing, China*

The tunneling anisotropic magnetoresistance (TAMR) in an antiferromagnet-based tunnel junction is a key element in antiferromagnetic spintronics. Here we report on the TAMR in an antiferromagnet-based perpendicular tunnel junction consisting of $L1_0$-MnGa/FeMn/AlO_x/Pt grown on GaAs (001) substrate by molecular-beam epitaxy. Recently, we have observed large spontaneous perpendicular exchange bias effect in $L1_0$-MnGa/FeMn bilayers, which indicates strong exchange coupling between ferromagnetic $L1_0$-MnGa and antiferromagnetic FeMn [1]. The rotation of antiferromagnetic spins in FeMn can be driven by perpendicularly magnetized $L1_0$-MnGa due to the exchange-spring effect at the interface. The tunnel junction shows TAMR signal up to 0.46% at 5 K and 0.85% at 300 K, which are larger than the previous results with similar structure [2]. The angular dependence of TAMR has been measured to further investigate the rotation behavior of antiferromagnetic spins in FeMn. All these results could help pave the way towards the development of antiferromagnetic spintronic devices with high thermal stability.

F7-01. Magnetic phase diagram of rare earth based high entropy alloys. *Z. Jaglicic*[1,2], J. Luznik[3], P. Kozelj[3], S. Vrtnik[3], A. Jelen[3], J. Luzar[3], J. Dolinsek[3] and A. Meden[4] *1. Institute of Mathematics, Physics and Mechanics, Ljubljana, Slovenia; 2. Faculty of Civil and Geodetic Engineering, University of Ljubljana, Ljubljana, Slovenia; 3. J. Stefan Institute, Ljubljana, Slovenia; 4. Faculty of Chemistry and Chemical Technology, University of Ljubljana, Ljubljana, Slovenia*

Three rare earth based high entropy alloys, namely Ho-Tb-Dy-Gd-Y[1], Ho-Tb-Dy-Gd-Lu, and Ho-Tb-Dy-Er-Tm with almost equimolar ratio of elements, have been studied by their magnetic, electric, and thermal properties. A typical magnetic phase diagram constructed by experimentally determined temperature dependent dc and ac susceptibility and isothermal magnetization curves is shown in Fig. 1. The transition temperature from antiferromagnetic phase into the spin glass or disordered ferromagnetic phase was determined from the maximum of the ac susceptibility. The maximum shifts with a frequency of the applied magnetic field. The spin glass or disordered ferromagnetic phase appears due to strongly interacting spins of different magnitudes randomly distributed on a hexagonal lattice. A large magnetoresistance of about – 8 % in a magnetic field of 9 T has been observed in Ho-Tb-Dy-Gd-Lu high entropy alloy just below the Néel temperature T_N = 174 K.

F7-03. Magneto-caloric effect of the Shastry-Sutherland compound $SrCu_2(BO_3)_2$. *S. Akimoto*[1], Y. Kohama[1], Y. Matsuda[1] and H. Kageyama[2] *1. Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan; 2. Graduate School of Engineering, Kyoto University, Kyoto, Japan*

$SrCu_2(BO_3)_2$ has the Shastry-Sutherland lattice, and Cu^{2+} (S = 1/2) dimers are arranged orthogonally to each other in the $CuBO_3$ layer. Due to the effects of quantum frustration from the characteristic geometrical arrangement, $SrCu_2(BO_3)_2$ exhibits various exotic quantum phenomena in magnetic fields[1]. In the present work, we have conducted magneto-caloric effect measurement on $SrCu_2(BO_3)_2$ in high magnetic fields up to 53 T. We have measured the temperature of a single crystal of $SrCu_2(BO_3)_2$ sample under pulsed magnetic fields. As the total duration of our pulsed magnetic field (~ 36 ms) is relatively short compared with the time for thermal exchange with environment, our measurement system is regarded to be approximate adiabatic condition. In adiabatic condition, the system temperature changes isentropically. Fig. 1 shows the magnetic field dependence of the temperature at different initial temperature. Magnetic field is applied parallel to the c-axis of the crystal. Clear anomalies at the boundaries of the 1/4 (34 T – 38 T) and 1/3 (40 T) magnetization plateaux have been observed. In addition, other anomalous field variations are found at 25.7 T and 43 T, which are more clearly seen in dT/dB curve (not shown) and will be discussed in terms of the B-T phase diagram.

F7-04. Ferromagnetic to Spin Liquid Transition in $HgCr_2Se_4$ under Large Pressures. *P. Jorba Cabré*[1], M. Schulz[2], P. Böni[1], V. Tsurkan[3], A. Loidl[3] and C. Pfleiderer[1] *1. Physics Department, Technical University of Munich, Muncih, Germany; 2. Forschungsneutronenquelle Heinz Maier-Leibnitz (FRM II), Garching, Germany; 3. Center for Electronic Correlations and Magnetism, University of Augsburg, Augsburg, Germany*

In the family of isostructural, geometrically frustrated Chromium spinels $HgCr_2Se_4$ has been advertised as a candidate material supporting Weyl physics. As an unexpected new facet of the wide range of ground states in the Chromium spinels, we report the identification of a ferromagnetic to spin

liquid transition in single-crystal $HgCr_2Se_4$ under large hydrostatic pressures. For our study we have developed the capability to perform neutron depolarization measurements up to 10 GPa down to mK temperatures using a Moissanite anvil cell as combined with focussing neutron guides. Under increasing pressure, the Curie temperature in $HgCr_2Se_4$ decreases and fragile reentrant neutron depolarization emerges in a finite temperature interval at pressures exceeding 3 GPa. Analogous neutron depolarization measurement in $HgCr_2S_4$ identify this behaviour as the Hall mark of a highly unusual spin liquid. The associated shift of paradigm underscores the potential of neutron depolarisation measurements as an easy to use probe in the search for unvconventional magnetic and superconducting ground states.

F7-05. The high-field susceptibility and magnetic anisotropy of the quasi-two-dimensional antiferromagnet $FePS_3$. D. Lançon[1,3], M.K. Chan[2], M.E. Zhitomirsky[4], M. Gvozdikova[1], V. Simonet[5], H.M. Ronnow[3] and *A.R. Wildes*[1] *1. Institut Laue-Langevin, Grenoble, France; 2. CEA, INAC-PHELIQS, Université Grenoble Alpes, Grenoble, France; 5. Institut Néel CNRS, Grenoble, France*

$FePS_3$ is a good example of a quasi-two-dimensional Ising-like antiferromagnet with a honeycomb lattice. It orders below its Néel temperature of 120 K, forming ferromagnetic zig-zag chains that are antiferromagneticaly coupled within the crystallographic ab planes, and the ordering is present even down to atomically-thin layers [1]. The moments are parallel to the normal to the planes. The magnons have previously been measured and were modelled with a Hamiltonian containing a large easy-axis single-ion anisotropy [2]. We have measured the magnetic susceptibility (dM/dH) of aligned single crystals in pulsed fields up to 65 Tesla (c.f. Figure 1). The magnetization shows a number of remarkable features. Measurements at 4K with the field parallel to the ordered moments show two transitions with a large hysteresis between 30 and 45 Tesla, resembling first-order phase transitions, consistent with spins flipping to form a new ferrimagnetic structure. The results are consistent with previous experiments [3]. Measurements with the field perpendicular to the moment directions show a hitherto unobserved anisotropy. The susceptibility with the field parallel to the zig-zag chains shows a smooth increase up to the maximum applied field. When the field is perpendicular to the chains the susceptibility shows a cascade of abrupt transitions with increasing field above 50 Tesla followed by a very sharp transition with decreasing field at around 30 Tesla. The results suggest that the chain direction is the easiest axis, and that a second anisotropy is found perpendicular to the chains. The results are discussed with regard to the strong Ising-like anisotropy of $FePS_3$, and the implications for other magnetic members of the transition metal-PS_3 family of compounds are examined.

F7-06. Effect of Carbon Content on TransformationTemperature in Mn_3SnC Antiperovskites. V. Gaonkar[1], E. Dias[2], K. Priolkar[1] and *A.K. Nigam*[3] *1. Goa University, Goa, India; 2. Tata Institute of Fundamental Research, Mumbai, India; 3. Department of Condensed Matter Physics and Materials Science, Tata Institute of Fundamental Research, Mumbai, Mumbai, India*

Mn_3SnC is a cubic antiperovskite that undergoes a first order magnetic transition from a low volume paramagnetic (PM) state to a high volume magnetically complex ordered state at about 280K [1]. It also exhibits a large magnetocaloric effect suitable for applications [2]. According to Goodenough-Kanamori rules, antiperovskites have competiting 90^0 Mn – Mn direct ferromagnetic (FM) interactions and the 180^0Mn – C – Mn antiferromagnetic (AFM) interactions [3]. This competition is alleviated by undergoing a volume expanding magneto-structural transition which is not the case in Mn_3SnC. Recent time dependent magnetization studies have shown that in the mixed magnetostructural transition of Mn_3SnC, the AFM component is not present when the transition is initiated but appears later in time [3]. Such a complex magnetic ordering has been attributed to local structural distortions of the Mn_6C octahedra which result in longer and shorter Mn-Mn bond distances even in a cubic phase [1]. These studies raise a question on the role of C in magnetic interactions between Mn atoms in antiperovskites. To probe this question, we have prepared a series of Mn_3SnC_x (x= 0.89, 0.97, 1.0, 1.05 and 1.07) and characterized them for their structural, magnetic and transport properties. The results show that increase in C content leads to increase in lattice constant '*a*', magnetostructural transition Temperature T_{ms} and magnitude of resistivity.The observed results can be explained on the basis of changesin Mn-Mn bond distances with change in C content. The decrease in C content leads to a decrease in unit cell volume and hence Mn-Mn distance decreases. Shortening of Mn-Mn distances strengthen AFM interactions which is evidenced by decrease in T_{ms}. Further with decrease in Mn-Mn distance implies larger band dispersion and therefore a decrease in resistivity.

F7-07. Competition of the magnetic anisotropies in $Ni_{1-x}Mn_xPS_3$.
Y. Morita[1], T. Watanabe[1], K. Takase[1] and Y. Takano[1] *1. Department of Physics, Nihon University, Tokyo, Japan*

We have investigated the magnetic properties of $Ni_{1-x}Mn_xPS_3$. The transition metal phosphorous trichalcogenides MPX_3 (M: transition metal ion, X: chalcogenide ion) are cation-ordered $CdCl_2$ type layered compounds, where the transition metal ions form a honeycomb lattice. MPX3 have a different magnetic structure at low temperature by the difference of the transition metal ions [1]. The competition of magnetic interactions is expected in the mixed compounds. The direction of the magnetic moment in ordered state is perpendicular to the *c*-plain in both $MnPS_3$ and $FePS_3$. The magnetic structure of $MnPS_3$ is different from that of $FePS_3$. Spin glass phenomena is observed in $Fe_{0.5}Mn_{0.5}PS_3$ [2]. On the other hand, the direction of the magnetic moment is parallel to the *c*-plain in $NiPS_3$. $Fe_{0.5}Ni_{0.5}PS_3$ is reported to be a spin glass [3]. However, in the mixed compounds $Ni_{1-x}Mn_xPS_3$, the competition of the magnetic anisotropy is also expected similar to $Fe_{1-x}Co_xCl_2$-$2H_2O$ [4]. The broad peak which is characteristic for low dimensional magnets is observed above T_N in the temperature dependence of the magnetization of all samples. The Néel temperature, T_N, of $NiPS_3$ and $MnPS_3$ are 160.4 K and 78.5 K, respectively. T_N decreases with increasing *x* and takes a minimum value of 58.4 K at $x = 0.5$. Then, T_N increases with increasing *x*. However, the magnetic anisotropy of $NiPS_3$ is kept to $x = 0.6$, and changes to that of $MnPS_3$.

F7-08. Magnetocaloric effect and the change from first- to second-order magnetic phase transition in $Pr_{0.7}Ca_xSr_{0.3-x}MnO_3$ polycrystalline compounds. *Y.D. Pham*[1], T. Thanh[2], N. Dung[2], M.V. Tien[1], W. Shon[3], J. Rhyee[3], D. Kim[1] and S. Yu[1] *1. Department of Physics, Chungbuk National University, Cheongju, The Republic of Korea; 2. Institute of Materials Science, VAST, Hanoi, Vietnam; 3. Department of Applied Physics, Kyunghee University, Gyung-gi, The Republic of Korea*

The work presents the magnetocaloric effect of $Pr_{0.7}Ca_xSr_{0.3-x}MnO_3$ compounds prepared by solid state reaction. Up to full replacement of Ca for Sr, type of unit cell of all compounds still unchanged, with a single-phase monoclinic structure. The ferromagnetic-paramagnetic (FM-PM) phase transition decreases from 268, 202, 138 to 126 K with increasing doping concentration from x=0 to x=0.4. The magnetic entropy change ($-\Delta S_m$) calculated indirectly from isothermal magnetization data was found to be 6.38, 7.18, 3.95 and 3.98 $J.kg^{-1}.K^{-1}$ with 50 kOe of field change for x=0-0.4, respectively. The relative cooling power (RCP) enhances with increasing doping due to the extension of peaks of $-\Delta S_m(T)$ curves. The maximum values of entropy change ($-\Delta S_{max}$) appear near the transition phase points. However, the shift to the higher temperarure side with the increasing field change was observed clearly in sample x=0.1. Besides, the considering magnetic phase transition of samples based on Banerjee's criterion showed a first-order phase transition (FOPT) in $Pr_{0.7}Ca_{0.1}Sr_{0.2}MnO_3$ (x=0.1) while samples with x=0.1, x=0.3 and 0.4 exhibited a second-order phase transition (SOPT) with magnetic behavior was assigned to 3D-Heisenberg kind.

Cerium based intermetallics remain a special subject of interest as they exhibit exotic magnetism. In the present work, physical properties of rare earth intermetallic compound Ce_4Ge_3 (Cubic, Th_3P_4-type, Space group I3d, No. 220) are studied by means of dc magnetization, neutron diffraction and heat capacity experiments. Magnetization data of Ce_4Ge_3 obtained in 10 mT field reveal a bifurcation between zero-field-cooled and field-cooled magnetization at ~12 K (T_C) and an antiferromagnetic-like cusp at ~6 K (T_N). The paramagnetic susceptibility follows Curie-Weiss law with a negative paramagnetic Curie temperature (-16 K) and the effective paramagnetic moment of 2.87 μ_B /Ce^{3+}. Heat capacity data in zero applied field indicate peaks close to T_C and T_N. Magnetization measured in 6.5 T field shows enhanced magnetic moment values below ~20 K and the antiferromagnetic cusp seem to vanish completely confirming strong field induced effects present. Accordingly, magnetization vs field (M-H) data obtained below T_N show complex metamagnetic transition. The hysteresis at 2 K in low applied fields asserts the presence of competing magnetic interactions. The magnetization value reaches 0.94 μ_B/Ce^{3+} at 2 K in 9 T field and it is comparable with that observed in the isostructural Ce_4Sb_3 compound. This value is much less than the expected 2.14 μ_B for the collinear alignment of Ce^{3+} ions, thereby confirming the presence of dominant antiferromagnetic interactions. Thus Ce_4Ge_3 system hosts strong antiferromagnetic interactions but also a ferromagnetic component rendering field-tunable magnetism. The isothermal magnetic entropy change calculated from the M-H data near magnetic transitions also reflects this signature of metamagnetic transition present in the system. The occurrence of double magnetic transitions and metamagnetism prompted the study of the magnetic structure. ND experiments were performed in the temperature range of 150 K-2 K using the high resolution powder diffractometer *D1B*, at a wavelength of 0.252 nm (ILL, France). The ND data at 2 K reveal antiferromagnetic ordering with noncollinear arrangement of Ce moments directed along (0 0 1) axis with magnetic moment value of 1.93 m_B/Ce^{3+}.

F7-11. Magnetic Critical Behavior and Magneto-caloric Effect in $Mn_{50}Ni_{41-x}Fe_xSn_9$ Heusler Alloys. *A. Rosales Rivera*[1], N. Salazar-Henao[1], R. González-Sánchez[1], A. Velásquez-Salazar[1], J. López-Tabares[1] and F. Saccone[2] *1. Laboratorio de Magnetismo y Materiales Avanzados, Universidad Nacional de Colombia, Sede Manizales, Manizales, Colombia; 2. Departamento de Física, Facultad de Ingeniería, Universidad de Buenos Aires, Buenos Aires, Argentina*

A study of the magnetic critical behavior and magneto-caloric effect is presented for the ribbons Heusler alloys $Mn_{50}Ni_{41-x}Fe_xSn_9$ with $x = 0$, 5, and 10 (at. %), prepared by the melt-spinning technique. The polycrystalline structural state of these ribbons was confirmed by X-ray diffraction studies. The temperature (T) and magnetic field (H) dependences of magnetization of each sample were measured using temperature cycling (H fixed) and field cycling (T fixed) in the ranges 50-400 K and 0.01-30 kOe, respectively, using a vibrating sample magnetometer (VSM-VersaLab by Quantum Design). The temperature cycling was made in the usual zero-field cooling (ZFC) and field-cooling (FC) procedures. The ZFC magnetization measurements indicate that at low temperatures and at low magnetic fields the magnetic structure of each sample is ferrimagnetic. At high fields, the ferrimagnetic arrangement is no longer seen and a magnetic field-induced ferromagnetic behavior appears. Furthermore, the magnetization is irreversible with relation to ZFC and FC procedures below an irreversible temperature $T_i(H)$. The magnetic critical behavior and magneto-caloric effect of these Heusler alloys are studied by determination of values for several critical exponents, including the zero-field magnetization (β), critical isotherm (δ), zero-field isothermal susceptibility (γ), in addition to the critical temperatures T_C, and change in magnetic entropy (DM_S), respectively, from magnetization measurements. The values of these critical exponents were determined using two independent methods, namely the Kouvel-Fisher method [1] and the Berger-Campillo et al method [2]. The resulting curves for (DM_S) *vs*. T show a symmetric peak in the vicinity of T_C, suggesting that a critical phase transition occurs in $Mn_{50}Ni_{41-x}Fe_xSn_9$, which may be from a ferromagnetic to paramagnetic behavior. The determined values for (β, δ, γ) seem to suggest that the previous Heusler alloys belong to the mean-field universality class with interactions of long-range. In general, all samples exhibit moderate relative cooling power in the vicinity of T_C. A possible correlation between the magnetic critical behavior and magneto-caloric response is analyzed for these Heusler alloys.

F7-12. Influence of Cobalt doping on the Magnetism in $NiBr_2$. *B.K. Rai*[1], A.D. Christianson[1] and A.F. May[1] *1. Oak Ridge National Laboratory, Oak Ridge, TN, United States*

The existence of an antiferromagnetic transition at $T_N = 52$ K and the emergence of an incommensurate magnetic structure below $T_{IC} = 23$ K makes $NiBr_2$ unique among transition metal dihalides. The incommensurate structure is characterized by a temperature-dependent propagation vector Q = (Q, Q, 3/2). A delicate balance between the first-neighbor ferromagnetic exchange constant and the antiferromagnetic second- and third- neighbor exchange constants likely promotes competing, magnetically-ordered ground states. The competition between magnetic ground states indicates that $NiBr_2$ may be especially susceptible to chemical pressure or doping. For instance, Zn-doping has been shown to transform the incommensurate magnetic structure to a commensurate one. In our study, we substituted Ni with Co in $NiBr_2$ to study how the magnetic phases evolve as a function of doping, and this poster will present the magnetic phase diagram of Co-doped $Co_xNi_{1-x}Br_2$. This research was supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, Materials Sciences and Engineering Division.

F8-01. Hydrostatic Pressure Modulated Spin-Reorientation Transition And Magnetocaloric Effect In PrGa Compound. J. Hao[2,1] and *J. He*[1]
1. Division of Functional Materials, Central Iron and Steel Research Institute, Beijing, China, Beijing, China; 2. Beijing National Laboratory for Condensed Matter Physics & State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, Beijing, China

As a promising magnetocaloric material, the intermetallic RGa (R: rare earth) compounds have attracted much attention because of their rich magnetic properties. Early studies showed that most of the RGa compounds exhibit a spin reorientation transition and a transition from ferromagnetic to paramagnetic phase due to the competition between the magnetic exchange coupling and the interaction with crystal field [1]. Further neutron powder diffraction studies, for PrGa compound, revealed that the magnetic moment cants away from ab-plane towards the c-axis with increasing temperature [2]. Furthermore, a considerable strain has been detected across the spin reorientation transition [3]. This result predicts the sensitivity of the spin reorientation transition to pressure. Here, we studied the effect of hydrostatic pressure (P) on the magnetic transitions and magnetocaloric effect in PrGa compound. Fig.1a displays the thermal magnetization curves of PrGa measured at 0.5T under different pressures. It can be seen that the spin-reorientation temperature TSR decreases from 37K to 16K with the increase of P from 0GPa to 1.14GPa, while the Curie temperature TC hardly changes under P<0.35GPa. However, as P increases to 1.14GPa, TC decreases from 37K to 32K. Such a phenomenon may be closely relative to the fact that crystal field is more sensitive to pressure compared with the exchange interaction. As shown in Fig.1b, the spinreorientation disappears when a magnetic field up to 5T is applied. From Fig.1c, the enlarged hysteresis gap indicates that hydrostatic pressure leads to an obvious enhancement of the first-order transition. The magnetic entropy change (ΔSM) was calculated according to the Maxwell relation (Fig.1d). Although the maximum ΔSM value decreases as pressure increasing from 0GPa to 1.14GPa, the refrigerant capacity (RC) value is improved by 8% from 99.5 J/kg to 107.4 J/kg, for a magnetic field change of 0-5T.

The isothermal magnetic entropy change of $La(FeSi)_{13}$ alloy series as a first-order phase transition magnetic refrigeration material was much larger than the Gd material. Due to advantages of the rich resources, the low prices, the easy preparation, and the controllable Curie temperature, it is expected to be a candidate for future room temperature magnetic refrigeration materials based on the first-order phase transition[1-3]. In this paper, we have systematically investigated the magnetocaroric effect of $LaFe_{0.94-x}Ni_xCo_{0.06}Si_{1.6}B_{0.25}$ (LaFeNiCoSiB) materials with changing the Ni element content. In order to meet the industrial demand, we are chose the industrial-grade raw materials to prepare the LaFeNiCoSiB materials by the smelting of the high frequency suspension furnace. After annealing under high purity argon environment protection, the block samples can be prepared by using the cutting machine. To analyze the magnetocaroric effect of of the block samples, we have measured the magnetocaloric property utilize the vibrating sample magnetometer with veriation of the temperature and the external magnetic field, as shown in Fig. 1 (a). With variation of the Ni doping, we have observed that the Curie temperature, operating temperature range, and relative cooling power of our samples are controllable near room temperature, as shown in Fig.1 (b). We think that our research will have great reference significance for the follow-up study of $La(FeSi)_{13}$ system materials. Keywords: magnetic refrigeration, magnetocaloric effect, magnetic alloy, magnetic entropy change

F8-04. Magnetic properties and magnetocaloric effect in Er_2Ni_2In compounds. *X. Zheng*[1], J. Xu[1], J. Zhang[1], S. Wang[1], Y. Zhang[2], J. Liu[2], Y. Liu[2] and B. Shen[2] *1. School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China; 2. State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, Beijing, China*

Magnetic refrigeration has attracted much attention because of its environmental friendliness, high efficiency and energy conservation compared with traditional refrigeration methods and magnetic materials with large magnetocaloric effect (MCE) are expected to be used in magnetic refrigeration technology. Magnetic materials with large/giant MCE at room temperature are $La(Fe,Si)_{13}$ [1], $Gd_5(Si,Ge)_4$ [2], NiMnIn [3] and so on. Low-temperature MCE material is expected to be used for gas liquefaction and has gradually become a hot area of research in recent years. The magnetic properties and MCE of Er_2Ni_2In compound have been systematically studied in this work. X-ray diffraction results show that the Er_2Ni_2In compound crystallizes in the orthogonal cubic Mn_2AlB_2-type structure (space group Cmmm). The magnetic measurement results show that Er_2Ni_2In undergoes an antiferromagnetic (AFM) to paramagnetic (PM) transition with temperature increasing, and the Néel temperature (T_N) is determined to be 7 K, which is in accord with literature [4]. The magnetic entropy change ($-\Delta S_M$) curves are calculated from the isothermal magnetization curves of Er_2Ni_2In compound. Results show that the peak value of magnetic entropy change ($(-\Delta S_M)_{max}$) is calculated to be 2.6 and 11.4 J/kgK under the magnetic field change of 0-2 T and 0-5 T, respectively. (Fig. 1) The refrigeration capacity (RC) under magnetic field change from 0 to 5 T reaches 161.8 J/ kg. It is worth noting that there is a good thermal reversibility in the temperature range around T_N, which is of great importance to practical application.

F8-05. Low temperature large magnetocaloric effect of $Ho_{0.7}Tm_{0.3}CuSi$ compound. J. Xu[1], *X. Zheng*[1], J. Zhang[1], S. Wang[1], Y. Zhang[2], J. Liu[2], Y. Liu[2] and B. Shen[2] *1. School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China; 2. State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, Beijing, China*

Magnetocaloric effect (MCE) is the intrinsic property of magnetic materials near transition temperature and MCE materials with low transition temperature has drawn much attention for the potential applications on gas liquefaction and gas storage.[1-2] Hexagonal Ni_2In-type RCuSi compounds have been reported to exhibit interesting magnetic property and large MCE.[3-4] The maximal magnetic entropy change ($(-\Delta S_M)_{max}$) of HoCuSi compound is as high as 33.1 J/kg K with a Neel temperature of 7 K.[4] In this work, 30 percent of Ho atoms were substituted by Tm atoms and the magnetic property and MCE were studied in detail. For $Ho_{0.7}Tm_{0.3}CuSi$ compound, the ground state is determined to be ferromagnetic (FM), which is different from HoCuSi compound. The Curie temperature (T_C) is calculated to be 6 K, which is smaller than HoCuSi. That is because Tm-substitution decreases the average spin of the system and spin is positively correlated with magnetic transition temperature. Magnetic entropy change ($-\Delta S_M$) is calculated for different magnetic field change. The maximal $-\Delta S_M$ is calculated to be 17.7 J/kgK for a field change of 0-5 T. As the applied field change increases from 0-1 T to 0-5 T, the temperature corresponding to the peak of $-\Delta S_M$ curves increases from 5.2 K to 6.7 K. (Fig. 1) Compared with HoCuSi compound, the temperature of the $-\Delta S_M$ peak is much lower and much closer to the boil point of liquid Helium. Thus, the MCE of $Ho_{0.7}Tm_{0.3}CuSi$ is smaller than HoCuSi compound, but it may be more suitable to liquefaction of Helium.

F8-06. Structural, magnetic properties and magnetocaloric effect in $SmNi_5$ compound. *A. Bajorek*[1,2] and P. Lopadczak[1,2] *1. A. Chelkowski Institute of Physics, University of Silesia in Katowice, Poland, Chorzów, Poland; 2. Silesian Center for Education and Interdisciplinary Research, University of Silesia in Katowice, Chorzów, Poland*

The $SmNi_5$ intermetallic compound was synthesized via arc-melting. The performed X- ray diffraction analysis and its interpretation by Rietveld refinement revealed the presence of the hexagonal $CaCu_5$ type of crystal structure structure (P6/mmm space group) with lattice parameters: a = 4.929 Å, c = 3.953 Å and c/a ratio 0.802. The additional $SmNi_2$ phase of about 0.86 % was detected. The domination of trivalent Sm states was confirmed based on Sm3d, Sm4d core level lines as well as valence band spectrum studied by X-ray photoelectron spectroscopy (XPS). The magnetic properties were determined based on wide-ranging SQUID magnetometer (Quantum Design MPMS, temperature from 1.9K to 400K and magnetic field up to 7T) series of different magnetic measurements. The magnetocaloric effect (MCE) was estimated at T_C based on magnetic isotherms. The AC as well as DC temperature dependence of magnetization exhibit a magnetic phase transition at about T_C = 32 K. The analysis of field cooled (FC) and zero field cooled (ZFC) thermomagnetic curves at various applied magnetic field (H_{ext}) reveals the negative ZFC magnetization at low $H_{ext} \leq 1000$ Oe. Such behavious may be caused by spin-orbital compensation or spin freezing at low temperatures. The estimated MCE is diminished starting form $\mu_0\Delta H$ = 7T (ΔS_m = 2.31 J/kgK) to $\mu_0\Delta H$ = 1T (ΔS_m = 0.58 J/kgK). The corresponding change of the relative cooling power RCP = 27.53 J/kg.

F8-07. Cooling by Sweeping: Establishing a Ferroic-based Refrigeration Cycle with Field Dynamics. D.J. Silva[1], *J.S. Amaral*[1] and V.S. Amaral[1] *1. CICECO & Physics dept., Universidade de Aveiro, Aveiro, Portugal*

Among all ferroic-based thermotechnologies, magnetocaloric refrigeration has been pointed out as one of the most promising alternatives to vapor compression systems [1]. However, most magnetocaloric refrigerators have been limited to designs and operation modes that include fluids in complex hydraulic components, increasing the overall production cost. It has been recently shown that substituting the hydraulic components by ideal thermally switchable components can result in viable refrigeration [2,3]. Nevertheless, the performance is still low if using non ideal thermally switchable components. In this work we show that by exploiting the external field application and removal dynamics a new mechanism of operation emerges: *cooling by sweeping* (Fig. 1a). With this operating mechanism a simple setup without any hydraulic or thermally switchable component can result in a refrigeration cycle. To prove the cooling by sweeping concept we have used the example of magnetocaloric refrigeration and computed numerically its performance by using a fully solid state refrigerator with Gd as magnetocaloric material without any thermally switchable components or fluid. We show that such a system can results in a non zero temperature span, as shown in Fig. 1b. In particular, a system working at 0.1 Hz using the sweeping of the magnetic field (H) with the application of H from the cold to the hor reservoirs in an accelerated motion, removal of H from the cold to the hot reservoirs in a decelerated motion, and an applied magnetic field of 1 T can reach a temperature span of ~ 0.8 K. A complete description of the operating modes as well as the most relevant results will be given.

F8-08. Influence of high hydrostatic pressure on the magnetic, magnetocaloric and crystallographic properties of the $Nd_{0.5}Sr_{0.5}CoO_3$ cobaltite. M.S. Reis[3], D.L. Rocco[3], R.J. Vivas[1], *M.d. Santos*[3,2], B. Pimentel[3], R. Torrão[3], L. Paixão[3] and A.M. Santos[4] *1. Centro Brasileiro Pesquisas Físicas, Rio de Janeiro, Brazil; 2. Centro Federal de Educação Tecnológica de Minas Gerais, Timóteo, Brazil; 3. Physics, Universidade Federal Fluminense, Niterói, Brazil; 4. Oak Ridge National Laboratory, Oak Ridge, TN, United States*

The magnetic properties of compounds type cobaltite $RETMCo_3$ (RE = rare earth and TM = transition metal) are dependent on the structural deformation, which can be induced by either replacing the rare earth with transition metal or applying hydrostatic pressure. These two approaches are not equivalent because the atomic substitution changes the ratio of Co^{+3} and Co^{+4}. It is well known that this additional electron of Co^{+3} plays a fundamental role in the magnetic and electric properties of those materials. Thus, the hydrostatic pressure is a clear way to access the magnetic and electric properties taking into account only the structural deformation without other influences. In this work we try to shed light on the rule only of lattice deformation by studying the magnetic and magnetocaloric properties of cobaltite $Nd_{0.5}Sr_{0.5}CoO_3$ submitted to a very high hydrostatic pressure. Our findings show that the even under hydrostatic pressure of 50 kbar, the structure maintains the same (orthorhombic), and the unit cell volume varies with a rate of $-5.50x10^{-4}$ $kbar^{-1}$. The unit cell volume dependence with the hydrostatic pressure allows to calculate the compressibility of the material or its bulk modulus. In addition, the magnetic properties show a weak dependence with pressure. The Tc changed with a rate of 0.5 K/kbar. The magnetocaloric potential of compound was evaluated and maintains constant over all pressure studied interval. Our results conclude that for strongly correlated electron system, like cobaltite, the very low modification of Co^{+3} and Co^{+4} ratio is much more critical for changing the magnetic properties than the structural deformation.

F8-09. Magnetocaloric effect of ball milled Gd_5Si_4. S.M. Harstad[1], *A.A. El-Gendy*[4], S. Gupta[3], V. Pecharsky[3,2] and R.L. Hadimani[2] *1. Mechanical and Nuclear Engineering, Virginia Commonwealth University, Richmond, VA, United States; 2. Department of Electrical and Computer Engineering, Iowa State University, Ames, IA, United States; 3. Division of Materials Science and Engineering, Ames Laboratory, US Department of Energy, Ames, IA, United States; 4. Physics, University of Texas at El Paso, El Paso, TX, United States*

Materials exhibiting large magnetocaloric effects (MCEs) near room temperature are critical for magnetocaloric refrigeration applications.[1] The MCE is commonly described by a change in entropy (ΔS_M) and/or temperature (ΔT_{ad}) of a material in response to a change in applied magnetic field. Ball milling generally broadens the effect, potentially extending the range of temperatures over which a single material can be useful. Gd_5Si_4 is attractive due to its magnetic transition at 340K and substantial magnetocaloric effect. Gd_5Si_4 was synthesized by arc-melting commercial Gd and 99.99% pure Si and ground into powder with an average particle size of 45μm. A two-step milling procedure was used where polyethylene glycol and then heptane were added as processing agents with total milling time of 2h (S1) and 3h (S2). After milling, PEG was removed by washing with ethanol. Figure 1 shows the $-\Delta S_M$ values calculated from magnetization isotherms. The magnetization as function of temperature is shown in Fig 2. The Curie temperature is lowered by ~20 K, and the transition is broadened by milling.[2] Compared to as-cast Gd_5Si_4, the maximum MCE of the milled samples is somewhat reduced and shifted down by ~30 K, but MCE persists over a broader temperature range. The resulting relative cooling power[3] of both milled samples is ~340 J/kg, which is a 70% increase from 200 J/kg for the as-cast material. As a result, temperature averaged entropy change figure of merit[4] is only slightly reduced, making powders interesting for applications. In summary, ball milling using PEG and heptane as processing agents produces sub-micron, polycrystalline particles of Gd_5Si_4 that exhibit a lower Curie temperature of 325 K compared to ~340 K in the as-cast. The MCE decreases as expected, but remains substantial and, likely, useful between 260K and 330K. For the most effective use of magnetocaloric materials, it is important that substantial MCE is recovered after the material is constituted as powders. Improved and innovative top-down approaches to achieve this goal are currently being pursued.

F8-10. Enhanced near room temperature magnetocaloric effect in $La_{0.6}Ca_{0.4}MnO_3$ for magnetic refrigeration application. *A.A. El-Gendy*[1], M. Tsui[2] and E. Carpenter[2] *1. Physics, University of Texas at El Paso, El Paso, TX, United States; 2. Chemistry, Virginia Commonwealth University, Richmond, VA, United States*

Perovskite manganite $La_{0.6}Ca_{0.4}MnO_3$ (LCMO) nanomaterials were synthesized by a modified Pechini sol–gel process followed by high temperature sintering. Polyethylene glycol of various molecular weights was used to control the particle size and morphology of the materials. XRD and Scherrer analysis were used to confirm the crystal structure and crystallite size of the LCMO nanomaterials. The LCMO nanomaterials showed a paramagnetic to ferromagnetic transition at 277 K. The maximum change in entropy was calculated to be 19.3 J kg^{-1} K^{-1} for a field change of 0–3 T and 8.7 J kg^{-1} K^{-1} for a field change of 0–1 T, and the relative cooling power was determined to be 627 J kg^{-1}. The $La_{0.6}Ca_{0.4}MnO_3$ reported in this work demonstrated an enhanced magnetocaloric effect compared to the current literature. These results showed the LCMO nanomaterials to be an excellent candidate for magnetic refrigeration applications as they are less costly in comparison to Gd based compounds.

Session F9
QUASI 1D MAGNETISM
(Poster Session)

F9-01. Feedback Controlled Entanglement Creation in a Heisenberg Spin Chain Permeated by a Magnetic Field. *J. Wang*[1] *1. University of Michigan Dearborn, Dearborn, MI, United States*

This work studies the feasibility of using quantum feedback to reduce the effect of decoherence and create entanglement in a Heisenberg chain permeated by an external magnetic field [1, 2]. The system reaches an improved steady state entanglement when feedback is present. The optimum strength of the external magnetic field is found to maximize steady state entanglement. The time-dependent entanglement evolution of the system is also studied. One potential application of this scheme is to raise the maximum operating temperature of spin entangled systems[3].

F9-02. Magnetic impurity effects on low-dimensional multiferroic material $Cu_3Mo_2O_9$ with spin frustration. *H. Kuroe*[1], M. Noda[1], Y. Ebukuro[1], H. Kuwahara[1], M. Hase[2], K. Oka[3], T. Ito[3] and H. Eisaki[3] *1. Physics Division, Sophia University, Tokyo, Japan; 2. Research Center for Advanced Measurement and Characterization, National Institute for Materials Science (NIMS), Tsukuba, Japan; 3. National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan*

We discuss the magnetic impurity substitution effect on $Cu_3Mo_2O_9$. Figure 1 shows a distorted tetrahedral quasi-one-dimensional spin structure made from Cu^{2+} ions in $Cu_3Mo_2O_9$. This system has a geometrical spin frustration and shows multiferroic behavior below T_N = 7.9 K [1,2]. By substituting S = 1 Ni^{2+} ions for the S = 1/2 Cu^{2+} ions, we affect the geometrical frustration effect of the parent material. We focus on the similarity and the difference between magnetic (Ni^{2+}) and nonmagnetic (Zn^{2+}) impurity substitution effects. Single crystals of $(Cu,Ni,Zn)_3Mo_2O_9$ were prepared with the continuous solid-state crystallization method by using an infrared furnace utilized for the floating-zone method [3]. We measured the temperature dependence of the magnetization M_a along the a-axis by using Magnetic Properties Measurement System (Quantum Design MPMS XL). Figures 2 we show M_a for one mole of the magnetic ions (Cu^{2+} and Ni^{2+} ions) as functions of temperature T. The strong enhancement of M_a below T_N is observed in the parent material [1]. Its temperature dependence reflects the temperature dependence of the order parameter [4]. Instead of this increment, we observed the reduction of M_a with decreasing temperature in the Zn-5.0% and the Ni-5.0% substituted samples. T_N in the Zn-5.0% and the Ni-5.0% substituted samples are 4.2 and 9.0 K, respectively, i.e. the Ni substitution increases T_N. In presentation, additionally, we discuss the following subjects: Ni concentration dependences of the specific heat and the magnetization, the phase diagrams depending on the Ni concentration, the change of lattice constants at room temperature. This work was supported by JSPS KAKENHI Grant Number JP16K05420.

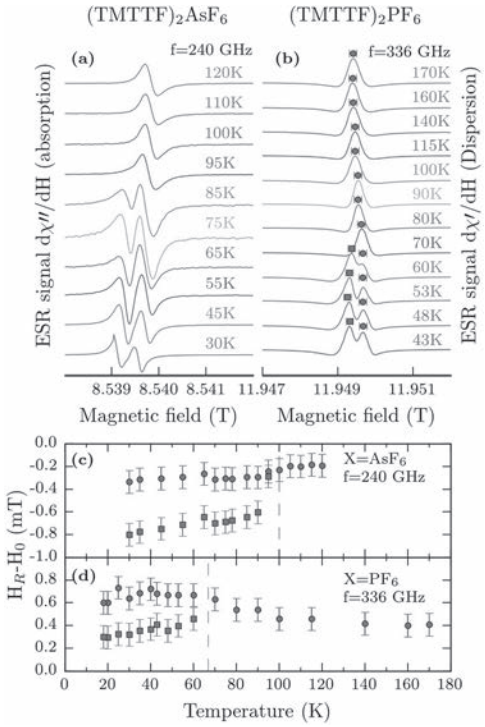
F9-03. Quasi-phases and pseudo-transitions in one-dimensional models with nearest neighbor interactions. *S.M. de Souza*[1] and O.R. Santos[2] *1. DFI, UFLA, Lavras, Brazil; 2. Departamento de Fisica, Universidade Federal de Lavras, Lavras, Brazil*



There are some particular one-dimensional models, such as the Ising-Heisenberg spin models with a variety of chain structures, which exhibit unexpected behaviors quite similar to the first and second order phase transition, which could be confused naively with an authentic phase transition. Through the analysis of the first derivative of free energy, such as entropy,

magnetization, and internal energy, a "sudden" jump that closely resembles a first-order phase transition at finite temperature occurs. However, by analyzing the second derivative of free energy, such as specific heat and magnetic susceptibility at finite temperature, it behaves quite similarly to a second-order phase transition exhibiting an astonishingly sharp and fine peak. The correlation length also confirms the evidence of this pseudo-transition temperature, where a sharp peak occurs at the pseudo-critical temperature. We also present the necessary conditions for the emergence of these quasi-phases and pseudo-transitions.

S.M.de Souza, OnofreRojas, Solid State Communications Volume 269, January 2018, Pages 131-134; https://doi.org/10.1016/j.ssc.2017.10.006

F9-04. Interchain superlattice induced by charge order in (TMTTF)2X (X = SbF_6, AsF_6 and PF_6) revealed by high field EPR. C. Dutoit[1], H. Van Tol[2], A. Stepanov[1] and *S. Bertaina[1] 1. Nanoscience, IM2NP - CNRS, Marseille, France; 2. NHMFL, Tallahassee, FL, United States*

The family of quasi-one-dimensional organic conductors $(TMTTF)_2X$ is known to have a rich phase diagram with a sequence of competing ground states between spin-Peierls (SP), antiferromagnetic (AF) or superconductor state, depending on the nature of counter anion X or external pressure. More particularly, the centro-symmetric X (X = SbF_6, AsF_6 and PF_6) is metallic at high temperatures, then it is an insulator, and finally, the ground state is either AF for SbF_6 (T_N = 8 K) or SP for AsF_6 (T_{SP} = 19K) and PF6 (T_{SP} = 13 K). The metal-insulator transition was first observed by conductivity and microwave measurements, and was attributed to a charge ordering (CO) inside the molecule. At $T > T_{CO}$, the charge (hole) is equality divided between the two TMTTF molecules, then at $T < T_{CO}$ a displacement of charge from one TMTTF to the other induces a 4kf ordering in the direction of the intrastack a axis (spin chain axis). The CO transition was considered structureless because no observation of the superlattice reflection was reported. Since it has been proven that the X-ray was responsible for the destruction of the CO transition. Only neutron scattering was able to directly show the displacement of the lattice during the CO transition. We have investigated the charge ordering phase of the quasi one dimensional quantum antiferromagnet $(TMTTF)_2X$ using high field/frequency electron paramagnetic resonance. In addition to the uniform displacement of the counter anions involved in the charge order phase, we report the existence of a superlattice between the spin chains in the direction c, caused by the space modulation of the charge order. At sufficient high fields, the magnetic decoupling of the spin chains allows us to estimate the interaction between the chains, Jc < 1 mK, three orders of magnitude lower than expected from the mean field theory.

HF-EPR recorded at temperature above and below T_{CO} for the magnetic field at 45° between the magnetic axis bm and cm.

F9-05. Construction and analysis of Langevin equation for charged particle in one dimensional random magnetic field Ising model spin chains. *M. Fundator[1] 1. Division on Behavioral and Social Sciences and Education, National Academies of Sciences, Engineering, and Medicine, Brooklyn, NY, United States*

Beginning from the construction and analysis of the model as the continuous limit of a one dimensional random walk with random asymmetric transition rates between the lattice sites, the analytical investigation continued in the view of The model as the continuous limit of a one dimensional directed walk on a lattice among traps characterized by a broad distribution of release time, defined by the following master equation for the probability for the particle to be on the nth site at time t that in the continuous limit viewed as derived equation for a Brownian particle in one dimension with succession of phases, characterized by different anomalous diffusion behavior, including Sinai's " ultraslow" logarithmic law and the occurrence of a continuously varying diffusion exponent. For the random field Ising model the two types of domain walls that occur diffuse in opposite random potentials, and domain walls annihilate when they meet.

Materials with 1D-channels have interesting magnetic properties where the ground state is determined by the complex correlation of both intra and inter chain interactions. The title compound, K2Cr8O16, belongs to a series of quasi-1D compounds synthesised using a high- pressure/-temperature technique. The channels are formed by zig-zag Cr2O4 chains parallel to the c-axis and K cations occupying the center. This is one of the few compounds undergoing metal to insulator transition while maintaining a ferromagnetic order [1, 2], established by a Peierls transition [3]. Pressure dependent studies on this compound is fairly limited and the complete phase diagram of this compound is not fully resolved, especially the low temperature / high pressure region [4]. Here, zero field (ZF) and weak-transverse field (wTF) muon spin rotation/relaxation (muSR) data is presented. The obtained paramagnetic (PM) to ferromagnetic (FM) transition temperature differs notably compared to previously published magnetisation measurements. The power of muSR uniquely allow us perform measurements in zero applied field and hereby access the true intrinsic material properties. In detail, the PM to FM transition temperature as a function of pressure is determined from wTF measurements. Moreover, ZF data establish a novel low temperature/ high pressure transition between two different magnetically ordered states, which was determined to be FM and antiferromagnetic (AF), respectively. Finally, neutron/X-ray scattering measurements and theoretical modelling have recently been conducted in order to elucidate the detailed nature of the two magnetically ordered phases. $BaCo_2V_2O_8$ is a realization of a spin-1/2 Ising-like quasi-one dimensional (1D) antiferromagnet with remarkable static and dynamical behaviors [1]. In zero-field, the excitations of the Néel phase consist in confined two-spinon excitations stabilized by weak interchain interactions. They form two interlaced long-lived Zeeman ladders with respective transverse and longitudinal character regarding the direction of the magnetic moments (along the chain *c*-axis) [2]. We have explored the influence of an external magnetic field on this spin dynamics by inelastic neutron scattering. A contrasting behavior is observed for a transverse and longitudinal magnetic field (i.e. perpendicular and parallel to the direction of the moments respectively). The former case has revealed a very interesting physics as a topological quantum phase transition occurs between two types of solitonic topological objects [3]. The present talk is devoted to our results obtained under the application of a longitudinal field in $BaCo_2V_2O_8$. We show that the Néel phase excitations keep their transverse or longitudinal character, simply showing a Zeeman splitting up to $\mu_0 H_c \approx 3.9$ T at which the Néel ordering turns into a longitudinal spin density wave (LSDW) [2,4]. This phase has raised a strong interest as it is a unique example of the Tomonaga-Luttinger liquid (TLL) physics experimentally accessible under moderate magnetic field [2,4,5]. The TLL longitudinal fluctuations expected in the purely 1D system [6], lacking long-range order, are transformed in a LSDW stabilized in $BaCo_2V_2O_8$ through the anisotropy and the weak interchain couplings. The dispersion spectrum in this exotic phase and the magnetic field dependence of the excitations have been investigated by neutron scattering on TASP (PSI) and through numerical calculations. We have shown that the nature of the magnetic excitations changes drastically in the LSDW phase with respect to the Néel phase in zero field: We observe original fluctuations along the ordered moments (i.e. longitudinal fluctuations) that become the lowest energy modes characteristics of this novel magnetic LSDW state, while the transverse excitations, the usual ones for conventional magnets, are shifted to higher energy.

Session F10
SOFT MAGNETIC MATERIALS AND MAGNETIC SHIELDING I
(Poster Session)

Jean Anne C. Incorvia, Chair
University of Texas at Austin, Austin, TX, United States

F10-01. Preparation and electro-magnetic properties of soft magnetic composites with ferrite nanofibres. *J. Fuzer*[1], M. Streckova[2], S. Dobak[1], L. Dakova[1], P. Kollar[1], M. Faberova[2], R. Bures[2], Y. Osadchuk[1], P. Kurek[2] and M. Vojtko[2] *1. Institute of Physics, Faculty of Science, P. J. Šafárik University, Kosice, Slovakia; 2. Institute of Materials Research, Slovak Academy of Sciences, Kosice, Slovakia*

Soft magnetic composites (SMCs) are extensively developed as a viable alternative to the laminated steel materials in a range of new applications, such as transformers, inductors, sensors, fast switching solenoids and electrical motors [1]. We present an innovative method for manufacturing the soft magnetic composites that may pave the way for magnetic cores with improved electromagnetic properties. In this paper, soft magnetic composites based on FeSi powder coated with the hybrid organic-inorganic coating composed of boron phenol-formaldehyde resin and $Ni_{0.3}Zn_{0.7}Fe_2O_4$ ferrite fibres were fabricated to investigate the effects of ferrite nanofibres on the structural and electromagnetic properties. The needle-less electrospinning was used for preparation of $Ni_{0.3}Zn_{0.7}Fe_2O_4$ soft magnetic fibres in large scale. The hybrid coating was deposited on a surface of spherical FeSi powder and processed by PM technology for a bulk sample for mechanical, electrical and magnetic tests. A uniformity of hybrid organic-inorganic coating is reflected in a high value of the electrical resistivity. A low porosity and extraordinary high values of mechanical hardness and flexural strength were found in prepared soft magnetic composites. The superior mechanical properties are found in the sample FeSi/PFRB/0. 49ferrite, which achieved the appropriate composition and homogenous distribution of insulation phase. The resin coating causes the enhanced frequency stability of real permeability component up to 1 MHz and the relaxation frequency is mainly affected by electrical resistivity. The sample FeSi/PFRB/0.49ferrite is endowed with the lowest power losses at all measured frequencies. Our results show that the electro-magnetic properties of soft magnetic composites can be enhanced by appropriate content of ferrite fibres in the boron phenol-formaldehyde resin and value of electrical resistivity is much higher than common last-year results obtained by combining of Fe or their alloys with Ni-Zn or Mn-Zn coating prepared via different ways. The results presented can be used for future materials design of soft magnetic composites.

For decades, studies and research in relation to the magnetic behavior of phenomena is increasing considerably. One of the main challenges in the academic field is to develop magnetic materials with high magnetic saturation, relatively large magnetic anisotropy, high temperature Curie and high corrosion resistance. From these requirements, the hexagonal ferrites M-type $BaFe_{12}O_{19}$, also called BaM, gather interests that are increasing since they are expected to solve such problems. Thus, they can be applied in different materials, such as: permanent magnets, recording media, telecommunication, and as components in microwave, higher-frequency, and magneto-optical devices. With the objective of obtaining a lower cost to produce hexaferrite, since the syntheses of the material usually use reagents of high cost and harmful to the environment, this work proposes the synthesis of said material through the proteic sol–gel process, in which it uses the coconut water for dilution of precursor materials. Studies related to spin-phonon coupling have been performed for several magnetic materials, however there are few reports related to M-type hexaferrite barium. In this work we investigated the spin-phonon transition of the M-type hexaferrite of Ba through Raman spectrometry varying the temperature from the environment to 750 K, thus verifying changes in the position and intensity of the vibratory modes with the increase of temperature, from these changes was it is possible to detect the spin-phonon coupling in the study material. It is also shown, X-ray diffraction and Rieltveld refinement, indicating the formation of the single phase of the material being studied.

F10-03. Magnetic properties of Y-type hexaferrite $Ba_xSr_{2-x}Ni_2Fe_{12}O_{22}$ (x = 0, 1.5) by using Mössbauer spectroscopy. *J. Kim*[1], J. Lim[1] and C. Kim[1] *1. Department of physics, Kookmin University, Seoul, The Republic of Korea*

We studied the polycrystalline $Ba_xSr_{1-x}Ni_2Fe_{12}O_{22}$ (x = 0, 1.5) sample of Y-type hexaferrite prepared by using polymerizable complex method. The samples were investigated the crystal structure by X-ray diffraction (XRD) and magnetic properties by vibrating sample magnetometer (VSM) at various temperature ranging between 4.2 and 750 K, and Mössbauer spectroscopy at various temperature ranging between 4.2 and 300 K. Also, the dielectric properties of samples were investigated by network analyzer (NA). We analyzed by Rietveld refinement method and confirmed to be $Ba_xSr_{1-x}Ni_2Fe_{12}O_{22}$ (x = 0, 1.5) single phases of the hexagonal structure with space group *R-3m*. The lattice constants (a_0, c_0) of sample were a_0 = 5.84, c_0 = 43.38 Å (x = 0), and a_0 = 5.83, c_0 = 43.25 Å (x = 1.5), respectively. From the temperature dependence of the Zero-field-cooled (ZFC) magnetization curves under 100 Oe between 4.2 and 300 K, the spin transition temperature (T_S) of sample were found to be T_S = 47 K (x = 0), T_S = 188 K (x = 1.5). The magnetic hysteresis curve of the sample was measured by applying a magnetic field of up to 15 kOe at various temperatures and was not saturated at x = 1.5. At 295 K, the saturation magnetization (M_s) and coercivity (H_c) were found to be M_s = 21.94 emu/g, H_c = 115.77 Oe (x = 0), M_s = 20.03 emu/g, H_c = 83.74 Oe (x = 1.5). Mössbauer spectra were analyzed 6 different interstitial sub-lattices, which are $3b_{VI}$, $6c_{IV}$*, $6c_{VI}$, $18h_{VI}$, $6c_{IV}$, $3a_{VI}$. $3b_{VI}$ site was considered to have a hyperfine field (H_{hf}) greater than $18h_{VI}$ site due to the Ni ions. Also, the measured isomer shifts (δ) of all sample indicates that the Fe ions are the same as the Fe^{3+}. The network analyzer was used to measure the permeability (μ) and permittivity (ε) of samples from 50 MHz to 4 GHz. The permeability in the region of 800 MHz is μ = 4.0 (x = 0)

F10-04. Development of Soft Z-Type Hexa Nanoferrites for Antenna Miniaturization up to S-Band. *A.K. Manhas*[1] and M. Singh[1] *1. Department of Physics, Himachal Pradesh University, Shimla 171005, Shimla, India*

The paper comprises, high-frequency soft Co_2Z-type hexa nanoferrites of the series $Ba_{3-X}Sr_XCo_2Fe_{24}O_{41}$ (where x = 0, 0.5, 1.0, 1.5 and 2.0) synthesized by sol-gel auto combustion method. Of particular interest in controlling electromagnetic losses with enhanced real part of complex permeability and permittivity over the frequency range 2 GHz to 3.43 GHz for antenna applications. Successfully obtained appreciable magnetic and microwave properties due to Sr^{2+} substitution for Ba^{2+}, in which magnetic moments of Co_2Z-type hexaferrite lie in the basal plane at room temperature. The desirable results obtained at 2 GHz for composition $Ba_{1.5}Sr_{1.5}Co_2Fe_{24}O_{41}$, as the real permeability is 5 and real permittivity is 4.7 with controlled magnetic and electric loss tangents close to zero i.e. 0.003 and 0.006, respectively. This composite has almost equal values of real permeability and permittivity, as well as the low magnetic and dielectric loss tangents. Such magneto-dielectric substrate material could be valuable for the design of antennas with reduced physical dimensions and good impedance-matched to free space.

F10-05. The Effect of the Sintering Temperature on the RF Complex Permeability of NiCuCoZn Ferrites for Near Field Communication (NFC) Applications. *P. Lathiya*[1] and J. Wang[1] *1. Electrical Engineering, University Of South Florida, Tampa, FL, United States*

Introduction: Recently, radio frequency identification technology (RFID) is a newly merging method used in wireless communication fields. Near field communication (NFC) operating at 13.56 MHz is very attractive in many application areas such as mobile transactions, identity tags and access control. Soft magnetic ferrites are viewed as the most promising materials because of their high permeability, low losses, high resistivity, and high curie temperature for employment of low and high frequency applications[1][5]. Ni-Zn ferrites carry desirable properties among all ferries due to the high resistivity, high permeability and low losses at HF, VHF or even UHF frequencies[2]. These properties of Ni-Zn ferrites depends on the chemical composition, microstructure, choice of additives and preparation method that can be modified easily through different synthesis parameters[3][4]. Enhancement of the magnetic property and Q-factor with varied strategic choice of dopants in Ni-Zn ferrites has been reported[6][4]. In this work, the effect of sintering temperature on the complex permeability of NiCuCoZn ferrites at RF frequencies has been studied without addition of sintering aid. Experimental Section: NiCuCoZn ferries were prepared via solid state synthesis. All constituent materials were weighed according to their resp. molecular weight percentages and mixed together in planetary ball mill, followed by calcination at 800 C. The fine powder was mixed with PVA binder to make cylindrical samples and sintered in air at different temperatures. Results: Addition of Co_2O_3 in NiCuZn during the synthesis route has enhanced permeability as compared to that of NiCuZn sintered at the same temperature. Increase in real part of permeability from 83 to 152 is observed with raised sintering temperature from 1080 C to 1120 C With increase in the sintering temperature, the magnetic loss also increases from 0.02 to 0.03. Conclusion: Choice of composition in Ni-Zn and sintering temperature strongly influence the microstructure of the ferrite, which affects the grain growth and densification of ferrites. Combined high permeability and low magnetic loss of ferries at RF and microwave frequencies is desirable for high frequency applications.

F10-06. Magnetic properties of FeSi/ hybrid resin based composite with different $Ni_{0.3}Zn_{0.7}Fe_2O_4$ ferrite content. *L. Dakova*[1], J. Fuzer[1], P. Kollar[1], Y. Osadchuk[1], M. Streckova[2], M. Faberova[2], R. Bures[2], P. Kurek[2] and M. Vojtko[2] *1. Department of Condensed Matter Physics, P.J. Safarik University, Kosice, Slovakia; 2. Institute of Materials Research, Kosice, Slovakia*

Soft magnetic composites (SMCs) consist of pressed insulated ferromagnetic powder particles and they offer possibility of production into the different size and shape. This material exhibits 3D isotropic behavior, low total losses at medium and high frequencies, high electrical resistivity and relatively high permeability [1] [2]. The preparation, magnetic and electrical properties of soft magnetic composite based on hybrid polymer coated FeSi powder are presented in this study. Samples were prepared by powder metallurgy in the form of a ring and a cylinder for magnetic and electrical measurements. SMCs consist of individually coated FeSi powder particles which are covered by phenol-formaldehyde resin modificated by boron with different amounts of ferrite nanofibers (0, 0.24, 0.49, 1.46 wt % ferrite). The ring samples served for magnetic measurements of hysteresis loops in quasi-static fields and alternating magnetic fields up to 37 kHz as well as for determination of the complex permeability dependencies in the frequency range from 1 kHz to 40 MHz. Specific electrical resistivity measurements indicate that the samples are characteristic by very high resistivity (6.14 Ωm). For eddy current losses calculation, the average cross section area of the ferromagnetic component was determined by ImageJ software. Loss separation was used for all prepared SMCs. The results demonstrate that the composite with 0.49 wt % $Ni_{0.3}Zn_{0.7}Fe_2O_4$ ferrite fibers shows the lowest total losses from all samles. This sample has the most suitable insulated particles what is indicated by its high specific electrical resistivity. The real part of complex permeability is dependent on the density. Sample with 1.46 wt % $Ni_{0.3}Zn_{0.7}Fe_2O_4$ ferrite fibers acquired the highest value of real part of complex permeability. The number of active magnetic objects (MOs) depending on H_{exc} and the fit determining the number of activated MOs in quasi-static magnetization were analyzed for all studied samples (Fig. 1).

F10-07. Modulation of magnetic properties in Ni-Zn ferrites by additives. K. Mun[1] and *Y. Kang*[1] *1. Department of Materials Science and Engineering, Korea National University of Transportation, Chungju, The Republic of Korea*

Ni-Zn spinel ferrites are widely used material system in various electromagnetic devices, such as telecommunication, microwave devices, power transformer because of their high magnetic permeability with low magnetic loss and high electrical resistivity [1-3]. The application into the high-frequency devices can be classified based on the complex relative permeability, $\mu = \mu' - j\mu''$. High μ' and $\mu'' \approx 0$ are ideal for applications to magnetic field shielding, wireless charging, inductors, and transformers. Also, low μ' and high μ'' are required for the electromagnetic wave absorber in the corresponding frequency range. In this study, $Ni_{0.4}Zn_{0.6}Fe_2O_4$ samples were prepared at by conventional ceramic processes with various additives of CoO, Cu_2O, SiO_2, $CaCO_3$, and MgO (all 1wt%), respectively. The complex permeability behaviors in the frequency range from 1MHz to 1GHz were significantly depends on the kind of additives as shown in Fig. 1(a) and 1(b). The respective doping of Cu_2O, $CaCO_3$, and MgO shift the resonance frequency (f_r), defined as the frequency where μ'' has the maximum point, to the lower frequency with increasing both of μ' and μ'' at low frequency region while the CoO and SiO_2 shift the f_r to the higher frequency with decreasing both of the μ' and μ''. The Cu_2O and CoO are more effective than the other additives to modulate the μ' and μ'' because large shift of the μ' and μ'' spectra could be achieved by the same doping amount (1 wt%). In the next stage, 1.5wt% CoO, 2.0 wt% CoO, and co-doping of 1.5wt% CoO + 0.5wt% Cu_2O were also tried with the same process and the complex permeability spectra are presented in Fig. (c) and (d). The resonance peak (f_r) moves gradually to the higher frequency with increasing the CoO amount up to 2.0 wt% (see Fig.1 (d)). The co-doped sample with 1.5wt% CoO and 0.5wt% Cu_2O have slightly higher μ' (125.3) with smaller μ'' (9.0) than the 1.5wt% CoO solely doped sample ($\mu' = 124.0$, $\mu'' = 5.9$) at the frequency of 13.56 MHz (RFID). Besides, the applicability of the Ni-Zn ferrites and the correlation between kind of additives, magnetic properties, and microstructure will be discussed.

Z-type hexaferrites can exhibit magnetoelectric properties, and thus, they are important for technological applications, in particular, in data storage and microwave communications [1]. The electrical polarization partly stems from transverse conical spin configurations and strongly depends upon an external magnetic field and temperature. Moreover, since the Fe atoms are ferro- or antiferromagnetically coupled to the Fe atoms occupying other sublattices, a preferential substitution of iron in one of them can result in a drastic change of the magnetization. Mössbauer spectroscopy is the optimal tool for such studies since the spectra of barium hexaferrites consist of several well-separated components corresponding to the sublattices occupied by Fe atoms. We measured the Mössbauer spectra for a series of $Ba_3Co_{2+x}Mo_xFe_{24-2x}O_{41}$ samples as functions of their composition (x=0 and 2, Fig.1), temperature (4.2 – 300 K), and external magnetic field. Despite the fact that there are ten inequivalent crystallographic sites of Fe, the spectra were almost perfectly fitted with four components which correspond to the groups of the crystallographic sites showing similar hyperfine parameters [2]. Two of these are spin-up and the other two spin-down sites. We have found that the spectra change qualitatively with increasing x, as evidenced by the disappearance of particular components. The components of the Mössbauer spectra become better separated and change their contributions with increasing temperature, suggesting a spin configuration that depends on the temperature. Only the application of an external magnetic field significantly changes these spectra, thus allowing for a more complex interpretation of their non-collinear magnetic structure. We conclude that the competition between the uniaxial and planar magnetic anisotropies may produce either an easy magnetization axis, cone, or plane. This eventually depends on the types and amounts of the substitutional cations in the unit cell.

Ferrites are incorporated as microwave absorbers to reduce the electromagnetic pollution arised from the development of high speed electronic devices [1-4]. Here we report microwave absorption characteristics as well as the corresponding mechanisms of M-type $Ba_{0.5}Sr_{0.5}Co_xLa_xFe_{12-2x}O_{19}$ (x = 0.0, 0.2, 0.4, 0.6, 0.8 and 1.0) hexagonal ferrite compositions prepared by using double sintering method. X-ray diffractograms (Philips X'pert diffractometer) and fourier transform infrared spectra (Perkin -Elmer spectrophotometer, model 1430) confirmed the M-type hexagonal structure in the ferrites. The conventional hysteresis loops (VSM SQUID, Quantum Design) were observed in the compositions. The microwave absorption was investigated from calculated reflection loss (RL) by measuring complex permeability and permittivity in the frequency range of 8.2 GHz to 12.4 GHz using a vector network analyzer, Agilent model N5225A; higher the RL, more is the absorption. . The substitution of Co^{2+} and La^{3+} ions enhances absorption, bandwidth and improves impedance matching required for absorption. The magnetic loss tangent is maximum in the high frequency region and vice-versa for dielectric loss tangent. The maximum RL of -46.28 dB is seen in x = 0.2 at 10.77 GHz and 3.9 mm, attributed to the more contribution of the quarter wavelength (figure 1) and impedance matching mechanism (figure 2). -10 dB wideband absorption bandwidth (WAB) of 2.65 GHz is seen in x = 0.6 while -10 dB and -20 dB narrowband absorption bandwidth of 60 MHz and 330 MHz is seen in x = 0.4 and 0.2 respectively. Hysteresis parameters (DC) also comply with microwave absorption (AC) with the lowest ceorcivity of 17 Oe observed in x = 0.2 which is the pre-requisite for absorber. The magnetic loss varies in accordance with the ratio of saturation magnetization and anisotropy field. The investigated mechanisms can be implemented to optimize microwave absorption and design microwave absorbers.

Ferroxdure, ferrites, are utilized as microwave absorbers to suppress the unwanted microwave radiation generated by high speed electronic devices [1-3]. In this investigation, we have analyzed mechanisms accompanying microwave absorption in Co^{2+}-Hf^{4+} doped M-type Ba-Sr hexagonal ferrite with compositions x = 0.0, 0.2, 0.4, 0.6, 0.8 and 1.0 prepared by conventional sintering method. M-type hexagonal structure was verified from X-ray diffractograms and fourier transform infrared spectra. The microwave absorption was studied in the frequency range of 8.2 GHz to 12.4 GHz using a Agilent vector network analyzer and it was analyzed from calculated reflection loss (RL) by measuring complex permeability and permittivity; large RL corresponds to enhanced absorption. The substitution of Co^{2+} and Hf^{4+} ions considerably enhances absorption and improves impedance matching. Figure 1 displays maximum RL of -46 dB in composition x = 0.8 at 6.4 mm in the middle frequency region and attributes to the existence of quarter wavelength (figure 1) and impedance matching mechanism. In general,-20 dB narrowband and wideband absorption is found encompassing the entire investigated frequency region. The hysteresis parameters (Table 1) also contribute to microwave absorption: coercivity (H_c) increases from x = 0.0 to 0.4 and decreases thereafter, saturation magnetization (M_s) remains nearly same from x = 0.0 and 0.8 and steeply drops in x = 1.0. The various investigated mechanisms can be used to design microwave absorbers with tunable frequency as well as thickness.

M-type hexaferrites are the potential microwave absorbers to attenuate the electromagnetic radiation emanating from high speed electronic devices [1-3]. In this paper, we report mechanisms governing microwave absorption in Co-Cr doped M-type BaSr hexaferrite with compositions x = 0.0, 0.2, 0.4, 0.6, 0.8 and 1.0 prepared by conventional sintering method. M-type hexagonal structure was found from X-ray diffractograms and fourier transform infrared spectra. The microwave absorption was studied in the frequency range of 8.2 GHz to 12.4 GHz using a Agilent vector network analyzer and it was evaluated from calculated reflection loss (RL) by measuring

complex permeability and permittivity; higher RL leads to large absorption. The substitution of Co^{2+} and Cr^{3+} ions causes considerable improvement in absorption, bandwidth and improves impedance matching. Composition x = 0.8 exhibits RL of -53 dB at 5.6 mm in the low frequency region associated with existence of quarter wavelength (figure 1) and impedance matching mechanism, and resonance in complex permeability (figure 2). x= 0.8 also shows large dielectric loss and -20 dB good narrowband absorber behavior among the compositions. The investigated mechanisms can be used to design tunable microwave absorbers with desired frequency and thickness.

F11-01. High-Frequency Dynamics of Honeycomb Artificial Spin Ice in Different Microstates. *D.M. Arroo*[1], J.C. Gartside[1] and W.R. Branford[1]
1. Department of Physics, Imperial College London, London, United Kingdom

The exponentially large microstate space available to artificial spin ice (ASI) systems has identified them as promising candidates for applications as reprogrammable magnonic crystals [1,2]. In such applications, different microstates possess different spin-wave eigenmodes, while inter-island coupling and the periodicity already present in most ASI geometries leads to the formation of a band structure through Bragg reflection. It has recently been demonstrated that ASI systems may be prepared in any desired microstate via 'Topological Defect-Driven Magnetic Writing' (TMW) using the localised field of a magnetic-force microscopy tip[3], bringing devices based on moving between selected microstates within reach. Here, the prospects of integrating TMW directly into reconfigurable ASI devices is explored via micromagnetic simulations[4] with a view to applications tuning the spin-wave dynamics. It is found that altering the microstate of ASI on a honeycomb lattice allows substantial control over spin-wave eigenspectra, including the ability to frequency-shift and activate or deactivate individual resonant modes. ASI systems with integrated TMW are thus demonstrated to offer strong prospects as core components of reprogrammable magnonic devices and microwave filters.

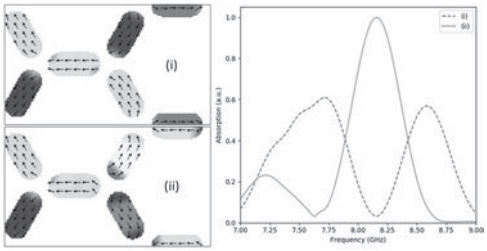

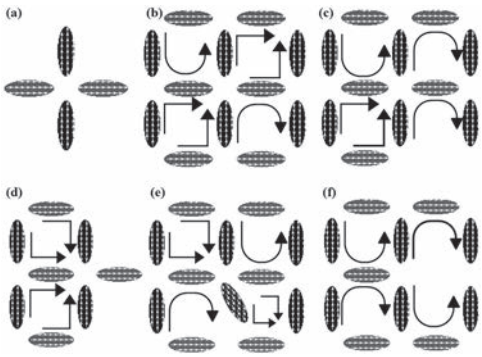

Figure 1: By moving between different microstates of a honeycomb ASI system, the spin-wave eigenspectrum may be dramatically altered. Here moving from state (i) to state (ii) (shown left) splits an eigenmode centred at 8.2 GHz and opens up a gap of ~1 GHz with the microwave absorption at 8.2 GHz suppressed by -15 dB (right).

F11-02. Defect-mediated Monopole-like States in Square Artificial Spin Ice Systems. *N. Keswani*[1] and P. Das[1] *1. Department of Physics, Indian Institute of Technology Delhi, New Delhi, India*

Artificial spin ice (ASI) is an engineered designer material system involving elongated magnetic nanostructures (islands) with strong shape anisotropy [1]. Special arrangement of the nanostructures in different geometries such as square, hexagonal, etc., lead to magnetic behavior of macrospins which offer possibilities to study magnetic frustration in a very controlled manner. In square lattice, a vertex has two-in two-out macrospin state (spin ice rule) which leads to ground state degeneracy. The excitation of such systems leading to local defects violating spin ice rule has attracted tremendous attention of researchers in the recent years [2-4]. During fabrication disorder in the nanostructures may be unintentionally introduced which may also play a significant role in defining the magnetic states of such systems. Therefore, understanding the impact of disorder/defect in the ASI systems is very important. In this work, we report the results of detailed investigation of remanent states for $Ni_{80}Fe_{20}$ based square ASI systems involving defects. Fig. 1 shows the remanent states for ASI with open- and close-edged single vertex structures where defects in form of missing/tilted islands are introduced (Fig. 1c-f). Our detailed micromagnetic simulations show that a robust three-in one-out state arises as a result of the interplay of defect and dipolar interactions (Fig. 1d). Such magnetic state corresponds to emergent magnetic monopole which appears as a local excitation in case of defect-free two-in two-out state [5]. Thus, these results demonstrate that unusual magnetic states can be created by introduction of defects in the ASI systems. The monopole-like state was found to be robust against inter-island separation of up to the simulated value of 700 nm. The interplay also modifies the magnetic switching behavior of these structures. Thus, our results indicate that high-sensitive experiments for *individual* ASI vertices with defects are important to understand the role of defects in such frustrated nanomagnetic systems.

Magnetic nanoparticle (NP) assemblies form a novel type of artificial material which hold the promise to display properties that are not found in nature. [1] It is known that dense, randomly closed packed arrangements behave like a canonical spin glass, and are therefore termed superspin glasses [2, 3]. Using a novel centrifuge assisted sedimentation technique, we have succeeded in fabricating large 3D nanoparticle arrangements. They are composed of spherical iron oxide (Fe_2O_3) particles with a diameter of 15nm. The size and size distribution of the individual nanoparticles were characterized using small angle x-ray scattering (SAXS) at our in-house instrument GALAXI, as well as dynamic light scattering. Their internal structure was investigated using transmission electron microscopy. The initial dispersion was centrifugated which results in a separation into a dense dispersion and a nearly clear supernate. After the supernate is removed, a silicon substrate is added, on which the NP crystals then grow. [4] The morphology of these crystals was examined using scanning electron microscopy (SEM), which showed that the growth of macrocrystals up to 300-1000μm in size was possible. Their structure was then investigated using SEM and SAXS (see fig. 1). The macroscopic magnetic behavior was characterized using magnetometry including zero field cooled, field cooled and aged zero field cooled curves. The microscopic magnetic correlations between the particle moments were investigated using spin-polarized small angle neutron scattering. The systems exhibit characteristics of spin glasses, but show intriguing deviations from canonical spin glasses (see fig. 2), probably hinting at a novel class of frustrated magnetic behavior.

Magnetospirillum gryphiswaldense is a microorganism able to biomineralize high quality magnetite nanoparticles, called magnetosomes. These helical cells contain a variable number of 45 nm cuboctahedral single domain magnetite magnetosomes arranged in a chain [1]. Thus, the chain behaves like a large single permanent magnetic dipole able to orient the whole cell along earth magnetic field. In this sense, magnetosome chain is a natural paradigm of 1D magnetic nanostructure. Due to the large magnetic anisotropy, such arrangements show potential for biomedical applications [2-3] and actuation devices as nanorobots [4]. Rather than the a priori expected straight lines, magnetosome chains are slightly bent. The present work sheds light on the underlying mechanisms that determine the arrangement of the magnetosomes and consequently the geometry of the chain. We have explored the direction of the magnetic moment using state-of-the-art techniques on a set of different bacterial arrangements: i) small angle neutron/x-ray scattering (SANS/SAXS) on a bacterial colloid, ii) macroscopic magnetometry on 3D and 2D fixed arrangements of randomly distributed and aligned bacteria, and iii) x-ray photoemission electron microscopy (XPEEM) on an individual chain of magnetosomes extracted from bacteria (Fig.1). Our experimental and theoretical findings [5] suggest that due to the competition between the magnetocrystalline and shape anisotropies, the effective magnetic moment of individual magnetosomes is 20° tilted out of the chain axis ([111] crystallographic easy axis of Fe_3O_4). This tilt does not affect the direction of the chain net magnetic moment, which remains along the chain axis, but turns out to be the key to understand the arrangement of magnetosomes in

helical-shaped chains. In fact, by considering an interplay between the magnetic dipolar interactions between magnetosomes and a lipid/protein-based mechanism, modelled as an elastic recovery force exerted on the magnetosomes, we were able to reproduce the experimental chain geometry imaged by cryotomography.

F11-05. Topological Magnetic Writing: Defining specific magnetization states in nanostructures. *W.R. Branford*[1], J.C. Gartside[1], D.M. Arroo[1] and L.F. Cohen[1] *1. Physics, Imperial College London, London, United Kingdom*

Networks of magnetic nanostructures are of broad interest from novel data storage and computation to magnonic crystals. One family of nanomagnetic arrays, characterized by strong and frustrated magnetic interactions are the artificial spin ices (ASI).1 ASI structures have provided vast amounts of physical insight in recent years [1-4] in part due to their ability to model complex systems [5] and exhibit exotic phenomena such as 'magnetic monopole'-like states [6]. The power of these networks stems from the extraordinary number of unique microstates, even in systems comprising relatively few nanostructures. However, magnetic nanoarrays in general, and ASI structures in particular, have yet to realise their full potential as the majority of microstates remain inaccessible due to the rudimentary state-writing tools currently available. An experimental means to prepare all potential microstates has huge implications, including realising ASI as a tunable-bandgap magnonic crystal [7] or reconfigurable neural-network [8]. We present a novel MFM-tip based state writing technique,[9] building on our previously demonstrated domain-wall injection process.[10] It requires no global fields and is applicable to all nanostructure architectures, providing control over the spin-configuration and access to every possible microstate. We demonstrate our method via realisation of several exotic and thus-far unobserved states, unachievable via global field-protocols: 'magnetic monopole-defect' chains and the spin-crystal ground state [11] of kagome ASI.

F11-06. Trapping Ferromagnetic Domains in Pentagonal Cairo-tilings. *J.L. Palma*[1,2], E. Saavedra[3] and J. Escrig[4,2] *1. Departamento de Ciencias Básicas, Universidad Central de Chile, Santiago, Chile; 2. Center for the Development of Nanoscience and Nanotechnology CEDENNA, Santiago, Chile; 3. Departamento de Física, Universidad de Santiago, Santiago, Chile; 4. Departamento de Física, Universidad de Santiago Chile, Santiago, Chile*

We study the magnetic behavior and the pining of the magnetization in different periodic lattices generated by magnetic stripes. We start with a square lattice, known as Shakty lattice [1], but in our case, all the ferromagnetic elements are interconnected. The squared lattice is deformed in order to obtain pentagonal lattice (one case is like Cairo tiling) up to reach a square lattice again, with smaller elements. Magnetic domains are trapped in all pentagonal cases. Pentagonal lattices were studied by micromagnetic simulations, and experimental measurements. Synthesis was made by mean of electron beam lithography (EBL) technique and magnetic properties were measured, by magneto-optic Kerr effect (MOKE). For pentagonal Cairo tiling, magnetization is trapped in isolated ferromagnetic elements, as magnetic bits. Magnetic imaging obtained by magnetic force microscopy (MFM) corroborate the above findings, which show the magnetic structure of the arrays to depend strongly on the array morphology.

Recent studies showed that artificial spin ices, lithographically defined two-dimensional analogs of geometrically frustrated spin ices,[1] offer the opportunity to study ensembles of frustrated magnetic elements using real-space imaging techniques such as x-ray photoemission electron microscopy. While ferromagnetic nanoislands can have high magnetostatic energy barriers that cannot easily be reached via thermal means, reducing the volume of magnetic material to approach the superparamagnetic limit has been effective in the observation of thermally active behavior in artificial spin ice geometries.[2] However, small changes in island volume can result in large changes in the superparamagnetic blocking temperature and can provide unexpected randomness to the manner in which the system explores its energy landscape during thermalization. We have recently shown that epitaxial complex oxide $La_{0.7}Sr_{0.3}MnO_3$ nanomagnets (bulk Curie temperature of 370 K) avoided the need for superparamagnetic elements by displaying thermally activated behavior as low as 325 K.[3] By varying both nanomagnet volume and inter-island distance, we have studied the effect of the coupling strength and annealing protocol on the population of low energy vertex configurations arranged in square, brickwork, shakti, tetris, and kagome-based lattices. In the limit of high coupling strength, we found that heating to 350 K is sufficient to drive both square and brickwork lattices into large scale ground state domains, and spin-spin correlation coefficients of thermalized kagome arrays match well with theoretical and experimental values found for metallic spin ice systems. Furthermore, as these nanomagnets are embedded in an amorphous paramagnetic matrix during fabrication, anisotropic magnetoresistance measurements could be a sensitive complementary probe of chiral effects and motion of charge excitations in addition to the real space imaging presented in this work.

Artificial Spin Ice (ASI), consisting of a two dimensional array of nanoscale magnetic elements [1], provides a fascinating opportunity to observe the physics of out of equilibrium systems. Recent studies have accessed the out-of-equilibrium dynamic, fluctuating state [2,3,4]. This opens up exciting possibilities such as the observation of systems exploring their energy landscape through monopole quasiparticle creation, potentially leading to ASI magnetricity. In this work [5] we have measured and analysed the magnetic relaxation of thermally active ASI systems by means of SQUID magnetometry. We fabricated and measured square ASIs formed by nanomagnets made of Permalloy ($Ni_{80}Fe_{20}$) with lateral dimensions of 68x22nm^2, with two different thicknesses: 5nm and 6nm, and three different lattice spacings: 138nm, 175nm and 208nm, for a total of six samples. We investigated the effect of the interaction strength on the magnetization dynamics at different temperatures in the range where the nanomagnets are thermally active. We have observed that they follow an Arrhenius-type Nèel-Brown behaviour. An unexpected negative correlation of the average blocking temperature with the interaction strength is also observed, which is supported by Monte Carlo simulations. The magnetization relaxation measurements show faster relaxation for more strongly coupled nanoelements with similar dimensions. The analysis of the stretching exponents obtained from the measurements suggest 1-D chain-like magnetization dynamics, indicating that the nature of the interactions between nanoelements lowers the dimensionality of the ASI from 2-D to 1-D. Finally, we present a way to quantify the effective interaction energy of a square ASI system, and compare it to the interaction energy calculated from a simple dipole model and also to the magnetostatic energy computed with micromagnetic simulations.

Lawrence Berkeley National Laboratory, Berkeley, CA, United States*

Spatial arrangements of magnetic micro and nano structures resembling macro spins have emerged as leading prototypical systems to study spin frustration, correlation and fluctuations in artificial spin ice, glass and liquid at the micro scale. The advantage of these artificial systems over their "real" counterpart is the versatility of tailoring the governing magnetic (stray field) interactions and order/symmetry at an experimentally accessible time and length scale. While most efforts have focused on artificial spin ice structures, little work has been done on artificial spin glass and liquid. We prepared circular nano disk arrays with various spacing and virtually absent energy barrier to study magnetic ordering, correlations and fluctuations in planar square and honeycomb XY macrospin lattices utilizing X-ray photoemission electron microscopy. The lack of an energy barrier in individual disks leads to a high sensitivity of the magnetization configuration on the lattice parameters and temperature, with fluctuation rates orders of magnitude larger than those of biaxial spin systems. We find experimental evidence of a Berezinskii-Thouless-Kosterlitz-like phase transition solely mediated by magnetostatics that favors a trigonal vortex lattice similar to Skyrmion lattices stabilized by the Dzyaloshinskii-Moriya interaction. Our results open up a new avenue in the field of artificial spin ice towards XY spins, spin liquids, Kitaev's XYZ honeycomb lattices and magnonics. Supported by DOE BES MSED under contract #DE-AC02-05-CH11231.

F11-13. Bloch point states in arrays of dipole-coupled magnetic nanodots. *I. Nekrashevich*[1] and D. Litvinov[1,2] *1. Materials Engineering, University of Houston, Houston, TX, United States; 2. Nanofabrication Facility, University of Houston, Houston, TX, United States*

There is increasing capability to engineer and manipulate non-uniform magnetic textures, i.e. topological defects, at the nanoscale in the form of domain walls, vortices, magnetic monopoles, skyrmions and Bloch points, some of which are proposed as building blocks for the future data processing and storage devices. Several studies of Bloch point domain walls emergence and propagation in ferromagnetic nanowires were performed over the recent years. In these experimental and numerical studies only exchange interaction and demagnetizing field within the isolated specimen were taken into account. However, longer range dipolar interparticle interactions can also affect the occurrence of such topological objects as Bloch points in nanomagnets. We focus on the effect of non-uniform stray magnetic fields on collective magnetic behavior and formation of the Bloch points in closely packed arrays of interacting magnetic nanodots. In this report a study of collective behavior and magnetization inside 60 nm $Ni_{80}Fe_{20}$ (permalloy) cuboid nanomagnets arranged in a square lattice is presented. Minimized contribution from shape anisotropy and small distance between cubic nanomagnets allow for dipole-dipole interaction to play considerable role in collective magnetic behavior and affects magnetization textures within individual magnetic nanodots arranged in a closely packed square lattice. To demonstrate the effects of interdot coupling the evolution of magnetic behavior in arrays with respect to spacing between neighboring nanodots is explored while geometry of individual cuboid magnetic nanodots is kept constant. Micromagnetic simulations demonstrate an evidence of stable topologically protected Bloch point magnetization textures inside the most densely packed (60 nm side length with 90 nm center to center distance) magnetic nanocubes.

Artificial spin ice structures (ASI) have attracted great attention, serving as potential analogues for frustrated magnetic systems, such as bulk spin ice materials[1]. They also have applications in reprogrammable logic circuits and neural networks[2]. The results procured from magnetotransport measurements on a family of magnetically frustrated hexagonal systems are presented. A single vertex, an extended magnetically connected honeycomb lattice and an electrically connected but magnetically disconnected (hybrid) honeycomb lattice are shown in figure 1. We fabricated ASI structures from Permalloy films having dimensions close to 1μm long, 100nm wide and 10nm thick. For the hybrid lattice, gold vertices were used to electrically connect the lattice. We have carried out magnetotransport measurements on a single honeycomb vertex structure, the connected lattice and the hybrid lattice, see figure 2. We have also simulated the magnetotransport response of a single connected vertex structure. Comparing the single vertex simulation with the experimental data gathered from a single vertex, the inferred reversal procedure was consistent with a frustrated system. The magnetotransport data concerning lattices showed that for a connected lattice, where a single domain wall has been known to switch multiple vertices[3], the obtained electrical signal was smaller than the equivalent measurement on the hybrid lattice. The magnetotransport data for the hybrid lattices produced a larger signal corresponding to the reversal events, this is due to the presumption that a domain wall needed to be nucleated in every vertex, accumulating a larger signal. The data obtained for the hybrid case was akin to the single vertex data but the very sharp resistance changes present in the single vertex data were not as sharp in the hybrid data, see figure 2.

F12-01. Large Anomalous Hall Effect in the Noncollinear Antiferromagnet Mn_5Si_3. *C. Sürgers*[1], T. Wolf[2], P. Adelmann[2], W. Kittler[1], G. Fischer[1] and H. von Löhneysen[2] *1. Physikalisches Institut, Karlsruhe Institute of Technology, Karlsruhe, Germany; 2. Institute for Solid State Physics, Karlsruhe Institute of Technology, Karlsruhe, Germany*

The anomalous Hall effect (AHE) of magnetic materials has experienced a revival in recent years. In particular, certain antiferromagnets with a noncollinear arrangement of magnetic moments and a nonvanishing Berry curvature exhibit a sizeable AHE at room temperature in spite of their small net magnetization [1,2]. This bears considerable potential for future applications in antiferromagnetic spintronics. Antiferromagnetic Mn_5Si_3 is an interesting compound which allows to explore the AHE and its sensitivity to the details of the magnetic texture [3]. Below 60 Kelvin the magnetic structure becomes noncollinear by realignment of Mn_2 moments and additional ordering of Mn_1 moments due to a magneto-structural distortion. The different Mn moments generate six magnetic sublattices. Here we report on measurements of the AHE, magnetoresistance, planar Hall effect, and magnetization performed on Mn_5Si_3 single crystals [4]. In the noncollinear antiferromagnetic phase we observe a large anisotropic AHE with multiple transitions and sign changes at different magnetic fields. These features are attributed to rearrangements of the magnetic structure at low fields and a metamagnetic phase transition at high fields. In contrast, variations of the total magnetization and magnetoresistance are rather small below the metamagnetic transition as often found in this class of antiferromagnets. We exploit the sensitivity of the AHE to the details of the magnetic texture and propose a modified magnetic phase diagram for Mn_5Si_3 with an additional field-induced noncollinear phase below the collinear phase developed above the metamagnetic phase transition.

F12-02. Photo-induced anomalous Hall effect in nickel. *A. Ruotolo*[1,2], D. Li[1,2] and K. Lin[3] *1. City University of Hong Kong, Kowloon, Hong Kong; 2. City University Shenzhen Research Institute, Shenzhen, China; 3. Department of Materials Science and Engineering, National Chung Hsing University, Taichung, Taiwan*

Photo-induced Hall effect in ultra-thin metallic films has recently been reported [1]. The system consists of a metal, such as platinum or gold, that forms a Schottky contact to a semiconductor. Light reaching the interface results in the injection of charge from the space charge region. If an in-plane magnetic field is applied, a transverse, open-circuit voltage appears at the metal edges that is proportional to the field, as well as light intensity. Since no net current flows in the device, performance are not affected by Joule heating. By using nickel (Ni), a ferromagnetic metal with high work-function, we show that an anomalous contribution arises, in addition to the standard Hall effect. This allows studying the anomalous Hall effect (AHE) in ultra-thin Ni when the external magnetic field is applied in the film plane. Ultra-thin Ni (thickness 3, 4 and 5 nm) was sputter-deposited on 1 x 1 cm^2 un-doped (100) silicon (Si) dice. The voltage was measured by connecting the midpoints of two opposite edges of the metallic film to a voltmeter. The magnetic field was applied in the plane and perpendicular to the voltage direction. Light was shed on the sample by using a bulb lamp emitting unpolarized, visible light. A sample with platinum was also prepared as a refence. For high magnetic field (much larger than the saturation magnetization of Ni) a linear dependence of the open-circuit voltage on the applied field was measured, similarly to the previously reported case of platinum and gold [1]. Yet, for the case of Ni, a clear hysteresis appears around zero field (see figure 1), revealing a contribution from AHE. The results are interpreted in the context of modern semiclassical treatment of the AHE [2].

F12-03. Surface roughness tuned anomalous Hall effect in Fe thin films. *Q. Zhang*[1], Y. Wen[1], P. Li[1], Y. Zhao[1], S. Zhang[1] and X. Zhang[1]
1. Physical Science and Engineering Division (PSE), King Abdullah University of Science and Technology (KAUST), Jeddah, Saudi Arabia

The samples, seed layer (0.2 nm)/Fe (5 nm)/SiO_2 (5 nm) with different seed layers (Ta, $Ir_{20}Mn_{80}$, MgO, Ru, $Co_{60}Fe_{20}B_{20}$, SiO_2, Co, Ni, CuN, Cu), were prepared by sputtering system. By using different materials of seed layers, we could tune the surface roughness of Fe layers and study the surface roughness effect on the anomalous Hall effect (AHE). The HRTEM images of the cross-sections for samples with seed layers of Ta and Cu were shown in Fig. 1 to demonstrate the variation of surface roughness. The longitudinal resistivity (ρ_{xx}) measured at 5 K increases by one order from sample Ta/Fe to Cu/Fe, which could be ascribed to the surface roughness. In Fig. 2(a), the anomalous Hall resistivity (ρ_{AHE}) shows nonmonotonic dependence on ρ_{xx}, suggesting very complicated roughness scattering effect on the AHE. The new scaling relation[1], $\rho_{AHE}=\alpha\rho_{xx0}+\beta\rho_{xx0}^2+b\rho_{xx}^2$, was applied to our data. The skew scattering (α), side jump (β) and intrinsic contribution (b) to AHE depend on the ρ_{xx}, as proposed in our previous study[2]. The three contributions were extracted from the data. The values of b in Fig. 2(b) show linear dependence on the longitudinal conductivity (σ_{xx}). The sign of both α and β changes, as shown in Fig. 2(c). The surface roughness effect on the AHE can't be ignored, which could be applicable for spin Hall effect[3].

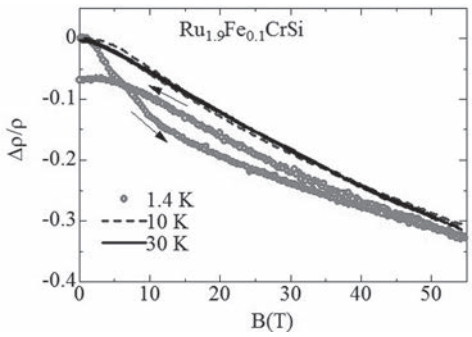
F12-04. Hall effect and resistivity in epitaxial MnSi thin films and nanostructures under ambient and high pressure. *D. Menzel*[1], D. Schroeter[1], N. Steinki[1], S. Süllow[1], A. Fernandez-Scarioni[2], H. Schumacher[2], H. Okuyama[3], H. Hidaka[3] and H. Amitsuka[3] *1. Institut für Physik der Kondensierten Materie, Technische Universität Braunschweig, Braunschweig, Germany; 2. Physikalisch-Technische Bundesanstalt, Braunschweig, Germany; 3. Department of Physics, Hokkaido University, Sapporo, Japan*



Topological states in condensed matter physics play an important role for many areas like, e.g., quantum Hall effect, topological insulators and phase transitions. Also in the context of spintronics, complex topological spin structures such as skyrmions have evolved as an intriguing topic both for fundamental research and from the view of possible applications for modern information technology. The first experimental proof of the existence of skyrmions in magnetic materials was found in single crystals of the cubic B20-helimagnet MnSi [1], which represents the prototype solid-state system exhibiting such topological spin textures within a two-dimensional skyrmion lattice. Although for MnSi bulk material, the investigations of the properties regarding the skyrmion objects have been comprehensively done, experimental studies of epitaxial MnSi thin films on a Si(111) substrate have as yet been inconclusive. Some indications from indirect measurements may be interpreted as occurrence of skyrmions [2], although a topological Hall effect as unique signature of the A-phase in bulk MnSi [3] has never been reliably observed in thin films. In this situation, we have reinvestigated the (magneto-)resistivity and Hall effect in MnSi thin films, which have been grown by molecular beam epitaxy. Afterwards we have lithographically produced nanostructures of various sizes in Hall geometry and determined the transport properties by means of Hall and resistivity experiments under ambient and high pressure [4]. The resistivity of the thin films and nanostructures behave differently from bulk crystals and leads us to the conclusion that possibly an electronic inhomogeneity is inherently present in MnSi thin films. We discuss our experimental results and the possible influence of disorder induced by strain and epitaxial growth modes. The anomalous Hall effect, which is influenced both by the magnetization and the resistivity of the films, reflects in principle the behavior of bulk samples. However, measurements at high pressure imply that spin fluctuations play a crucial role for the transport properties above the Néel temperature and high magnetic fields.

F12-05. Anomalous Hysteresis in Magnetoresistance in $Ru_{1.9}Fe_{0.1}CrSi$ under Pulsed Magnetic Fields. *M. Hiroi*[1], I. Shigeta[1], A. Kondo[2] and K. Kindo[2] *1. Department of Physics and Astronomy, Graduate School of Science and Engineering, Kagoshima University, Kagoshima, Japan; 2. High Field Laboratory, Institute for Solid State Physics, the University of Tokyo, Kashiwa, Japan*

Magnetoresistance (MR) in the Heusler compound $Ru_{1.9}Fe_{0.1}CrSi$ was measured at temperatures between 1.4 K and 30 K under magnetic fields up to 55 T using a pulsed magnet. $Ru_{1.9}Fe_{0.1}CrSi$ was found to exhibit no magnetic order but instead spin-glass freezing at 14 K [1,2]. In static fields due to a superconducting magnet, the resistivity ρ of $Ru_{1.9}Fe_{0.1}CrSi$ was found to decrease with increasing magnetic field *B*. Specifically, the MR of $Ru_{1.9}Fe_{0.1}CrSi$ was found to be negative up to 14.5 T. The absolute value of the MR ratio $\Delta\rho(B)/\rho_0 = (\rho(B)-\rho_0)/\rho_0$, where $\rho(B)$ is the resistivity at a magnetic field of *B* and ρ_0 (=$\rho(0)$) is that at 0 T, was found to increase with decreasing temperature and to become 10% at *B* = 14.5 T at low temperatures [3]. As shown in the figure, in a pulsed field the resistivity continues to decrease between *B* = 15 T and 55 T and does not show any sign of saturating. The absolute value of the MR ratio does not change much at temperatures below 30 K, becoming roughly 30% at 55 T. Notably, characteristic hysteresis in $\rho(B)$ with increasing and decreasing magnetic fields is seen at temperatures below 4 K and becomes more remarkable at lower temperatures, as shown in the figure. The facts that this behavior depends on temperature, is not seen above 10 K, and has been observed only in this compound demonstrate that this hysteresis reflects the intrinsic properties of this compound, probably related to the spin-glass state. Hysteresis behavior appears also in static magnetic fields but is less prominent and has a different appearance. This implies that although the hysteresis in MR is intrinsic, a pulsed field either enhances the hysteresis or alters its appearance.

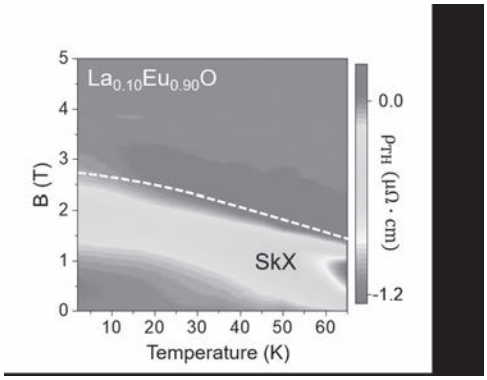
Magnetoresistance (MR) of $Ru_{1.9}Fe_{0.1}CrSi$ measured using a pulsed magnet up to 55 T at 1.4, 10, and 30 K. For 1.4 K remarkably characteristic hysteresis is observed.



F12-06. Tuning the Magnetic and Transport properties of the new double perovskite Tl_2NiMnO_6. *P. Manuel*[l], L. Ding[2], D. Khalyavin[1], J. Blake[1,3], F. Orlandi[1], W. Yi[4] and A. Belik[4] *1. ISIS Pulsed Neutron Facilty, Rutherford Appleton Laboratory, Chilton, United Kingdom; 2. ISIS Facility, Rutherford Appleton Laboratory, Science and Technology Facilities Council, Oxford, United Kingdom; 3. Department of Physucs, Royal Holloway University of London, Egham, United Kingdom; 4. National Institute for Materials Science (NIMS), Tsukuba, Japan*

We report magnetization and neutron powder diffraction measurements on two samples of the new double perovskite Tl2NiMnO6 synthesized under different conditions of pressure and high temperature[1]. The chosen samples, one with ~70% ("ordered") and the other with ~31% ("disordered") cationic ordering clearly illustrate the dramatic influence of Ni2+/Mn4+ cation ordering on the magnetic properties : the ordered sample undergoes a ferromagnetic transition at 80 K, whereas the disordered one exhibits only short range spin correlations and spin glass like behaviour. Interestingly, ordered Tl2NiMnO6 represents the first realization of a ferromagnetic insulating double perovskite, showing large low-field magnetoresistance (MR) usually found in double perovskite that are both ferrimagnetic and half-metallic[2]. We also present spin polarised density functional theory calculations supporting our experimental observation that this effect can be assigned to a suppression of spin-dependent scattering between ferromagnetic domains.

F12-07. Role of La doping for Topological Hall Effect in Epitaxial EuO Films. Y. Yun[1,2], *Y. Ma*[1,2], T. Su[1,2], W. Xing[1,2], Y. Chen[1,2], Y. Yao[1,2], R. Cai[1,2], W. Yuan[1,2] and W. Han[1,2] *1. International Center for Quantum Materials, School of Physics, Peking University, Beijing 100871, China; 2. Collaborative Innovation Center of Quantum Matter, Beijing 100871, China*

We report the critical role of La doping in the topological Hall effect observed in $La_xEu_{1-x}O$ thin films (~ 50 nm) grown by molecular beam epitaxy. When La doping exceeds 0.036, the topological Hall effect emerges, which we attribute to the formation of magnetic skyrmions. Besides, the La doping is found to play a critical role in determining the phases, densities, and sizes of the skyrmions in the $La_xEu_{1-x}O$ thin films. The maximum region of the skyrmion phase diagram is observed on the $La_{0.1}Eu_{0.9}O$ thin film. As the La doping increases, the skyrmion density increases while the skyrmion size decreases. Our findings demonstrate the important role of La doping for the skyrmions in EuO films, which could be important for future studies of magnetic skyrmions in Heisenberg ferromagnets.

The phase diagram of topological Hall resistivity ρ_{TH} (μΩ*cm) in the $La_{0.1}Eu_{0.9}O$ thin film as a function of magnetic field and temperature.

$Mn_5Ge_3C_{0.8}$ and $Mn_5Si_3C_{0.8}$ show enhanced ferromagnetic properties at room temperature compared to pure Mn_5Ge_3 and Mn_5Si_3 which makes these materials highly suited for spintronics applications, especially for integration into CMOS technology [1,2]. The magnetotransport properties of magnetron-sputtered Mn_5Ge_3, $Mn_5Ge_3C_{0.8}$, and $Mn_5Si_3C_{0.8}$ films with Curie temperatures at and well above room temperature have been previously investigated and contributions arising from the ordinary and extraordinary, i.e., anomalous Hall effect have been separated [3]. In this work, the thermal-magnetotransport properties have been experimentally investigated in thin films deposited on Ge (111) substrates by electron-beam evaporation or magnetron sputtering. For the thermal-magentotransport measurements we have used configurations with different orientations of the temperature gradient and charge flow into Pt, W, Ta, and Cu electrodes to disentangle the contributions arising from the spin Seebeck effect and the anomalous Nernst effect (ANE). The ANE coefficients for all the films show a positive sign at high temperatures until at about 100 K the sign changes to negative for the germanide films but not for the $Mn_5Si_3C_{0.8}$ film. This behavior follows the same change of sign behavior of the anisotropic magnetoresistance ratio and ordinary Hall coefficient previously observed for these compounds [3]. The change of sign of the ANE is a direct consequence of the Mott relation in our ferromagnetic films [4] even if the sign of the anomalous Hall coefficient remains unchanged.

F12-09. Equilibrium and Nonequilibrium Spin Current Fluctuations in Quantum Paramagnets. J. Aftergood[1], D. Joshi[2], A. Schnyder[2] and *S. Takei*[3] *1. Physics, CUNY Graduate Center, New York, NY, United States; 2. Max Planck Institute for Solid State Research, Stuttgart, Germany; 3. Physics, CUNY Queens College, Queens, NY, United States*

Low frequency noise in tunneling spin current across magnetic insulator-normal metal interfaces have been shown recently to contain important information on the effective spin of tunneling quasiparticles, interfacial heating as well as the effective spin Hall angle [1,2]. These works have considered magnetic insulators where the spin current can essentially be understood as tunneling of weakly interacting magnons. However, there is a rich plethora of quantum paramagnets, in which strong quantum fluctuations lead to exotic ground states that are adiabatically disconnected from weakly interacting counterparts, and the properties of spin current fluctuations in such systems have received little attention. In this work, we study the spin current noise generated across two weakly coupled S=1/2 XXZ antiferromagnet chains, a prototype quantum paramagnet with strongly-interacting ground states, and show how Luttinger liquid correlations give rise to noise signatures that differ strikingly from spin current noise generated by weakly interacting magnons [3]. We then consider the effects of the irrelevant umklapp scattering on the tunneling spin current noise, and also discuss how the noise can be detected using a leaky resonant microwave cavity. In the second part of this talk, we theoretically study the equilibrium spin current fluctuations and the corresponding charge noise generated by inverse spin Hall effect (ISHE) in a metal with strong spin-orbit coupling deposited on top of an S = 1/2 quantum spin ladder that hosts a trivial ground state of singlet product states but topologically-protected fractional spin excitations localized at its ends [4]. We report the utility of the equilibrium spin current noise as a tool to unambiguously detect the topological phase transitions in the system, and purport the general usefulness of the ISHE-mediated spin noise spectroscopy for the detection of topological phases in quantum paramagnets.

F12-10. Spin-Lattice Coupling Suppress Phonon Lifetimes in Paramagnetic CrN as Revealed by Combined Atomistic Spin Dynamics and *Ab Initio* Molecular Dynamics. *I. Stockem*[1,2] and B. Alling[1,2] *1. Department of Physics, Chemistry and Biology (IFM), Linköping University, Linköping, Sweden; 2. Max-Planck-Institut für Eisenforschung GmbH, Düsseldorf, Germany*

Semiconducting CrN has a common magnetic and structural transition near room temperature. Although no magnetic long range order exists above the transition temperature, the experimentally observed thermal conductivity differs drastically from non-magnetic semiconductors: Instead of a 1/T decrease with temperature, the thermal conductivity of the paramagnetic B1 CrN phase is low and largely temperature independent (Fig. 1) [1]. Such anomalous behavior points out the importance of magnetic dynamics and short-range order (SRO) in the paramagnetic state, and its coupling to the lattice. We develop a method [2] allowing to study this mutual dynamical coupling by combining atomistic spin dynamics [3-4] and *ab initio* molecular dynamics [5-7] (ASD-AIMD). We study the phonon lifetimes (Fig. 1), as well as the correlation between atomic distances and spin orientations (Fig. 2) in paramagnetic CrN and compare ASD-AIMD with two magnetic treatments which make the usual assumption that magnetism is adiabatically fast. When using disordered local moment – *ab initio* molecular dynamics (DLM-AIMD) [8], where magnetism is treated as adiabatically fast with no SRO, we see longer phonon lifetimes and a standard decrease with temperature. We then perform Monte Carlo based magnetism - *ab initio* molecular dynamics (MC-AIMD), at which the magnetic state is again adiabatically fast, but includes spatial SRO. The MC-AIMD results are similar to DLM-AIMD for phonon lifetimes underlining the dynamical, non-adiabatic, coupling as the main reason for phonon-life-time reduction in the paramagnetic state. A weakening of this coupling at higher temperatures compensates the increased phonon-phonon scattering and results in the unusual almost temperature independent trend for thermal conductivity in the paramagnetic state of magnetic semiconductors.

F12-11. Tuning the Magnetic Anisotropy of Co Metals on Two-dimensional van der Waals Materials : A Role of Hybridization of Tetrahedral sp^3-d Coupling. *S. Rhim*[1], D. Odkhuu[2], S. Choe[3] and S. Hong[1] *1. Physics, University of Ulsan, Ulsan, The Republic of Korea; 2. Department of Physics, Incheon National University, Incheon, The Republic of Korea; 3. Seoul National University, Seoul, The Republic of Korea*

The reorientation of magnetization of Co on *hexagonal* BN (*h*-BN) and graphene multilayers is presented using first-principles calculations. A formation of tetrahedral bonding between sp^3 and d orbitals at the interface is the key driving force, where the intrinsic π-bond of *h*-BN and graphene is transformed to sp^3 as a result of strong hybridization with metallic d_{z^2} orbital. Two tetrahedral bondings exhibit different features well demonstrated in charge density and density of states in the vicinity of interface along with associated band structure near the K valley.

F13-01. Scanning tunneling microscopy study of the spin Hall effect in highly-resistive tungsten film. *T. Xie*[1], M. Dreyer[2], D. Bowen[3], D. Hinkel[3], R. Butera[3], C. Krafft[3] and I. Mayergoyz[1] *1. ECE, University of Maryland, College Park, MD, United States; 2. Physics, University of Maryland, College Park, MD, United States; 3. LPS, College Park, MD, United States*

There has been considerable interest in the development of materials with strongly pronounced spin Hall effect (SHE) [1]. It is known that high electric fields can be achieved in high-restive material for smaller values of sample currents. These electric fields result in the enhancement of the spin-orbit coupling, which is the physical foundation of the SHE. Usually, high resistivity beta phase tungsten films are used for this purpose. Recently, we fabricated a tungsten film with a very fine (nanoscale) granular structure by using DC magnetron sputtering technique under UHV conditions. This film has a thickness of about 5 nm and a length and width of about 2.5 mm and 4 mm, respectively. The measured resistance (per unit length) of this film was about 5 times larger than the resistance of previously fabricated beta phase tungsten films of comparable dimensions. The STM image of surface morphology of this film is presented in Fig. 1. By using the STM based technique for the study of the SHE developed in previous publications [2-5], we studied the SHE caused spin-polarized electron accumulation on the surface of this film for different values of sample currents. This study was performed by reversing the polarity of tunneling voltage and observing the tunneling current asymmetry with respect to this reversal. This asymmetry can be viewed as a manifestation of the SHE [2-3]. The plot of this tunneling current asymmetry as a function of sample current is presented in Fig. 2. It is clear from this figure that the asymmetry of about 37% has been observed for the sample current of 3 mA. This is in contrast with our previous observation of the SHE caused asymmetry for beta-phase tungsten films, where practically no asymmetry was observed for this value of sample current [2-3]. This can be viewed as a clear indication that the SHE is more pronounced in the fabricated highly-resistive tungsten film in comparison with the manifestation of the SHE in previously fabricated beta-phase tungsten films.

Spin-orbit torque (SOT) allows electrical control of magnetization orientation in magnetic heterostructures[1-3]. Magnitude of SOT, having two components with different symmetries: the Slonczewski-like (SL) and

field-like (FL) torques, is characterized by spin torque efficiency parameters (ξ_{SL}, ξ_{FL})[4], where ξ_{SL} is equivalent to the effective spin Hall angle. To achieve efficient control of magnetization, material system that exhibits large ξ_{SL} is desirable. W is a promising material exhibiting large ξ_{SL}[5-7] and a recent study showed a variation of ξ_{SL} by a factor of 2-3 with W resistivity ρ_W in the range of 100-200 μΩcm[7]. Here we study the SOT of W/CoFeB/MgO heterostructures, where ρ_W is controlled over a wide range (100-630 μΩcm) and discuss the mechanism for SOT generation in the heterostructures. All stacks are deposited on Si substrates by sputtering. Figure 1(a) shows W thickness (t_W) dependence of sheet conductance (G_{Sheet}) for W(t_W)/Ru(1 nm) blanket films deposited at various Ar gas pressures. ρ_W determined from the inverse of slope increases with Ar gas pressure by a factor of 6 (Fig. 1(b)). SOT effective fields are then evaluated for microfabricated devices using an extended harmonic Hall measurement technique[8,9]. Figures 2(a) and (b), respectively, show ρ_W dependence of ξ_{SL} and ξ_{FL} in W(5 nm)/CoFeB/MgO structures, together with the reported values[5-7]. The results before and after an annealing at 300°C are shown. Our results follow the trend and show the highest ξ_{SL} that reaches unity as ρ_W increases. It is also found that $\xi_{SL(FL)}$ decreases (increases) by annealing, as previously reported[10]. Figure 2(c) shows a relation between the transverse resistivity (ρ_{xy}) and ρ_W, which represents an underlying mechanism causing SOT. A better description by a quadratic function implies a dominant contribution of intrinsic spin Hall effect and/or side-jump scattering[11-13]. This work was partly supported by ImPACT Program of CSTI, JST-OPERA, and GP-Spin of Tohoku Univ.

F13-03. Spin-orbit torque induced switching of in-plane nanomagnet arrays evaluated through differential planar Hall effect. *Y. Takahashi*[1], Y. Takeuchi[1], C. Zhang[2,1], B. Jinnai[3], S. Fukami[1,3] and H. Ohno[1,4] *1. Laboratory for Nanoelectronics and Spintronics, Research Institute of Electrical Communication, Tohoku University, Sendai, Japan; 2. Frontier Research Institute for Interdisciplinary Sciences, Tohoku University, Sendai, Japan; 3. Center for Spintronics Integrated Systems, Tohoku University, Sendai, Japan; 4. WPI Advanced Institute for Materials Research, Tohoku University, Sendai, Japan*

Spin-orbit torque (SOT) induced magnetization switching has attracted great attention as a new writing method for magnetoresistive random access memories (MRAMs) [1-3]. SOT-MRAMs with in-plane easy axis achieve sub-ns and field-free switching whose properties depend on the easy axis direction [4], and it is of high importance to systematically and statistically investigate the dependence of switching properties on the design of nanomagnet towards low-power and reliable operations. Here we develop a scheme to statistically evaluate the SOT switching properties of in-plane nanomagnets, where the planar Hall effect (PHE) is utilized to detect the magnetization direction. Using the scheme, switching properties are systematically evaluated as a function of size, aspect ratio, and easy axis direction of nanomagnets and current pulse duration. A stack, Ta/W/CoFeB/MgO/Ta, is deposited by sputtering on a Si substrate and patterned into devices with an array of elliptic CoFeB/MgO nanomagnets with various designs on top of a micrometer-scaled Ta/W Hall cross (Fig. 1). This structure allows to provide a short turn-around time, sufficient signal-to-noise ratio (S/N), and statistical information. To detect the magnetization state, transverse resistance due to PHE is measured under an application of off-axis and bidirectional in-plane fields. The field rotates the magnetization and gives rise to a differential Hall resistance ΔR whose sign depends on the original magnetization direction [5]. We confirm that this scheme works for all the studied nanomagnet designs with arbitrary easy-axis angles by choosing a proper off-axis field direction. A typical ΔR vs applied current density J is shown in Fig. 2. Clear hysteresis loop with high S/N is observed for all the designs. We systematically evaluate threshold current density for various samples using current pulses with various widths. Based on the obtained results along with macrospin and micromagnetic simulations, we discuss the favorable design to realize high-speed and low-current SOT-MRAM. A portion of this work was supported by the ImPACT Program of CSTI and JST-OPERA.

F13-04. Charge pumping induced by magnetic texture dynamics in Weyl semimetals. *Y. Araki*[1,2] and K. Nomura[1] *1. Institute for Materials Research, Tohoku University, Sendai, Japan; 2. Frontier Research Institute for Interdisciplinary Sciences, Tohoku University, Sendai, Japan*

Magnetic textures, such as domain walls, skyrmions, spin spirals, etc., may significantly alter the behavior of conduction electrons, when they come together with electron spin-momentum locking. One of the candidate materials that can host both electron spin-momentum locking and magnetic textures is a magnetic Weyl semimetal (WSM): WSMs are characterized by the conical band structure with the pair(s) of "Weyl cones" split in momentum space. Recent theoretical studies have proposed that some alloys can show the Weyl semimetallic phase due to their magnetic orders, such as the ferromagnetic order in Co-based Heusler alloys (e.g. $Co_3Sn_2S_2$) [1], and the chiral antiferromagnetic order in Mn-based materials (e.g. Mn_3Sn) [2]. There have been several theoretical works on the static properties of magnetic textures, such as the localized states and electric charge, in these materials [3]. On the other hand, the dynamical properties of magnetic textures in WSMs are much less understood, while it is important as well in reading and writing information in future spintronic devices. In this work, we focus on the adiabatic dynamics of a magnetic texture in a magnetic WSM, and show that it induces a pumped electric current that flows together with the magnetic texture [4]. Unlike the electron flow driven by the spin motive force in conventional magnetic metals [5], the pumping current here is free from backscattering and induces no Joule heating. This pumped current can be described phenomenologically in terms of a regular Hall current induced by axial electromagnetic fields, which are equivalent to the temporal and spatial variation of the magnetic texture. Taking a magnetic domain wall as a test case, we demonstrate that a moving domain wall generates a pumping current, which accounts for the localized charge at the domain wall (see Fig. 1).

F13-05. Spin–orbit torque switching of Ta/CoFeB/Ta/CoFeB/MgO composite layer. C. Siao[1], *C. Yang*[2], P. Chen[3] and C. Lai[4] *1. Material Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan; 2. Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan; 3. Material Science and Engineering, National Tsing-Hua University, Hsinchu, Taiwan; 4. National Tsing Hua University, HsinChu, Taiwan*

Spin–orbit torque switching has been proposed to be the most promising writing scheme for next-generation magnetic random access memory (MRAM). In addition to writing speed, the thermal stability of the free layer in MRAM cells is also quite critical; therefore, a composite free layer composed of CoFeB/interlayer/CoFeB has been used in the spin-transfer-torque (STT) MRAM to increase the anisotropy field H_k and thermal stability [1]. In this work, we investigate the spin-orbit torque switching in the composite free layer structure. The samples of substrate/Ta(5.0)/CoFeB(1.07)/Ta(t)/CoFeB(1.13)/MgO(2.0) (unit: nm) were deposited by sputtering and then annealed at 350 Celsius for 30 minutes. All samples revealed perpendicular anisotropy after annealing. According to the thermal stability equation $=K_{eff}V/K_BT$, we can use $Ms*H_k*t$ to estimate thermal stability; the relationship between thermal stability and Ta interlayer thickness is shown in Fig. 1. The thermal stability is improved by increasing interlayer Ta thickness, suggesting that the perpendicular anisotropy is enhanced with thicker interlayer Ta. We used the lock-in method to measure the effective field on the hall-cross devices. The measured transverse effective field is larger than the longitudinal one in all samples, consistent with other reports. The transverse effective field H_T is decreased with increasing interlayer Ta thickness, as shown in Fig. 2. The reduced effective field can be explained by the plausible cancellation of spin current generated from the bottom and interlayer Ta. In fact, we observed that the critical switching current density is significantly increased from $9.68*10^6$ A/cm^2 (the single CoFeB sample) to $2.18*10^7$ A/cm^2 (sample with 0.5 nm Ta interlayer), which can be attributed to both reduced effective field and enhanced anisotropy. To summarize, we reveal that a trade-off exists between the thermal stability and the critical switching current density for the spin-orbit torque switching in the composite free layer structure.

F13-06. Control of spin-orbit torque driven by W/Pt multilayers.
S. Karube[1,2], N. Tezuka[2], M. Kohda[1,2], S. Fujikawa[2], M. Matsuura[2], S. Sugimoto[2] and J. Nitta[1,2] *1. Center for Spintronics Research Network, Tohoku University, Sendai, Japan; 2. Department of Materials Science, Graduate School of Engineering, Tohoku University, Sendai, Japan*

Spin-orbit torque (SOT) via the spin Hall effect is a key ingredient for inducing magnetization reversal. For more efficient SOT generation, it is desired to design new materials in a controlled manner. From the view point of SOT engineering, it is expected to make new spin Hall materials (SHM) by fabricating multilayers. Here we focus on multilayers consisting of Pt and W which are conventional SHMs with different sign of spin torque efficiency (STE) each other. We prepared several multilayer films by a dc magnetron sputtering machine as following Py(18nm)/W(18nm), Py(18nm)/{W(9nm)/Pt(9nm)}$_1$, Py(18nm)/{W(4.5nm)/-Pt(4.5nm)}$_2$, Py(18nm)/{W(3nm)/Pt(3nm)}$_3$, Py(18nm)/{W(2.25nm)/Pt(2.25nm)}$_4$, and Py(18nm)/{W(1nm)/-Pt(1nm)}$_9$. The number {}$_i$ corresponds to stacking number. Spin-torque ferromagnetic resonance (ST-FMR) technique was employed for extracting STE ξ_{ST} as shown in Fig.1. Applied radio-frequent power and frequencies were 6 dBm and 10 GHz, respectively. The obtained ST-FMR data is shown in Fig.2(a). For a t_W=9 nm thick W case, the symmetric components of ST-FMR are almost same amplitudes between positive and negative field. This is a conventional behavior in the ST-FMR measurement. While in t_W=2-3 nm cases, the symmetric component has different amplitude each other between both of the fields surprisingly. Based on these results, we estimated the STE in each case as shown in Fig.2(b). We take an average between both of them for the discussion and find a drastic change of the STE at t_W=2.25 nm which is close to the spin diffusion length of W. Therefore, a control of the SOT is realized by combination between W and Pt. We discuss plausible origins for explaining this controlled SOT including the different amplitude of the SOT between positive and negative field, and also relationship of the stacking number to these results in this conference.

F13-08. Spin Relaxation at Ferromagnetic Metal/Metal Oxide Interface.
A. Asami[1] *1. Applied Physics and Physico-Informatics, Keio University, Kanagawa, Japan*

Spin-orbit torques arising from the spin-orbit coupling in solids enable current-induced magnetization switching in spintronic devices. The spin-orbit torques generally arise from spin-orbit coupling of heavy metals. However, even in a heterostructure where a metallic magnet is sandwiched by two different insulators, a nonzero spin-orbit torque is expected because of the broken inversion symmetry; an electrical insulator can be a source of the spin-orbit torques. Recently, we have demonstrated that oxygen incorporation into Pt turns the heavy metal into an electrically-insulating generator of the spin-orbit torques.[1] The experimental results show that spin-orbit torques originate from the spin-orbit coupling at the ferromagnet/Pt oxide interface. In this study, we study the spin relaxation at the ferromagnet/Pt-oxide. To investigate the spin relaxation at the interface between $Ni_{81}Fe_{19}$ and Pt oxide, we compared the magnetic damping of a $Ni_{81}Fe_{19}$/Pt-oxide bilayer with that of a $Ni_{81}Fe_{19}$/Cu/Pt-oxide trilayer, where the direct contact between the ferromagnet and Pt-oxide is absent. Figure 1 shows the current-induced ferromagnetic resonance spectra for the $Ni_{81}Fe_{19}$/Pt-oxide bilayer measured at various frequencies. From the frequency dependence of the linewidth, we determined the magnetic damping of the $Ni_{81}Fe_{19}$/Pt-oxide bilayer and $Ni_{81}Fe_{19}$/Cu/Pt-oxide trilayer. We found that the magnetic damping of the $Ni_{81}Fe_{19}$/Pt-oxide bilayer is clearly larger than that of the $Ni_{81}Fe_{19}$/Cu/Pt-oxide trilayer, which demonstrates that the $Ni_{81}Fe_{19}$/Pt-oxide interface is an efficient spin-current absorber.

Spin-based electronics, or Spintronics, requires reproducible and robust transport of spin as well as charge. Recent studies have demonstrated the presence of pure spin currents which would result in the absence of an Oersted field and lower Joule heating losses, leading to new functionalities. Recently, bilayers with $Y_3Fe_5O_{12}$ (YIG), a ferromagnetic insulator (FMI), has attracted much attention, because only spin currents are expected to transport in the YIG layer. Thus, one would anticipate the separation of spin current from charge current. Consequently, the bilayer Pt/YIG has been intensively investigated owing to the large spin-orbit coupling of Pt. However, an unconventional Hall effect was reported, indicating the importance of the interface between Pt and YIG. [1-5] The presence of the perpendicular magnetic anisotropy in Pt/YIG thin film also points out the interfacial effect. [6] Therefore, it is important to detect the difference between the bulk and bilayer thin films. To investigate the electronic structures of single crystal YIG and the bilayers, we have employed X-ray absorption spectroscopy and X-ray circular dichroism. Our experimental results combined with theoretical simulations indicate the different electronic structures of Fe in YIG single crystal and bilayer thin films and also show a coupling of the Fe magnetic moment and the induced magnetic moment.

F13-10. Vertical Spin Injection Devices for Spin-to-Charge Conversion: Scaling with Size. *C. Lin*[1], S. Manipatruni[1], T. Gosavi[1], D.E. Nikonov[1], K. Oguz[1], V. Pham[2], I. Groen[2], E. Sagasta[2], F. Casanova[2,3] and I. Young[1] *1. Components Research, Intel, Hillsboro, OR, United States; 2. CIC nanoGUNE, 20018 Donostia-San Sebastian, Spain; 3. IKER-BASQUE, Basque Foundation for Science, 48013 Bilbao, Spain*

Electrically detecting the state of a magnet is a critical function in both spintronic memory and logic. The discovery of new spin-to-charge conversion methods based on spin-orbit effects give a promising way to read out a magnetic state.[1] Here, we demonstrate conversion of a magnetic/spin state into an electric signal using spin-orbit effects in a Local Spin Injection Spin-Orbit (LSISO) device. LSISO devices allow for increased signal strength compared to non-local spin-to-charge devices[2]. Furthermore, the spin-to-charge conversion output signal is increased by reducing the width of the ferromagnet and the spin-orbit material, which is a highly favorable scaling law for miniaturization. The Pt/CoFe LSISO device is shown in Fig. 1. Pt (spin-orbit material) and CoFe (ferromagnet) are 15 nm and 20 nm thick, respectively. By applying charge current (I_C) from Lead 1 to GND, the spin-polarized current generated in CoFe is injected into Pt. Due to the spin Hall effect in Pt, a transverse charge voltage output (V_{SO}) can be measured between Lead 2 and 3. The amplitude of spin-to-charge conversion is $R_{SO}=V_{SO}/I_C$ (see inset in Fig. 1). Note that this output signal, V_{SO}, is a cascadable voltage source for the next input stage in a closed-loop spintronic logic circuit.[3] In order to understand the dimensional scaling law, we independently tune the width of CoFe (W_{CoFe}) and of Pt (W_{Pt}) in the device from 1 μm to 100 nm. The efficiency of interfacial spin injection set by the spin Hall effect, as well as the resistivity of CoFe and Pt, are fixed for all devices, so that the change of R_{SO} is directly related to the size variations. As shown in Fig. 2, we observe that R_{SO} is inversely proportional to both W_{CoFe} and W_{Pt}, which indicates the output signal is enhanced with size reduction. Besides, the contribution from the anomalous Hall effect in CoFe is negligible based on calculations[4,5]. In summary, we demonstrated a vertical spin injection device with good scalability by using spin-orbit effects for read out, which is an essential ingredient for future spin logic and memory.

Current-induced spin-orbit torques (SOTs) in magnetic/non-magnetic bilayer systems have been proposed as promising candidates for next-generation spintronic applications due to their high energy efficiency and fabrication simplicity [1, 2]. Despite the bilayer nature of the system, current-induced SOTs were often exclusively attributed to the strong spin-orbit interaction in the nonmagnetic materials or the interface. SOTs originating from the magnetic layer are usually neglected. Recent results show signatures of spin current generated near magnetic/non-magnetic interfaces in "spin-valve-like" structures [3, 4]. However, the origin of the spin current, whether interfacial or bulk, remains elusive. Here, we report direct observation of large surface-spin-orbit torques (SSOT) via the Magneto-optic Kerr effect (MOKE) in a single layer permalloy (Py) film. The extracted spin-orbit torque efficiency turns out to be 0.06±0.006, which is comparable to the reported values of platinum (Pt). [5] This result is further verified in a "Py/Copper/Pt" structure, where we observe the SSOT originating in the Py overwhelms the contribution from Pt. The SSOT does not vary significantly when the terminating layer of Py is changed to aluminum oxide, silicon oxide or copper, suggesting the SSOT may arise from the Py itself. Our

results reveal long-overlooked spin-orbit effects with transverse spin in magnetic materials. They open a new path for manipulating magnetic order via the internal spin-orbit interaction of magnetic materials. This work was funded in part by the NSF MRSEC No. 1720633.

F13-13. Spin-orbit torque induced by nonequilibrium spin density on the surface of an 3D topological insulator. *R. Chang*[1], S. Chen[2] and C. Chang[3] *1. Department of Applied Physics, National Taiwan University, Taipei, Taiwan; 2. Department of Applied Physics and Chemistry, University of Taipei, Taipei, Taiwan; 3. Department of Physics, National Taiwan University, Taipei, Taiwan*

Spin-orbit torque (SOT) has been widely studied for its potential applications in realizing the novel memory MRAM [1], in which the magnetization switching induced by SOT is of great importance [2]. In this abstract we investigate the SOT caused by the nonequilibrium spin density in the quasi-1D topological insulator (TI) bismuth selenide covered with a monodomain ferromagnetic (FM) overlayer. Spin-orbit torque can be decomposed into field-like torque and antidamping-like torque. The former can make the magnetization precess and the latter is possible to switch the magnetization direction. Having the nonequilibrium Green functions (NEGF) as our main numerical tool, we analyze the spatial distributions of SOT with contributions from the bias window (current-induced) and Fermi sea electrons. One thing needed to be stressed is that, in our NEGF calculation with low bias (1.0×10^{-3} eV) applied between two leads, we replace the traditional normal metal (NM) leads with TI leads so as to make our system a homogeneous 1D quantum wire that might be able to diminish the scattering between the sample and the leads(Fig.1). Our calculation results show that the SOT contributed from the bias window electrons is irregularly distributed in real space and two orders of magnitude smaller than that contributed from the Fermi sea electrons. So we will focus on the Fermi sea contribution in the following analysis. In the figure of spatial distributions of field-like torque and antidamping-like torque(Fig.2), we find that the field-like torque is localized around the upper and lower egdes while the antidamping-like torque is localized around the left(negative) and right(positive) edges. Therefore, the magnetizations, originally along the z-axis, are more possible to be switched on the right edge. In the future we may add impurities, gating, antiferromagnetism [3] for investigating if the spatial symmetry could be altered by these additional influences. Another prospective work is to study the spatial behaviors of SOT with the FM overlayer replaced with a multidomain one [4].

F13-14. Effect of interfacial spin-transparency and magnetic dissipation on Pt/Ferromagnet/Capping layers. *D. Lee*[1,2], H. Koo[2], B. Min[2], K. Lee[1] and O. Lee[2] *1. Korea University, Seoul, The Republic of Korea; 2. Center for Spintronics, Korea Institute of Science and Technology (KIST), Seoul, The Republic of Korea*

For highly efficient spin memory devices, a reduction of switching current is required. While a spin orbit torque driven switching current density is proportional to the spin Hall angle (θ_{SH}) and inverse to magnetic damping (α), recent researches have shown that the spin-transparency at the interface of heavy metal(HM)/ferromagnet(FM) plays an important role in determining the magnitude of spin Hall angle; e.g. θ_{SH}(Pt|Co)~0.11 vs θ_{SH}(Pt|Py)~0.05 [1,2,3]. Also most spin memory devices require tunnel barriers as readout of magnetoresistance. And the oxide of tunnel barrier influences magnetic properties. We investigate two types of spin-orbit torques, the damping-like torque and the field-like torque, and magnetic properties of Pt/Ferromagnet/Capping multilayers by using spin-torque ferromagnetic resonance technique (ST-FMR) and conventional ferromagnetic resonance technique(FMR). To identify interfacial effects of both ferromagnetic interface, Pt/FM and FM/Capping, We compared three ferromagnetic materials (Py, Co and $Co_4Fe_4B_2$) in contact to a platinum and different types of capping layers (MgO, HfO and TaN). From the thickness dependence of the damping and the spin Hall angle, we can estimate the values of damping-like torque efficiency (θ_{DL}), field-like torque efficiency (θ_{FL}), spin-transparency (T), and spin mixing conductance ($\sigma_{\uparrow\downarrow}$). Our results show that the magnitude of the spin Hall angle is determined by the interface material in contact to the Pt layer which is consistent with the spin-transparency model [1]. However we observed that the interface contributes to the field-like torque and the damping-like torque in a different way. Also we observe the enhancement of the magnetic damping by varying the capping layer. In this presentation, we will show detailed results and analysis methods from our conventional- and ST-FMR for the different ferromagnetic and capping layer. And we will discuss about Pt/FM and FM/Capping interface effects on damping and spin-orbit torque efficiency.

F14-01. Low Temperature Annealing of Superconducting Bismuth Nickel Bilayers. *M. Vaughan*[1] and G. Burnell[1] *1. Physics and Astronomy, University of Leeds, Leeds, United Kingdom*

Bismuth nickel interfaces are of interest as the mechanism for the superconductivity is yet unclear with speculation of unique states of such as p-wave or topological superconductivity [1,2]. This work shows bismuth nickel bilayers will anneal at room temperature over a period of several days, increasing the T_C of the samples until it has saturated to 3.8k (Fig.1). The annealing creates a $NiBi_3$ alloy at the interface as indicated by a XRD $NiBi_3$ peak which is an already known superconductor with a similar T_C of 4.1k. The Arrhenius plot is created by measuring the change in the onset of the meissner effect after annealing, giving an activation energy of (0.86±0.06)eV which is lower than for similar interface systems [3]. The out-of-plane and in-plane upper critical fields are close fits for the Ginzburg-Landau model of a 2D superconductor (Fig.2), but a similar linear dependence has also been seen in bulk $NiBi_3$ [4]. This aging process poses a challenge to studying distinct Bi/Ni interfaces as any slight heating will degrade the interface.

The out-of-plane (Black) and in-plane (Green) H_{C2} data fits well with for a Ginzburg-Landau model 2D superconductor. The critical field values are $H_{C2}^{\perp}$=2.244T and $H_{C2}\|$=2.70T.

F14-02. Vortex Structures and Configurations in a Superconductor / Chiral-Helimagnet Hybrid System. S. Fukui[1], *M. Kato*[1], Y. Togawa[2] and O. Sato[3] *1. Department of Mathematical Sciences, Osaka orefecture Univeristy, Sakai, Japan; 2. Department of Physics and Electronics, Osaka Prefecture University, Sakai, Japan; 3. Osaka Prefecture University College of Technology, Neyagawa, Japan*

Vortex configuration and dynamics in a superconductor are important issue for application of superconductors. From this point of view, ferromagnet / superconductor hybrid systems have been studied widely. For example, pinning of vortices by the magnetic domain structures was studied by several researchers. We proposed a new hybrid system consist of a chiral helimagnet and a superconductor. Previously, we studied vortex structures and their stability in a two-dimensional superconductor under a helical magnetic field. In such case, only normal component of the magnetic field is effective. Therefore, we only considered vortex states under a spatially oscillated field. In order to clarify how chirality of helical magnetic field affects vortex states, we must consider three-dimensional systems. So, we have solved three dimensional Ginzburg-Landau equations for a superconducting rectangular parallelepiped under a helical magnetic field, using the finite-element method. We have found that vortices tend to be perpendicular to the surface of the superconductor. Also, we have found that when two vortices appear in a region where normal component of the magnetic field is large, two vortices tilt toward the helical axis. Schematic vortex configuration is shown in Figure 1. This tilting direction depends on the chirality of helical magnetic field. Therefore, this is a unique feature of the vortex configuration under the chiral helical magnetic field. We discuss origins of this configuration by examining detailed shielding current distribution and current around vortices under the helical magnetic field.

F14-03. Non-uniform magnetisation in Nb/Ho/Nb Josephson junctions. *B. Börcsök[1] 1. Department of Material Science and Metallurgy, University of Cambridge, Cambridge, United Kingdom*

Epitaxial Nb/Ho/Nb structures are promising candidates to study long-range triplet penetration as the helimagnetic structure of Ho presents intrinsic magnetic inhomogeneity [1,2]. The strength and the magnitude of the interaction between superconducting Nb and rare earth ferromagnets are strongly influenced by interface and grain boundaries, epitaxial structures showing larger effects than polycrystalline structures [3,4]. In this work, we explore the Josephson effect in epitaxial Nb/Ho/Nb junctions and present a theoretical explanation of the experimental data. The results indicate that the non-uniform magnetisation inside the junction causes extra resonances to appear.

F14-04. Determining the "0-π" thickness in Magnetic Josephson Junction using Magnetometry. *T. Ambrose[1] 1. Northrop Grumman Corporation, Linthicum, MD, United States*

A magnetic Josephson Junction (MJJ) consists of a superconductor/ferromagnet/superconductor (S/FM/S) trilayer. In such a device, the critical current (Ic) has been shown to decay non-monotonically with the FM layer thickness (t_{FM}). Specifically Ic ~ exp ($-t_{FM}/\xi_1$)cos (t_{FM}/ξ_2) where ξ_1 and ξ_2 are related to proximity effects and magnetic interactions. For $I_c<0$, e.g. $\pi/2< t_{FM}/x_2<3\pi/2$, the equilibrium junction phase is π. For $I_c>0$ the equilibrium phase is 0. Current theories rely on the interaction of the Cooper pair with the exchange field interaction of the FM layer, while other physical quantities such as saturation magnetization (M_s) are not considered. If the exchange field interaction is important, then a relationship between the "0-π" thickness and the exchange energy must exist. Since this exchange energy is also related to the FM layer Curie temperature (T_C) where $E_{ex} \sim k_B T_C$, a plot the "0-π" transition versus T_C for a variety of FM materials is shown in Fig. 1a. This compilation has been gathered from published results over the last 25 years, and includes transition and rare earth FM metals. No apparent relationship exists between T_C and the "0-π" thickness. In contrast, by comparing M_S and the "0-π" transition, shown in Fig. 1b, we indeed see a functional $1/M_s$ dependence. Remarkably, the measured "0-π" values, taken from many different S/FM/S samples fabricated at different labs and processed using different fabrication methods, fall onto a universal curve! A simple phenomenological model to describe the dependence of the "0-π" transition on M_s will be suggested. Furthermore, the "0-π" thickness can easily be manipulated by preparing different buffer layers that effect the M_s of the FM layer. Lastly these findings may provide a critical step toward defining a thin film magnetic standard that is based upon the "0-π" thickness in a MJJ (analogous to the volt standard) where M_s is determined from t_{FM} when Ic drops to zero.

F14-05. Magnetic and superconductive proximity effects in bilayer and trilayer thin film hybrids of a topological insulator, ferromagnet and cuprate superconductor: A possible new platform for Majorana nano-electronics. *G. Koren[1] 1. Physics, Technion - Israel Institute of Technology, Haifa, Israel*

Magnetic proximity effect of a topological insulator in contact with an itinerant ferromagnet is reported in thin film bilayers of 15 nm thick $Bi_{0.5}Sb_{1.5}Te_3$ on either 15 or 40 nm thick $SrRuO_3$ on (100) $SrTiO_3$ wafers [1]. We also report on strongly suppressed superconductive proximity effect and ferromagnetism in topological insulator, ferromagnet and superconductor thin film trilayers of 20 nm Bi_2Se_3 on 10 nm $SrRuO_3$ on 30 nm of underdoped $YBa_2Cu_3O_y$ [2]. By comparing our transport and magnetoresistance results of the bilayers and trilayers to those of reference ferromagnetic films, and reference trilayer with the topological layer replaced by a highly overdoped and non-superconducting $La_{1.65}Sr_{0.35}CuO_4$ layer, we found that the surface currents of the topological layer strongly affect both proximity effects [1, 2]. While a conventional proximity effect was found in the bilayers, these surface currents strongly suppressed the superconductive proximity effect in the trilayers which led to the creation of a 2D network of 1D channels of weak-link superconductivity on the wafer. Conductance spectra of micro-bridges pattern on these trilayers reveal zero bias conductance peaks which are sensitive to magnetic field and could be attributed to Majorana zero energy bound states. Though our trilayer network of weak-link channels is disordered, it is similar in concept to that of the ordered network demonstrated in the literature by growing selectively Al on InAs [3]. Both systems could provide a platform for future Majorana electronics for quantum computing.

F14-07. Photoemission spectroscopy in 2-dimensional Topological Kondo Insulators. *E. Ramos Rodriguez[1]*, R. Franco[1], J. Silva Valencia[3] and M. Figueira[2] *1. Departamento de Física, Universidad Nacional de Colombia, Bogotá D. C., Colombia; 2. Departamento de Física, Instituto de Física Universidad Federal Fluminense, Niterói, Brazil; 3. Physics, Universidad Nacional de Colombia, Bogotá, Colombia*

We study the photoemission spectroscopy considering a version of Periodic Anderson Model (PAM) on a 2D square lattice proper to describe topological *Ce*-based compounds in two dimensions in the U→∞ limit, taking into account the effects of the short range magnetic correlations (SRMC) represented by the correlation between the localized states (J_H) that give rise to pseudo-gap for the topological Kondo insulators (TKI). We observe the $4f^1 \rightarrow 4f^0$ transition respect E_F considering electron-hole symmetry. This model is adequate to study a novel class of intermetallic 4f and 5f orbitals materials [Werner13,Coleman84,Dzero12,Steglich,Xboson]: the Kondo topological insulators in the intermediate-valence regime whose paradigmatic material is the compound SmB_6.

F15-01. Casimir Amplitudes at Topological Quantum Phase Transitions. *M.A. Continentino*[1] and M.A. Griffith[1] *1. Centro Brasileiro de Pesquisas Fisicas, Rio de Janeiro, Brazil*

Topological phase transitions represent a new class of quantum critical phenomena. They can not be described within the usual framework of the Landau theory since, in general, the different phases can not be distinguished by an order parameter, neither be related to different symmetries. In most cases however, one can identify a diverging length at these topological transitions. This allows to describe them using a scaling approach and to introduce a set of critical exponents that characterize their universality class. Here we consider some relevant models of quantum topological transitions associated with well defined critical exponents that are related by a quantum hyperscaling relation. We extend to these models a finite size scaling approach based on techniques for calculating the Casimir force in electromagnetism. This procedure allows to obtain universal Casimir amplitudes Δ_C for different classes of non-trivial topological models [1]. These amplitudes are defined by the singular part of the finite size contribution for the free energy of a slab of size L at the quantum critical point of the topological transition of the bulk system. This contribution can be written as, $\delta F_C = \Delta_C L^{-(d+z-1)}$, where d is the dimension of the system and z the dynamic critical exponent. We also discuss the possibility of discontinuous or first order topological transitions. Our results verify the validity of finite size scaling for some topological transitions. We show however that for Lifshitz transitions finite size scaling breaks down. Finally we confirm the values of the critical exponents for topological transitions obtained previously using the renormalization group and numerical methods [2].

F15-03. Ultracold dipolar fermions as an experimental platform for the reduction of topological classification. *T. Yoshida*[1], I. Danshita[2], R. Peters[1] and N. Kawakami[1] *1. Department of Physics, Kyoto University, Kyoto, Japan; 2. Yukawa Institute for Theoretical Physics, Kyoto University, Kyoto, Japan*

Recent extensive studies of correlated topological systems have elucidated that electron correlations under the topologically nontrivial structure trigger off various intriguing phenomena which cannot be observed for free-fermions[1-3]. In particular, it has been discovered that electron correlations lead to the reduction of topological classification[1]. For instance, the reduction, $Z \rightarrow Z_8$, occurs for one-dimensional topological superconductors of class BDI, indicating that the superconductors follow Z classification at a mean-field level, while they follow Z_8 classification under electron correlations. The above fact means that electron correlations can gap out all of the edge modes without symmetry breaking at edges of the one-dimensional topological superconductor with the winding number ν=8. As the results of recent extensive studies[2], the periodic table of topological insulators/superconductors has been extended to correlated systems. In spite of these extensive studies, the following crucial question remains unsolved[4]: "in which system one can observe the above phenomenon?" In the presentation, we address this challenging issue and propose a feasible testbed of the reduction for cold atoms where a distinct experimental evidence is available thanks to the high controllability of cold atoms[5]. We also give a detailed account of how to access this phenomenon in experiments.

F15-04. Interaction effects on the Kane-Mele Model in the Hofstadter regime. *A. Mishra*[1] and S. Lee[1] *1. Physics, Korea Advanced Institute of Science and Technology (KAIST), Daejeon, The Republic of Korea*

Considering interacting Kane-Mele model of honeycomb lattice in the Hofstadter regime, we realize that the orbital motion of electrons can induce versatile topological phases with spontaneously broken symmetries. In the Hofstadter regime without spin orbit coupling, the interactions lead to the breaking of translational and rotational symmetries of the system resulting in nematic and ferrielectric phases [1, 2]. Here, within the mean field framework, we extend the study and consider the onsite and nearest neighbor interactions in the Kane-Mele model and discuss possible phases in the absence and presence of magnetic field at each integer filling of electrons. 1. Interaction effect on Kane Mele model at zero magnetic field: At half filling, the interplay of intrinsic spin-orbit coupling and onsite interaction leads to the phase transition from quantum spin Hall insulator to an antiferromagnetic Mott insulator with magnetization in the xy-plane. At quarter filling, we study this interplay and show that the combined effect opens a wide region of ferromagnetic Chern insulating phase in between metal and normal insulator. We further discuss the experimental realization of these phases in series of transition metal trichalcogenides [3]. 2. We extend our study to analyze the collaborative effect of magnetic field, spin orbit coupling and interactions. Focusing on $2\pi/3$ magnetic flux per plaquette, we realize numerous interesting phases like insulator with noncoplanar magnetic ordering, ferrimagnetic Chern insulator with nematic charge order, ferrimagnetic-ferrielectric Chern insulators etc. Many of these phase transitions are also accompanied with the change in the topology of the system. Our theoretical study broadens the field of topological phases accompanied with multiferroic like properties, as a consequence of the interplay of magnetic field, spin orbit coupling and interactions [4].

F15-05. Competing Exotic Order of Dirac Fermions on the Honeycomb Lattice - A Functional Integral Approach. *E. Christou*[1], B. Uchoa[3] and F. Kruger[1,2] *1. University College London, London, United Kingdom; 2. Rutherford Appleton Laboratory, Oxford, United Kingdom; 3. University of Oklahoma, Norman, OK, United States*

We consider the extended Hubbard model on the honeycomb lattice at half filling and zero temperature. At mean-field level, sufficiently strong next-

nearest neighbour interactions can lead to the formation of a topological Mott insulator [1] or competing charge ordered states [2]. We derive the low energy theory of these broken symmetry phases and apply a functional integral approach to analyse the leading instabilities of the Dirac semimetal in the presence of collective fluctuating quantum fields. Our analytical results show that fluctuations suppress the topological states and instead favour charge ordering, in agreement with previous numerical studies [3]. Remarkably, on closer inspection we find that the critical point is not of the putative semimetal-Mott insulator variety. Due to the frustrated nature of the interactions, the charged ordered state remains metallic with an unusual directional dependence of the Fermi velocity. A Mott gap only develops at stronger coupling or in the presence of additional interactions. We conjecture that this transition is not in the Gross-Neveu universality class [4] that describes the leading instabilities for onsite and nearest neighbour interactions.

F15-06. Topological insulators of Shastry-Sutherland lattice at integer filling. *H. Yang*[1] and S. Lee[1] *1. Physics, Korea Advanced Institute of Science and Technology (KAIST), Yuseong-gu, The Republic of Korea*

We studied Shastry-Sutherland lattice at quarter filling to investigate a possible quantum spin hall insulator. The tight binding model is simplified to preserve time-reversal and inversion symmetries for simplicity but other lattice symmetries are to be lowered, particularly non-symmorphic symmetries which protect line degeneracies in Brilloune zone. A spin-orbit (SO) coupling term is introduced to open a gap, which may lead to a topological insulator. Then the Hamiltonian at time-reversal invariant momentum (TRIM) points are examined to arrange symmetries protecting the TRIM points and obtain Z2 invarinat characterizing topologically distinct insulators. The robust degeneracy at M point against lowering symmetries is argued and the existence of odd number of Dirac cones is confirmed when the Z2 invariant indicates non-trivial phases in the absence of SO coupling. Also the edge spectrum verifying topological phases is exhibited.

F15-07. Tunable hybrid state of Weyl semimetals under electromagnetic field. *Z. Alisultanov*[1,2] *1. Amirkhanov Institute of Physics, Makhachkala, Russian Federation; 2. Department of Physics, Dagestan State University, Makhachkala, Russian Federation*

Due to the unique properties, Weyl semimetals (WSMs) are promising materials for future electronics. Currently, the two types (type-I and type-II) of WSMs are discovered experimentally. The WSMs of different types has the various topological and transport properties. Besides pure type-I and type-II WSMs, there exists a novel type, dubbed “hybrid Weyl semimetal” [1], which contains the both types Weyl points. Such WSMs can be called as type-3/2 WSMs. Recent studies of transport properties of these hybrid WSMs [2, 3] show that in such materials the anomalous Hall transport is realized. In this paper we demonstrate theoretically that in WSM under crossed magnetic and electric fields a coexistence of type-I and type-II Weyl fermions (WFs) can be realized. Such phase controlled by electromagnetic field is absolutely new for physics of topological systems. It is obvious that in this regime, the new features of electron transport will appear. We showed that this effect also can be considered as mechanism of a strain induced type-II-type-I transition.

The investigation of spin-wave phenomena plays an important role in magnetism research [1]. In particular, spin waves are seen as signal carriers for future spintronic information and communication technology devices, with a high potential for further device miniaturization and reduced power consumption. Yet a successful implementation of magnonic technology requires the usage of spin waves with nanoscale wavelengths. Recently, novel spin-wave excitation mechanisms were found, which overcome the minimum excitable wavelength limit conventionally imposed by the smallest patterning size of the antenna. One of those methods utilizes the gyration of layered spin vortex cores to locally generate propagating spin waves in a controlled way [2]. Here we will show that this vortex core based excitation mechanism can be generalized to plain magnetic films, in our case a $Ni_{81}Fe_{19}$ layer of 80 nm thickness [3]. The resulting spin waves were directly imaged by means of time-resolved x-ray microscopy, where a 7.4 GHz excitation led to the emission of concentric spiraling spin waves with 140 nm wavelength. Furthermore, the emitted waves can be tuned in wavelength by the excitation frequency between 5 and 10 GHz, showing ultrashort waves of $\lambda \sim 80$ nm at 10 GHz. At such frequencies, remarkably, the spin waves observed exhibit much shorter wavelengths than those of the common Damon-Eshbach mode, showing a characteristic quasi-uniform precession amplitude over the film thickness. By means of analytic calculations we identified the emitted spin waves to belong to the first higher order mode of the Damon-Eshbach geometry, known to be antisymmetric in amplitude over the film thickness (bearing a precessional node in both dynamic components) for the ferromagnetic resonance case of infinite wavelengths. In contrast to the latter, we show that for the short wavelengths observed, multi-mode hybridisation leads to a heterosymmetric spin-wave thickness profile with a node in only one of the dynamic magnetization components. This peculiar profile coincides with a cross-sectional line of pure linear magnetic oscillation and regions with anti-Larmor precession sense.

Institute for Applied Physics, University of Muenster, Muenster, Germany; 6. LabSTICC, CNRS, Université de Bretagne Occidentale, Brest, France*

The discovery of spin orbit torque (SOT) effect has attracts a lot of attention as it allows generation and detection of pure spin current in magnetic films. In that matter, it is particularly interesting for future applications exploiting magnonic concepts which tends to use the spin degree of freedom as information vector in a form of a spin waves (magnon). It has been established [1] that magnons can be induced and detected between two Pt electrodes deposited few microns apart on top of Yttrium Iron Garnet (YIG) by spin Hall Effect. Since the magnons are generated by electron-magnon scattering at the Pt/YIG interface, this lead to a broad excitation in the magnon frequency range. Recent studies [2] proved that the magnon transport in YIG films subjected to small SOT are governed by thermal magnons (spin waves close to the thermal energy) that dominate the other modes. However the nature of the magnons excited at large SOT is still an open issue. We report a study on the non-local spin transport properties of YIG thin film excited around the damping compensation threshold. The device (Fig. 1) consist of a 18 nm YIG film with two Pt(10nm) wires separate by a 1.2 µm gap. By using YIG ultra-thin-film and injecting high current density in Pt source strip we are able to put our system strongly out of equilibrium. The main contribution of this work is an experimental evidence of a crossover from spin transport dominated by exchange magnons (thermal magnon at THz) to spin conductance dominated by magnetostatic magnons (GHz) around the damping compensation threshold $Jc = 6.10^{11}$ A/m^2 [3] an can be seen in Fig 2. This picture is supported by microfocus Brillouin Light Scattering spectroscopy. Since our system is subject to a high current density, the temperature of YIG can reach 400K during the measurement. We will show that at such high temperature, an exponential decrease of the electrical resistivity of the YIG must be taken into account and give rise to a parasitic non-magnetic offset voltage in the detector strip which is not related to magnon propagation [4].

G1-03. Propagating Spiral Spin Waves in Magnetic Nano-patches. *D. Osuna Ruiz*[1], A.P. Hibbins[1] and F.Y. Ogrin[1] *1. University of Exeter, Exeter, United Kingdom*

Spin waves in confined structures have widely been a subject of interest in the field of computing and magnetic memories. In nanostructures, spin waves can be excited in the GHz regime, but this is not always a desirable phenomenon since it could cause interferences while reading or writing stored data in simple structures such as circular disks. Therefore, understanding the sources, propagation and dispersion characteristics of spin waves becomes a fundamental topic for improving future technological applications. In a relaxed single vortex state, widely used for bit storage, spin waves with circular or spiral wave fronts can usually be excited depending on the orientation of an alternating magnetic field [1]. In our work we study differences between thin and thick circular disks. We found that, depending on thickness, propagating spiral spin waves are more efficiently excited from different regions of the disk such as the edge and core vicinity. We give a simple explanation for the origin of spiral spin waves in thick samples through Landau-Lifshitz equation of motion [2]. We also show dispersion relations of the different modes, which allows to easily identify their frequency range of work. We also study the influence of the size of the patch, showing that spin waves from the center of the thick shape also show dependence on the sample's diameter. Spiral spin waves can offer a new variety of interesting applications in contrast to circular spin waves.

G1-04. Magnon-phonon conversion in a nonuniform magnetic field and detection of the phonon spin. *S.M. Rezende*[1], J.H. da Silva Júnior[1], D. Souto Maior[1] and A. Azevedo[1] *1. Departamento de Fisica, Universidade Federal de Pernambuco, Recife, Brazil*

Owing to the magnetoelastic interaction, the magnetic excitations in magnetic materials, spin waves (magnons), can become strongly coupled to elastic waves (phonons), forming magnetoelastic waves – a hybridized magnon-phonon excitation. Several decades ago the conversion of magnons into phonons was studied in bulk samples of the low loss ferrimagnetic insulator yttrium iron garnet (YIG) with the shape of rods and disks that have internal nonuniform magnetic external fields. Here we report experiments that demonstrate the conversion of magnons generated by a microwave field into phonons in a YIG film under a non uniform magnetic field. Two types of experiments were carried out. In the first we used pulsed microwave signals to launch spin-wave packets at one end of the YIG film and use time resolved measurements to observe the delayed pulse at the other end of the film. In the second we used wavevector resolved Brillouin light scattering (BLS) to measure the field dependence of the signal generated by continuous (CW) microwave driving, at various positions of the YIG film under a nonuniform magnetic field. Comparison of the measured field dependencies of the time-delay and the wavevector with calculations, using the magnetoelastic wave dispersion, shows that the magnon-phonon conversion occurs with constant energy and varying linear momentum. While it is well established that photons in circularly polarized light carry a spin, the spin of phonons has had little attention in the literature. With the BLS experiments we show that the light scattered by the phonons generated in the magnon-phonon conversion process is circularly polarized, thus demonstrating that the phonons have spin [1].

G2-01. Nonreciprocal propagation of microwaves, magnons, and acoustic waves in noncentrosymmetric magnets. *Y. Onose[1] 1. Institute for Material Research, Tohoku University, Sendai, Japan*

Simultaneous breaking of spatial inversion and time-reversal symmetries completely lifts the degeneracy between $+k$ and $-k$ states of elementary excitations in solids. In this case, the decay rate and phase velocity depends on the sign of k, and, hence, the propagation of the elementary excitation becomes nonreciprocal. The photonic nonreciprocity, which is denoted as magnetochiral or optical magentoelectric effect, has been investigated extensively in the last two decades. Here, we experimentally study the nonreciprocal propagation of magnons and acoustic waves as well as microwaves in noncentrosymmetric magnets.

G2-02. Gigantic nonreciprocity of luminescence in multiferroic CuB_2O_4. *S. Toyoda[1,2]*, N. Abe[1] and T. Arima[1,2] *1. Advanced Materials Science, The University of Tokyo, Kashiwa, Japan; 2. RIKEN CEMS, Wako, Japan*

In materials where both space-inversion and time-reversal symmetries are simultaneously broken, luminescence intensities can be different between the opposite emission directions, as depicted in Figure 1. However, only small directional asymmetry has been reported so far [1,2]. A possible reason is that the effect has been investigated only in paramagnetic materials where time-reversal symmetry is violated by an external magnetic field. In this presentation, we will report that the effect is robust in CuB_2O_4 crystal with spontaneous breaking of space-inversion and time-reversal symmetries. The material crystalizes in a noncentrosymmetric I-42d, and shows canted antiferromagnetic order below Néel temperature $T_N = 21$ K. The magnetic and optical properties originate from Cu^{2+} ions which have one hole ($S = 1/2$). It has been reported that the optical absorption drastically changes by the reversal of the propagation direction of light at 1.40 eV which corresponds to the intratomic d-d transition of Cu^{2+} holes [3,4]. Since the emission of light is an inverse process of the optical absorption, the luminescence intensity may also show gigantic nonreciprocity. The sample was excited the by a He-Ne laser of wavelength 633 nm, and the photoluminescence spectra were measured by using a grating-type optical spectrometer. We have found that the luminescence intensity at 1.3988 eV changes by 70 % between the opposite directions of the emission, which is about 100 times stronger than the previously reported values. We also demonstrate that such a gigantic nonreciprocal emission of light can be applied to the imaging technique of magnetic domain structures. Figure 2 illustrates the magnetic domain image of Ni-doped CuB_2O_4 obtained by the luminescence. The magnetic domain structure is resolved as the contrast of the luminescence intensity. The observation of the effect and its application to the magnetic domain imaging are important from the viewpoint of technological applications such as optical reading technique for magnetic memory devices as well as fundamental physics.

G2-03. Femtosecond activation of magnetoelectricity. *D. Bossini*[1,2], K. Konishi[2], S. Toyoda[2,3], T. Arima[4], J. Yumoto[2] and M. Kuwata-Gonokami[2] *1. TU Dortmund, Dortmund, Germany; 2. The University of Tokyo, Tokyo, Japan; 3. RIKEN, Tokyo, Japan; 4. The University of Tokyo, Tokyo, Japan*

In magnetoelectric and multiferroic materials, the magnetic(electric) degree of freedom can be controlled by means of an electric(magnetic) field. A significant amount of research has been devoted to exploiting this effect for magnetoelectric data storage and manipulation devices driven by d.c. electric fields[1,2]. Aiming at ever-faster schemes of magnetoelectric manipulation, a promising alternative approach has the potential to offer a similar control on the femtosecond timescale, relying on laser pulses[3] to control both the charge[4] and the magnetic order of solids[5]. In this perspective, the possibility to photo-induce and arbitrarily manipulate (i.e. activate, enhance and suppress at will) the magnetoelectricity in solids on the femtosecond timescale would open up novel horizons for concepts of magnetoelectric devices. Moreover, deep fundamental questions regarding the microscopic mechanisms allowing such phenomena would be triggered. In this talk I will present our demonstration of the femtosecond activation of magnetoelectricity and multiferroicity in the dielectric antiferromagnet CuB_2O_4[6]. This process is triggered by the resonant optical generation of the highest-energy magnetic excitations - magnons with wavevectors near the edges of the Brillouin zone. These collective spin quasiparticles have been recently induced and coherently manipulated in other antiferromagnets on the femtosecond time-scale[7,8]. The most striking consequence of the photo-excitation in CuB_2O_4 is that the absorption of light becomes non-reciprocal, which means that the material exhibits a different transparency for two opposite directions of propagation of light. The photo-induced magnetoelectricity does not show any decay on the picosecond timescale. Our findings uncover a path for ultrafast manipulations of the intrinsic coupling between charges and spins in multiferroics, which may reveal unexplored magnetic configurations and unravel new functionalities in terms of femtosecond optical control of magnetism.

G2-04. Nonreciprocal DC Magnetoelectric Response in $CaBaM_4O_7$ (M=Co, Fe) Single Crystals. *H. Kuwahara*[1], M. Noda[1], Y. Ebukuro[1], M. Akaki[2] and H. Kuroe[1] *1. Physics Division, Sophia University, Tokyo, Japan; 2. Center for Advanced High Magnetic Field Science, Graduate School of Science, Osaka University, Toyonaka, Japan*

The present compounds, $CaBaM_4O_7$ (M=Co, Fe), have been attracting attention for their nontrivial magnetism because of the geometrically frustrated crystal structure consisting of triangular and Kagome layers. From the viewpoints of the studies of multiferroics, we have expected that the magnetic ordering would couple with the spontaneous electric polarization (P) due to the crystal structure with a polar point-group of $mm2$. Indeed, we have observed the change of P_c induced by the weak ferromagnetic ordering in $CaBaCo_4O_7$ [1]. Then the magnetic-field (H_b)-induced giant variation in P_c was reported and the magnetostriction mechanism was proposed [2]. Also in the case of $CaBaFe_4O_7$, the magnetoelectric coefficient ${}^{H}\alpha_{cc}$ with a maximum value of 39 ps/m defined as $\Delta P_c = {}^{H}\alpha_{cc} H_c$ was reported for the measurements of H_c-induced change of P_c at 80 K below the ferrimagnetic transition temperature of 275 K [3]. In this work, we have systematically investigated nonreciprocal DC magnetoelectric response, i.e., crystalline (polar) direction dependence of magnetoelecric coefficients for $CaBaM_4O_7$ (M=Co, Fe) single crystals. Especially, we focused on the electric-field (E_c)-induced magnetization (M_b or M_c) in $CaBaM_4O_7$ (M=Co, Fe), which had almost not yet been performed. Figure shows the crystalline (polar) direction dependence of the electric-field (E_c)-induced magnetization (M_b) in $CaBaCo_4O_7$. The obtained magnetoelecric coefficient ${}^{E}\alpha_{32}$ defined as $\Delta M_b = {}^{E}\alpha_{32} E_c$ has a different sign depending on the polar direction as clearly evidenced in the right panel in Figure. We will present a comparative study of such nonreciprocal DC magnetoelecric response of $CaBaCo_4O_7$ and $CaBaFe_4O_7$ single crystals in E and/or H. This work was partly supported by JSPS KAKENHI Grant Number JP15K05184.

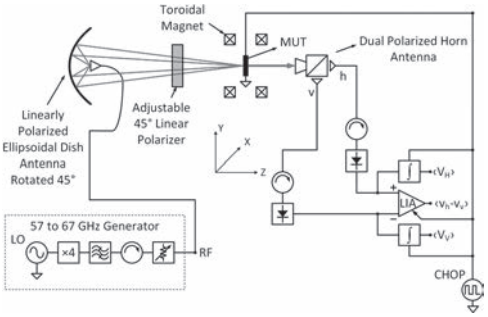
G2-05. Millimeter-wave Faraday Rotation from Magnetoelastic Multiferroic Materials. *N. Parsa*[1], R.C. Toonen[1], F. Peng[2] and M. Cakmak[3] *1. Electrical and Computer Engineering, The University of Akron, Akron, OH, United States; 2. Polymer Engineering, The University of Akron, Akron, OH, United States; 3. Materials and Mechanical Engineering, Purdue University, West Lafayette, IN, United States*



Non-reciprocal components, such as isolators and circulators, which manipulate the propagation direction of electromagnetic waves, are typically narrow in bandwidth and there is currently a critical need for innovating such components with frequency agility. Magnetoelastic multiferroic materials due to their promise of voltage-controlled magnetism can be a potential solution for designing such frequency agile components [1]. However before one can explore the frequency agility from these materials there is a need to characterize the material properties. One such property is Faraday rotation caused due to magnetically-broken time-reversal symmetry [2]. In this work we have explored the rotation of the linear polarization angle of millimeter-wave Gaussian beams (with frequencies centered around 61.25 GHz), from 30 micrometer thick membranes of silicone rubber infused with micrometer-scale ferromagnetic (nickel) particles. These composite materials were fabricated using electromagnetic processing in conjunction with roll-to-roll (R2R) manufacturing [3]. Fig. 1 shows the SEM image of silicone rubber with nickel microparticles. A customized system with quasi-optical and waveguide based components was built to measure Faraday rotation angle in these membranes, as shown in Fig.2. The membranes were stretched across and fixed to piezoelectric ceramic annuli with a silicone-based adhesive (MUT). A low-frequency AC signal applied across the thickness of an annulus resulted in the excitation of a radial resonance, which in-turn caused the magnetoelastic membrane to expand and contract in the radial direction. We isolated the influence of nickel particle density modulation on rotation of linear polarization using a lock-in detection technique. The amount of rotation scaled linearly with the amplitude of the low-frequency AC voltage signal.

G3-01. Monolayer WSe_2 spin and valley Hall effect transistors controlled via electric field for spintronic applications. *J.C. Incorvia*[1], E. Barré[2], S. Kim[3], C. McClellan[2], E. Pop[2], H. Wong[2] and T. Heinz[3] *1. Electrical and Computer Engineering, University of Texas at Austin, Austin, TX, United States; 2. Electrical Engineering, Stanford University, Stanford, CA, United States; 3. Applied Physics, Stanford University, Stanford, CA, United States*

Monolayer transition metal dichalcogenide (TMD) materials have exciting potential for applications in spintronics. Due to the monolayer geometry and strong spin-orbit coupling, they are predicted to have a coupled spin and valley Hall effect (SVHE), where valley-polarized conduction carriers have opposite spin [1, 2, 3]. This could provide a valley-preserved spin Hall effect for switching future magnetic memories. WSe_2 is an attractive 2D material in this context because of its large valence band spin splitting. Lifetimes of spin and valley polarized carriers in monolayer WSe_2 have been measured from 0.7 ns to 1 μs at 10 K [4, 5, 6]. Such long lifetimes combined with reasonable mobilities lead to spin-valley accumulation that can be imaged via the magneto-optical Kerr effect (MOKE). For use in applications, it is necessary to electrically control the SVHE and push it towards room temperature. We will present results on fabricating monolayer WSe_2 p-type transistors and spatially mapping out the SVHE using MOKE. Figure 1 shows a microscope image of one transistor studied, with Pd source/drain contacts and a Si/SiO_2 (285 nm) back-gate. The transistor is turned on using DC back-gate voltage V_G = -90 V and AC source-drain voltage V_D = 10 V (peak) at 2.5 kHz. We raster the sample underneath a 672 nm laser, with scan area shown by the dotted box. Figure 2 shows a resulting MOKE map taken at 240 K and 2.25×10^{-6} Torr. We see two distinct bands of positive (red) and negative (blue) Kerr rotation, across the flake, corresponding with accumulation of opposite spins and valleys on either side of the sample close to room temperature. The measurements show a maximum population difference between opposite spin carriers of ~ 6×10^{10} cm^{-2}, or 2% polarization. We will show that the magnitude and shape of the Kerr signal is in agreement with a drift diffusion model. We will present our results on controlling the SVHE by controlling the electric field in the transistor and show in samples cooled to 20 K that the spin accumulation is confined to the sample edges. These results demonstrate the robustness of the SVHE and its potential for spintronic device applications.

G3-02. Grain size dependence of magnetic domain wall motion in soft-magnetic materials. *H. Tsukahara*[1], K. Iwano[1], C. Mitsumata[2], T. Ishikawa[1] and K. Ono[1] *1. KEK, Tsukuba, Japan; 2. NIMS, Tsukuba, Japan*

High-performance motors with small energy loss are strongly demanded owing to the global shift toward electric vehicles. One of the energy losses is a hysteresis loss which is caused by a delay of magnetization in soft-magnetic materials. Magnetic nucleation core formation and magnetic domain wall motion play an essential role in the magnetization process and are important in understanding the energy loss in the electric motor. We performed micromagnetics simulation using quasi-two-dimensional isotropic iron sheet whose size is 5120 × 2560 nm^2 with 5 nm mesh. The simulation systems for the iron sheet contain flat grains with an averaged diameter of 100 nm and 600 nm because, according to G. Herzer, a coercivity of the soft-magnetic materials has the maximum value when the grain diameter is around 100 nm [1]. Magnetization dynamics are calculated by solving Landau-Lifshitz-Gilbert equation under periodic boundary condition in x and y-direction. The simulations were performed on Hitachi SR 16000 super-computing system using our simulator [2]. The external magnetic field of 200 Oe is applied to the positive x-direction. Figure 1 shows snapshots of magnetization dynamics during magnetization reversal process. Magnetic bubble domain structures appear in Fig. 1 (a), and the structures remain even after 1.0 ns. Figure 2 shows averaged magnetization along x-direction as a function of time. The higher response to an applied magnetic field is

observed with the averaged grain diameter of 600 nm compared to that of 100nm. However, the magnetization at 1.0 ns is lower than the saturation magnetization due to the magnetic bubble domain structure. This suggests the better high-frequency performance in larger grain size.

G3-03. Measurement Study of Magnetic Properties of Different Electrical Sheet Steel under Different Temperature, and DC Bias.
D. Chen[1], Z. Feng[1] and B. Bai[1] *1. School of Electrical Engineering, Shenyang University of Technology, Shenyang, China*

Abstract: Large power transformer iron core is mainly composed of electrical sheet steel, which is easily affected by temperature, and DC bias. So it is necessary to measure the magnetic properties of different electrical sheet steel under different temperature, and DC Bias. This paper presents the experiment measurement system for the different electrical steel sheet. And the B-H magnetization curve, permeability, and loss curve under different temperature, and different DC bias are given respectively. It provides a reference for optimizing the design of power transformer. I. Introduction The phenomena such as the DC power grid, geomagnetic storms change, DC voltage of converter transformer may result in DC bias. Then the DC bias leads to the magnetic leakage flux increase in cores, metal structure losses, temperature rise, local overheating, dielectric breakdown, noise vibration, even the permanent damage to transformer [1]. Meanwhile, the rise of temperature will also affect the magnetic properties of electrical sheet steel. Manufacturers of electrical sheet steel can provide magnetic parameters, such as loss of iron core, that usually are measured at room environment temperature. The measured electromagnetic performance of transformer has a certain error compared with the actual operation temperature [2]. When temperature, and DC bias change at the same time, the transformer operation condition will be more complicated. II. Principles, results and discussions The whole test instrument system is shown in the Fig.1. Fig.2 to Fig.5 shows the B-H curve, relative permeability and loss under different electrical sheet steel when DC bias is 0A, 2A and different temperature. Fig.6 and Fig.7 shows the magnetic flux density curve of power transformer application of measurement results of electrical steel sheet at different temperatures. III. Conclusion This paper is the first time to do the measurement study of the different oriented electrical sheet steel magnetic properties considering both different temperature and DC bias, and shows the curve of magnetic properties under different temperatures, and DC bias. It can provide guidance for the design and optimization of transformer.

G3-04. Evaluating the Suitability of Partial Recrystallisation as a Strengthening Method for High Strength-Thin Gauge Non-Orientated Electrical Steel.
M. O'Reilly[1], C. Pleydell-Pearce[1], E. Sackett[1] and F. Robinson[2] *1. Engineering, Swansea University, Bristol, United Kingdom; 2. Cogent Power, Newport, United Kingdom*

One way to improve electric motor efficiency is to increase the rotational speed of the motor to between 10,000rpm and 30,000rpm. This subsequently requires the rotor section of the motor to have high yield strength together with excellent fatigue properties. Historically, NGO electrical steels have been developed with only magnetic properties in mind. As a result, there is a need to investigate opportunities to increase NGO yield strength via current processing methods that would not require significant (and potentially excessive capital expenditure) changes to the manufacturing methods but produce competitively strengthened and priced products. This paper looks at the effect of different soak temperatures during the final anneal to determine if the well-known process of recovery, recrystallisation and grain growth can be manipulated to optimize magnetic and mechanical properties of NGO electrical steel to suit future rotor specifications. In addition to mechanical and magnetic assessment, detailed material characterization was employed to determine this tripartite structure-property interdependence. It was found that it is possible to manipulate the microstructure using this process to increase yield strength of NGO electrical steel whilst keeping acceptable magnetic properties that persists during operational conditions.

When compared against current commercially available high strength NGO grades the properties produced were found to be globally competitive.

G3-05. Exploration of the 3D Printing of Transformer Structures with Embedded Ferrite Cores. *D. Bowen*[2] and D. Basu[1] *1. University of Maryland, College Park, MD, United States; 2. Laboratory for Physical Sciences, College Park, MD, United States*

As broadband signal transformers are being used at higher frequencies, parasitic winding capacitances are known to have a significant effect on device performance [1]. To increase manufacturing control of winding capacitance, it is desirable to fabricate the windings using lithography or computer numerical control [1]. To fabricate in these ways, the device must be planar, and is limited to fewer turns than wire-wound devices. To maximize the turn number, 3D printing is being considered to create high-aspect ratio and high-density vias around the core. It is the subject of this study to explore the process of fabricating a planar transformer winding around a ferrite core using 3D printing. In this study, two core geometries were used ($\mu_r \approx 10k$) : *small racetrack* and *large toroid*. The small racetrack transformer had five turns / winding, OD = 10mm, ID = 5.76mm, l= 4mm, and h = 1.3mm. The large toroid (Fig. 1) had OD = 36mm, ID = 23mm, h = 10mm, and was fabricated in two configurations: eight interleaved turns / winding, and eleven nested turns / winding. The insulating structure was printed using fused deposition modeling (FDM) printing of poly lactic acid (PLA) plastic on a Voxel8 3D printer. The embedding of the ferrite core was accomplished by printing a core pocket, pausing the print to insert the ferrite, and then resuming the print. The windings were fabricated in two ways: silver paste was printed by syringe with the PLA plastic on the dual head Voxel8, or a low viscosity silver ink was manually injected into a liquid-tight winding tunnel after the device was finished printing [2]. It was found that the printed windings with low-solvent silver paste had a much lower resistance than the injected silver ink windings. The inductance of most devices was found to be near what was predicted from inductor theory; it is believed some turns of the 11-turn nested devices were shorted (Fig. 2a). The high resistance injected-winding transformers were found to have poorer broadband coupling to modest 100Ω loads, typical of network isolation (Fig. 2b).

There is a widespread interest in using ensembles of nanoparticles for applications that utilize their collective behavior in functional devices. Ensembles of nanoparticles can have properties that differ from those of individual particles as well as from those of the bulk. The key to well-ordered nanoparticles ensembles is self-assembly. Self-assembly is a low-cost method that provides controllable, simple mechanisms for the arrangement of the nanoparticles into ordered structures, which can be achieved either through the direct interaction of the building blocks or by using a template or external field. This work describes the three-dimensional self-assembly of colloidal magnetite nanoparticles from a very dilute water-based ferrofluid (concentration far below 1 vol %) onto a silicon surface and the dependence of its magnetic structure on the applied field. The nanoparticles used are highly spherical, have a core diameter of 25 nm and a small size distribution of only 6% in diameter. They were assembled onto a silicon wafer that was coated with an APTES layer after a piranha-etch. An APTES layer helps the particles to wet the silicon surface providing a strong amine bond between its silane groups and the carboxylic acid in the nanoparticle shell. The mechanism for and stability of protein adsorption by a silane layer on silicon surfaces is described in [1]. The detailed characterization of the layering and the magnetization behavior in the layers was achieved using polarized neutron reflectometry together with model calculations of the arrangement of the nanoparticles within the layers [2]. With additional input from small-angle neutron scattering measurements, a full characterization of the core/ shell nanoparticle dimensions, degree of chaining, arrangement of the nanoparticles within the different layers, and the magnetization depth profile was provided. The nanoparticles not only wet the silicon surface but also self-assemble into several layers on the functionalized silicon substrate as can be seen in Figure 1. The layers which build up close to the silicon are close-packed layers with concentrations up to 200 times higher than that in the dilute ferrofluid. These layers are followed by more loosely packed ones. The layering behavior is field dependent. For both different field cases used (low and high magnetic field), a very dilute loose particle layer, which has a low volume concentration that nearly matches that of the free ferrofluid, forms between the free ferrofluid and the 3D self-assembled particle structure. This layer plays a key role as the magnetization orientation of the entire stack is triggered by this loose particle layer. The reason for this behavior is the different remagnetization mechanism of free and bound monodomain nanoparticles. In bound particles the magnetization might flip via a process known as Neél relaxation [3] whereas in a liquid suspension, each nanoparticle is able to physically rotate by Brownian motion, which occurs on a much faster timescale and costs less energy [4]. As the particles in the loose layer do not strongly interact with the substrate or other particles, they are free to rotate into the field direction and thus have the highest net magnetization in the stack. In the other layers, the particles are bound more tightly because of different packing configurations and/or interstitial material composition. Therefore, the particles in these bound layers are less mobile and their magnetization cannot be changed as readily by rotation of the particles. The competing energetics of the free and bound layers leads to the partial formation of quasi-domain structures in the latter with a lower net magnetization triggered by dipolar coupling.

G4-02. Effects of Shape and Spatial Arrangement of Nanoparticle Assemblies on their Hyperthermia Performance. *O. Iglesias*[1,2] and X. Rey-Martín[1,2] *1. Dpt. Condensed Matter Physics, University of Barcelona, Barcelona, Spain; 2. Institut de Nanociència i Nanotecnologia UB, Barcelona, Spain*

Magnetic hyperthermia is one of the most promising biomedical applications of magnetic nanoparticles (NP) and is intended to be alternative to cancer therapies based on drug delivery and radiotherapy. It is based on the fact that magnetic NP dissipate heat when an oscillating magnetic field is applied to them in a quantity (specific absorption rate, SAR) that is closely related to the area of the hysteresis loop. The main problem in the field has become to find the suitable range of parameters that maximize SAR for a given material [1], SAR depends of course on the amplitude of the applied magnetic field and its frequency, but also on intrinsic parameters of the NP such as saturation magnetization, anisotropy, shape and size [2]. Although the role of external parameters is somehow well contrasted, there is still ongoing controversy on the role that particle interactions play on SAR because both enhancement and suppression when increasing the NP concentration have been reported. Analysis of the response of NP assemblies to an ac field is usually based on what is called linear response theory [3]. However, such an approach is limited to low applied fields and NP interactions cannot be

incorporated easily. Here, we will present the results of theoretical modelling and Monte Carlo simulations of assemblies of NP interacting through dipolar interactions (DI) in the macrospin approximation [4], studying the effects that interparticle separation, particle size and spatial arrangement of the NP have on SAR. In particular, we will show results for spin chains, randomly placed NP with varying concentrations, and assemblies in SC lattices with different shape. It is found that formation of chain-like arrangements or in assemblies with prolate, lead to considerable increases in SAR due to DI. Metal-organic interactions are weaker than the covalent ones, allowing the bond formation and breaking necessary to self-assemble, but are stronger than the purely intermolecular interactions. This is why metalorganic networks own so interesting properties. In this work, we grow and characterize Fe upon a selected molecular network under ultra-high vacuum conditions. The resulting self-assembled structures are characterized by means of Scanning Tunnelling Microscopy and Low Energy Electron Diffraction. We use a Cu(111) monocrystal as substrate and generate a self-assembled, extended metalorganic network which is stable at room temperature [1,2]. It will be shown that depending on the molecular coverage the porous network evolves into a compact structure detectable by LEED. Once the porous network is formed, Fe atoms are evaporated on the surface. Instead of the usual bi-layer islands [3], the Fe forms single atomic height nanoclusters. We have performed a STM study of the Fe nanostructures as a function of coverage and deposition temperature. In addition, X-ray Magnetic Circular Dichroism experiments at the European Synchrotron Radiation Facility show that the Fe nanostructures (stable also at room temperature) significantly change their magnetic anisotropy compared to the case when the molecular layer is missing [4].

G4-04. Strongly Exchange Coupled Core|Shell Nanoparticles with High Magnetic Anisotropy: A Strategy Toward Rare-Earth-Free Permanent Magnets. *A. López-Ortega*[1], C. de Julián Fernández[2] and C. Sangregorio[3] *1. nanomagnetism, CIC nanoGUNE, Donostia – San Sebastian, Spain; 2. CNR-IMEM, Parma, Italy; 3. CNR-ICCOM, Firenze, Italy*

Magnetic nanoparticles (NPs) have attracted a great interest in the last decades thanks to their novel fundamental properties emerging from their extremely reduced size. Special attention has been devoted to Co-ferrite ($Co_xFe_{3-x}O_4$) NPs due to their cheap manufacturing and high magnetic anisotropy.[1] In particular, the application of Co-ferrite in the realization of permanent magnet has attracted a renewed interest as an alternative to rare-earth base materials in low energy applications. Therefore, a deeper understanding of the structural, size-dependent and morphological effects on final magnetic properties appears necessary. We present the chemical synthesis of a series of Co-ferrite NPs with a broad range of particle sizes (from 4 to 60 nm). We evaluated the $(BH)_{max}$ product, the figure of merit of permanent magnets, obtaining the maximum values ever reported in the literature for Co-ferrite NPs (2.1 MGOe).[2] In a second step, we have used the Co-ferrite NPs for building blocks of more complex heterostructures based on antiferromagnetic(AFM)|ferrimagnetic(FiM) core|shell (CS) particles.[3] The CS structure has been generated by topotaxial oxidation of the core region.[4] The sharp interface, the high structural matching between both phases and the good crystallinity of the AFM material have been structurally demonstrated and are corroborated by the robust exchange-coupling between AFM and FiM phases.[3] These properties induce a huge improvement of the capability of storing the energy of the material, a result which suggests that the combination of highly anisotropic AFM|FiM materials can be an effective strategy towards the realization of novel rare-earth-free permanent magnets.

Magnetic nanoparticles are essential for a variety of applications, but it is difficult to determine and control the governing *intra*- and *inter*-particle magnetic interactions. In past work, we have used polarization analyzed small-angle neutron scattering (PASANS) methods to determine spin structures in chemically homogeneous Fe_3O_4 and $CoFe_2O_4$ nanoparticles [1-2]. While the experiments showed interesting single particle magnetic structures, such as an entirely magnetic core-shell morphology for Fe_3O_4, it was more challenging to extract the nature of any longer range correlations. Here, we report the results of PASANS experiments that explicitly probe such correlations in close-packed polycrystals of core-shell nanoparticles with a chemically distinct core and shell [3]. From other structural measurements, the particles have an average Fe_3O_4 core diameter of 6.4 nm with a 0.5 nm thick $Mn_xFe_{3-x}O_4$ shell, with x ~ 1.0, as depicted in Fig. 1(a). The PASANS data reveal that a significant portion of the nanoparticle magnetic moments are not aligned in a large applied magnetic field, as schematically shown in Fig. 1(b). More strikingly, this system also displays a prominent inter-particle magnetic Bragg peak with components parallel and perpendicular to the field. The nature of the magnetic scattering component perpendicular to the field varies substantially with temperature and field as shown in Fig. 2. The angular dependencies of the PASANS data show further anomalies, indicating as well the changing extents of correlation from nanoparticle to nanoparticle. These data have been fit against a model of close-packed, stacked layers where the layer size and thickness can be adjusted to reflect the competition between dipolar and Zeeman energies. This work was supported in part by NSF grants DMR-1606887 and DOE grant DEFG0208ER4648.

G5-01. Computational Search for Giant Magnetocaloric Materials: Application to MnAs. *J.S. Amaral*[1], N.M. Fortunato[2] and J. Gonçalves[3]
1. CICECO & Physics dept., Universidade de Aveiro, Aveiro, Portugal; 2. Physics, University of Aveiro, Aveiro, Portugal; 3. Departamento de Física, Aveiro, Portugal

Current high performance magnetic refrigerants are the result of years of extensive experimental work, after thousands of samples were prepared and characterized in laboratories around the world. Computational tools to assist the search for new and optimized magnetocaloric materials would be welcome, but the challenges for their development are considerable. The approach must be predictive and not merely descriptive, without the use of experimental data as simulation inputs. While Density Functional Theory (DFT) allows the ab-initio determination of microscopic parameters, these need to be fed to a thermodynamic model to make predictions of performance parameters such as Tc and entropy change. This model must be able to describe first-order phase transitions to allow the search for giant magnetocaloric materials. We report on the combined use of DFT and Monte Carlo simulations of a compressible Heisenberg-like model [1], applied to describe the giant magnetocaloric effect of MnAs. Our DFT calculations follow previous reports [2], estimating the magnetic exchange parameters as a function of structural distortion between the ferromagnetic ordered phase, where the total magnetic and structural energy is minimized, and the paramagnetic disordered phase, where only the structural energy E_0 is minimized. Our estimates of structural/magnetic phase transition temperatures and magnetocaloric effect show good agreement with experiment [3, 4], highlighting the entropy change contribution of the structural phase transition. The generalization of this approach to other magnetic systems is discussed.

G5-02. Ultra-low Hysteresis in Giant Magnetocaloric $Mn_{1-x}V_xFe(P,Si,B)$ Compounds. *J. Lai*[1,2], B. Huang[1,2], N. van Djik[3], E. Brück[3] and D. Zeng[2]
1. Applied Science, Delft University of Technology, Delft, Netherlands; 2. School of Materials Science & Engineering, South China University of Technology, Guangzhou, China; 3. TU Delft, Delft, Netherlands

Magnetic refrigeration technology has widely attracted attention due to its high efficiency, environment-friendly nature, low noise, and long service life. The giant magnetocaloric effect (GMCE) is the key factor to determine its working capability. The GMCE originates from the first-order magnetic transition (FOMT), which has been discovered in the Gd5Ge2Si2, LaFe13-xSix, MnFeP1-x-ySixBy [1], MnCoGeBx and Heusler compounds. However, the thermal hysteresis (ΔThys) is still an important issue that limits the working efficiency. The discontinuous nature of the entropy in the FOMT results in the GMCE. Therefore, in the premise of keeping a sufficiently large GMCE, the thermal hysteresis should be made as narrow as possible. Through B substitution in the MnFeP1-x-ySixBy compounds, the optimized ΔThys can be reduced to 2.0 K in DSC measurements in a field of 1 T. [1] This material has been cycled for 10 thousand times and the sample geometry was found to remain intact. Adding more B can further decrease ΔThys, but also reduces the GMCE. [2] It is essential to find a new approach to further decrease the ΔThys and simultaneously provide a sufficiently large GMCE. One of the criteria to evaluate the strength of the GMCE is the adiabatic temperature change (ΔTad). ΔTad should be larger than 2 K, since cooling may be ineffective for smaller values. [3] In this work, through V substitution, an ultra-low ΔThys (0.7 K) and a giant ΔTad (2.3 K) can be achieved in a field of 1 T. Thus, the current Mn1 xVxFe(P,Si,B) compounds can provide a fairly feasible alternative for high-frequency near room temperature magnetic cooling applications.

G5-03. Magnetic and Magnetocaloric Effect Studies on MnSb and $MnSbR_{0.05}$ (R: Gd, Tb, Dy, Ho and Er). R. P[1] and *G. Markandeyulu*[1]
1. Physics, Indian Institute of Technology, Chennai, India

The search for materials exhibiting second order magnetic transition (SOMT) accompanied by large change in magnetic entropy (ΔS_M) close to transition temperature and at low applied fields has been important in magnetic refrigeration technology. Magnetocaloric effect studies (MCE) in SOMT materials are helpful to identify materials with high the efficiency of magnetic refrigeration, as they are free from thermal hysteresis. The study of changes in magnetic entropies (ΔS_M) close to the Curie temperatures (T_C) at low applied fields (≤ 1.5 kOe) in MnSb, $MnSbR_{0.05}$ (R: Gd, Tb, Dy, Ho and Er), materials exhibiting SOMP, are presented in this paper. Polycrystalline samples of MnSb, $MnSbR_{0.05}$ (R: Gd, Tb, Dy, Ho and Er) were prepared by solid state reaction. XRD patterns revealed that all the samples crystallized in the hexagonal NiAs type of structure (space group – $P6_3/mmc$). With the inclusion of '*R*', lattice parameter *a* increased and *c* decreased and therefore, c/a decreased while the volume of the unit cell increased, demonstrating anisotropic expansion of the unit cell. The '*R'* atoms preferentially occupy the vacant trigonal bipyramidal sites and the anisotropic expansion of $MnSbDy_{0.05}$ is seen to be the largest, probably due to the large anisotropy of the 4f charge cloud of Dy. In all the compounds, magnetic transitions were observed from the temperature variations magnetizations, at 500 Oe. Positive slopes of Arrott plots (M^2 vs. H/M) near the respective Curie temperatures confirmed SOMT in all compounds investigated. Changes in magnetic entropy (ΔS_M) were investigated at temperatures close to T_C, for change of magnetic field (ΔH) from zero to 15 kOe. The largest value of ΔS_M of 0.99 $J(kgK)^{-1}$ was observed in $MnSbEr_{0.05}$, among all the compounds investigated. The relatively large ΔS_M at low applied fields (15 kOe) in $MnSbEr_{0.05}$ close to its T_C can be useful for applications in high temperature magnetic refrigeration.

G5-04. Element-specific view on $La(FeSi)_{13}$. *K.J. Ollefs*[5], A. Terwey[5], K.P. Skokov[1], M. Krautz[2], F. Wilhelm[3], A. Rogalev[3], B. Eggert[5], J. Landers[5], S. Salamon[5], I.A. Radulov[1], V. Brabänder[1], M.Y. Hu[4], E.E. Alp[4], J. Zhao[4], W.-. Keune[5], O. Gutfleisch[1], M. Gruner[5] and H. Wende[5] *1. FM, TU Darmstadt, Darmstadt, Germany; 2. IFW Dresden, Dresden, Germany; 3. ESRF, Grenoble, France; 4. Argonne National Laboratory, Lemont, IL, United States; 5. Faculty of Physics and CENIDE, University of Duisburg-Essen, Duisburg, Germany*

The itinerant electron metamagnet $La(FeSi)_{13}$ is of great technological interest due to the large magneto-caloric effect observed at its magnetic first-order transition, which has potential use in solid-state refrigeration. In order to disentangle the magnetic interactions in this material and how they change at the transition, we have performed element specific studies utilizing X-ray absorption spectroscopy together with nuclear resonant inelastic X-ray scattering (NRIXS) at synchrotron radiation facilities and laboratory-based Mössbauer spectroscopy investigations. These studies not only allow us to investigate the intrinsic properties of the pure compound but also the specific effects related to doping by H and Mn. Loading of interstitial hydrogen, and Mn doping to prevent its segregation, is used to raise the transition temperature up to room temperature, whilst retaining a large magnetocaloric effect. X-ray magnetic circular dichroism measure-

ments in the low temperature phase at the Fe K-edge and La $L_{2,3}$-edges reveal not only a magnetic moment on Fe but also a sizable magnetic moment in the 5d states of La. Magneto-optical sum-rule analysis and DFT calculations indicate an anti-parallel alignment of the Fe and La spin moment. By employing ^{57}Fe nuclear resonant inelastic X-ray scattering as in [1,2], we determine the Fe-projected vibrational density of states (VDOS). We can observe significant changes in the VDOS, which can be associated with the itinerant electron metamagnetism linked to Fe. It results in a pronounced magneto-elastic softening despite the large volume decrease at the transition. Our results demonstrate that knowledge of the VDOS is important to understand intrinsic thermodynamics of first-order magnetocaloric materials. With Mössbauer spectroscopy we can measure the (local) magnetic and electric hyperfine interactions [3] and follow e.g. the reduction of the local magnetic polarization at the Fe sites by interactions with Mn. Disentangling the different magnetic contributions and lattice dynamics in $La(FeSi)_{13}$ may reveal the impact of particular degrees of freedom on the thermodynamic properties and hysteresis. Funding by the DFG (SPP 1599) and U.S. DOE (DE-AC02-06CH11357) is acknowledged.

G5-05. Tuning of Magnetocaloric effect in $La_{0.7}Ca_{0.3}MnO_3$ films using different substrates. *S. Giri*[1], R. Wu[1] and J. Driscoll[1] *1. Department of Materials Science, University of Cambridge, Cambridge, United Kingdom*

Epitaxial $La_{0.7}Ca_{0.3}MnO_3$ (LCMO) thin films were fabricated by using pulsed laser deposition technique on LAO (001), STO (001) and BTO (001) substrates to tune its magnetocaloric effect (MCE). We have also investigated to signify the correlation between the MCE and substrate induced film lattice strain. LCMO films on LAO and STO substrates which are under compressive and tensile strain, respectively. No signature of first order-like magnetic phase transition has been observed in case of films on LAO and STO substrates. But in BTO, during structural transformation from cubic to tetragonal phase at 393 K, the change in biaxial lattice distortion is positive whereas it is negative for the structural transformation from tetragonal to orthorhombic at 278 K and orthombic to rhombohedral phases at 178 K. Here we have observed noticeably large MCE in epitaxial LCMO film on BTO substrate near first order structural phase transition compare to the films on LAO and STO substrates, respectively. Again the relative cooling power is also significantly enhanced in case of films on BTO substrate. These have been explained as a result of sudden substrate structural transformation corresponds to a reversal of magnetic anisotropy, which reorients the magnetic easy axis within the film plane. Our findings of this strain modulated MCE may be useful for practical application in case of active magnetic refrigerant materials.

The influence of defects and local stresses on the martensitic transformation (MT) and magnetic properties has been analyzed in Ni-Mn-Sn and Ni-Mn-Sn-Co alloys at both macroscopic and atomic scale level. Even without modifying the atomic order, it is shown that slight microstructural distortions brought by soft milling can be used to properly tune the MT, and, as a result, their related multifunctional properties. In Ni-Mn-Sn alloys, anti-phase boundaries linked to dislocations promote the antiferromagnetic coupling between the Mn atoms, which ultimately affect the MT and the magnetic properties [1]. Besides, the evolution of the magnetization saturation has been discussed in terms of the density of the non-magnetic inclusions (defects) [2]. Upon annealing, as long as the non-magnetic inclusions decrease, both the MT characteristics and the nanoscale magnetism are enhanced. The recovery-process of the microstructure has been characterized by Differential Scanning Calorimetry and ^{119}Sn-Mossbauer spectroscopy (^{119}Sn-MS). The recovery of the MT, in fact, can be directly tracked by monitoring the non-magnetic component revealed by ^{119}Sn-MS (see Figure 1a) [1]. Moreover, the nanoscale magnetism is investigated as a function of the microstructural state in Co doped alloys in both austenite and martensite phases, Figure 1b. In contrast to the ternary alloy, in Ni-Mn-Sn-Co alloys the presence of defects, far for worsening, enhance the magnetocaloric effect comparing with its annealed counterpart [3]. These results show the potential of ^{119}Sn-MS in order to quantify the overall contribution of defects to the

MT, opening the door to the thermomechanical control, of the otherwise hardly tunable functional properties of Ni-Mn-Sn and Ni-Mn-Sn-Co alloys.

G6-01. Classification of topological antiferromagnets for spintronics. *L. Šmejkal*[1,2]*, J. Sinova[1,2] and T. Jungwirth[2,3] *1. Johannes Gutenberg University, MAINZ, Germany; 2. Academy of Sciences of the Czech Republic, Prague, Czechia; 3. University of Nottingham, Nottingham, United Kingdom*

Merging topology with magnetism is rapidly becoming a new direction in the field of topological quantum materials boosted by the recent discoveries of Dirac and Weyl semimetals [1]. Our prediction of the interplay between topological Dirac quasiparticles and Néel spin-orbit torque in an antiferromagnet [2] indicates antiferromagnets might become the leading magnets on the route towards topological spintronics [1]. In this contribution, we will classify topological antiferromagnets based on crystalline and magnetic symmetries and minimal models. We will demonstrate that antiferromagnets are natural candidates for combining magnetic order with topological Dirac quasiparticles owing to their unique effective time-reversal symmetries, which are not present in ferromagnets [1,2]. We will formulate the generic symmetry criteria for Dirac semimetals in antiferromagnets, as parent phases for Weyl semimetals, topological insulators, or quantum anomalous Hall insulators. The presence of tunable topological quasiparticles can lead to a large signal/noise ratios and novel functionalities in read-out signals in spintronics devices [1]. For example, based on ab initio theory, we have predicted a large anisotropic magnetoresistance (AMR) reaching 6% in Mn2Au antiferromagnet which was recently observed in current induced torques experiments [3]. Finally, we will present our proposal of potentially extremely large topological AMR. Topological AMR can be understood as a limiting case of AMR originating in the topological-metal insulator transition. We will show real material candidates, for instance antiferromagnetic CuMnAs.

G6-02. Spin Hall effects in non-collinear antiferromagnetic Mn_3X (X = Ir, Sn, Ge) thin-films. *J.M. Taylor*[1], E. Lesne[1], A. Markou[2], C. Felser[2] and S.S.P. Parkin[1] *1. Max Planck Institute of Microstructure Physics, Halle (Saale), Germany; 2. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany*

Antiferromagnetic (AFM) materials have potential applications in spintronic devices operating without net magnetization. Non-collinear AFMs are of particular interest to antiferromagnetic spintronics, because the topological character of their chiral spin texture drives novel phenomena such as a large anomalous Hall effect (AHE) [1], [2] and an intrinsic spin Hall effect (SHE) [3], [4], [5]. In this work, we report the deposition of thin films of the non-collinear AFMs Mn_3X (X = Ir, Sn, Ge) using magnetron sputtering. Mn_3Ir was grown in both cubic (001) and (111) orientations, whilst Mn_3Sn and Mn_3Ge were crystalized with hexagonal (0001) structure, as determined by X-ray diffraction. Meanwhile transmission electron microscopy (TEM) demonstrates the high-quality epitaxy of the films. The magnetic properties of the thin films were characterized using SQUID magnetometry; small uncompensated in-plane magnetization with coercivity $\mu_0 H_C \approx 4$mT is observed in Mn_3Sn and Mn_3Ge films. When interfaced with a ferromagnetic (FM) layer large exchange coupling, with exchange bias fields of up to $\mu_0 H_{EB} = 30$mT, is achieved. In addition, we present the first results of XLMD-PEEM experiments, in an attempt to study the antiferromagnetic domain structure of these materials. Magnetotransport, as a function of temperature and applied field angle, was measured in lithographically patterned devices. Temperature dependent AHE and anisotropic magnetoresistance (AMR) are explained in connection to the materials' magnetic properties. Finally, temperature dependent spin torque ferromagnetic resonance (ST-FMR) experiments in the Mn_3X/FM bilayers are shown, in order to investigate SHE. A spin-orbit torque (SOT) generated by the AFM is detected, and its relationship to exchange bias explored. We discuss possible origins of this SOT, in terms of both bulk and interface antiferromagnetism.

G6-03. Spin Currents in Non-Collinear Antiferromagnets. *J. Zelezny*[1]
1. Department of Spintronics and Nanoelectronics, Institute of Physics, ASCR, Prague, Czechia

Antiferromagnets have recently attracted considerable attention in the spintronics community because they have some unique advantages over ferromagnetic materials and spintronics provides means of accessing and utilizing the antiferromagnetic order. Compared to ferromagnetic materials, however, the range of spintronic functionalities available in the most studied simple collinear antiferromagnets, is limited. In contrast, in non-collinear antiferromagnets, symmetry is lower and more spintronics effects can be present. The non-collinear antiferromagnets could thus combine the advantages of collinear antiferromagnets such as fast magnetic dynamics with the useful functionalities of ferromagnets. Here, we discuss spin currents in non-collinear antiferromagnets of the Mn_3X type (see Fig. 1). Our work [1] shows that a spin current flowing in the same direction as the charge current occurs in these antiferromagnets. In other words, this means that, like in ferromagnets, the charge current in the Mn_3X is spin-polarized. In addition, we also show that a transverse spin currents occur in these antiferromagnets. This includes the conventional spin Hall effect, but also a new type of spin Hall effect, originating from the magnetic structure. These spin currents could be utilized in a variety of devices. For example, the spin-polarized current will result in a spin-transfer torque in an antiferromagnetic junction (see Fig. 2), whereas the transverse spin current will result in a spin-orbit torque in an antiferromagnet/ferromagnet bilayer system. We present microscopic calculations of such torques in nanoscopic devices.

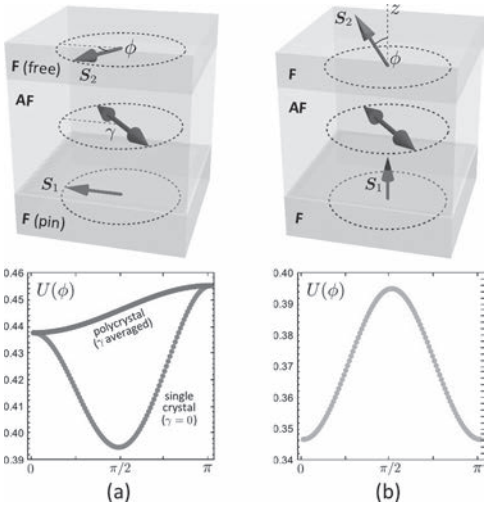
G6-04. Lifetime of Antiferromagnetic Skyrmions. P. Bessarab[2], D. Yudin[3], D. Gulevich[3], P. Wadley[4], M. Titov[3,5] and *O. Tretiakov*[1]
1. Tohoku University, Sendai, Japan; 2. University of Iceland, Reykjavik, Iceland; 3. ITMO, Saint Peterburg, Russian Federation; 4. School of Physics and Astronomy, The University of Nottingham, Nottingham, United Kingdom; 5. Radboud University, Nijmegen, Netherlands

The two-dimensional Heisenberg exchange model with out-of-plane anisotropy and Dzyaloshinskii-Moriya interaction is employed to investigate the lifetime and stability of antiferromagnetic (AFM) skyrmion as a function of temperature and external magnetic field. An isolated AFM skyrmion is shown to be metastable at zero temperature in a certain parameter range set by two boundaries separating the skyrmion state from the uniform AFM phase and a stripe domain state, see Fig. 1. The distribution of the energy barriers for the AFM skyrmion decay into the uniform AFM state complements the zero-temperature stability diagram and demonstrates that the skyrmion stability region is significantly narrowed at finite temperatures [1]. We show that the AFM skyrmion stability can further be enhanced by an application of magnetic field, which strength is comparable with the spin-flop field. This stabilization of AFM skyrmions in external magnetic fields is in sharp contrast to the behavior of their ferromagnetic counterparts. Furthermore, we demonstrate that the AFM skyrmions are stable on the timescales of milliseconds below 50 K for realistic material parameters, making it feasible to observe them in modern experiments.

[1] P. F. Bessarab, D. Yudin, D. R. Gulevich, P. Wadley, M. Titov, and O. A. Tretiakov, arXiv:1709.04454 (2017).



Antiferromagnetic skyrmion stability diagram at zero temperature. The skyrmion exists above the black line all the way up to the transition to the AFM stripe phase (dashed line -- numerical, dotted line -- analytically derived in the continuous approximation). The color scale denotes the height of the energy barrier, which skyrmion needs to overcome to decay into the uniform AFM state. Several spin congurations are shown at five different points on the stability diagram.

G6-05. Interlayer Couplings Mediated by Antiferromagnetic Magnons.
R. Cheng[1,2], D. Xiao[1] and J. Zhu[3,2] *1. Physics, Carnegie Mellon University, Pittsburgh, PA, United States; 2. Electrical and Computer Engineering, Carnegie Mellon University, Pittsburgh, PA, United States; 3. Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, PA, United States*

Collinear antiferromagnets (AFs) support two degenerate magnon excitations carrying opposite spin polarizations, by which magnons can function as electrons in spin transport. We explore the interlayer coupling mediated by antiferromagnetic magnons in an insulating ferromagnet (F)/AF/F trilayer structure. The internal energy of the AF depends on the orientations of the two Fs, which manifests as effective interlayer interactions JS1.S2 and K(S1. S2)^2. Both J and K are functions of temperature and the AF thickness. Different from the electron-mediated RKKY interaction, our J decays as 1/L^3 with the spacer thickness L and is not oscillatory. Interestingly, J is antiferromagnetic at low temperatures and ferromagnetic at high temperatures. In the high-temperature regime, J is estimated to be much larger than the interlayer dipole-dipole interaction, allowing direct experimental verification.

[1] R. Cheng, D. Xiao, and J.-G. Zhu, submitted, preprint: arXiv:1802.07709.
[2] R. Cheng, D. Xiao, and J.-G. Zhu, submitted, preprint: arXiv:1802.07867.

Two different configurations of the F/AF/F trilayer structure (with the bottom layer pinned in both cases) and their corresponding thermal magnon energies as functions of the free layer direction.

(a) The decay of the exchange coupling J fits into 1/L^3 and that of the anisotropy K fits into K0+K1 with K1~1/L^3 and K0 being the interfacial contribution independent of L (for T=0.6 and \xi=0.6). The temperature dependences of J, K0, and K1 are plotted in (b), (c), and (d), respectively (for L=4). The insets show the logarithmic plots of the dependence of J, K0, and K1 on the interfacial exchange coupling \ xi, which fits well into \xi^2.

G7-01. Electric-field control of spin-orbit torque in magnetically doped topological insulators. *Y. Fan*[1,2] and K.L. Wang[1] *1. Electrical Engineering, UCLA, Los Angeles, CA, United States; 2. Massachusetts Institute of Technology, Cambridge, MA, United States*

Recent advances of spin-orbit torques (SOTs) generated by topological insulators (TIs) have drawn increasing interest to the spin-momentum locking feature of TIs' surface states, which can potentially provide a very efficient means to generate SOTs for spintronic applications [1-5]. In this presentation, we will show the magnetization switching through current-induced SOT in both TI/Cr-doped TI bilayer structures and uniformly Cr-doped TI films. In particular, we show that the current-induced SOT has a large contribution from the spin-momentum locked surface states of TIs. Furthermore, we will show the electric-field control of the large SOT in magnetically doped TIs through modulation of the Dirac fermion populations on the two surfaces of the film [3], which suggests promising gate-controlled spin-torque device applications. In the second part of the talk, we will present the calibration of the SOT in magnetic TI materials by the magneto-optical measurements, which can re-confirm the existence of the large SOT. Finally, we will also review the recent advances in the TI-based spintronics research and discuss the challenges and opportunities. The large SOT and efficient current-induced magnetization switching exhibited by the TI-based structures may lead to innovative spintronic applications such as ultralow-power dissipation memory and logic devices.

G7-02. Systematic experimental and theoretical study of giant voltage-controlled-magnetic-anisotropy (VCMA) effect in a strained MgO/CoFe/Ir. *Y. Kato*[1], H. Yoda[1], S. Kwon[2], N. Kioussis[2], K. Fujii[1], M. Yoshiki[1], A. Tiwari[1], A. Buyandalai[1], S. Oikawa[1], H. Sugiyama[1], K. Koi[1], M. Ishikawa[1], T. Inokuchi[1], N. Shimomura[1], M. Shimizu[1], S. Shirotori[1], Y. Ohsawa[1] and A. Kurobe[1] *1. Toshiba Corporation, Kawasaki, Japan; 2. Physics and Astronomy, California State University, Northridge, Porter Ranch, CA, United States*

The voltage-controlled-magnetic-anisotropy (VCMA) effect in magnetic tunnel junctions (MTJs) has been actively investigated with the aim of creating new spintronics-based magnetoresistive memories [1, 2]. Recently, giant VCMA coefficients of more than 1000 fJ/Vm have been predicted theoretically by *ab initio* calculations in epitaxial strained Au, Ta and Ir cap/CoFe/MgO junctions [3-5]. Experimental demonstrations of the giant VCMA coefficients of around 1000 fJ/Vm were also reported in MgO/CoFe/Ir systems [6]. We experimentally demonstrate a giant VCMA coefficient in a crystallographically strained CoFe layer with a relatively thick ferromagnetic CoFe layer (~15 ML in thickness) in an MgO/CoFe/Ir system. We observed strong applied voltage dependence of saturation field and asymmetric concave behavior with a giant VCMA coefficient of -758 fJ/Vm and 1043 fJ/Vm, as shown in Fig. 1. To clarify the mechanism of the observed giant VCMA effect, we experimentally investigate the structural and magnetic properties, and theoretically understand the electronic structure. The experimental result reveals epitaxial-like growth in MgO/CoFe/Ir layers. The CoFe layer has a body-centered-cubic structure and a tetragonal distortion due to the lattice mismatch. The CoFe layer has large perpendicular magnetic anisotropy, which is consistent with the calculation result. As an example of Fig. 2, *ab initio* electronic structure calculations reveal that epitaxial strain and its thickness have a dramatic effect on the VCMA. These systematic experimental and theoretical studies suggest that crystallographically strained CoFe system would open a path to realization of novel spintronics-based magnetoresistive memories using the giant VCMA effect. This work was partly supported by the ImPACT Program of the Council for Science, Technology and Innovation (Cabinet Office, Government of Japan).

G7-03. Controlling the magnetization of insulators with voltages and interfacial rare-earth atoms. *A. Leon*[1], A. Cahaya[1] and G. Bauer[1,2] *1. Institute for Materials Research, Tohoku University, Sendai 980-8577, Sendai, Japan; 2. Zernike Institute for Advanced Materials, University of Groningen, Groningen, Netherlands*

The *voltage control of magnetism* has been proposed as a low-power-consumption alternative to the use of magnetic fields in memory technologies [1]. In magnetic multilayers, both voltage-induced ferromagnetic resonance [2,3] and magnetic switching [4,5] have been realized by the electric field dependence of the magnetic anisotropy [6]. However, a stronger spin-charge coupling would be highly desirable for practical applications of voltage-controlled devices. Here we demonstrate that this can be achieved by employing the strong spin-orbit interaction of the 4f subshell in rare earth atoms and the large electric field gradients at insulator|metal interfaces. We study rare-earth magnetic moments with partially filled 4f-shells that are characterized by large spin-orbit interactions (SOI), which lock the 4f charge and spin densities. Space and time-varying voltages couple to the charge quadrupole of the ionic charge distribution, and via the SOI move the magnetic moment much more efficiently than for 3d transition metal ions. A possible device is made of rare-earth-doped or substituted yttrium iron garnet with metal contacts, and it could be used for magnetization reversal and ferromagnetic resonance, among others. *We acknowledge the financial support from JSPS KAKENHI Grants No. 25247056, No. 25220910, and No. 26103006, JSPS Fellowship No. JP15J02585, and Financiamiento Basal para Centros Científicos y Tecnológicos de Excelencia FB 0807.*

G7-04. Control of Magnetic and Topological Orders with a DC Electric Field. *K. Takasan*[1] and M. Sato[2] *1. Department of Physics, Kyoto University, Kyoto, Japan; 2. Department of Physics, Ibaraki University, Mito, Japan*

In recent years, the control of solid states with external electric fields has been intensively studied. While plenty of interesting scenarios with AC electromagnetic fields or laser light has been proposed [1], the control with low-frequency or DC (static) electromagnetic fields has been also studied (e.g. electric-field-controlled magnetism in multiferroics [2] and dielectric breakdown in Mott insulators [3]). However, varieties of DC-field driven phenomena have been still limited compared with AC-field studies. In contrast, recent experimental techniques of generating strong DC fields and low-frequency AC fields (e.g. Tera Hz laser) have been rapidly developed [5]. Therefore, now is the best time to theoretically propose novel scenarios for DC- or low-frequency AC-driven phenomena. In this talk, we present our theoretical proposal which provides a new route to control magnetic and topological orders in a broad class of insulating magnets with a DC electric field [6]. We show from the strong-coupling expansion that magnetic exchange interactions along the electric-field direction are generally enhanced in Mott insulators. It indicates that we can control the spatial structure of the interactions in magnets with a DC electric field. To illustrate this idea, we particularly focus on two kinds of magnets, frustrated magnets and quasi-one-dimensional magnets, and obtain phase diagrams including several magnetic or topological ordered phases such as quantum spin liquids and Haldane-gap states. Our proposal is effective especially for weak Mott insulators and magnets in the vicinity of quantum critical points, and would also be applicable for magnets under low-frequency AC electric fields such as terahertz laser pulses. In this talk, we give several candidate materials and experimental setups for our scheme. Our result would pave a promising way to control the exotic states of matter in magnets.

G7-05. Witten effect and emergent gauge fields on domain wall between topological insulators and spin ice components. *I. Kanazawa*[1] *1. Physics, Tokyo Gakugei University, Tokyo, Japan*

The three-dimensional topological insulators BiSb in a certain range composition has been predicted, and Dirac fermions on the surface of these topological insulators have been observed experimentally [1]. Also Castelnovo et al.[2] have reported that magnetic monoploles emerge in a class of exotic magnets known collectively as spin ice components Dy2Ti2O7 and Ho2Ti2O7. Kanazawa and coworkers [3-5] have proposed that there might be emergent quasiparticles with fractional electronic charge such as dyons on the domain wall between topological insulators and spin ice components through the Witten effect [6]. In this study, we will discuss the interection between the Dirac fermions and excited magnetic monopoles and curvature effect on domain wall between topological insulators and spin ice components.

Quantum spin liquid (QSL) is a highly entangled magnetic state found in frustrated magnetic systems. This is generally characterized by the absence of static magnetism together with the presence of highly correlated excitations known as spinons. In systems with isotropic interactions, such phenomenon is usually sought in lattices where magnetic ions form triangular or tetrahedral arrangements and are interacting via antiferromagnetic interactions. Several compounds have been reported to show the spin liquid behaviour in two dimensionally (2D) frustrated lattices such as the kagome in Herbertsmithite and Kitaev Honeycomb in α-$RuCl_3$. In three dimensions (3D), the experimental realization is mostly limited to pyrochlore systems which are formed by corner-shared tetrahedral, whereas, *three-dimensional networks of corner-sharing triangles* such as hyperkagome lattice are very rare. In this context, we explore a new three-dimensional magnet $PbCuTe_2O_6$, consisting of antiferromagnetically coupled S-1/2 ions that form a 3D network of corner-sharing triangles. This lattice, which we define as the hyper-hyperkagome, has three triangles connected per magnetic ion as shown in Fig1 and hence is distinctly different from the generally known hyperkagome. By performing a combined dc susceptibility and neutron scattering experiments we confirm that its ground state does not develop any static magnetism and its excitations form diffuse, dispersionless spheres as shown in Fig2. These excitations are similar to the broad diffuse rings observed in the 2D QSL candidates like Herbertsmithite and $Ca_{10}Cr_7O_{28}$ [1,2]. Therefore, these results suggest a quantum spin liquid state in the new 3D frustrated hyper-hyperkagome lattice. Furthermore, with the help of Curie-Weiss temperature from dc susceptibility and density functional theory calculations we determine the magnetic Hamiltonian which reproduces all crucial characteristics of the spin liquid behavior in $PbCuTe_2O_6$ [3].

G8-03. Disorder and its consequences in Pr-based quantum spin ices. *O. Benton[1] 1. Center for Emergent Matter Science (CEMS), RIKEN, Wako, Japan*

Pr-based pyrochlores, such as Pr2Zr2O7 and Pr2Hf2O7, have emerged as promising candidates for the realization of a quantum spin liquid ground state. Interest in these materials is fuelled not only by a lack of conventional magnetic order, but also by neutron scattering measurements tantalisingly reminiscent of predictions for a U(1) spin liquid [1,2]. Recent work has highlighted how quenched structural disorder plays a crucial role in these systems, by splitting the low lying crystal electric field doublets [3,4,5]. Here, I present a theoretical treatment of these effects, deriving a phase diagram for disordered Pr pyrochlores based on a controlled perturbation theory. This perturbation theory allows us to address the two key instabilities of the spin liquid phase- spinon condensation and confinement- in a quantitative way. Calculating the thresholds for each kind of instability allows us to infer a phase diagram for Pr pyrochlores in the presence of quenched structural disorder. By comparing published thermodynamic data to numerical linked cluster calculations, we are able to quantify the strength of disorder in currently studied Pr pyrochlores, and thus to locate them on the phase diagram. This study resolves some long-standing mysteries about these materials and has implications for the prospects of realising a spin liquid ground state in experiment [6].

G8-04. Electronically Highly Cubic Conditions for Kitaev Physics in Alpha-$RuCl_3$. *S. Agrestini[1,2], C. Kuo[1], K. Ko[1], Z. Hu[1], D. Kasinathan[1], H.B. Vasili[2], J. Herrero-Martin[2], M. Valvidares[2], E. Pellegrin[2], A. Henschel[1], M. Schmidt[1], L. Jang[3], A. Tanaka[4] and L. Tjeng[1] 1. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 2. Experiments Division, CELLS-ALBA, Cerdanyola, Spain; 3. National Synchrotron Radiation Research Center, Hsinchu, Taiwan; 4. Department of Quantum Matter, Hiroshima University, Higashi-Hiroshima, Japan*

alpha-RuCl3 is the most promising candidate for the long-sought materialization of the Kitaev model. Prerequisite for these expectations is that the non-cubic crystal field splitting is small compared to the spin-orbit coupling (SOC) and, hence, does not perturb in a significant way the description of the electronic ground state in terms of the J_eff = 1/2 state. In this context, contradictory reports are available in literature. In this talk I present a study of the local Ru 4d electronic structure of RuCl3 by means of polarization dependent x-ray absorption spectroscopy at the Ru-L2,3 edges [1]. The observed linear dichroism is vanishingly small indicating that electronically the Ru 4d local symmetry is highly cubic. Consistent with our magnetic circular dichroism measurements, the ratio of the orbital and spin moments is found to be 2.0, the value expected for a J_eff = 1/2 ground state. The magnetic g factor is estimated to be fairly isotropic. The data thus show that as far as the Ru 4d local properties are concerned, RuCl3 is an ideal candidate for the realization of the Kitaev physics.

G8-05. A High-Temperature Quantum Spin Liquid with Atomic-Cluster Spins in 1*T*-TaS_2. *D. Arcon[1,2] 1. Institute "Jozef Stefan", Ljubljana, Slovenia; 2. Faculty of mathematics and physics, University of Ljubljana, Ljubljana, Slovenia*

The Anderson's proposal of a resonating valence bond state [1] was put forward to account for the unusual magnetic properties of a perfect triangular atomic lattice of Ta atoms in the layered transition metal dichalcogenide 1*T*-TaS_2. Compared to some recent candidates for quantum spin liquids (QSL), e.g., $YbMgGaO_4$ [2] or κ-$(ET)_2Cu_2(CN)_3$ [3], layered dichalcogenides have perfect triangular lattice geometry and a weaker spin-orbit coupling, offering a possibility for obtaining a unique insight into the competition between antagonistic QSL and Néel states. Here we report [4] on an almost ideal QSL that appears to be realized by atomic-cluster spins on the triangular lattice of a charge-density wave (CDW) state of 1T-TaS_2. In this system, nuclear magnetic quadrupole resonance and muon spin relaxation experiments reveal that the spins show gapless quantum spin liquid dynamics and no long range magnetic order down to 70 mK. Canonical T^2 power-law temperature dependence of the spin relaxation dynamics characteristic of a QSL is observed from 200 K to T_f = 55 K (Fig. A). Below this temperature we observe a new gapless state with reduced density of spin excitations and high degree of local disorder (deduced from the decrease of stretching exponent p to ~ 0.5, Fig. B)signifying new quantum spin order emerging from the QSL. The QSL is at first robust against applying chemical pressure in doped samples before giving a way to superconducting state.

We report an experimental study applying uniaxial stress and magnetic field at very low temperature on the ferromagnetic superconductor URhGe. This system is famous for the co-existence of superconductivity and ferromagnetism at ambient pressure, but also for its remarkable phase diagram under magnetic field. When a field is applied along the b-axis, transverse to the easy magnetization c-axis, two separate pockets of superconductivity exist, one at low field, and a re-entrant superconducting phase appearing under field. Here we show that uniaxial stress can spectacularly modify the phase diagram, pushing the high field superconductivity pocket to lower fields so that it reconnects to the low-field superconducting phase. This implies that the field HR where the magnetic moments rotate from the easy axis to align with the field is strongly suppressed by stress. Simultaneously superconductivity is significantly enhanced and the critical temperature at high field reaches 1K, twice higher than at ambient pressure, while the critical temperature at zero field also increases. This enhancement of superconductivity is directly related with the increase of the magnetic susceptibility perpendicular to the easy axis, and to a reduction of the ferromagnetic anisotropy. We show also preliminary results using stress on the other known ferromagnetic superconductors UCoGe and UGe_2. This provides novel input for theories of superconductivity in correlated ferromagnetic materials and many perspectives for future experimental studies.

Dimensionality Driven Enhancement of Ferromagnetic Superconductivity in URhGe. D. Braithwaite et al. Phys. Rev. Lett. 120, 037001 (2018)

Ferromagnetic and superconducting T-H phase diagram of URhGe for different values of uniaxial stress applied along the b-axis

It is well known that the critical fluctuations associated with magnetic quantum critical points (QCP)—that is magnetic instabilities occurring at zero temperature and as function of a non-thermal control parameter such as pressure—are crucial for the emergence of novel states of matter such as unconventional superconductivity. However, their exact nature remains an outstanding question. Most notably, according to theory both the relaxation time and correlation length of the fluctuations are expected to diverge when the QCP is approached. However, to date this has not yet been observed, partially because this requires extreme energy and momentum transfer resolution. For ferromagnetic QCPs this problem may be overcome using the newly developed longitudinal MIEZE (Modulated Intensity by Zero Effort) option available at the instrument RESEDA at MLZ (Garching) that achieves ultra-high energy resolution of 1μeV or better. Using this approach, we have investigated the magnetic fluctuations in the heavy fermion system UGe_2 at ambient pressure. Microscopic coexistence of ferromagnetism and unconventional superconductivity renders UGe_2 a candidate for spin-triplet superconductivity. To avoid pair-breaking, spin-triplet superconductivity is mediated by longitudinal spin fluctuations. This results in at least partially contradicting requirements; longitudinal spin fluctuations are typically promoted by magnetic Ising anisotropy that arises from localized electrons due to spin-orbit coupling; at the same time the formation of Cooper pairs typically involves spin fluctuations arising from itinerant electrons. Our ultra-high neutron spectroscopy measurements show—for the first time—that this dichotomy may drive spin-triplet superconductivity in UGe_2. Notably, they reveal purely longitudinal spin fluctuations in UGe_2 with a dual nature arising from 5*f* electrons that are neither fully itinerant nor fully localized. Local spin fluctuations are perfectly described by the Ising universality class in three dimensions, whereas itinerant spin fluctuations occur over length scales comparable to the superconducting coherence length.

G9-03. Ferromagnetic superconductivity mediated by pressure-enhanced spin fluctuation developed around the phase boundary of FM1 and FM2 in UGe_2. *N. Tateiwa*[1], Y. Haga[1] and E. Yamamoto[1]
1. Advanced Science Research Center, Japan Atomic Energy Agency, Naka, Tokai, Japan

Uranium ferromagnetic superconductors UGe_2, URhGe, and UCoGe have been extensively studied from both experimental and theoretical sides[1]. We report the dynamical magnetic property under high pressure in UGe_2 deduced from the analysis of magnetic data with spin fluctuation theory. Figure 1 (a) shows the pressure-temperature phase diagram in UGe_2[2]. The Curie temperature T_C decreases with increasing pressure and the ferromagnetic state disappears at 1.5 GPa. There is an additional boundary Tx(P) whose origin has not been understood yet. The boundary splits the ferromagnetic phase into FM2 and FM1 regions. The superconductivity (SC) appears above 1.0 GPa. We have measured the magnetization of UGe_2 under high pressure with a miniature ceramic anvil cell (mCAC)[3]. The magnetic data has been analyzed with Takahashi's spin fluctuation theory to investigate the dynamical magnetic property under high pressure[4]. We have have shown the applicability of the spin fluctuation theory to actinide 5*f* electrons system[5]. Fig. 1(b) shows the pressure dependencies of spin fluctuation parameters T_0 and T_A, the widths of the spin fluctuation spectrum in the energy and the momentum spaces, respectively. Both show anomalous behavior around a pressure region where the superconductivity appears. There is a peak in the pressure dependence of $T_0(P)$ at P_x where the superconducting transition temperature T_{sc} shows a maximum value. When the pressure dependence is expressed as $T_0(P)=T_0^*+\Delta T_0(P)$ where T_0^* is a pressure-independent term, the pressure dependence of $\Delta T_0(P)$ scales with that of $T_{sc}(P)$. This suggests that the ferromagnetic superconductivity is mediated by pressure-enhanced spin fluctuation developed around P_x. Figure 2 shows relations between T_{sc} and T_0 for UGe_2, URhGe and UCoGe, heavy fermion superconductors, and high-T_c cuprate superconductors. The data for the uranium ferromagnetic superconductors deviate from those of the other unconventional superconductors. We will discuss peculiar features of the uranium ferromagnetic superconductors.

Recently, ferromagnetic (FM) quantum phase transitions in clean metals have attracted much interest because a first-order quantum phase transition is commonly observed at low temperatures below a tricritical point (TCP) [1]. Below the TCP, a FM first-order plane (wings) is expected in the three-dimensional phase diagram. This type of "*T-p-H* phase diagram" has

been studied in itinerant FM compounds, such as UGe_2, URhAl, UCoGa, and $ZrZn_2$ with pressure as a tuning parameter [2-5]. Whereas much theoretical work has been reported, the wings have been studied experimentally to a much less extent because a high-pressure environment is usually required in the observation of the wings. By contrast, as a magnetic field H_b parallel to the magnetic hard b axis being the tuning parameter, URhGe provides a good opportunity to investigate the wings in the whole FM phase diagram [6, 7]. In this system, the location of TCP is under debate [8, 9], regarding the origin of reentrant superconductivity that is possibly be induced by ferromagnteic fluctuations [7]. Previously, we have succeeded, for the first time, in directly determining the detailed profiles of the wings and the position of the TCP, which locates above 4 K, in the three-dimensional T-H_b-H_c phase diagram of URhGe by means of high-precision angle-resolved dc magnetization measurements [10]. A hystereresis of magnetization curve (a evidence of a first order transition), however, is observed only below 1 K, having a question whether the transition is of first order in the temperature range between 1 K and T_{TCP} (> 4 K).

The natural mineral linarite $PbCuSO_4(OH)_2$ is a realization of a frustrated one dimensional spin chain with ferromagnetic nearest neighbor interaction and antiferromagnetic next nearest neighbor interaction. Residual interchain coupling leads to a magnetically ordered state for temperatures below T_N=2.8 K. An elliptical helical spin structure was found in zero magnetic field as a result of the frustration. A rich magnetic phase diagram including four distinct phases for an applied magnetic field along the chain direction was determined by means of thermodynamic measurements [1]. We present a detailed study of the magnetic phase diagram via neutron diffraction technique, which reveals a two-step spin-flop transition into a commensurate phase and a transition transforming a helical magnetic ground state into an unusual magnetic phase with sine-wave-modulated moments [2]. For this unusual phase, the incommensurate propagation vector k=(0, k_y, 0.5) is studied field and temperature dependently. Three regions were found: at low magnetic fields the propagation vector component k_y decreases with increasing temperature, at higher magnetic fields k_y increases with increasing temperature and at high fields close to saturation no significant change of k_y is observed. The results will be discussed in the context of high-order exotic spin-density wave states.

University of Ljubljana, Ljubljana, Slovenia*

Elementary excitations are a basic concept used to describe dynamical processes in condensed matter and are essential for explaining fundamental physical phenomena. Their variety is vast; ranging from established phonons and magnons to exotic magnetic monopoles [1] and Majorana fermions [2]. Yet, when order parameters intertwine, identification of elementary excitations is extremely difficult. For instance, the elusive excitations in high-temperature superconductors that propel enigmatic fluctuating-charge-stripe, i.e., electronic nematic, phases [3] are still unidentified. Here we report on a new type of elementary excitations in a spin-stripe state, which occur as two perpendicular amplitude-modulated magnetic components with different modulation periods slide through each other. Exploring the frustrated zigzag spin-1/2 chain compound β-$TeVO_4$ [4,5] by muon-spin relaxation, neutron diffraction and dielectric spectroscopy, we find that the spin-orbit coupling introduces sizable anisotropic- and fourth-order-exchange interactions, which stabilize the spin-stripe phase and set the energy scale of underlying excitations. These, so-called wigglon excitations, occur in the megahertz range and are well separated from other types of excitations in ordered magnetic systems (Figure 1), e.g., collective spin-wave excitations or persistent quantum spin fluctuations. The proposed type of spin-stripe excitations thus offers a unique perspective on the stripe physics that avoids the problem of intertwining degrees of freedom hindering the research in high-temperature superconductors.

G10-03. Cluster-Based Haldane State with Finite Magnetization. *T. Sugimoto*[1], K. Morita[1] and T. Tohyama[1] *1. Applied Physics, Tokyo University of Science, Tokyo, Japan*

The S=1 Haldane state has attracted much attention due to its topological characters, e.g., the string order and the symmetry-protected topological phase, and its potential for a quantum memory in the measurement-based quantum computation [1]. This state emerges not only in the S=1 spin chain, but also in an S=1/2 two-leg spin ladder with a ferromagnetic rung interaction [2]. Additionally, our recent study on low-temperature magnetism in a naturally occuring mineral Fedotovite, has shown the Haldane state consisting of cluster-based S=1 spins, in collaboration with experimental groups [3]. In this compound, edge-shared tetrahedral spin clusters which include six spins

in a cluster, are linked by a nearest-neighbor antiferromagnetic inter-cluster interaction in one dimension. This low-energy state in a cluster is a triplet and the inter-cluster interaction is perturbative as compared with the intra-cluster excitation energy, so that we can explain the low-temperature physics in an effective S=1 spin model obtained by projection into cluster's triplet states. To realize a quantum memory using the Haldane state, it is important to develop our knowledge about conditions for emergence of the Haldane state. In present study, we thus extend the cluster-based Haldane state to spin-cluster systems which have odd-number S=1/2 spins in a cluster. Since the odd-number spin system with time-reversal sysmetry obeys the Kramer's theorem, even-number states degenerate as its ground states. Therefore, it is difficult to make an effective S=1 spin in a cluster. To overcome this difficulty, we consider magnetized state emerging in an applied magnetic field. Magnetic fields break the time-reversal symmetry, and thus, the ground state can have an odd-fold degeneracy. We investigate odd-number S=1/2 spin-cluster systems with Heisenberg interactions in magnetic fields, and find conditions of three-fold ground states in a cluster, which can be regarded as an effective S=1 spin states. Moreover, we introduce proper inter-cluster Heisenberg interactions in one dimension, and confirm the emergence of cluster-based Haldane state with finite magnetization. Our study is useful for strategical design of the Haldane state by using S=1/2 spins.

G10-04. Quantized excitation spectra by magnon confinement in quasi S=1 spin-chain systems. *T. Suzuki*[1] and S. Suga[1] *1. University of Hyodo, Himeji, Japan*

Quantized excitation spectra below the Néel temperature have been observed in recent inelastic-neutron-scattering measurements on quasi-one-dimensional (Q1D) antiferromagnetic (AF) magnets, (Ba/Sr) $Co_2V_2O_8$ [1-4]. The observed peak positions of the quantized spectra have been well explained by negative zeros of the Airy function (NZAF). In these compounds, Co ions carry S=1/2 effective magnetic moments and compose the AF Ising-like XXZ chains [5]. In the low-energy excitation in the S=1/2 AF Ising-like XXZ chain, there appears the excitation continuum composed by spinons. When the weak interchain interaction is taken into account, the interchain interaction confines the two spinons and results in quantized spectra [6]. If both weak longitudinal and transverse fields are applied to the ferromagnetic Ising spin chain, a linear potential works between two spinons in the excitation continuum and causes the quantized spectra explained by the NZAF [7]. Since the Q1D AF spin systems with the Ising anisotropy on bipartite lattces are effectively expressed by the ferromagnetic Ising-like XXZ chain in a uniform longitudinal field after spin axis rotations for sublattices, this mappping qualitatively explains the origin of the characteristic spectra observed in the above compounds. In this study, we focus on the AF S=1 spin chains that show excitation continuum originated from magnons and investigate the possibility of quantized spectra due to the interchain couplings. We calculate dynamical spin structure factors for infinite AF S=1 spin chains by utilizing the iTEBD method. From the numerical results, we show that the magnon continuum in the AF S=1 spin chain also shows the quantized excitation spectra due to perturbative interactions such as the interchain interaction. The peak positions are explained by the NZAF only if the system is placed at the Ising limit, where the single ion anisotropy is quite strong in contrast to the Heisenberg interaction. Although the peak position deviates from the NZAF as the system leaves from the Ising limit, the quantized spectra survive even in the Haldane phase.

G10-05. Defects in spin ladders. *S. Galeski*[1], K. Povarov[1], D. Blosser[1], J. Ollivier[2] and A. Zheludev[1] *1. Laboratory for Solid State Physics, ETH Zurich, Zurich, Switzerland; 2. Institut Laue-Langevin, Grenoble, France*

Recently the rather old problem of defects in low dimensional magnets [1] has received renewed attention. It was inspired by new numerical findings and experiments on novel materials closely representing idealised models [2]. In this talk we will present the results of a long lasting project aimed at investigating the role of non-magnetic defects on spin ladders, throughout their phase diagram. In our studies we have focused on two zinc substituted spin ladder materials: DIMPY and BPCB. Both materials were shown to be excellent realizations of the spin ladder Heisenberg hamiltonian in the strong leg and strong rung limits, respectively [3,4]. Through performing low field neutron time of flight spectroscopy, and comparing it with extensive numerical studies we have demonstrated that all the low-energy zero field physics of these systems is captured by a model of defect-free chains composed of effective spins with random and sign-alternating interactions. The effective chain model quantitatively reproduces not only the thermodynamics, but also the emergent low-energy dynamics, including in-gap excitations (Fig. 1) [2]. This description remains valid as long as the ladder remains in the Haldane phase, however when the magnetic field drives the system to the Luttinger phase the nature of the correlations fundamentally change and the emergent spin island picture breaks down. Through the study of low temperature thermodynamics and comparison with numerical studies we have established that depletion in the gapless phase truncates the transverse correlations leading to depression of the 3D ordering temperature (Fig.2). We will discuss these findings within the context of analytical solutions for finite size Luttinger liquids [5].

H1-01. Photomagnetic Control of Nanoparticles with Radical Pair System: A Promising New Area of Liposomal DDS. *H. Nakagawa*[1] and M. Ohuchi[1] *1. Department of Electrical and Electronic Engineering, Tokyo Denki University, Adachi-ku, Japan*

Background: Over a long period of time, so many liposomal nanoparticles (LNPs) have been evaluated as biocompatible carriers for drug-release technologies. Previously, we demonstrated the design of LNPs equipped with radical pair mechanisms to show the broad potential opportunities in drug delivery systems (DDSs) [1], [2]. For the rapid progress of the methodology, we attempted a further detailed evaluation of the drug-release potential and invasivity. Experimental: The preparation of flutamide (FM)-containing LNPs (FM-LNPs) and the field-effect measurements with FM release were carried out in the same way as in Nakagawa *et al.* [1]. Figure 1 shows the scheme for the photochemical reactions after excitation of FM in the biomembrane. For the quantitative analysis of FM-corresponding escape-radicals, we utilized the rate of the disappearance of FM (Fig. 1A), and the appearance of a cleavage product derived from a FM-corresponding cage product (Fig. 1C). The relative yields of the escape-radical with magnetic field effects were determined referring to the reported method [3]. Results and Discussion: For evaluating the drug-release potentials with radical pair mechanisms on the photochemical reaction developing in the liposomal biomembrane, we prepared various types of FM-LNPs equipped with possible magnetic controls. When 1-stearoyl-2-linoleoyl-phosphocholine was used as the lipid component of the FM-LNP, a close connection between magnetic field effects and the escape-radical releases was observed depending on the field strength. In the case of the other two kinds of the FM-LNP prepared from 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine or 3-*sn*-phosphatidylcholine lipid molecules, the escape-radical releases with the field effects were strikingly faithful to the *S-T* Intersystem. Our system may provide the best possible balance between clinical performance and low invasivity. We believe the idea that magnetic fields are extremely suitable for the gentle control of chemical reactions *in vivo*.

H1-02. Effect of the Organic Coating on the Magnetic Behavior of $CoFe_2O_4$ Nanoparticles. *E. Agostinelli*[1], N. Ntallis[2], M. Vasilakaki[2], M. Giuseppe[3], D. Fiorani[1], D. Peddis[1] and K.N. Trohidou[2] *1. Istituto di Struttura della Materia- ISM, Consiglio Nazionale delle Ricerche - CNR, Monterotondo Scalo (RM), Italy; 2. Institute of Nanoscience and Nanotechnology, NCSR 'DEMOKRITOS', Athens, Greece; 3. Physics and Astronomy, Uppsala University, Uppsala, Sweden*

The electronic, structural, and magnetic properties of nanoparticles are known to be modified at and near the surface. Interestingly, the addition on a magnetic nanoparticle of a non-magnetic surface coating affects the surface properties [1]. In our effort to study magnetic nanoparticles in ionic liquids for magnetothermoelectric applications, we studied the effect of different ligands bonded at the nanoparticle surface on their magnetic behavior. We studied two different organic surfactants: diethylene glycol (DEG) and Oleic Acid, bonded at the surface of $CoFe_2O_4$ nanoparticles [2]. We performed DFT calculations using the VASP package [3] in order to study the modification of the structure of the $CoFe_2O_4$ surface in the presence of these two different coatings. The cationic distribution used was the one observed by Mössbauer spectroscopy [2]. Our results showed: (a) different spatial distortions of the surface atoms for the two different coatings, (b) a net moment larger for the DEG coating and (c) an increase of the surface anisotropy that is larger in the case of oleic acid. DFT results were used as inputs in a mesoscopic scale model of an assembly of interacting coated $CoFe_2O_4$ nanoparticles where each particle is represented by 3-macrospins [4]. We used the Monte Carlo (MC) simulation technique with the implementation of the Metropolis algorithm to calculate the isothermal hysteresis loops and the temperature depended magnetization curves. Our MC results demonstrated that in the case of DEG coating the saturation magnetization and the blocking temperature increase whereas the coercive field decreases as compared to the system with oleic acid surfactant. The MC results were compared with the experimental findings and a very good agreement was observed. The authors acknowledge the FET-Proactive MAGENTA Project (Contract N. 731976).

Introduction: At present, the use of nanotechnology for biomedical applications has had an important development, specifically the use of magnetite at nanoscale, where the main challenge is to obtain particles with high crystallinity and low polydispersity in aqueous medium for biomedical applications. Aim: Optimize the transfer of rare earth co-doped magnetic nanoparticles to aqueous media through ligand exchange. Methods and materials: We studied

the synthesis of rare earth co-doped magnetic nanoparticles. The synthesis was performed by thermal decomposition. Subsequently, the size of the MNPs synthesized using TEM, as well as their crystallinity using their XRD spectrum, and their magnetic properties were determined with a vibrating sample magnetometer. Finally the nanoparticles were transferred to aqueous medium through the binder exchange reaction using DMSA. Results: Results showed that the maximum particle size obtained was 8 nm with superparamagnetic characteristics. Conclusions: The transfer to aqueous medium was suitably carried out, because the nanoparticles showed a high colloidal stability and these observations suggest that Fe3O4:Yb^{3+},Er^{3+} NPs turns out to be an important candidate in biomedical applications for simultaneous optical imaging and hyperthermic therapy.

H1-04. Low temperature synthesis of $L1_0$ MPt (M = Fe, Co, Ni) nanoparticles by salt layered precursors. G. Varvaro[1], *E. Agostinelli*[1], D. Fiorani[1], P. Imperatori[1], S. Laureti[1], D. Peddis[1] and A. Capobianchi[1]
1. ISM - CNR, Monterotondo Scalo (Roma), Italy

Chemically ordered $L1_0$ magnetic alloys have garnered a great deal of attention in the last few decades due to their peculiar magnetic properties and excellent chemical stability that make them of potential interest for various technological applications. To promote the $L1_0$ ordering, the processing temperature needs to be higher than the kinetic ordering temperature and lower than the order-disorder thermodynamic temperature $T_{O\text{-}D}$. As sample size decreases from bulk to nanometer-scale the optimum temperature window reduces and for binary alloys with a low $T_{O\text{-}D}$ the ordering cannot be achieved anymore. Therefore, lowering the kinetic ordering temperature becomes a critical issue being also desired for practical applications. In this work, layered $M(H_2O)_6PtCl_6$ crystal salts (M = Fe, Co, Ni) consisting of alternating planes of pure M and Pt atoms were used as precursors to synthetize $L1_0$ MPt nanoparticles [1-3]. Such a strategy allowed to significantly decrease the ordering kinetic energy thus leading to a strong reduction of the temperature needed to obtain the $L1_0$ high-anisotropy FePt and CoPt alloys (T = 420 °C and 450 °C, respectively). Moreover, despite the low order-disorder temperature of the NiPt alloy (660 °C), ordered $L1_0$ nanoparticles were obtained at T = 350 °C thus paving the way for a powerful and simple method for the low-temperature synthesis of $L1_0$ binary magnetic alloys.

Instituto de Sistemas Optoelectrónicos y Microtecnología, Universidad Politécnica de Madrid, Madrid, Spain*

The synthesis of molecularly imprinted polymers (MIPs) in the form of micro- or nanostructures, as well as their combination with other materials in composites, has been a major focus of research interest over the past decade. Thanks to their improved properties, these formats are especially suited for some applications, such as sensing, drug delivery or even analytical separations, over the more common bulky configurations. Different techniques have been applied to the preparation of nano and micro-MIP features including, electrical deposition, photolithography, microstereolithography, mechanical microspotting, soft-lithography, e-beam or electrospinning [1]. The incorporation of superparamagnetic iron oxide cores has broadened up the applicability of MIPs to different fields [1]. The use of magnetic MIPs is particularly promising because the use of magnetic fields for the removal of the nanocomposites from the solutions is often much faster and efficient than centrifugation or filtration [2]. In this work, we describe the development of a novel approach to the preparation of molecularly imprinted polymer (MIP) coatings directly onto magnetic nanoparticles (MNPs) by using alternating magnetic fields (AMFs) to trigger the polymerization reaction. The MIPs were synthetized with rhodamine 123 (R123) as model template molecule, methacrylic acid (MAA) as functional monomer and trimethylolpropanetrimethacrylate (TRIM) as cross-linker. The amount of iron oxide nanoparticles (NPs, 10 mg) and the composition of the polymerization mixture were optimized to enable thermal polymerization of thin MIP shells onto the magnetic core by using electromagnetic heating, without altering the properties of the recognition layer. The thickness of the polymerized MIP layer grafted onto the MNPs was tuned by adjusting the dose of electromagnetic field (101.4 kHz, total power dissipation = 105 W). The resulting magnetic MIP nanoparticles (MNP-MIPs) have been characterized by ATR and X-ray diffraction (XRD) spectroscopy, transmission electron microscopy (TEM) and dynamic light scattering (DLS), as well by SQUID magnetometry. The recognition properties of the imprinted polymer have been evaluated in batch rebinding experiments.

H1-07. Size-tunable fabrication of multiferroic $BiFeO_3$ nanoparticles and syntheses of porous $BiFeO_3$ networks with enhanced visible-light photocatalytic activity. *T. Cadenbach*[1], M. Benítez[2], L. Lascano[2], C. Costa[2], A. Debut[3] and C. Arroyo[3] *1. Ingeniería Ambiental, Universidad San Francisco de Quito, Quito, Ecuador; 2. Departamento de Física, Escuela Politécnica Nacional, Quito, Ecuador; 3. Center of Nanoscience and Nanotechnology, Escuela Politécnica del Ejército, Sangolqui, Ecuador*

In the past few years much attention has been paid to multiferroics, i.e. materials in which at least two parameters of (anti)ferroelectric, (anti)ferromagnetic, and ferroelastic ordering coexist in the same phase.[1-3] Due to the magnetoelectric coupling, these materials have potential applications in information storage, spintronics, and sensors.[3-7] Since ferroelectricity depends in principle on empty d-shells while magnetism in general requires partially filled d-shells, such systems are rare in nature. Only few examples have been synthesized successfully, among these is single phase bismuth ferrite $BiFeO_3$ (BFO). In this poster, we present the synthesis of multiferroic $BiFeO_3$ nanoparticles with controlled particle size via a facile co-precipitation method. In addition, porous networks of doped and undoped $BiFeO_3$ were synthesized via an auto-combustion method. The samples were characterized by X-ray powder diffraction, transmission electron microscopy, scanning electron microscopy, atomic force microscopy, UV–vis diffuse reflectance spectroscopy and magnetometry. The photocatalytic activity of all $BiFeO_3$ samples was further tested in the degradation of Rhodamine B dye in an aqueous solution under visible light irradiation. For the samples prepared by the co-precipitation method, we found that through the time of base addition during synthesis the particle size can be controlled easily. Longer addition times resulted in smaller particle sizes exhibiting narrower band gaps. Moreover, it was shown that smaller particle sizes affected largely the photocatalytic activity of the corresponding samples. Furthermore, the synthesized porous networks of doped and undoped $BiFeO_3$ showed nanoscale properties such as band gaps and highly enhanced visible-light photocatalytic activity even though the size of the samples were in the macrometer range.

H1-08. Magnetic and Excellent Microwave Absorbing Properties Exhibited by $Ni_{0.5}Zn_{0.5}Fe_{1.9}Er_{0.1}O_4$ Ferrite/Polyaniline Nanocomposite. *R.N. Kambale*[1,2], A.K. Patel[3], S.K. Yadav[4], K. Suresh[3] and V.A. Bambole[1] *1. Department of Physics, University of Mumbai, Mumbai, India; 2. Department of Physics, KV IIT Powai, Mumbai, Mumbai, India; 3. Department of Physics, IIT Bombay, Mumbai, India; 4. Department of Physics, IIT Delhi, Delhi, India*

Er doped Ni-Zn ($Ni_{0.5}$ $Zn_{0.5}Fe_{1.9}Er_{0.1}O_4$) ferrite nanoparticles have been synthesized by sol- gel auto combustion technique and ferrite /polyaniline (PANI) nanocomposite was synthesized by in-situ polymerization. The structural and morphological properties of the prepared samples were characterized by X- ray diffraction (XRD), Field emission scanning electron microscopy (FEG-SEM), Field emission gun transmission electron microscopy (FEG-TEM) and magnetic properties of the samples at room temperature were studied by Vibrating Sample Magnetometer (VSM). X-ray patterns confirmed the formation of single phase cubic structure with space group Fd-3m. The crystallite size of synthesized ferrite nanoparticles are found to be in the range of 20-68 nm. The saturation magnetization was decreased by adding PANI in ferrite as shown in figure 1. The microwave absorbing properties of ferrite and ferrite/polyaniline composite was investigated using Vector Network Analyzer in the frequency range of 2GHz to 18GHz shown in figure 2. The minimum value of reflection loss was -18dB at the frequency of 10.64 GHz for $Ni_{0.5}$ $Zn_{0.5}Fe_{1.9}Er_{0.1}O_4$ ferrite nanoparticles (thickness 1.9mm) and -25.55dB at frequency of 14.8GHz for PANI/ $Ni_{0.5}$ $Zn_{0.5}Fe_{1.9}Er_{0.1}O_4$ ferrite nanocomposite (thickness 17.0mm). The microwave absorbing properties increase drastically and significant absorption frequency shifting in higher level by forming a nanocomposite with conducting polyaniline due to its high electric conductivity and controllable dielectric loss.

H1-09. Temperature Dependence of Magnetic Anisotropy Constant in Ferrimagnetic $ZnFe_2O_4$ Nanoparticles. *S. Yoon*[1] *1. Department of Physics, Gunsan National University, Gunsan, The Republic of Korea*

The temperature dependence of the effective magnetic anisotropy constant of ferrimagnetic $ZnFe_2O_4$ nanoparticles was studied based on the VSM and the SQUID magnetometry measurements [1]. First, the dependence of the blocking temperature upon the size of particle radius (inset of Fig. 2) was calculated by combining the particle size distribution and the anisotropy energy barrier distribution (Fig.1) obtained from temperature dependence of superparamagnetic fraction in the sample (inset of Fig. 1) and the magnetic thermal decay curve, respectively. Finally, the magnetic anisotropy constant at a temperature was computed from the r-T_B graph using the Néel-Arrhenius relation. The resultant effective magnetic anisotropy constant (Fig. 2) increased monotonically with lowering temperature from 0.2×10^4 (J/m^3) at 60 K to 11.3×10^4 (J/m^3) at 4.2 K.

H1-10. Formation of $Sm_3Fe_5O_{12}$ with controllable morphology by changing the addition of KOH. W. Shen[1], B. Ren[1] and *W. Wang*[1] *1. State Key Laboratory of Chemical Resource Engineering and School of Science, Beijing University of Chemical Technology, Beijing, China*

Rare-earth garnets with general formula $RE_3Fe_5O_{12}$ display excellent physical and chemical characteristics. It should be noted that the properties of rare-earth garnets are sensitive to their particle morphology. So, in this work, by changing the concentration of KOH of the raw materials, the tuning of structure, morphology and performance of $Sm_3Fe_5O_{12}$ is revealed so as to further find the new materials and expand their application field of garnets. Here, in the raw materials, different concentration of KOH is added to obtain different products. (1)Sample 1: when the concentration of KOH is 1.125g/ml, the product is pure $Sm_3Fe_5O_{12}$; (2)Sample 2: keep KOH concentration to 1.125g/ml, and add it to the solution by four times at 10 min interval, then $Sm_3Fe_5O_{12}/SmFeO_3$ composite is obtained; (3)Sample 3: If decreasing the KOH concentration to 0.275 g/ml, $SmFeO_3$ with small amount of impurity Fe_2O_3 is formed. Fig. 1a presents XRD patterns of the synthesized samples. For S1, obvious characteristic peaks of garnet structure can be observed. Whereas, in S2, XRD patterns show some other main diffraction peaks belonging to $SmFeO_3$, which implies the formation of $Sm_3Fe_5O_{12}/SmFeO_3$ composite. In S3, some weak peaks assigned to Fe_2O_3, and other main peaks are in correspondence to $SmFeO_3$, that is, S3 is $SmFeO_3$/ Fe_2O_3 composite. The sharp and strong XRD diffraction peaks imply good crystallization of the samples. Fig. 1b shows magnetic hysteresis loops of samples S1 and S2, and the insert is the loop of S3. The corresponding saturation magnetizations are 11.6, 7.8 and 0.3 emu/g, respectively. According to the formula $Ms=r_1M_{S1}+r_2M_{S2}+r_3M_{S3}$, where r_1, r_2 and r_3 are the volume of $Sm_3Fe_5O_{12}$, $SmFeO_3$ and Fe_2O_3. M_{S1}, M_{S2}, M_{S3} are saturation magnetization of $Sm_3Fe_5O_{12}$, $SmFeO_3$, Fe_2O_3, respectively. Due to weaker Ms of $SmFeO_3$ and

Fe_2O_3, $M_S(S1)>M_S(S2)>M_S(S3)$. Fig. 3 is TEM images of S1, S2 and S3. From Fig. 3a, S1 exhibits regular hexahedron. S2 appears the cube structure in Fig. 3b. Then, in Fig. 3c, a rod-like shape of S3 is shown. These confirm that the component and shape of garnet ferrites can be tuned by changing the addition method and concentration of KOH.

H1-11. Structural, magnetic and electrochemical activity of $Ti_{0.5}Ni_{0.5}Fe_2O_4$ nanoparticles synthesized by high energy ball milling. *N.S. Osman*[1] *1. Institute of Laser, Sudan University of Science and Technology, Khartoum, Sudan*

High energy ball milling technique was used to synthesize $Ti_{0.5}Ni_{0.5}Fe_2O_4$nanoparticles. The spinel phase structure was formed after short milling time of 1.5 hours. The phase formation was confirmed by X-ray diffraction measurements. William-son plot shows homogenous strain in the sample. The elemental composition was confirmed by energy dispersive X-ray and furtherbyinductively coupled plasma optical emission spectrometry. The morphology was studied by high-resolution transmission electron microscope and high-resolution scanning electron microscope. The results show mono-dispersive character of the synthesized sample. The magnetic properties were investigated by vibrating sample magnetometer and Mössbauer spectroscopy. The values of the saturation magnetization and coercive field are71.5±0.1 emu/g and 216±16 Oerespectively. The electrochemical sensing characteristic of the synthesized nanoparticles was investigated using cyclic voltammetry. The $Ti_{0.5}Ni_{0.5}Fe_2O_4$nanoparticles modified glassy carbon electrode ($Ti_{0.5}Ni_{0.5}Fe_2O_4$/GCE) displayed excellent electrocatalyticbehaviortowards potassium ferricyanide, a typical redox species as evidenced by a decrease in peak potential and a substantial increase in peak current. The $Ti_{0.5}Ni_{0.5}Fe_2O_4$ nanoparticles are thus envisaged to be novel and promising candidates for constructing electrochemical sensors with high performances.

H1-12. Ferromagnetism and Giant Paramagnetism of Copper Nanoparticles Coated by Carbon Shell. *A.N. Kocharian*[1], M. Estiphanos[1], O. Bernal[1], E. Sharoyan[2], A. Manukyan[2] and H. Gyulasaryan[2] *1. Physics and Astronomy, California State University. Los Angeles, Los Angeles, CA, United States; 2. Institute for Physical Research, National Academy of Sciences, Ashtarak, Ashtarak, Armenia*

Systematic XRD, STEM, EPR and PPMS measurements were performed for structural and magnetic properties in different sizes copper nanoparticles coated by carbon matrix using solid phase pyrolysis of polycrystalline phthalocyanine (CuPc, Pc= C32N8H16). The weight concentration in percentages of copper in obtaining samples consistently varies from 0 to 12 wt% and the sizes of copper nanoparticles vary from 2 nm to 500 nm. Samples containing 8 and 12 wt% Cu have a bimodal size distribution. Our results on magnetization carried out by vibrational magnetometer for average sizes of copper nanoparticles in range of 2-6 nm provide a strong evidence for coexistence of ferromagnetism and giant paramagnetism in wide range of temperature and magnetic field. At low temperatures we observed a giant paramagnetism, apparently due to the (ballistic) conduction electron (large orbital magnetism). The values of the specific susceptibility at T= 10K show a record high giant paramagnetism with magnetic specific susceptibility of $\approx 1.5\times10^{-4}$ emu/gOe order while ferromagnetic behavior with hysteresis is preserved up to the room temperature. This work was supported by the RA MES State Committee of Science, in the frames of the research project number 15T-1C249. The work at California State University was supported by the National Science Foundation-Partnerships for Research and Education in Materials under Grant DMR-1523588.

H1-13. Separation and identification of various diamagnetic and paramagnetic particles based on the variances of magnetization assigned to individual materials. *C. Uyeda*[1] *1. Osaka University, Graduate School of Science, Toyonaa, Japan*

In a recent report, ensemble of various weak magnetic (i.e. diamagnetic and paramagnetic) particles was separated into groups of different materials. As shown in Fig.1, separation proceeded as they translated in an area of monotonically decreasing field [1][2] ; field distribution was generated by a small Niobium magnet. The particles were composed of bismuth, diamond, enstatite, graphite, magnesia and olivine which had different χ values. The above separation (& identification) is possible because magnetization induced in a weak magnetic particle is a simple sum of magnetization assigned to single molecules and ions [3]. It was generally considered that a dynamical motion would not occur at a field intensity below several Tesla [4]. Conventional separators using superconducting magnets were successful in extracting weak magnetic particles by binding a magnetic bead to the particles [5]. The separation observed in the weak magnetic particles was first proposed according to the properties of their field-induced magnetization [3]; it is proportional to field intensity B, mass of particle m and intrinsic χ (per unit mass) of material. This means that acceleration of a particle is independent to m. Accordingly, particles that belong to the same material have same separation from their initial position; here particles are released at a same position [1]. The experimental χ values obtained from the field-induced velocities [1] nearly overlap with the range of published χ values compiled for many materials [6], indicating that the proposed principle of separation & identification is effective for existing solid materials. In the present report, validity of the proposed method is experimentally confirmed in volatile materials, namely ice Ih and solid CO_2, which is the major solid material in outer space. The possibility of improving the efficiency of the proposed method is discussed; in principle, the published χ values compiled in [6] could be distinguished by further technical improvements.

H2-01. First-principles calculations of Ru-substitution effect on magnetic anisotropy and Curie temperature in $L1_0$-type FePt alloys.
Y. Kota[1] *1. National Institute of Technology, Fukushima College, Iwaki, Japan*

Heat-assisted magnetic recording is a promising technology for further increase of the recording density of hard-disk drive. $L1_0$-type FePt is an important material as the recording media because of its strong magnetocrystalline anisotropy, however, the high Curie temperature (~750 K) leads to energy dissipation and serious damage by heating for writing operation. To solve this problem, Ono *et al.* reported that the Curie temperature of $L1_0$-type FePt thin film can be reduced by Ru-substitution while keeping the large magnetocrystalline anisotropy [1]. For the detailed analysis of the Ru-substitution effect, in this study, we perform first-principles calculations of the magnetocrystalline anisotropy energy and the effective exchange coupling constant [2,3], by using the tight-binding linear muffin-tin orbital method based on the local spin-density approximation. We consider the $L1_0$-type FePt ordered alloys where (a) a part of Fe is substituted by Ru, (b) a part of Pt is substituted by Ru, and (c) a part of Fe and Pt is substituted by Ru. To treat the substitutional disorder, the coherent potential approximation is employed. Figures 1 and 2, respectively, show the calculation results of the magnetocrystalline anisotropy energy (ΔE) and the effective exchange coupling constant (J_0) in $(Fe_{1-x}Ru_x)Pt$, $Fe(Pt_{1-x}Ru_x)$, and $(Fe_{1-0.5x}Ru_{0.5x})(Pt_{1-0.5x}Ru_{0.5x})$ for $x \leq 0.2$. By the Ru-substitution, ΔE and J_0 tend to be reduced. We found that in $Fe(Pt_{1-x}Ru_x)$ the J_0 value, which is directly related to the Curie temperature, decreases significantly, whereas the large ΔE is maintained. This fact reveals that substituting Ru for Pt in $L1_0$-type FePt is one of effective approaches to develop a material for heat-assisted magnetic recording media.

H2-02. Magnetocrystalline anisotropy and magnetic microstructures in the ferromagnetic phase of $Nd_{0.7}Sr_{0.3}MnO_3$.
Y. Fujibayashi[1], A. Kotani[1], K. Harada[2,1], Y. Ishii[1] and *S. Mori*[1] *1. Materials Sceince, Osaka Prefecture University, Osaka, Japan; 2. RIKEN, Wako, Japan*

In recent years, magnetic skyrmions and magnetic bubbles in the field of spintronics have attracted attention because they exhibit unconventional physical properties such as current-driven motions and unique Hall effects. Recently, we have investigated magnetic microstructures and their magnetic field responses of $La_{1-x}Sr_xMnO_3$ (x = 0.175) using Lorentz electron microscopy and small angle electron diffraction. It was found that the stripe-shaped magnetic domains in the orthorhombic structure (space group; *P*bnm) changes into magnetic bubbles by applying magnetic field in the [001] direction as shown in Fig. 1(a), where [001] is the easy axis of magnetization. In this study, we focused on $Nd_{1-x}Sr_xMnO_3$ with the orthorhombic ferromagnetic phase (space group; *P*bnm), and investigated the relationship between crystalline magnetic anisotropy and magnetic microstructures. The crystalline magnetic anisotropy in $Nd_{1-x}Sr_xMnO_3$ (x = 0.3) is 1.15×10^5 J / m^3 (100 K), and the magnetocrystalline anisotropy of $La_{1-x}Sr_xMnO_3$ (x = 0.175) is 1.52×10^5 J / m^3 (90 K) [2]. The observation with Lorentz microscopy revealed that elliptical magnetic nanodomains were formed in the ferromagnetic phase of $Nd_{1-x}Sr_xMnO_3$ (x = 0.3) by applying magnetic fields along the [001] direction, as shown in Fig. 1(b). In addition, we examined the relationship between crystalline magnetic anisotropy and magnetic microstructures in Al-doped $La_{1-x}Sr_xMnO_3$ (x = 0.175). In the presentation, we report the dependence of the magnetic microstructures on the crystalline magnetic anisotropy.

Brazilian Nanotechnology National Laboratory, Brazilian Center for Research in Energy and Materials, Campinas, Brazil*

Transition metal dichalcogenides (TMDs) [1] are layered materials composed by covalently bonded atoms in the basal plane and with weak van der Waals interactions coupling the layers. Some TMDs, such as molybdenum disulfide (MoS_2) has been extensively studied due to their unique transport and magnetic properties which are going to render them numerous potential applications in the field of spintronics [2] and storage data [3]. In this work we showed magnetic characterization of the bulk (M00) and few-layer (M01) MoS_2 samples produced by a simple method of exfoliation, applying ultrassonication in organic solvent. The samples were characterized by X-ray diffraction (XRD), transmission electronic microscopy (TEM), Raman spectroscopy and magnetization measurements using MPMS3 by Quantum Design. From Raman spectra we observe clear signals of the in-plane and out-of-plane vibration modes at 381.4 cm^{-1} and 406.1 cm^{-1} corresponding to the E_{2g} and A_{1g} modes, respectively, of the bulk MoS_2 with a close-packed hexagonal structure (2H-MoS_2) [4]. A decrease in the Raman bands frequency difference ($\Delta\omega$) was observed for the exfoliated sample in comparison to the bulk material, indicating a high degree of exfoliation, approximately 4 layers [5]. Magnetization measurements as a function of applied magnetic field were performed in different temperatures and directions of basal plane of sample M01 and we observed the sample M01 presents a high anisotropy. From a phenomenological model we calculated magnetic anisotropy constants of zero, first and second orders simultaneously and it was observed there is a strong dependence of these constants as function of temperature, in which the two-dimensional behavior of the sample was confirmed.

H2-04. Formation of A1 and $L1_0$ CoPt in CoPt/TiN films and the perpendicular magnetic coupling on glass substrate. *H. An*[1] *1. Keio University, Yokohama, Japan*

Heat-assisted magnetic recording (HAMR) media is expected to be the most promising recording media for the next generation of the high-density hard disk drives (HDDs). For the practical application, highly (001)-textured $L1_0$ FePt or CoPt films need to be deposited on glass substrate to obtain large perpendicular coercivity. At present, much effort has been put to optimize the structure of the films, besides which, some other obstacles also need to be overcome; for instance, the too large switching field distribution [1]. Previous studies [2,3] proposed an exchange coupled composite media to decrease the switching field, in which hard and soft magnetic phases are exchange coupled. The hard phase can keep high energy barrier and the soft phase can assist the switching of the hard phase at a lower external magnetic field. In this work, we study the magnetic properties of CoPt film by using TiN spacer layer deposited on glass substrate. After annealing at 700 °C in vacuum, a highly (001)-textured $L1_0$ CoPt has been obtained (as shown in Fig. 1). However, by increasing the annealing temperature to 800 °C, Al and $L1_0$ CoPt two magnetic phases are formed despite of the better crystallinity of CoPt than which annealed at 700 °C. By measuring the minor magnetic hysteresis loops of the samples, we further study the magnetic coupling between A1 and $L1_0$ CoPt phases in perpendicular direction of the films. Our work may provide a piece of information for other studies on HAMR.

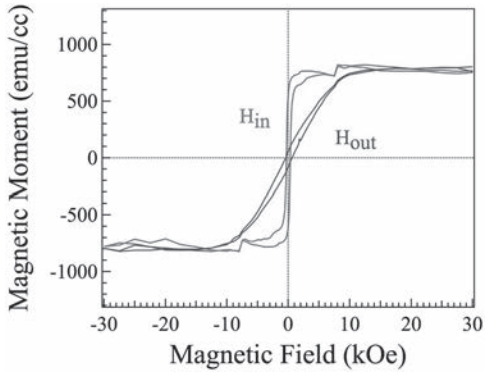
H2-05. Structural analysis of PLD grown $L1_0$-FeNi film. *M. Saito*[1], H. Ito[1], T. Mizushima[2], F. Komori[2], T. Koganezawa[3], M. Mizuguchi[4], K. Takanashi[5] and M. Kotsugi[1] *1. Faculty of Industrial Science and Technology, Tokyo Univesity of Science, Katsushika, Japan; 2. The Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan; 3. SPring-8, Japan Synchrotron Radiation Research Institute (JASRI), Sayo, Japan; 4. Tohoku University, Sendai, Japan; 5. Institute for Materials Research, Tohoku University, Sendai, Japan*



Magnetic thin films with large magnetic anisotropy (K_u) attract huge attention for realizing environmental friendly spintronics materials. $L1_0$-FeNi is a potential candidate because of large K_u and magnetization. Moreover, it consists of only ubiquitous elements[1]. Its artificial fabrication is currently progressing rapidly, and the relationship between growth conditions, K_u, and crystal structures is actively discussed[2]. We, here, focused on pulsed laser deposition (PLD) technique and investigated properties of films fabricated by PLD. An iron seed layer (1 nm) and an Au layer (20 nm) were deposited at 70 °C on MgO(100) substrate, and a Cu buffer layer (50 nm) was deposited at 300 °C. 50 ML of Fe/Ni was deposited by alternate monoatomic deposition. Substrate temperature (T_s) during deposition was varied from RT to 400 °C. The surface roughness and morphology were monitored by reflection high energy electron diffraction (RHEED) and observed by atomic force microscopy (AFM). X-ray diffraction with synchrotron radiation (SR-XRD) was used to analyze structural properties. Magnetic properties were estimated by superconducting quantum interference device (SQUID) magnetometer. Figure 1 shows diffraction patterns by SR-XRD. FeNi(110) superlattice peaks and FeNi(220) fundamental peaks were clearly observed for all films. $L1_0$-type ordered structure was successfully constructed in all sample. FeNi(110) peak shows maximum intensity at T_s = 300 °C. This temperature is responsible for the order-disorder transition temperature (320 °C) of Fe-Ni system. The atomically smooth surface was also confirmed in this sample by AFM. The result suggests that thermal treatment promotes layer-by-layer growth. Figure 2 shows magnetization curves for the sample

of T_s = 300 °C. Saturation magnetization (M_s) and K_u was estimated to be 800 emu/cc and 1.60 × 10^6 erg/cc, respectively. K_u increased with increasing order parameter S, and this is consistent with the previous study. It suggests that improvement of magnetic anisotropy is promoted by atomically flatness in terms of crystallographic structure and morphology.

H2-06. Controlled growth rate of Pt buffer layer promotes fcc (111) orientation of [CoFe/Pt]$_5$ multilayers allowing to tailor its anisotropy field. *L.E. Fernandez-Outon*[1,2], W.G. Schmidt[2], A.M. Fortini[1], M.D. Martins[2] and W. Macedo[2] *1. Departamento de Física, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 2. Centro de Desenvolvimento da Tecnologia Nuclear, Belo Horizonte, Brazil*

Materials with perpendicular magnetic anisotropy (PMA), in the form of superlattices, multilayers or patterned heterostructures are of interest due to their technological applications, such as spin-transfer-torque random access memories (STT-MRAM), current-induced magnetisation switching or domain wall motion based spintronic devices. PMA in thin films can be originated by magnetocrystalline anisotropy as in the case of $L1_0$ FePt superlattices. In multilayer structures of the type of Co(Fe)/Pt(Pd) it is found that PMA arises from interface anisotropy due to either electron hybridization, interface symmetry breaking, or magnetoelastic anisotropy due to interface strain [1]. In this work, we report the development of perpendicular magnetic anisotropy (PMA) in Pt/[$Co_{60}Fe_{40}$/Pt]$_5$ multilayer films and the behaviour of the anisotropy field. Samples were obtained by DC-sputtering with different growth rate (0.35 to 2.5Å/s) of the 4 nm-thick Pt buffer layer (BL). All other parameters were kept constant. X-ray reflectivity, X-ray diffraction, atomic force microscopy and transmission electron microscopy revealed similar interfacial roughness, thickness, and grain size in the samples studied. It was observed that highly crystallized atomically flat sublayers of CoFe/Pt (Fig. 1) enhance PMA, which suggest an interfacial nature. Same lattice relaxation between the buffer and the CoFe/Pt multilayer was observed in the samples studied. However, PMA is enhanced by magnetocrystalline anisotropy, as it is the formation of an ordered phase of PtCoFe, with fcc (111) orientation (Fig. 2), which regulates the anisotropy field in these multilayer systems (inset Fig.2). An optimum growth rate (~0.7Å/s) of the Pt BL is obtained, which allows enhancing the fcc (111) texture of the alloy-like Pt/CoFe multilayer.

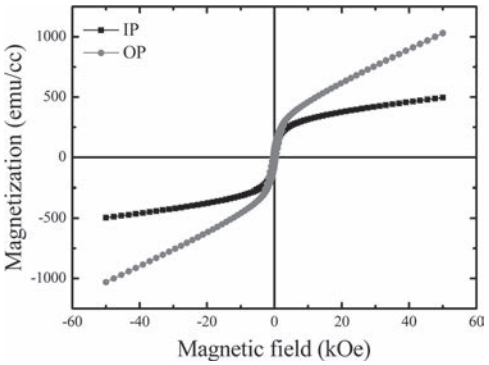
H2-08. Evolution of the interfacial perpendicular magnetic anisotropy constant of the Co_2FeAl/MgO interface upon annealing. *A. Conca*[1], A. Niesen[2], G. Reiss[3] and B. Hillebrands[1] *1. Physics, TU Kaiserslautern, Kaiserslautern, Germany; 2. Physics Department, Bielefeld University, Bielefeld, Germany; 3. Center for Spinelectronic Materials and Devices, Physics Department, Bielefeld University, Bielefeld, Germany*

For the PMA properties of thin Heusler films, the interface-induced perpendicular anisotropy plays a critical role and its strength is given by the value



of the perpendicular interfacial anisotropy constant K_S. The interfacial properties and the value of the constant, are strongly modified by the exact conditions of the annealing treatment for the stack, which is required to improve the crystalline order of the Heusler films [1, 2, 3] and to achieve large TMR values [4]. We investigate a series of films with different thickness of the Heusler alloy Co_2FeAl in order to study the effect of annealing on the interface with a MgO layer and on the bulk magnetic properties. Our results reveal that while the perpendicular interface anisotropy constant K_S is zero for the as-deposited samples, its value increases with annealing up to a value of 1.14 ± 0.07 mJ/m^2 for the series annealed at 320°C and of 2.0 ± 0.7 mJ/m^2 for the 450°C annealed series owing to a strong modification of the interface during the thermal treatment. This large value ensures a stabilization of a perpendicular magnetization orientation for a thickness below 1.7 nm. The data additionally shows that the in-plane biaxial anisotropy constant has a different evolution with thickness in as-deposited and annealed systems. The Gilbert damping parameter α shows minima for all series for a thickness of 40 nm and an absolute minimum value of $2.8 \pm 0.1 \times 10^{-3}$. The thickness dependence is explained in terms of an inhomogeneous magnetization state generated by the interplay between the different anisotropies of the system and by the crystalline disorder. Since the in-plane anisotropies and the Gilbert damping parameter change with varying thickness and annealing temperature, also their evolution is reported. For comparison reasons we present also measurements of K_S for the CoFeB/MgO interface and for the systems with a Co_2FeAl/Ta interface. The relevance of the study is not limited to Co_2FeAl but it is a model for all TMR systems with Co-based Heusler alloys and an interface with a MgO tunneling barrier. Financial support by M-era. Net through the HEUMEM project is gratefully acknowledged.

H2-09. Magnetic anisotropy and ferromagnetic resonance in nitrogen-incorporated $NiFe_2O_4$ thin films. A. K B[1], U. Kodam[2], S. A[1] and *G. Markandeyulu[1] 1. Physics, Indian Institute of Technology, Chennai, India; 2. Jabalpur Engineering College, Jabalpur, India*

Nitrogen incorporated nickel ferrite (N-NFO) thin films deposited by RF magnetron sputtering were found to exhibit interesting magnetic properties upon heat-treatment. The magnetizations with the magnetic field in-plane (IP) and out-of-plane (OP) of the heat-treated N-NFO thin films measured at 20 K and 300 K were seen not to saturate, indicating a large perpendicular magnetic anisotropy (PMA) [1,2]. The coercive field (H_c) value was found to decrease (3900 Oe to 400 Oe) upon heat-treatment, due to the weakened pinning of domain walls upon decrease of grain boundary volume [3]. The IP and OP magnetizations of 1000°C-heat-treated film (100 W) measured at 300 K are compared in Fig.1. The IP magnetization exhibits a tendency to saturate at high fields whereas the OP magnetization does not, indicating the existence of easy magnetization direction (EMD) in the plane of the film [1,2]. The room temperature ferromagnetic resonance (FMR) spectra were recorded in both IP and OP configurations (shown in Fig.2). The existence of EMD in the plane of the film was confirmed by comparing the FMR spectra recorded in the two configurations. The spectra indicated increase of FMR line width upon nitrogenation: 500 Oe in NFO and 830 Oe in N-NFO deposited at 100 W in the IP configuration, while the corresponding values in the OP configuration were 470 Oe and 870 Oe. This reveals the increase of magnetic anisotropy induced by nitrogen in the lattice [2,4]. An increase in the resonance field (H_r) value (2160 Oe) was observed for the N-NFO film grown at 100 W, compared to that of NFO (2080 Oe) in the IP configuration, while a decrease in the value was observed for OP (4510 Oe of NFO and 3220 Oe of N-NFO), which can be attributed to an enhanced in-plane magnetic anisotropy [4,5]. The films grown at 120 W and 140 W showed decrease in H_r value in IP configuration and increase in OP, which is attributed to the increase in thickness-dependent PMA [4,5].

Scientific Research Division, National Synchrotron Radiation Research Center, Hsinchu, Taiwan*

Antiferromagnetic (AFM) thin film is recently proposed to be an alternative to conventional materials for achieving a better control of perpendicular magnetic anisotropy (PMA) in ferromagnetic (FM) thin films [1-3]. Considering the potential application for the high density magnetic device, however, the magnetic ordering temperature of AFM film would be unavoidably decreased when the size or thickness is reduced, according to the finite size effects. This would therefore limit its supportability to the PMA of the FM films. Here, by means of the *in-situ* measurements including low energy electorn diffraction, magneto-optical Kerr effects, and element-resolved x-ray photoemission electron microscropy, this work determined that the antiferromagnet-induced PMA occurred in magnetic thin films can be effectively supported by applying an ultrathin in-plane magnetic layer through mechanism of magnetic proximity effects at room temperature. This finding suggests a possibility of promoting the thermal stability of a low dimensional antiferromagnet, ensuring its antiferromagnetism to sustain at the higher temperature. In detail, in a series of the 12 ML Ni/2 ML Co/Mn/Co/Cu(001) films as presented in Figure 1, the PMA of top 12 ML Ni/Co films as well as the strength of long-range AFM ordering of the Mn film was found to be significantly enhanced upon an establishment of the FM ordering of the bottom in-plane magnetic Co film. This clearly demonstrates a mechanism

of the magnetic proximity effects behind. Moreover, we also revealed that the bottom Co film can modulate the perpendicular magnetization of top 12 ML Ni/Co film through the exchange spring-like direct exchange coupling.

Universidad Autonoma de Madrid & IMDEA Nanoscience, Madrid, Spain*

A major challenge for future spintronics is to develop suitable spin transport channels with superior properties such as long spin lifetime and propagation length. Graphene can meet these requirements, even at room temperature [1]. However, the development of all-graphene spintronic devices requires that, in addition to its passive capability to transmit spins over long distances, other active properties are incorporated to graphene. The generation of long range magnetic order and spin filtering in graphene have been recently achieved by molecular functionalization [2,3] as well as by the introduction of giant spin-orbit coupling (SOC) in the electronic bands of graphene [4]. On the other side, taking advantage of the fast motion of perpendicular magnetic anisotropy (PMA) chiral spin textures, i.e., Néel-type domain walls (DWs) and magnetic skyrmions, can satisfy the demands for high-density data storage, low power consumption and high processing speed [5]. Here, we report on high quality, epitaxial graphene/Co(111)/Pt(111) stacks grown on MgO(111) crystals, characterized by STM, LEED, STEM, Kerr Magnetometry, XMCD and Kerr Microscopy, that exhibit enhanced PMA for Co layers up to 4 nm thick and left-handed Néel-type chiral DWs stabilized by interfacial Dzyaloshinskii–Moriya interaction (DMI) localized at both graphene/Co and Co/Pt interfaces with opposite sign [6]. While the DMI at Co/Pt side is due to the intrinsic SOC, the sizeable DMI experimentally found at the gr/Co interface has Rashba origin [6]. The active magnetic texture is protected by the graphene monolayer and stable at 300 K in air, and, since it is grown on an insulating substrate, amenable to transport measurements.

The prototypical quasi-one-dimensional (Q1D) compound $Ca_3Co_2O_6$ belongs to the *R*-3*c* space group and its rhombohedral structure consists of one-dimensional Co-O chains along the c-axis separated by the Ca ions. The Q1D cobalt oxides are one of the more intriguing groups of compounds. They display extremely complex magnetic behaviour due to the competition between 1D intrachain ferromagnetic (FM) and 2D interchain antiferromagnetic (AF) interactions. In combination with the fact that the chains form a triangular lattice in the ab-plane, yields a very intriguing 1D-system with geometrical frustration and strong uniaxial anisotropy. This compound has been investigated by many different experimental techniques but there are still a large number of unresolved issues. For instance, it is expected that a long-range (LR) 1D- FM order should exist for T = 100-150 K. In this work we present a combination of ZF and high-TF m^+SR measurements [1], together with a magnetization and neutron scattering investigation. Our μ^+SR Knight-shift measurements clearly show an anomaly at T = 140 K that can be connected to the onset of a LR 1D-FM order. Further, we propose that in the low-temperature regime, a competing Q1D ferrimagnetic order co-exist within a LR AF phase, which has been confirmed by recent neutron scattering studies [2]. This research is funded by Swedish Foundation for Strategic Research (SSF) within the Swedish national graduate school in neutron scattering (SwedNess) and the Swedish Research Council (VR) through a neutron project grant (BIFROST, Dnr. 2016-06955) as well as a Starting Grant (Dnr. 2017-05078).

H3-02. Magnetic Behavior of Quasi-One-dimensional Frustrated Quantum spin systems $(Rb,Cs)_2Cu_2Mo_3O_{12}$. *Y. Yasui*[1], S. Iguchi[1], S. Nakamura[2], Y. Kono[2], S. Kittaka[2] and T. Sakakibara[2] *1. Physics, Meiji University, Kawasaki, Japan; 2. The Institute for Solid State Physics, The University of Tokyo, Chiba, Japan*

We report the magnetic behavior of the quasi-one-dimensional frustrated quantum spin system $Rb_xCs_{2-x}Cu_2Mo_3O_{12}$, which are formed of edge-sharing CuO_4 square planes called as CuO_2 ribbon chains. The spin system with the CuO_2 ribbon chain attracts much attention, because the competition between the nearest -neighbor exchange interaction J_1 and the second neighbor interaction J_2 often induce the anomalous physical properties and exotic quantum states. Authors' group has investigated the magnetic and dielectric properties of the CuO_2 ribbon chain systems $A_2Cu_2Mo_3O_{12}$ (A=Rb and Cs) [1-3]. The ground states of $A_2Cu_2Mo_3O_{12}$ (A=Rb and Cs) have been found to be different from each other: The ground state of $Rb_2Cu_2Mo_3O_{12}$ is a non-magnetic state, and that of $Cs_2Cu_2Mo_3O_{12}$ is antiferromagnetic long-range-order state at transition temperature T_N = 1.85 K [2-3]. In this study, we have controlled the magnetic properties and magnetic ground state from an antiferromagnetic order to a nonmagnetic state by making a solid solution system $Rb_xCs_{2-x}Cu_2Mo_3O_{12}$. The magnetic susceptibility and specific heat measurements have been carried out for the various samples with $0<x<2$ in the temperature (T) region $0.3K<T<300K$ up to 9T. As results of the specific heat measurements, we have found that $Rb_{1.5}Cs_{0.5}Cu_2Mo_3O_{12}$ exhibits an antiferromagnetic transition at T_N = 0.46 K. In the magnetic field (H), the spin system has maximum transition temperature T_N = 1.29 K at H=6T. On the other hand, the ground state of $Rb_{1.8}Cs_{0.2}Cu_2Mo_3O_{12}$ and $Rb_{1.9}Cs_{0.1}Cu_2Mo_3O_{12}$ is found to be a non-magnetic state. We present the various experimental data of the solid solution system $Rb_xCs_{2-x}Cu_2Mo_3O_{12}$ with samples of $0 < x < 2$. The magnetic properties and ground states of the solid solution system $Rb_xCs_{2-x}Cu_2Mo_3O_{12}$ are also discussed.

H3-03. Magnetic Field Induced z=2 Quantum Phase Transitions in Spin Chain and Spin Ladder Compounds. *D. Blosser*[2], N. Kestin[1], K. Povarov[2], R. Bewley[3], E. Coira[1], T. Giamarchi[1] and A. Zheludev[2]
1. Department of Quantum Matter Physics, University of Geneva, Geneva, Switzerland; 2. Laboratory for Solid State Physics, ETH Zurich, Zurich, Switzerland; 3. ISIS Facility, Rutherford Appleton Laboratory, Chilton, Didcot, United Kingdom

We study magnetic field induced quantum phase transitions with dynamical exponent z=2 in quasi-one-dimensional spin chain and spin ladder compounds. While in three dimensions such transitions are well understood as a Bose-Einstein condensation of magnons [1], in one dimension a unique 'zero-scale-factor universality' has been predicted [2]. In the S=1/2 Heisenberg spin chain compound $K_2CuSO_4Cl_2$, by means of high-resolution inelastic neutron scattering we have measured the full spin excitation spectrum at saturation at several different temperatures (figure) [3]. On the one hand we find critical correlations characteristic of the z=2, d=1 quantum critical point. At the same time we find a novel thermally activated longitudinal mode that remains underdamped across most of the Brillouin zone. Using finite temperature density matrix renormalization group (DMRG) calculations we can quantitatively explain the experimental data and identify the various modes that were experimentally observed. In the well characterized strong rung quantum spin ladder compound Bis(Piperidinium)-Tetrabromocuprate(II) (BPCB) the same magnetic field induced z=2, d=1 quantum critical point occurs at the critical magnetic field where the spin gap is closed by the Zeeman interaction and triplet excitations condense. Measurements of various quantities such as specific heat and magnetization allow us to extract critical exponents characteristic of the z=2, d=1 quantum critical point. At some distance from the quantum critical point, however, we find strong deviations from the predicted universal behavior. This allows us to precisely determine the range where the nature of the quantum

critical point universally determines the physical behavior and to characterize non-universal behavior that dominates further away from the quantum critical point.

Spin excitation spectra at the field of saturation measured in the Heisenberg spin chain compound $K_2CuSO_4Cl_2$

H3-04. Magnetism in the frustrated spin-chain compound Sr_3NiIrO_6 studied by muon-spin spectroscopy. *J. Barker*[1], D. Adroja[2], J. Sannigrahi[2], A. Hillier[2] and E. Sampathkumaran[3] *1. Laboratory for muon-spin spectroscopy, Paul Scherrer Institut, Villigen-PSI, Switzerland; 2. ISIS neutron and muon facility, Rutherford Appleton Laboratory, STFC, Harwell Campus, Didcot, Oxfordshire, United Kingdom; 3. Tata Institute of Fundamental Research, Mumbai, India*

The Ising-like spin-chain material Sr_3NiIrO_6 is a member of a family of oxides that have attracted much attention, as they exhibit a wide variety of unconventional magnetic properties. The structure consists of alternating IrO_6 distorted octahedra and NiO_6 trigonal prisms arranged in chains along the *c*-axis, with Sr spacers dispersed between the chains. A complicated magnetic structure arises as a result of the interplay between low-dimensionality, magnetic frustration, and magneto-crystalline anisotropy. We have performed muon-spin spectroscopy measurements on a polycrystalline sample of Sr_3NiIrO_6, as a complement to neutron measurements of this material [1]. By analyzing the internal fields experienced by implanted muons (see Fig. 1), we show that this system appears to have two distinct regions in the magnetic phase diagram: a frozen regime below about 40 K, and a highly dynamic region between 40 and 70 K. We compare our results to those from the neutron study, and attempt to find a description of this system that satisfies all experimental observations to date.

Graduate School of Material Science, University of Hyogo, Ako, Japan*

We study the spin-1/2 two-leg ladder system in which the exchange interaction in the rungs, J_r, is ferromagnetic, while the exchange interactions along the two legs, J_a and J_b, are different from each other. We are particularly interested in the case of J_a J_b < 0, where the system has the frustration and may exhibit exotic ground states. Using the numerical exact-diagonalization and density-matrix renormalization-group methods, and also the analytical perturbation approach, we determine the ground-state phase diagram mainly for the strong rung-coupling regime, |J_r| >> |J_a|, |J_b|, as functions of exchange-coupling constants and exchange-anisotropy parameters. We have found that in addition to the ferromagnetic and ferrimagnetic phases, the model exhibits several phases including (i) the Neel phase with magnetic long-range order (LRO) of the Neel type, (ii) the Haldane phase with a finite excitation gap above the spin-singlet ground state, (iii) a (conventional) Tomonaga-Luttinger liquid (TLL) phase in which both the longitudinal and transverse spin correlation functions exhibit quasi-LRO, and (iv) the nematic-TLL phase characterized by formation of two-magnon bound states, quasi-LROs of longitudinal-spin and nematic correlations, and short-ranged transverse-spin correlation. The phase boundaries are determined by the level-spectroscopy and phenomenological renormalization-group analyses, and the characteristics of each phase are confirmed by monitoring asymptotic behaviors of the correlation functions. The structure of the phase diagram is well understood by mapping the present ladder system with strong ferromagnetic rung interaction to the effective spin-1 chain with uniaxial anisotropy.

H3-06. Magnetic Response of NBCT, an S = 1 Antiferromagnetic Chain near the D/J Quantum Critical Point. D. Pajerowski[2], A. Podlesnyak[2], N. Patel[3], J. Herbrych[3], J. Singleton[5], L. Engelhardt[5], S. Lapidus[6], A. Garcia[7], S. Brown[7], J.L. Manson[8], M. Peprah[1], P. Quintero[1], J. Xia[1,4], J. Perez[1], P. Edwards[1], J.M. Cain[1] and *M.W. Meisel*[1,4] *1. Intriguing structural, low temperature, and high magnetic field properties of $[Ni(HF_2)(3\text{-}Clpy)_4]BF_4$ (py = pyridine), or NBCT, suggest this $S = 1$ chain system is close to the $D/J \gg 1$ quantum critical point with easy-plane anisotropy $D = 4.3$ K, intrachain antiferromagnetic interaction $J = 4.86$ K, and no evidence of long-range order down to 25 mK. A study of the magnetization ($50\ \text{mK} \leq T \leq 1$ K) placed an upper bound on the critical field, associated with a possible gap, of (35 ± 10) mT [2]. Now, inelastic powder neutron scattering data have been acquired down to 300 mK in zero field, and these results are compared with numerical results obtained by density matrix renormalization group theory. The data and analysis constrain the Hamiltonian and the parameters used to describe spin excitations. The temperature dependence ($T > 2$ K) of the low field, $B = 0.1$ T, susceptibility has been studied as a function of pressure up to 1.4 GPa. These data are contrasted with PXRD studies made with applied pressure. These data sets provide insight about potential pressure tuning of the D/J ratio through the quantum critical regime. Two types of magnetic excitations exist in an ordered state. They are gapless transverse (T)-mode (Nambu-Goldstone mode) and gapped longitudinal (L)-mode (amplitude Higgs mode) excitations corresponding to fluctuations in directions perpendicular and parallel to ordered magnetic moments, respectively. The T-mode excitations are well known as spin wave excitations. The L-mode excitation has weak intensity and spontaneously decays into a pair of T-mode excitations. However, the L-mode excitation can be well-defined in the ordered state in the vicinity of the quantum critical point. The L-mode excitations were actually observed in a pressure-induced or magnetic-field-induced ordered state of interacting antiferromagnetic (AF) spin-1/2 dimer compounds $TlCuCl_3$ and $KCuCl_3$. The L-mode excitations may be also observed in an ordered state appearing on cooling at atmospheric pressure and zero magnetic field in interacting spin-cluster compounds [1]. We can expect spin-1 tetramers in $Rb_2Ni_2Mo_3O_{12}$. The Hamiltonian is $J_1S_2S_3+J_2(S_1S_2+S_3S_4)$. We investigated its magnetism using powder samples. The magnetic susceptibility shows a broad maximum around 16 K and decreases rapidly at low T as shown in Fig. 1 [2]. The magnetization at 1.3 K increases monotonically without magnetization plateaus and is saturated around 45 T. The isolated spin-1 AF tetramer model with $J_1 = 9$ K and $J_2 = 18$ K (Cal 1) can closely reproduce the experimental susceptibility. We were able to explain the magnetization curves at various temperatures using the interacting spin-1 tetramer model with the effective intertetramer interaction $J_{eff} = 4$ K (Cal 2). We can see a peak in the temperature dependence of the specific heat above 3 T, indicating a phase transition to a magnetically ordered state. As shown in Fig. 2, the transition temperature TN(H) increases with H. From the H dependence of TN(H), probably, the ordered state appears around 1.8 K even in 0 T. The ordered state in 0 T, however, is not stable enough like an order in the vicinity of a quantum critical point.

Laboratory for Solid State Physics, ETH Zurich, Zurich, Switzerland

We have studied relaxation in spin ladder magnet called DIMPY $(C_7H_{10}N)_2Cu_{(1-x)}Zn_xBr_4$. DIMPY is unique compound described by strong-leg spin ladder model (J_{leg}=1.42 meV, J_{rung}=0.82 meV, Δ=0.33 meV) [1]. Non-magnetic Zn doping in DIMPY results in the formation of "spin islands" near dopant [2]. "Spin island" is a cluster of spins which are bonded antiferromagnetically. Such clusters are strongly correlated because of strong interaction along the leg of the spin ladder and their interaction leads to local suppression of spin liquid state. The earlier study of pure DIMPY revealed the presence of uniform Dzyaloshinskii-Moriya interaction, causing zero-field splitting of triplet states and affecting spin relaxation [3]. Because of the gap, ESR absorption signal in pure DIMPY is freezing out on cooling. In doped DIMPY ESR signal follows the same route above 4K, but does not vanish at low temperatures down to 450 mK. Thus, we could highlight two regimes of spin dynamics in doped DIMPY: triplets-dominated (T>appr.4 K) and clusters-dominated (T<appr.1 K). Temperature evolution of ESR linewidth was studied through both regimes for different doping levels. Scaled angular dependencies in the triplets-dominated regime for different concentrations of Zn (x=0-6%) are the same, it means that type of the relaxation also is the same. However, we observed narrowing of ESR line (i. e. increase of spin excitations lifetime) in both regimes. The decrease of ESR linewidth in triplets-dominated regime indicates suppression of some relaxation channels with doping. Tentatively this can be interpreted as a reduction of mean DM vector length. The decrease of ESR linewidth in clusters-dominated regime indicates clusters interaction and increasing of the lifetime of the triplets excitations. Work was supported by RSF grant No 17-12-01505 and also by Program of fundamental studies of HSE.

H3-09. Revisiting of Sliding density wave in incommensurate spin-ladder $Sr_{14}Cu_{24}O_{41}$. *R. Bag*[1] and S. Singh[1] *1. Physics, Indian Institute of Science Education and Research, Pune, India*

Low-dimensional quantum magnets are well-known to show intriguing properties not present in their higher-dimensional analogues. $Sr_{14}Cu_{24}O_{41}$ is a hybrid chain-ladder system that shows rich phenomena of quantum magnetism and has been well studied in the past [1]. It has an incommensurate structure because of which it has been conjectured that this system shows a gap sliding motion [2] between the mutually incommensurate chain and ladder planes. Very recently, this sliding motion has also been observed in the inelastic neutron scattering [3]. In such incommensurate structure the excess vibrational degrees of freedom, such as the sliding density wave in $Sr_{14}Cu_{24}O_{41}$, is expected to give rise to an excess specific heat contribution at the low temperatures, which is also referred to as the Boson peak in the glassy materials [4]. Here, we have performed the specific heat measurement on the high-quality single crystals of $Sr_{14}Cu_{24}O_{41}$, grown in optical floating zone furnace [5]. We show a clear presence of the excess specific heat deviated from the Debye law (~T^3) near 10 K. By doping impurities in the chain/ladder planes the excess specific heat diminishes suggesting that the impurities strongly pin the sliding density wave in agreement with the theoretical prediction [6].

H3-10. Phase Diagrams of Heisenberg Chains with Extra Three-Spin Exchange Terms. *N.B. Ivanov*[1,2] *1. Theoretical Department, Institute of Solid State Physics, Sofia, Bulgaria; 2. Fakultaet fuer Physik, Universitaet Bielefeld, Bielefeld, Germany*

Based on extensive density-matrix renormalization group and exact-diagonalization numerical calculations, we establish the quantum phase diagrams of different mixed-spin Heisenberg chains containing extra frustrating exchange terms related to three-site exchange processes. In particular, we consider Heisenberg chains with two kinds of site spins (S_1 and S_2 in the elementary cell, where (S_1,S_2) = (1,1/2) and (3/2,1/2). These two systems define simple but realistic prototype models admitting extra three-body exchange terms, and exhibit completely different phase diagrams due to different values of the cell spin S_1+S_2 in both models [1-4].

H4-01. Effect of Fe-B layer on Microstructure and Magnetic Properties of Exchange Coupled Nd-Fe-B/Mo/Fe-B Nanocomposite Multilayer Films. *K. Ohashi*[1], K. Koike[1], T. Suzuki[1], N. Inaba[2], H. Kato[1], M. Kondo[3], M. Itakura[3] and M. Nishida[3] *1. Graduate School of Science and Engineering, Yamagata University, Yonezawa, Japan; 2. Department of Electrical Engineering, Yamagata University, Yonezawa, Japan; 3. Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasuga, Japan*

The exchange coupled hard/soft nanocomposite magnet is expected to have a huge maximum energy product $(BH)_{max}$ [1]. However, reported experimental $(BH)_{max}$ values of $Nd_2Fe_{14}B/\alpha$-Fe system are not exceeded alone. Recently, Toga *et al*. pointed out that the presence of a negative exchange coupling constant J_{ex} value at the $Nd_2Fe_{14}B(100)/\alpha$-Fe(110) interface is the cause of magnetization reduction by the first principle calculation [2]. We confirmed the negative and positive constants J_{ex} at the $Nd_2Fe_{14}B/\alpha$-Fe interfaces with different crystal orientation [3, 4]. We also reported the appearance of perpendicular magnetic anisotropy in the $Nd_2Fe_{14}B$/Mo/α-Fe multilayer films annealed at 700°C [5]. In this study, we report the effect of Fe-B soft magnetic layer on the microstructure and magnetic propeties of Nd-Fe-B/Mo/Fe-B multilayer films. The multilayer films were deposited on an MgO(001) substrate heated at T_s = 300°C using UHV sputtering. The form of films is Mo(20 nm)/[Nd-Fe-B(30 nm)/Mo(0, 1 nm)/Fe-B(5 nm)/Mo(0, 1 nm)]$_5$/Mo(10 nm). UHV annealing was carried out in the range of 400°C to 750°C. The Nd-Fe-B/Fe-B multilayer films annealed at 750°C showed soft magnetic property, while the annealed Nd-Fe-B/Mo/Fe-B multilayer films exhibited hard magnetic property with weak perpendicular magnetic anisotropy. The steep slope of the FORCs and a positive peak of Δ*M* plot of out-of-plane direction of annealed Nd-Fe-B/Mo/Fe-B multilayer film are shown as Fig. 1 and Fig. 2, respectively. These results indicate existence of positive exchange coupling interaction between the Nd-Fe-B and Fe-B layers. It was confirmed by cross-sectional TEM observation and EDS analysis that the existence of the $Nd_2Fe_{14}B$, and α-Fe, and Fe-based amorphous alloy phases and the disappearance of a part of Mo interlayer in the annealed Nd-Fe-B/Mo/Fe-B multilayer film. Therefore, these results are suggested that the exchange coupling occurred by partial direct contact between the $Nd_2Fe_{14}B$ and the Fe–B layers at the Nd-Fe-B/Mo/Fe-B interfaces.

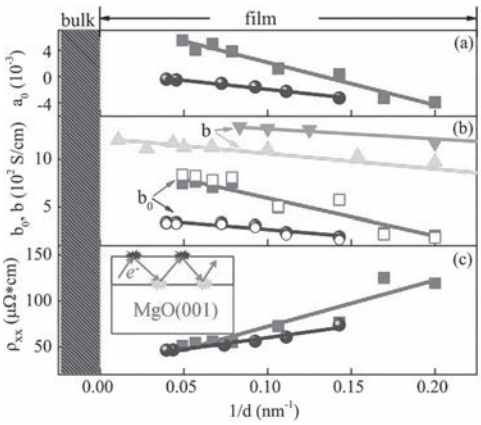
H4-02. Epitaxial $Fe_{16}N_2$ Thin Film on Nonmagnetic Seed Layer. *X. Hang*[1], X. Zhang[2], B. Ma[2], V. Lauter[3] and J. Wang[2,1] *1. Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, MN, United States; 2. Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States; 3. NSSD, Oak Ridge National Laboratory, Oak Ridge, TN, United States*

$Fe_{16}N_2$ has attracted much interest as a candidate for rare-earth-free hard magnetic materials. However, the study of its magnetic properties, including its saturation magnetization (M_s), has been greatly hindered by difficulties of materials synthesis. In thin film studies a layer of Fe was commonly used as seed layer to support the growth of $Fe_{16}N_2$, adding complexity to extracting the intrinsic magnetism of $Fe_{16}N_2$. Here we demonstrate that $Fe_{16}N_2$ thin films were grown epitaxially on a nonmagnetic Cr seed layer with MgO

(001) substrates by facing-target sputtering. Lattice constants calculation shows that no noticeable strain can be assigned to $Fe_{16}N_2$. In addition, the as-obtained $Fe_{16}N_2$ film has high phase purity and good crystallinity. The order parameter, which quantifies the degree of N ordering in $Fe_{16}N_2$ (the N-disordered phase is α'-Fe_8N martensite) reaches 0.75 for Cr-seeded samples. The XRD results show that the $Fe_{16}N_2$ film is textured in all three directions with epitaxial relation MgO (001)[110] || Cr (001)[100] || $Fe_{16}N_2$ (001)[100]. The intrinsic M_s of this non-strained $Fe_{16}N_2$ thin film at room temperature is determined to be 2.31 T by polarized neutron reflectometry (PNR) and confirmed with VSM. The out-of-plane M-H loop of Cr-seeded $Fe_{16}N_2$ film shows an interesting easy-axis switching behavior, the magnitude being 2% - 4% of the total magnetic moment. This perpendicularly magnetized component (PMC) is probably caused by some interface. Further investigations on the thickness and seed layer dependence are being carried out to find the origin of this PMC.

(a) Experimental and fitted polarized neutron reflectivity as a function of wave vector transfer for spin up and spin down. The corresponding neutron scattering length density (SLD) depth profiles are shown in (b). The increased NSLD on the bottom $Fe_{16}N_2$/Cr interface is enriched with N, the top interface of 3.2 nm corresponds to a mixed Cr/$Fe_{16}N_2$ layer with a slightly reduced magnetization. Sample structure: MgO/Cr(10.2 nm)/$Fe_{16}N_2$(26.7)/Cr(10.2).

M-H loops of MgO/Cr(10.2 nm)/$Fe_{16}N_2$(26.7)/Cr(10.2) sample, with the field applied both in-plan (dashed) and along film normal (sloid). The switching in the out-of-plane loop is indicated by red arrows.



H4-03. Magnetic anisotropy of α″-$Fe_{16}N_2$ for potential rare earth free permanent magnet: Impurity doping and multilayer. I. Khan[1] and *J. Hong[1] 1. Physics, Pukyong National University, Busan, The Republic of Korea*

Using the first principles method, we investigated the electronic structure and magnetocrystalline anisotropy of α″-$Fe_{16}N_2$ systems. To tune the magnetic anisotropy, we considered impurity doped and multilayer systems. The impurity doping induced local lattice distortions near the impurity site. Nonetheless, the volume of the cell and total magnetic moment of the doped systems were not much affected. The substitutional heavy 4d, 5d elements were found to be more helpful for the enhancement of magnetocrystalline anisotropy than interstitial doping of 2s and 2p elements. The enhancement of the magnetocrystalline anisotropy results in almost 15 to 67 % enhancement of the coercivity for 4d element doping while we found 80 to 137 % enhancement for 5d element doping. The maximum energy products were also enhanced compared to the pure α″-$Fe_{16}N_2$. The maximum enhancement was observed in Rh and Pt doped systems where the energy products were 119 to 120 MGOe. In multilayer system, we studied two systems, (i.e) α″-$Fe_{16}N_2$/Ag/ α″-$Fe_{16}N_2$ and α″-$Fe_{16}N_2$/Au/ α″-$Fe_{16}N_2$. Here, the magnetocrystalline anisotropy constant was enhanced from 0.57 MJ/m^3 in pure $Fe_{16}N_2$ to 1.58 MJ/m^3 and 0.89 MJ/m^3 in $Fe_{16}N_2$/Ag/$Fe_{16}N_2$ and $Fe_{16}N_2$/Au/$Fe_{16}N_2$ multilayer systems. This enhancement in magnetocrystalline anisotropy results in the enhancement of the coercive field. The coercive fields were about 30 and 16.7 kOe in Ag and Au multilayer systems. Overall, we suggest that the α″-$Fe_{16}N_2$ can be a potential candidate for rare earth free permanent magnet by proper treatment.

H4-04. Clear evidence of interfacial anomalous Hall effect in epitaxial $L1_0$ FePt and FePd films. S. Xu[1], *Z. Shi*[1] and S. Zhou[1] *1. School of Physics, Tongji University, Shanghai, China*

Anomalous Hall effect in epitaxially grown $L1_0$ -ordered FePd and FePt films on MgO(001) has been investigated as a function of the film thickness (*d*). It is found that the anomalous Hall resistivity can be described by conventional scaling law, i.e., $\rho_{AH} = a\rho_{xx} + b\rho_{xx}^2$ with longitudinal resistivity ρ_{xx}. It is interesting to find that both *a* and *b* parameters approximately change as a linear function of the inverse film thickness. The linear 1/*d* dependencies can be attributed to the symmetry breaking at the surface. Moreover, the bulk and in particular the surface contributions to the parameters *a* and *b* in $L1_0$ FePt films are enhanced, compared with those of $L1_0$ FePd films, due to larger spin orbit interaction of heavier Pt atoms. It is indicated that not only the bulk but also the interface components of *a* and *b* are tuned by the spin orbit interaction. The present results might stimulate further theoretical investigation of the mechanism of the anomalous Hall effect.

For comparison, b_0 for $L1_0$ FePt (open squares) and FePd (open circles), and *b* for epitaxial Fe (solid upward triangles) [3], fitted with a new scaling law proposed by Tian *et al*. [3], are also given in (b). In (c), the measurements were performed at 275 K. Solid lines refer to the linear fitting results. The inset in (c) shows the electronic scattering at the surface and the interface.

H4-05. Superior hard magnetic properties of nano-island $L1_0$-FePt systems. *K. Son*[1], G. Ryu[2,3], Y. Chen[1], S. Tripathi[1], H. Jeong[1], P. Nagel[4], S. Schuppler[4], E.J. Goering[1] and G.A. Schütz[1] *1. Max Planck Institute for Intelligent Systems, Stuttgart, Germany; 2. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 3. Max Planck Institute for Solid State Research, Stuttgart, Germany; 4. Karlsruhe Institute of Technology, Eggenstein-Leopoldshafen, Germany*

Chemically ordered nano-island $L1_0$-FePt thin films with the thickness of 7 – 10 nm were prepared on MgO (001) and LSAT (001) substrates by magneto co-sputtering at 800 °C. In addition $L1_0$-FePt/MgO as-grown sample were subsequently heat-treated. The structural and magnetic properties were investigated by XRD, high-resolution electron microscopy and SQUID magnetometry. We clearly obtained at room temperature giant coercivity values of ≧ 60 kOe and high saturation polarization of 1.6 -1.8 T resulting in the highest energy product of about 80 MGOe. These results are closely associated with the reduction of tensile strain between film and substrate. In addition, we determined the Fe magnetic moment by x-ray magnetic circular dichroism (XMCD) studies on the same layers covered by a 3 nm Au layer to provide conductivity in the TEY method. These Au coverage only slightly modify the magnetic performance. The XMCD results confirm the significant increase of the Fe magnetic moments up to $m_{Fe} \sim +2.9\ \mu_B$ with a large orbital moment three time about larger than in the pure Fe metal. In addition to the expected Pt polarization of $m_{Pt} \sim +0.3\ \mu$ we can simply explain the high value of M_S on an atomic level. We will further discuss the atomic origin of the high coercivity and its relation to the orbital moments. The simplicity of the system not only allows new insights in fundamental magnetism. Our results represent also a promising material for room temperature spintronic devices, information technology, micororobotics and medicine based on the high performance nano sized hard magnetic components.

H4-06. Development of electroplated FePt thick magnetic films on silicon. *Y. Wang*[1] and D.P. Arnold[1] *1. Electrical and Computer Engineering, University of Florida, Gainesville, FL, United States*

The thick FePt magnetic films have been successfully fabricated on multiple metal substrates with coercivity up to 700 kA/m through electroplating [1-2]. In this work, we report the development of thick, lithographically patterned, near equiatomic FePt permanent magnetic films electroplated on silicon wafers with a higher coercivity of 900 kA/m. These thick-film micromagnets are intended to provide stray magnetic fields for various integrated magnetic devices (MEMS, RF/microwave components, biomedical devices, etc.). Magnetic films are electroplated using a co-deposition bath into 2 mm diameter patterns on to 25 nm Cr / 50 nm TiN / 25 nm Cr / 500 nm Cu / 500 nm Al_2O_3 seed layers on silicon substrates. The electroplating process uses constant currents ranging from 400 to 1000 mA/cm^2 at temperatures ranging from 50 to 70 °C, which yields high deposition rates up to 10 μm/h and film thicknesses up to ~10 μm. Electroplating current density is found to have a strong influence on the plating rate and surface morphology, without affecting film's atomic composition significantly. The films are subsequently annealed at 675 °C for 30 min to induce an A1 to $L1_0$ phase transformation and achieve harder magnetic properties [3-4]. Electroplating bath composition is evaluated and tuned to yield close to 50:50 Fe:Pt composition in order to maximize magnetic performance [Fig. 1]. Scanning electron microscopy (SEM) and vibrating sample magnetometer (VSM) is used to inspect the morphology and magnetic properties of both the as-deposited and annealed magnetic layers, respectively. The best-performing films plated at 400 mA/cm^2 exhibit slight anisotropic magnetic properties (easy axis in plane), with M_r=0.17 T and BH_{max}=4.8 kJ/m^3 [Fig. 2]. X-ray diffraction data confirms the presence of the $L1_0$ FePt phase.

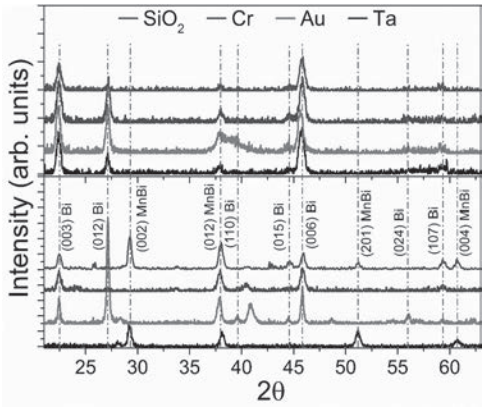
H4-07. Microstructures and perpendicular magnetic properties of $Co_{80}Pt_{20}$/Ru/Ag multilayer films. *S. Chen*[1,2], C. Wen[3], S. Chen[3], T. Chuang[3] and P. Kuo[3] *1. Department of Materials Engineering and Center for Thin Film Technologies and Applications, Ming Chi University of Technology, Taipei 243, Taiwan; 2. Department of Electronic Engineering, Chang Gung University, Taoyuan 333, Taiwan; 3. Institute of Materials Science and Engineering, National Taiwan University, Taipei 106, Taiwan*



Materials having high magnetocrystalline anisotropy constant (K_u) are generally desirable for high density magnetic recording applications due to their thermal stability even with smaller grain size. The K_u of hcp Co_3Pt alloy films is as high as $2x10^7 erg/cm^3$, and the temperature required for obtaining high perpendicular magnetic properties is relatively low at 300 °C. Therefore, Co_3Pt alloy films have significant potential to be utilized in ultra-high density (>1Tb/in^2) magnetic recording media. It has been reported that Co-rich Co-Pt films with perpendicular magnetic properties can be achieved by introducing a Pt underlayer or Ru/Pt bilayers. The lattice parameter of Ag is close to Pt and both structures are fcc. Furthermore, compared to a Pt underlayer, the Ag does not change the composition ratio of Co to Pt in the Co_3Pt magnetic layer, and the cost of Ag is much lower than that of Pt. In this study, $Co_{80}Pt_{20}$ films were deposited onto Ru/Ag bilayer films. The perpendicular magnetic anisotropy was achieved by depositing a $Co_{80}Pt_{20}$ film onto Ru/Ag bilayer films using an argon working pressure of 3 mTorr to sputter the Ru layer at ambient temperature. Its perpendicular coercivity and perpendicular squareness are 3980 Oe and 0.76, respectively. When the working pressure increases to above 10 mTorr, the perpendicular magnetic anisotropy of the films deteriorates greatly. However, both perpendicular coercivity and perpendicular squareness of the films can be increased to 4530 Oe and 0.82 respectively if the $Co_{80}Pt_{20}$ film is deposited on a higher texture Ru(0002)/Ag(111) bilayer that has been annealed at 300 °C. When this $Co_{80}Pt_{20}$/Ru/Ag multilayer film is subsequently post-annealed at 300 °C, the perpendicular coercivity and perpendicular squareness of the films are further increased to 5040 Oe and 0.87 respectively, which reveal its significant potential as perpendicular magnetic recording media for ultra-high density recording. Keywords: $Co_{80}Pt_{20}$ alloy films, magnetic properties, Ru/Ag bilayers, Perpendicular magnetic anisotropy.

H4-08. Effect of capping layer on formation and magnetic properties of MnBi thin films. *P. Quarterman*[1], D. Zhang[4], K. Schliep[3], T. Peterson[2], Y. Lv[4] and J. Wang[5] *1. NIST Center for Neutron Research, Gaithersburg, MD, United States; 2. Physics and Astronomy, University of Minnesota, Minneapolis, MN, United States; 3. NIST, Gaithersburg, MD, United States; 4. Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States; 5. Electrical and Computer Engineering, School of Physics & Astronomy, Minneapolis, MN, United States*

Magnetic memory technologies, such as spin-transfer torque and spin Hall effect based technologies, are of importance due to their intrinsic non-volatile properties, but currently these methods suffer from large write currents needed for deterministic switching. In order to obtain low write currents, magnetic materials with low magnetization (M_s) and damping (α) are needed, however, in parallel a large anisotropy (K_u) is needed in order to ensure thermal stability. Mn based magnetic materials have recently become of interest because they fulfill the necessary material properties discussed. We have examined the formation process of MnBi thin films by sputtering Bi/Mn bilayers with a capping layer of either Ta, Au, Cr, or SiO_2, which were then post annealed at the experimentally determined optimal temperature and time. The measured magnetization curves (Figure 1) show that when the MnBi films are capped with Ta and SiO_2, the films show ferromagnetic behavior with large perpendicular anisotropy. The samples capped with Cr and Au, however, show no ferromagnetic behavior. X-ray diffraction scans (Figure 2) confirm that the characteristic (002) MnBi peak for the low temperature phase only appears in the Ta and SiO_2 capped films. Scanning tunneling electron microscopy and optical microscopy were used to show that the dramatic difference in magnetic and crystallographic properties is due to poor adhesion of the capping layer and diffusion, which allows for oxidation of the Mn layer, and thus preventing formation of the stable MnBi phase. Finally, x-ray and neutron reflectivity characterization methods are being examined to further understand differences in oxygen diffusion in each of the samples at the capping layer/MnBi interface.

H4-09. Oriented Growth of Rare Earth Free Permanent Magnetic Thin Films. V. Bhardwaj[1], S.P. Pal[1] and *R. Chatterjee*[1] *1. Physics, Indian Institute of Technology Delhi, New-Delhi, India*

INTRODUCTION Development of rare *earth free permanent magnetic materials* is of immense interest in the area of materials science and technology today; since rare earth based permanent magnetic materials like $Nd_2Fe_{14}B$ or FePt are extremely expensive or subject to limited rare-earth supplies[1-2].CoZr is one such rare earth free system that is considered as one of the promising candidates to obtain hard magnetic phase. It is reported in literature that the composition $Co_{11}Zr_2$(or Co_5Zr) shows desirable hard magnetic behavior[3] and these are metastable phases. .In this report we demonstrate the formation of single-phase [110] oriented CZ5 thin-films (~ 100 nm) on MgO (100) substrates, using RF magnetron sputtering. The largest coercivity of ~ 950 Oe was obtained in the 110 nm film, when the field was applied along [100] direction. EXPERIMENTAL STUDY A $Co_{82}Zr_{18}$ single alloy target was used to deposit thin films on MgO(100) substrates using RF Magnetron sputtering system. The sputtering was done at optimized 3.5×10^{-3} mbar working pressure of Ar and $\sim5\times10^{-6}$ mbar base pressure of chamber. The depositions were done under varying substrate temperature and RF power to arrive at the optimum condition of 600 C substrate temperature, 170 and 190 watt RF power, henceforth denoted as sample A and B, respectively. RESULTS AND DISCUSSION The x-ray diffractograms shown in figure 1(a) depict the effect of substrate temperature on crystal structure of thin films for sample A, B and confirm the formation of CZ5 phase. In figure 2(a), we have shown the effect of RF power variation on the coercivity (H_C) values with magnetic field applied along [001] to (220) planes of sample A and B. When field was applied along [001],

MH loops become squarer and magnetization is getting fully saturated at low fields with much larger remanences. Obtained values of H_C, Mr, Ms for sample A and B are 647Oe, 193 emu/cm^3, 271 emu/cm^3 and 645Oe, 150 emu/cm^3, 225 emu/cm^3, respectively. Now as shown in figure 3(c), sample B shows H_c value of ~925Oe along [001] as compared to ~645Oe value along [100] direction. Next we have calculated BH_{max} for MH curve shown in fig 2(c) with H_C~925Oe. As shown in figure 2(d), calculated value of BH_{max} has been obtained as~ 0.13MGOe.

H4-10. Magnetic Relaxation Process in Perpendicular Anisotropy Heterostructures. *A. Lisfi*[1], S. Pokharel[1], A. Davis[1], S. Alomari[1], A. Alqarni[1], W. Morgan[1] and M. Wuttig[2] *1. Physics, Morgan State University, Baltimore, MD, United States; 2. Materials Science and Engineering, University of Maryland, College Park, MD, United States*

The increasing interest over magnetic media with perpendicular anisotropy is driven by fundamental science as well as technological demands such as data storage technology. Perpendicular magnetic media with small grains size and narrow switching field distribution have demonstrated their superior performance of high recording capacities. However, the magnetic stability of the media is compromised by the reduction of the grain size due to the thermal switching driven by the competition between thermal and magnetic anisotropy energies [1]. Cobalt ferrite is one the promising ceramics for overcoming this problem due its large anisotropy that can be generated through its giant magnetostriction combined with epitaxial strain. In this paper, we elucidate the thermal stability of epitaxial $CoFe_2O_4$ hetero-structures with a large perpendicular magnetic anisotropy. The $CoFe_2O_4$ films were deposited by pulsed laser deposition (PLD) from a polycrystalline target on (100) MgO substrate under well controlled growth conditions. The epitaxial nature of the films was confirmed through X-ray diffraction (XRD) and transmission electron microscopy (TEM) analyses. Magnetic relaxation measurements were performed with VSM under two different methods. (1) Direct measurement of the magnetization time dependence at constant applied magnetic field. (2) Measurement of hysteresis loops at different sweep rates of applied magnetic field in the range of 10-5000 Oe/s. As depicted by Fig. 1 (a) the time dependence measurements reveal a logarithmic decay of the magnetization over time and small magnetic viscosity weakly dependent on the external applied field. The investigation results will be presented and discussed based on the structural domains resulting from the epitaxy (Fig. 1(b)), the demagnetizing field imposed by the measurement geometry, the thermally activated irreversible process and the magnetization reversal mechanism in these epitaxial hetero-structures.

H5-01. Elastic anomalies under magnetic fields in the heavy-fermion ferromagnet YbPtGe. *I. Ishii*[1], X. Xi[2], Y. Noguchi[1], T. Mizuno[1], S. Kumano[1], K. Araki[3], K. Katoh[3] and T. Suzuki[4] *1. Hiroshima University, Higashi-Hiroshima, Japan; 2. Ames Laboratory, Ames, IA, United States; 3. National Defense Academy, Yokosuka, Japan; 4. Department of Quantum Matter, AdSM, Hiroshima University, Higashi-Hiroshima, Japan*

The Yb-based compound YbPtGe with the orthorhombic ε-TiNiSi-type structure was reported as a heavy-fermion ferromagnet with the phase transition temperature, T_C =5.4 K [1]. At high temperatures, 4*f*-electrons of Yb^{3+} ions have a localized character, and physical properties can be ascribed to the crystal electric field (CEF) effect. On the other hand, the Kondo effect and then a heavy-fermion state appear below 20 K. Previously, we carried out ultrasonic measurements on a YbPtGe single crystal and found an elastic softening of the transverse moduli due to an interlevel quadrupole interaction between the CEF states. The CEF level scheme and the magnetic field *H*-temperature *T* phase diagram along the *a*-axis were also reported [2]. In the present work, we measured the elastic moduli under *H* along the *b*-axis in order to investigate the magnetic ordered states in YbPtGe. The *T* and *H* dependences of the elastic moduli show clear anomalies indicating the phase transitions. From these results, we have drew the *H-T* phase diagram along the *b*-axis and found a new phase boundary in addition to the ferromagnetic phase boundary already reported [1]. The new phase boundary may arise from modulation of the magnetic structure.

H5-02. Multicritical points, Lifshitz transitions and spin flipping effects in the Underscreened Anderson Lattice Model under pressure and magnetic field. *S.G. Magalhaes*[1], A.C. Lausmann[2], E.J. Calegari[2] and P.S. Riseborough[3] *1. Physics, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 2. Physics, Universidade Federal de Santa Maria, Santa Maria, Brazil; 3. Physics, Temple University, Philadelphia, PA, United States*

We investigate the antiferromagnetic phases of the underscreened Anderson model which appear under pressure and the spin-flipping effects triggered by an applied magnetic field transverse to the easy axis. The underscreened Anderson Lattice Model was proposed to describe the competition between ferromagnetism and Kondo effect observed in uranium and neptunium compounds [1]. This model describes two 5f bands (of character a or be) which hybridize with one itinerant conduction band. The effect of pressure is assumed to increase the tight-binding hopping integrals for both the conduction and the 5f bands. Our results in the phase diagram temperature vs pressure without field show that two distinct Spin Density Waves phases (SDW1 and SDW2) appear below a second order transition temperature. This two phases are characterized by the gaps of bands a and b given by Da and Db, respectively, i. e., SDW1 occurs for Db>Da>0 while the SDW2 is given by Da>Db>0. At lower temperatures and for intermediate values of pressure, there is a direct first-order transition between SDW1 and SDW2 phases ending at a critical point. Alternatively, one can also interpret this direct transition in terms of large and small magnetic moment antiferromagnetism in different 5f-bands which interchange their order under pressure. As pressure is further increased, there is another phase transition between SDW2 and the paramagnetic (PM) phase displaying a tricritical point. We also examine the band structure and the Fermi surfaces and discussed the possible Lifshitz transition that accompanies the direct first order transition between SDW1 and SDW2 phases. The spin-flipping changes substantially the previous scenario. It tends to suppress the critical point as well as the tricritical one. As consequence, the Fermi Surface reconstruction in the transition between SDW1 and SDW2 phases is also suppressed. Moreover, it appears a Quantum Critical Point in the transition between SDW2 and PM phases.

H5-03. High pressure electrical resistivity of ferromagnetic heavy fermion compound $YbNi_4P_2$. T. Muramatsu[1], K. Kliemt[2], C. Krellner[2] and *S. Friedemann*[1] *1. HH Wills Laboratory, University of Bristol, Bristol, United Kingdom; 2. Physics, Goethe-University Frankfurt, Frankfurt, Germany*

$YbNi_4P_2$ is a heavy fermion system with a ferromagnetic transition temperature of T_C = 0.17 K. In the tetragonal $ZrFe_4Si_2$ type crystal structure ($P4_2/mnm$), Yb ions form one dimensional (1D) chains along *c*-axis, providing a rare example of 1D ferromagnetic system among strongly correlated electron systems [1]. In this work, electrical resistivity was measured under high pressure to investigate the unique property of the Yb-based heavy fermion system. The high pressure was generated by a diamond-anvil pressure cell to achieve beyond 10 GPa and high purity single crystal was used to investigate both the Kondo effect and the dimensionality. Contrary to Ce-based heavy fermion systems, $YbNi_4P_2$ becomes more magnetic as pressure increases and Kondo temperature initially decreases and start to level off above around 8 GPa. These behaviours are understood by competing nature of 4f valence fluctuation, RKKY interaction and Kondo effect [2]. The large anisotropy between *a*-axis and *c*-axis caused by the 1D nature remains regardless of the applied high pressure, meaning 1D ferromagnetic quantum criticality (QC) expected to exist under higher pressure can be studied in addition to the studied QC in $YbNi_4(P_{1-x}As_x)_2$ [3].

H5-04. Magnetic and transport properties of orthorhombic compounds R_3CoSn_6 (R = Ce and La). *M. Kimura*[1], K. Wakiya[1], T. Tomaki[1], J. Gouchi[2], Y. Uwatoko[2], M. Uehara[1] and I. Umehara[1] *1. Department of Physics, Faculty of Engineering, Yokohama National University, Yokohama, Japan; 2. Institute for Solid State Physics, University of Tokyo, Kashiwa, Japan*

Ce-compounds show interesting phenomena such as heavy fermion state, valence fluctuation, and unconventional superconductivity [1]. It has been shed light on the phenomena described by Doniach's diagram [2], which are caused by the competition between the Kondo effect and the anti-ferromagnetic RKKY interaction. However, there are a few reports on ferromagnetic Ce-compounds. Recently, Gribanova *et al.* have found a new Ce-compound Ce_3RuSn_6 with orthorhombic Yb_3CoSn_6-type structure (space group: *Cmcm*) [3]. They reported that Ce_3RuSn_6 exhibits a ferromagnetic ordering at T_C = 3 K and the estimated Kondo temperature T_K is close to T_C [4]. Therefore, in Ce_3RuSn_6, it is expected that the quantum critical phenomena arise

from the competition between the Kondo effect and the ferromagnetic interaction. On the other hand, the magnetic properties of isostructural Ce_3CoSn_6 have not been studied so far. It is expected that *c-f* hybridization is enhanced by the chemical pressure because the atomic radius of Co is smaller than that of Ru. In this study, we synthesized single crystalline samples of Ce_3CoSn_6 and non-magnetic reference La_3CoSn_6, and measured their magnetization, specific heat, and electrical resistivity. Figure 1 shows the temperature dependence of magnetic susceptibility *c* and inverse magnetic susceptibility χ^{-1} of Ce_3CoSn_6. Above 100K, χ^{-1} obeys a Curie-Weiss law with the effective magnetic moment 2.57 μ_B / Ce, which is close to 2.54 μ_B / Ce expected for the free trivalent Ce ion. Any magnetic transition is observed above 2 K in the electrical resistivity and magnetization, indicating that the magnetic transition temperature of Ce_3CoSn_6 is lower than that of Ce_3RuSn_6.

H5-05. Ferromagnetic ground state in $Ce_2Al_3Ge_4$ with colossal magnetic anisotropy. *S. Manni*[1], A. Thamizhavel[1] and S.K. Dhar[1] *1. Condensed Matter Physics & Materials Science, Tata Institute of Fundamental Research, Mumbai, India*

Studies of quantum criticality in metallic ferromagnets have been a subject of immense interest in last few decades. One of the reasons may be rather illusive nature of ferromagnetic quantum critical point compared to its antiferromagnetic counterpart. Often a ferromagnetic transion upon suppression pushed into a second order antiferromagnetic ordering or into another first order transition. [1] In recent days, few metallic ferromagnets (UGe_2, $LaCrGe_3$ etc.) are studied where ferromagnetic ordering temperature (T) is suppressed into a quantum tricritical point by the pressure (P) and magnetic field (H) and the T (P, H) phase diagram form a *"Wing structure"*.[2,3] In Ce-based ferromagnets the physics is even more complicated due to presence of strong Kondo interaction with the ferromagnetic RKKY interaction [4] and T (P, H) phase diagram appears to be much more complicated[5]. We have discovered a new Ce-based ferromagnet, $Ce_2Al_3Ge_4$, having T_c around 15 K. The system has been synthesized in single crystalline form by conventional flux method. The crystals are few millimeter in size. $Ce_2Al_3Ge_4$ crystallizes in Orthorhombic *Cmce* crystal structure. We have done anisotropic magnetization, electrical transport and thermodynamic measurements on oriented single crystal of $Ce_2Al_3Ge_4$. Magnetic susceptibility (χ) measurements for field along three crystallographic direction (*a*, *b*, *c*) reveals presence of a colossal magnetic anisotropy in $Ce_2Al_3Ge_4$, most likely due to strong crystal electric field effect. We have observed at 1 kOe magnetic field, $\chi_a \approx 100\ \chi_b \approx 30\ \chi_c$, near T_c where χ_a, χ_b and χ_c are magnetic susceptibility for field along *a*, *b* and c direction. In this paper, we have explored magnetic field dependent phase diagram of $Ce_2Al_3Ge_4$ which reveal its true ground state and other field induced magnetic states as well. $Ce_2Al_3Ge_4$ with a fairly high T_c and extremely large magnetic anisotropy appears to be an ideal material for study of ferromagnetic quantum critical behavior.

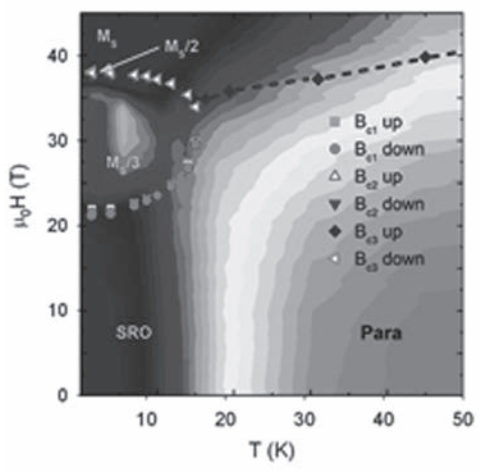
H5-06. Withdrawn

H5-07. Potential energy vs. kinetic energy in structural stability, ferromagnetism and magnetic anisotropy of f-d intermetallics. *M. Matsumoto*[1] *1. University of Tokyo, Institute for Solid State Physics, Kashiwa, Japan*



Interplay among ferromagnetism, magnetic anisotropy, and structural stability of f-d intermetallics is computationally addressed as motivated by the practical application of ferromagnetic 4f-3d intermetallics such as $Nd_2Fe_{14}B$ in the strongest permanent magnet (PM) and by the fundamental issue of itinerant ferrromagnetism involving both of localized magnetic moments and delocalized electronic state that contributes to the high Curie temperature which can reach close to 1000K for the case of $SmCo_5$. In most of 4f-3d intermetallics made of Fe-group elements and rare-earth elements with well localized 4f moments, 4f-electron magnetic anisotropy couples to itinerant 3d-electron ferromagnetism only indirectly via 5d-electron bands coming from rare-earth elements, rendering the high-temperature magnetic anisotropy weak. Even a tiny amount of enhancement in 4f-3d indirect exchange coupling is desired for the high-temperature application of PM's [1]. Here the preferred direction of magnetization coming from 4f-electron anisotropy is driven by the potential energy gain in a particular crystal field environment specific to each given material. In contrast, valence-fluctuating rare-earth elements can bring about kinetic-energy driven f-electron physics in orders of magnitude larger energy scale than the conventional magnetic anisotropy energy. We argue for the kinetic-energy-driven magnetic anisotropy in some valence-fluctuating ferromagnetic 4f-3d intermetallics at high temperatures on the basis of our realistic model constructed *ab initio* for the representative compounds RT_5 (R=rare earth, T=iron group elements) found in rare-earth permanent magnets. Possible gain in magnetic anisotropy energy is contrasted with the accompanying trends in ferromagnetism and structural stability. While the oveall gain is to be inspected for each given need considering the specifics such as the targetted operation temperature range, we elucidate some intrinsic trade-off among them originating in the dual nature of electrons having both of localized and delocalized nature. Possible utility of 5f-electrons is considered as well.

H5-08. Field-induced phases in a heavy-fermion $U(Ru_{0.92}Rh_{0.08})_2Si_2$ single crystal studied by high-field transport and magnetization measurements. *K. Prokes*[1], T. Förster[2], Y. Huang[3] and J.A. Mydosh[4] *1. Helmholtz-Zentrum Berlin, Berlin, Germany; 2. Hochfeld-Magnetlabor Dresden, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany; 3. Van der Waals-Zeeman Institute, University of Amsterdam, Amsterdam, Netherlands; 4. Kamerlingh Onnes Laboratory, Leiden University, Leiden, Netherlands*

We report the high-field induced magnetic phases and phase diagram of a heavy-fermion $U(Ru_{0.92}Rh_{0.08})_2Si_2$ single crystal. Our study, that combines high-field magnetization, electrical and Hall resistivity results, shows that three field-induced metamagnetic phase transitions at B_{c1} = 21.6 T, B_{c2} = 37.9 T and B_{c3} = 38.2 T for field applied along the c axis that is the easy magnetization direction. The magnetic phase above B_{c1} has one third of the saturated magnetization M_s. Neutron diffraction in static magnetic fields revealed that this phase is an uncompensated antiferromagnetic structure with propagation vector q =(2/3 0 0) with U moments of 1.45 (9) μ_B oriented along the c axis. The phase between B_{c2} and B_{c3} has magnetization equal to $M_s/2$. Abobe the B_{c3} the system is fully polarized. The magnetic state is reflected in the electrical (see the Figure) and Hall resistivities that show distinct phase boundaries indicative of first order reconstructions of the Fermi surface. Our results are qualitatively similar to the existing high-field

data for the 4 % Rh-doped URu_2Si_2 system and are discussed in context of the pristine URu_2Si_2.

Color-coded electrical resistivity of the 8% RH-doped URu_2Si_2 along with critical field values determined from the magnetization measurements. Red (blue) color denotes high (low) electrical resistivity with current and field along the c axis.

H5-09. Pressure Effects on the Field-Induced Magnetic Phases in the Heavy-Fermion Compound $CeAuSb_2$. *S. Seo*[1], S.M. Thomas[1], F. Ronning[1], E. Bauer[1], J. Thompson[1] and P. Rosa[1] *1. Condensed Matter and Magnet Science, Los Alamos National Laboratory, Los Alamos, NM, United States*

$CeAuSb_2$ is a heavy-fermion antiferromagnet in which the antiferromagnetic transition temperature T_N is gradually suppressed by a magnetic field along the c-axis [1]. With pressure, however, new phases emerge hindering the appearance of a pressure-induced quantum critical point [2]. At ambient pressure, two metamagnetic transitions are observed at $H_{c1} \sim 2.8$ T and $H_{c2} \sim 5.6$ T [3]. A recent neutron scattering study shows that the transition of magnetic structure occurs at H_{c1} from a striped to a woven spin density wave [4]. We report the magnetic field-pressure-temperature phase diagram of $CeAuSb_2$ derived from the temperature and field dependence of electrical resistivity under pressure. At low pressure, a new phase appears in the woven magnetic phase, and at high pressure the striped magnetic boundary splits into two transitions even at zero magnetic field. We will discuss the pressure and field effects on the multiple magnetic orders in the three-dimensional phase diagram.

H5-10. A possible explanation of meta-magnetic transition in $CeRu_2Si_2$ and magnetic behavior in Gd-poor (Ce-Gd)Ru_2Si_2. *K. Yano*[1], Y. Amakai[2], Y. Hara[3], K. Sato[4], E. Kita[4], H. Takano[2], T. Ohta[5] and S. Murayama[2] *1. College of Science and Technology, Nihon University, Funabashi, Japan; 2. Muroran Institute of Technology, Muroran, Japan; 3. National Institute of Technogy, Hitachinaka, Japan; 4. National Institute of Technology, Hitachinaka, Japan; 5. Quantum Design Japan, Tokyo, Japan*

$CeRu_2Si_2$ is one of the representatives of the Ce122 system and is well-known as a heavy fermion compound. We have been investigating two characteristic features[1] of meta-magnetic transition behavior around 7.7 Tesla and extraordinary small magnetic moment of Ce in perpendicular to c-axis (≒1/30-1/50) in $CeRu_2Si_2$. Our main aim is to get some clues to these two characteristics by employing the substitution of Ce by Gd, that is, (Ce-Gd)Ru_2Si_2 compound system. Regarding the meta-magnetic transition behavior in $CeRu_2Si_2$, we have preliminarily obtained an interesting result in $GdRu_2Si_2$[2], where Ce is replaced perfectly by magnetic element of Gd, and this $GdRu_2Si_2$ has shown 2-step spin-flip behavior in *M-H* curve below 15 K. Taking into account that Gd is the most simple rare earth element without *L* component, this result was considerably remarkable and in the structure of Ce122 system, even Gd was found to be anisotropic in a sense. During our study about the 2-step spin-flip behavior in Nd_3Co compound[3], which shows a typical 2-step spin-flip, we have recently noticed that the 1-step spin-flip behavior observed in $GdRu_2Si_2$ around 30 and 40 K seems to resemble to meta-magnetic transition behavior in $CeRu_2Si_2$ in shape. So we have measured *M-H* curves before and after at both 30 K and 40 K in $GdRu_2Si_2$, and we have confirmed that the 1-step spin-flip behaviors in $GdRu_2Si_2$ around 30 K and 40 K do resemble to that in $CeRu_2Si_2$. It follows that the meta-magnetic transition in $CeRu_2Si_2$ can be a 1-step spin-flip behavior and this explanation is just newly obtained by us recently. Regarding the second feature of extraordinary small Ce magnetic moment in hard direction (perpendicular to c-axis), it was found that Ce magnetic moment remains to be considerably small in Gd-poor contents below 10 at %, however, it increases to nearly equal value at Gd=0.5 and becomes identical to the value of easy axis by further increase of Gd to Gd=0.8.

H5-11. High pressure electrical resistivity of ferromagnetic heavy fermion compound $YbNi_4P_2$. T. Muramatsu[1], K. Kliemt[2], C. Krellner[2] and *S. Friedemann*[1] *1. HH Wills Laboratory, University of Bristol, Bristol, United Kingdom; 2. Physics, Goethe-University Frankfurt, Frankfurt, Germany*

$YbNi_4P_2$ is a heavy fermion system with a ferromagnetic transition temperature of $T_C = 0.17$ K. In the tetragonal $ZrFe_4Si_2$ type crystal structure (*P*42/mnm), Yb ions form one dimensional (1D) chains along c-axis, providing a rare example of 1D ferromagnetic system among strongly correlated electron systems [1]. In this work, electrical resistivity was measured under high pressure to investigate the unique property of the Yb-based heavy fermion system. The high pressure was generated by a diamond-anvil pressure cell to achieve beyond 10 GPa and high purity single crystal was used to investigate both the Kondo effect and the dimensionality. Contrary to Ce-based heavy fermion systems, $YbNi_4P_2$ becomes more magnetic as pressure increases and Kondo temperature initially decreases and start to level off above around 8 GPa. These behaviours are understood by competing nature of 4f valence fluctuation, RKKY interaction and Kondo effect [2]. The large anisotropy between a-axis and c-axis caused by the 1D nature remains regardless of the applied high pressure, meaning 1D ferromagnetic quantum criticality (QC) expected to exist under higher pressure can be studied in addition to the studied QC in $YbNi_4(P_{1-x}As_x)_2$ [3].

Session H6
MAGNETOCALORIC MATERIALS IV
(Poster Session)

Samir Kumar Giri, Chair
University of Cambridge, Cambridge, United Kingdom

H6-01. A comparative study of the magnetocaloric effect in MnFePSiGeB prepared by traditional sintering and spark plasma sintering. *G. Wang*[1], B. Yang[1], T. Jing[2], Z. Zhao[2], X. Zhang[2] and Y. Liu[2] *1. Key laboratory of Integrated Exploitation of Bayan Obo Multi-Metal Resources, Inner Mongolia University of Science and Technology, Baotou, China; 2. School of Science, Inner Mongolia University of Science and Technology, Baotou, China*

Fe_2P-based compounds are promising candidates for room-temperature application of magnetic refrigeration due to their excellent magnetocaloric properties, tunable Curie temperature and low costs of raw materials [1]. Traditionally, the Fe_2P-based compounds are prepared by annealing process at high temperature for a long time [2,3]. Spark plasma sintering (SPS) is a newly developed synthesis process characterized by the simultaneous application of pressure and a pulsed continuous current. In the present work, we show a comparative study of the magnetocaloric effect (MCE) in a Fe_2P-type MnFePSiGeB compound prepared by traditional sintering (TS) and SPS methods. Compounds with the same nominal composition of $Mn_{1.15}Fe_{0.85}P_{0.65}Si_{0.13}Ge_{0.2}B_{0.02}$ were prepared separately by TS at 1373 K for 24 h and by SPS at 1173 K under a pressure of 50 MPa for 15 min. By the use of Archimedes' principle, the densities of MnFePSiGeB prepared by TS and SPS are determined to be 6.14 and 6.51 g/cm^3, respectively. Analyses of X-ray diffraction patterns indicate that both compounds mainly crystallize in the hexagonal structure. Backscattered electron microscopy and energy dispersive spectroscopy measurements demonstrate that a minor of the secondary phase $(Mn,Fe)_3(Si,Ge)$ exists in the studied compounds. The thermal magnetization curves on heating and cooling show clear thermal hysteresis indicating that both compounds undergo first-order magnetic transitions. The compound prepared by SPS exhibits lower Curie temperature and sharper phase transition when comparing with those of the compound prepared by TS. The magnetocaloric parameter (isothermal entropy change, ΔS_T) has been determined from isothermal magnetization data using the Maxwell relation, as shown in Fig. 1. Upon a field change of 3 T, the maximum values of $-\Delta S_T$ are found to be 7.9 and 21.3 J/kgK for MnFePSiGeB prepared by TS and SPS, respectively. The significant enhancement of MCE reveals that the SPS method is an appropriate way to prepare magnetocaloric materials with high density and good magnetocaloric property.

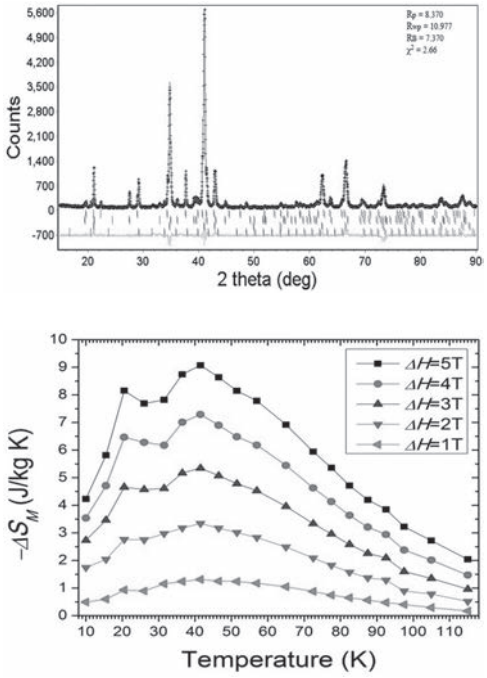
H6-02. Optimization of A Magnetic Heating Air-Conditioning & Refrigeration (HACR) Prototype for Experimental Purposes. *B. Huang*[1], D. Zeng[2], N. van Djik[1] and E. Brück[1] *1. Faculty of Applied Sciences, Delft University of Technology, Delft, Netherlands; 2. School of Materials Science and Engineering, South China University of Technology, Guangzhou, China*

Various studies on room-temperature (RT) magnetocaloric materals (MCM) have focused on the material properties such as the magnetization (M), the magnetic entropy change (ΔS), the Curie temperature (Tc), the thermal and field hysteresis (ΔThys/ΔHhys), etc. However, to study how these materials properties affect the actual heating or cooling performance in a realistic environment, complementary studies have to be performed on the experimental devices. Therefore, we present the results of a numerical optimization study to improve the performance of an RT HACR prototype developed in our group. The prototype is a rotary-type device based on the active magnetic regeneration (AMR) cycle. Two symmetrically placed fan-shaped magnetic structures are used to generate an average magnetic field of 0.875 T within a volume of 0.71 L. The sudden changes in the magnetic torque are neutralized by an asymmetric bracket with seven regenerators. The reciprocating flow is homogeneously distributed perpendicular to the flow direction by especially designed fluid dispersers in the AMR beds. The MCM packed bed is fabricated with epoxy bonded particles, for the first tests we use gadolinium spheres with a diameter range of 0.4-0.8 mm, which ensures a good packing density with a low pressure drop across the regenerators. With the performance data collected by the measurement system, a 2-D discrete model is developed to analyze the performance and predicting the optimal control parameters such as the working frequency, the utilization, and the hot-end temperature under different working conditions. In addition, A finite element model is applied to predict the magnetic torque for different mechanical system designs. All calculation data are then compared with the experimental results.



Overview of the prototype

H6-03. Table like Magnetocaloric Effect in $Ho_{36}Co_{48}Al_{16}$ Multiphase Alloy. E. Balfour[3], H. Fu[3], R.L. Hadimani[2] and *A.A. El-Gendy*[1] *1. Physics, University of Texas at El Paso, El Paso, TX, United States; 2. Department of Electrical and Computer Engineering, Iowa State University, Ames, IA, United States; 3. School of Physical Electronics, University of Electronic Science and Technology of China, Chengdu 610054, People's Republic of China, Chungdou, China*

Magnetocaloric effect (MCE) has recently gained wide attention in both fundamental research [1, 2], and application in magnetic refrigeration (MR) systems. It is promising as an efficiently competitive technology for the replacement of the potentially environmentally risky gas compression/expansion refrigeration [3-5]. Several Ho(Co, Al)-based binary and quasi-binary crystalline alloys are known to have good magnetocaloric properties. Therefore, we examine the Ho-Co-Al system to identify a suitable multi-phase region for study in expectation of a single bulk multi-crystalline alloy that exhibits table-like MCE. In particular, $HoCo_2$, HoCoAl, and Ho_2Co_2Al compounds have good magnetocaloric properties [6-8]. The four sets of vertical bars (blue) of Rietveld refinement shown in Fig. 1 correspond to the HoCoAl, Ho_2Co_2Al, $HoCo_2$ main phases and trace amount of Ho_2O_3, respectively from top to bottom. Lattice parameters and EDS analysis indicate that Al substitution for Co occurs in the $HoCo_2$ phase while the HoCoAl phase has higher Co content than the Co:Al ratio for equiatomic HoCoAl. Temperature dependence of magnetization under field cooled (FC) condition shows a broad transition, which is beneficial for obtaining table-like MCE. Maximum magnetization of isotherms reaches 172 emu/g at 7 K under applied field of 50 kOe. Small magnetic hysteresis is observed at 7 K but disappears with increasing temperature and is not visibly evident from 13 K. Again, no step-like magnetization could be seen for all the measured isotherms. It indicates that the first-order metamagnetic transition associated with $HoCo_2$ and its low Al-substituted counterparts is absent. The order of magnetic phase transitions in the $Ho(Co_{1-x}Al_x)_2$ alloys changes from first-order to second-order for $x > 0.06$ [9]. Therefore, the suppressed hysteresis and absence of the first-order transition are attributed to the high content of Al in the $HoCo_2$ phase. Table-like MCE is attained for the studied alloy under different applied field changes (ΔH) as shown in Fig. 2.

Division of Materials Science and Engineering, Ames Laboratory, US Department of Energy, Ames, IA, United States; 4. Department of Materials Science and Engineering, Iowa State University, Ames, IA, United States*

In order to improve performance of magnetic materials many groups explore novel materials, while others focus on altering the microstructure of existing systems.[1] In the latter case, there have been several reports on tuning magnetic properties by tailoring the anisotropy of nanostructured materials.[1,2] One way to accomplish this is to utilize the inherent shape and crystalline anisotropy of nanoparticles by alignment in an external magnetic field.[3] We demonstrate the ability to deposit thin magnetic films

with a defined anisotropy in a chosen direction which leads to the ability to manipulate magnetic properties, and approach those of single crystals. Particles of Gd_5Si_4 were synthesized by ball-milling in which polyethylene glycol (PEG) and heptane were used as processing agents. Thin films of the particles were deposited onto a substrate via dropcast process. During printing, one sample rested on top of a NdFeB permanent magnet to align the particles in the printing plane, and the second sample was not aligned. The external magnetic field aligns the magnetic particles along their magnetic easy axis. The combined effect of all the particles enhances the anisotropy of the film such that it approaches that of a single crystalline sample. Angle dependent magnetization measurements were used to investigate the effect of the aligning field on the magnetization behavior and entropy change in the films. Shown in Fig. 1 are the in- and out-of-plane hysteresis curves for the aligned and random printed films. The permeability of the aligned film decreases from in- to out-of-plane measurement which suggests that the successful formation of a magnetic easy axis in the aligned film. The change in magnetic entropy associated with magnetization of the films (Fig. 2) is ~40% higher in the aligned film. This value provides an estimate of the cooling potential of the films and shows that alignment can improve the cooling power of deposited films.

H6-05. Effect of rare-earth (R = Pr, Gd, Ho, Er) doping on the Magnetostructural phase transitions and Magnetocaloric properties in $Ni_{43-x}R_xMn_{46}Sn_{11}$ shape memory alloys. *A. Aryal*[1], S. Pandey[1], I. Dubenko[1], S. Stadler[2] and N. Ali[1] *1. Physics, Southern Illinois University, Carbondale, IL, United States; 2. Physics and Astronomy, Louisiana State University, Baton Rouge, LA, United States*

A series of rare-earth doped $Ni_{43-x}R_xMn_{46}Sn_{11}$ (x = 0, 1 and R = Pr, Gd, Ho, Er) alloys were fabricated by arc-melting method and their structural, magnetic and magnetocaloric properties (MCE) were studied through room temperature X-ray diffraction (XRD), differential scanning calorimetry (DSC) and magnetization measurements. Analysis of XRD data reveals that the alloys crystallize in the cubic *L*21 austenite (AP) as major phase with small trace of martensitic phase (MP). The martensitic transition temperature (T_M) shifts towards higher temperature by the corresponding substitution of Pr, Gd, Ho, and Er. A drastic shift in T_M by ~ 60 K relative to the parent compound (T_M = 195 K) was found for $Ni_{42}PrMn_{46}Sn_{11}$ alloy. Doping small amount of rare-earth ions strengthened the antiferromagnetic interactions of the MP resulting in large change in magnetization (ΔM) between AP and MP. Large values of magnetic entropy changes (ΔS_M) of 32 $JKg^{-1}K^{-1}$(Pr), 28 $JKg^{-1}K^{-1}$ (Gd), and 25 $JKg^{-1}K^{-1}$ (Ho) were obtained at T_M for ΔH = 5 T. Maximum value of refrigeration capacity (RC) of ~ 250 J Kg^{-1} was obtained in the vicinity of T_M for ΔH = 5 T for Ho doped compound. A significant magnetoresistance (MR) ~ - 20 % was observed for $Ni_{42}GdMn_{46}Sn_{11}$ alloy near T_M for the magnetic field change of 5 T. Large exchange bias (EB)effect with H_{EB} ~ 1.1 kOe at 10 K was observed for Pr doped compound in its MP. The observed large values of MCE, RC, MR and EB illustrate the potential of rare-earth doped $Ni_{43-x}R_xMn_{46}Sn_{11}$ compounds for applications. Acknowledgements: This work was supported by the U.S. Department of Energy (DOE), Office of Science, Basic Energy Sciences (BES) under Award No. DE-FG02-06ER46291 (SIU) and DE-FG02-13ER46946 (LSU).

H6-06. Theoretical investigation of magnetocaloric and magnetoresistance on $PrNi_5$ compound. *B.d. Alho*[1], P.d. Alho[1], V.G. de Paula[1], E.P. Nóbrega[1] and P. von Ranke[1] *1. Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brazil*

The magnetic properties of the paramagnetic $PrNi_5$ have been extensively studied because this material is used as a working medium to reach the ultra-low temperature of about 1 mK by the nuclear adiabatic demagnetization technique. However, $PrNi_5$ exhibit an anomalous inverse isothermal entropy change (ΔS_T) behavior. This anomaly is ascribed to the approximation of the two lowest magnetic energy levels (Γ_4 and Γ_1) with increasing magnetic field along the easy axis [1]. It is well known that there is a strong correlation between the temperature dependence of the usual ΔS_T and the isothermal magnetoresistivity change (Δρ) [2]. Thus, one may expect a correlation between these anisotropic quantities of $PrNi_5$ as well. However, as far as we know, this issue has not yet been ascribed in literature for $PrNi_5$ compound. In this work, we theoretically investigated the correlation between anisotropic ΔS_T and Δρ for the PrNi5 compound. Our model Hamiltonian includes the crystalline electrical field interaction for the hexagonal symmetry, Zeeman and exchange interactions. As a preliminary result we obtained a similar behavior between the anisotropic Δρ *vs.* T and ΔS_T *vs.* T curves, highlighting its correlations. Keywords: Magnetoresistivity, Magnetocaloric Effect, $PrNi_5$, Anisotropy.

H6-07. Magnetostructural Phase Transitions and Magnetocaloric properties in Ag doped $Mn_{1-x}Ag_xCoGe$ compounds. *A. Aryal*[1], S. Pandey[1], I. Dubenko[1], S. Stadler[2] and N. Ali[1] *1. Physics, Southern Illinois University, Carbondale, IL, United States; 2. Physics and Astronomy, Louisiana State University, Baton Rouge, LA, United States*

The effects of Ag-doping on the structural, magnetic, and magnetocaloric properties of $Mn_{1-x}Ag_xCoGe$ ($0.01 \leq x \leq 0.10$) have been studied through

room temperature X-ray diffraction, differential scanning calorimetry, and magnetization measurements. A change in crystal structure from orthorhombic to hexagonal was observed in the XRD data with increasing Ag concentration. The doping of small amounts of Ag for Mn results in a decrease in the martensitic transition temperature (T_M). For the concentration range $0.05 \leq x \leq 0.06$, T_M was found to coincide with the ferromagnetic transition temperature (T_C), resulting in a first-order magnetostructural transition (MST) near room temperature. A Curie-temperature window of 85 K was observed between the Curie temperatures of austenite and martensite phases. The maximum values of the magnetic entropy changes ($-\Delta S_M$) at the MST were found to be ~ 22.0 J kg^{-1} K^{-1} and 9.4 J kg^{-1} K^{-1} for $\Delta H = 5T$ for x = 0.06 and 0.05, respectively. Large values of the refrigeration capacity (RC) of 308 J Kg^{-1} and 272 J Kg^{-1} were found for x = 0.06 and x = 0.05, respectively, for $\Delta H = 5T$. A structural and magnetic phase diagram of $Mn_{1-x}Ag_xCoGe$ compounds has been constructed. The observed large values of the MCE and RC at the MST illustrate the potential of $Mn_{1-x}Ag_xCoGe$ compounds in magnetic cooling technology. Acknowledgements: This work was supported by the U.S. Department of Energy (DOE), Office of Science, Basic Energy Sciences (BES) under Award No. DE-FG02-06ER46291 (SIU) and DE-FG02-13ER46946 (LSU).

H6-08. Powdering and Sintering effect on The Magnetocaloric Properties of MnNiSi-based Compounds. *H. Zhang*[1], I. Hidayah[1], Q. Lu[1], Y. Ming[1] and W. Liu[1] *1. Beijing University of Technology, Beijing, China*

MnNiSi-based compounds have attracted much attention due to the strong magnetostructural coupling, giant magnetocaloric effect, and its low cost raw materials. The materials are usually brittle and even naturally collapse into powders during preparation. In this work, spark plasma sintering (SPS) has been used to increase the density and strength of the sintered bulks, while the structural transformation and magnetic properties have also been investigated. One can see from Fig. 1 that with the decrease of particle size, the structure changes from the orthorhombic TiNiSi to hexagonal Ni_2In phase. After sintering and compacting process, the P1 and P2 samples exhibit pure hexagonal phases, while the P3 and P4 samples with smaller particles show the coexistence of the orthorhombic and hexagonal phases, indicating that the transformation temperature has decreased evidently. After SPS process, the T_{TM} and thermal hysteresis are decreased to a certain extent. Based on microstructure observation, we found a destruction of the particles during the hot pressing process, which will introduce more defects into the sample and thus causes the further decrease of T_{TM}. The maximal magnetic entropy change ($-\Delta S_M$) are 15.81, 14.44, 13.44, 9.59 J/kg.K for P1, P2, P3, and P4, respectively, as shown in Fig. 2.a. The values of the refrigerant capacity (RC) are 198.41, 196.59, 183.61, and 154.09 J/kg for P1, P2, P3, and P4, respectively.

H7-01. Onset of magnetic vortex state in CeGe compound: A dc and ac susceptibility, resistivity and heat capacity study. *K. Singh*[1] and K. Mukherjee[1] *1. School of Basic Science, Indian Institute of Technology, Mandi, Mandi, India*

We explore the magnetic vortex state below the ordering temperature in a compound CeGe by means of dc and ac susceptibility, resistivity and heat capacity studies. From magnetization and heat capacity studies, it is noted that the compound undergoes two magnetic transitions around $T^{I} \sim 10.5$ and $T^{II} \sim 7.6$ K. Resistivity measurement shows the opening of superzone gap below transition temperature T^{I}, as also observed in similar type of compounds [1]. Also it is noted that the heat capacity varies as T^{2} below T^{I} (Fig. 1). Such linear T^{2} dependence in heat capacity is an intrinsic feature of the presence of vortices [2]. Hence observation this feature in CeGe possibly indicates the presence of vortex state. Further, evidence of this state is derived from dc field response of ac-susceptibility (Fig. 2). As the dc field is increased it is observed that ac-susceptibility shows a sinusoidal feature. A mirror image of ac susceptibility is noted on reversing the dc field, a characteristic which indicates the presence of magnetic vortices [3]. The observation of superzone gap and magnetic vortex state suggest interplay between the exchange and magnetic dipole-dipole interaction. Also, it is observed that the ac-field influences the dynamics of vortex pinning. With increasing ac-field, the broadening of feature decreases due to oscillating the vortices to larger distance resulting in decrease of pinning strength with increasing ac-field. Thus our results confirms the presence of magnetic vortex state in CeGe compound.

H7-02. Novel ferromagnetic Peierls insulators AMg$_4$Mn$_6$O$_{15}$ (A = K, Rb, Cs). *T. Yamaguchi*[1], K. Sugimoto[2], Y. Ohta[1], Y. Tanaka[3] and H. Sato[3]
1. Department of Physics, Chiba University, Chiba, Japan; 2. Center for Frontier Science, Chiba University, Chiba, Japan; 3. Department of Physics, Chuo University, Tokyo, Japan

Recently, Tanaka and Sato [1] discovered a series of manganese oxides AMg$_4$Mn$_6$O$_{15}$ (A = K, Rb, Cs), which are ferromagnetic insulators with a cubic crystal structure. The Mn ions are in a mixed-valent state of Mn^{3+} and Mn^{4+} with an average oxidation state of 3.5+ ($3d^{3.5}$) and are fully spin-polarized in the ground state with a ferromagnetic transition temperature of ~170 K. The electric resistivity shows an insulating behavior in the entire temperature range observed. In our presentation, we will show that a mechanism of insulating ferromagnetism similar to that of $K_2Cr_8O_{16}$ [2] also applies in this manganese series. Namely, using the density-functional-theory (DFT) based electronic structure calculations, we will demonstrate that the electronic state near the Fermi level may simply be described as a three-dimensional (3D) arrangement of the one-dimensional (1D) chains of O 2p orbital and Mn 3d orbital running along the three axes of the cubic lattice (Fig.1). Thus, a surprisingly simple electronic structure resides in this series. We will show that these chains are ferromagnetic due to double-exchange mechanism operating between localized t_{2g} and itinerant e_g orbitals. Based on the tight-binding model, we will moreover show that the electronic structure near the Fermi level can be described as follows (see Fig. 2): First, the nearest-neighbor d-p model of these chains (including only t^{pd}) describes the essential features of the bands (red curve). Then, addition of the interchain hopping parameters t^{dd} explains the band features more quantitatively (green curve). Finally, inclusion of the lattice dimerization due to Peierls mechanism actually leads to the opening of the band gap at the Fermi level (blue curve). The ferromagnetism is kept intact by this gap formation [3]. We thus conclude that the present manganese series are ferromagnetic due to the double-exchange mechanism and are distorted by the Peierls mechanism to make the systems insulating [4].

H7-03. Exciton condensation in excitonic insulators investigated by NMR. S. Li[1], S. Kawai[1], Y. Yamamoto[1], Y. Kobayashi[1] and *M. Itoh*[1]
1. Department of Physics, Nagoya University, Nagoya, Japan

Exciton condensation in excitonic insulators is one of major issues in condensed matter physics. In narrow-gap semiconductors and semimetals, electron-hole pairs (excitons) are formed, if the binding energy of the electron-hole pair is much stronger than the energy gap between conduction and valence bands. In the excitonic insulators, the Bardeen-Cooper-Schrieffer (BCS) condensation or Bose-Einstein condensation (BEC) takes place and sets in the excitonic insulator state. Recently Ta_2NiSe_5 [1, 2] and 1T-$TiSe_2$ [3] have a superconducting phase at high pressure have attracted attention as a new candidate of the excitonic insulator. In this study we have conducted nuclear magnetic resonance (NMR) measurements on Ta_2NiSe_5 and 1T-$TiSe_2$ to study the excitonic condensation in the excitonic insulators. The exciton condensation is expected to appear in magnetic susceptibility mainly composed of spin and orbital susceptibilities. In particular, the diamagnetic orbital susceptibility is expected to appear via the exciton condensation [4, 5]. We have measured the Se Knight shift tensors of the three Se sites in Ta_2NiSe_5 and obtained the temperature dependence of the Knight shift. We found that the Knight shift has a component not described by spin susceptibility. The exciton condensation is also able to be detected by the nuclear spin-lattice relaxation rate $1/T_1$ which monitors the dynamical susceptibility. In Ta2NiSe5, 1/T1 is proposed to show no coherence peak just below the transition temperature T_c from the theoretical study based on the two-dimensional three-band model [6]. Indeed we observed no coherence peak of $1/T_1$ and the thermally activated temperature dependence below T_c in Ta_2NiSe_5. We will also present the experimental results of the Se Knight

shift and $1/T_1$ in 1*T*-$TiSe_2$ which has a character of the charge-density-wave transition. The present study shows that NMR is a useful probe to study the exciton condensation in the excitonic insulators.

H7-04. Thermal properties of the single crystal $TrTe_3$ (*Tr* = transition metal). *S. Watanabe*[1], K. Kondo[1], N. Kase[1] and N. Miyakawa[1] *1. Dept. of Applied Physics, Tokyo University of Science, Katsusikaku, Japan*

Transition-metal chalcogenide is known as a group having a low-dimensional structure. Because charge-density wave (CDW) state competes with superconductivity in this agent group, many compounds show bulk superconductivity by suppressing CDW. However, we succeeded to find a new superconductor $HfTe_3$ last year [1]. In this compound, remarkable behavior suggesting coexistence of CDW and superconductivity has been confirmed. $ZrTe_3$ shows increasing T_c with suppression of CDW, when a part of Te is substituted to Se [2]. In addition, thermal conductivity measurements suggest that $ZrTe_{2.96}Se_{0.04}$ is a multiband superconductor [3]. However, there is no report on discussing the superconducting state from specific heat measurements, and it is not clear what type of superconductivity appears. Thus, our purpose is to reveal superconducting state of $ZrTe_3$ and Se-doped compounds. Based on these previous studies, we research to reveal the superconducting state from specific heat and Seebeck effect measurements of the $ZrTe_{3-x}Se_x$ single crystals. The single crystals can be grown as a thin plate, and its mass is so small that thermal properties cannot be obtained. In fact, our synthesized crystals are about 2.0 mm × 3.0 mm × 0.02 mm with the mass of about 1.0 mg. Our sample of $ZrTe_3$ shows no superconductivity above 2.8 K. On the other hand, in Se-doped compound ZrTe2.96Se0.04, superconducting transition was obviously found at 5.5 K by electrical resistivity measurements. Since T_c is strongly dependent on the sample quality, specific heat and Seebeck effect measurements are needed by using one single crystal to reveal the superconducting and normal state. In this presentation, we show development of precision specific heat and Seebeck effect measurements system, and the resulets of the thermal properties of $ZrTe_{3-x}Se_x$. Furthermore, we discuss the appearance of CDW and superconductivity properties with changing Se content by specific heat measurement.

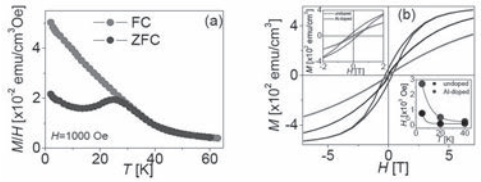
H7-05. The origin of charge density wave and superconductivity in $Lu*P*_2$ In (*P* = Pd, Pt). *H. Kim*[1], B. Min[1] and K. Kim[3] *1. Physics, POSTECH, Pohang, The Republic of Korea; 3. Max Planck Institute POSTECH/Korea, Pohang, The Republic of Korea*



We have explored the charge density wave (CDW) instabilities and superconducting behaviors in $LuPd_2In$ and $LuPt_2In$ cubic-Heusler compounds, using band structure and phonon dispersion calculations based on the *ab initio* density functional theory. We have found a dominant Fermi-surface (FS) nesting vector of q_M = (0.5, 0.5, 0.0). In the calculation of real susceptibility, the largest peak exists along the same q vector for both compounds. However, the phonon softening instability occurs only for $LuPt_2In$ as is consistent with experimental result. We have demonstrated that the presence and the absence of CDW instabilities, respectively, in $LuPt_2In$ and $LuPd_2In$ originate not from the difference in the FS nesting or the spin-orbit coupling strength but from the difference in the electron-phonon coupling strength. In the CDW ground states, Pt ions in $LuPt_2In$ are distorted into Pt cubes, which have a rotation within the Heusler structure. This transition induces the suppression of density of state of Pt *d*-band near the Fermi level. We have also discussed the superconducting behaviors in $Lu(Pt_{1-x}Pd_x)_2In$.

H7-06. Impact of the Al-doping on the ferromagnetic response of epitaxial $TbMn_{0.9}Al_{0.1}O_3$ thin films. *O. Morán*[1,3], J.L. Izquierdo[2], A. Astudillo[3], J. Martinez[3] and G. Bolaños[3] *1. National University of Colombia, Medellín, Colombia; 2. Institucion Universitaria Pascual Bravo, Medellín, Colombia; 3. Universidad del Cauca, Popayan, Colombia*

The influence of the Al-doping on the ferromagnetic response of epitaxial $TbMn_{0.9}Al_{0.1}O_3$ thin films (~100 nm thin) is experimentally studied. Epitaxial $TbMn_{0.9}Al_{0.1}O_3$ thin films (~100 nm thin) were grown on on (001)-oriented SrTiO3 substrates by means of high-oxygen pressure dc magnetron sputtering technique. Anomalous ferromagnetism observed in the undoped $TbMnO_3$ films, which can be atributed to strain generated by the lattice mismatch between the film and substrate. Although Al has the same valence as substituted Mn its small size gives rise to microstructural strain, which can modify the multiferroic properties of the undoped TbMnO3 films. X-ray diffraction patterns show that the films are epitaxial with the c-axis oriented in the (00l) direction. The introduction of Al in the films is evidenced by the shift of the (00l)-reflections to lower angles as compared with those of the undoped film. The undoped and Al-doped films show a well-defined transition at ~40 K, which is very close to the magnetic ordering temperature (~42 K) from the paramagnetic phase to the sinusoidal antiferromagnetic structure of the manganese spins. Moreover, the enhanced ferromagnetic behavior of $TbMnO_3$ films upon Al-doping is clearly evidenced by the larger remanence and coercivity observed in the magnetization vs. field dependences at low temperatures.

H7-07. Schottky specific heat of the lightly Mn-substituted electron-doped $SrTiO_3$. *T. Okuda*[1,2], R. Kajimoto[3], M. Noda[4] and H. Kuwahara[4] *1. Graduate School of Science and Engineering, Kagoshima University, Kagoshima, Japan; 2. JST-CREST, Tokyo, Japan; 3. J-PARC Center, Ibaraki, Japan; 4. Physics, Sophia University, Chiyoda-ku, Japan*

Large changes in the low-temperature specific heat (low-T_C) by applying magnetic fields up to 9Tesla were found in the lightly Mn-substituted electron-doped perovskites $SrTiO_3$. [1] The changes in the low-T_C are qualitatively well explained by the Schottky specific heat (C_{Sch}) of localized spins of the Mn 3d electrons in weak internal magnetic fields via itinerant electrons. Accoding to the analysis by using the conventional model, the doped Mn ions are apparently not Mn^{4+} (S = 3/2) ions, but are Jahn-Teller active Mn^{3+} (S = 2) ions or mixtures of Mn^{3+} and Mn^{2+} ions, which support our scenario of the reduction of the thermal conductivity by the Mn substitutions [2]. However, the actual numbers of localized spins estimated from C_{Sch} are about 30% smaller than the expected values. Part of the localized spins of the Mn 3d electrons may disappear due to Kondo coupling with the itinerant electrons, leading to the observed enhancement of the electronic specific heat coefficients [1,2].

H7-10. Phase separation in Bi doped $La_{0.67}Sr_{0.33}MnO_3$. *A. Subramanian*[1] and N. Kambhala[1] *1. Centre for Nano and Soft Matter Sciences, Bangalore, India*

We have observed remarkable phase separation behaviour in $La_{0.67}Sr_{0.33}MnO_3$ doped with Bi^{3+} ion at La site. The polycrystalline $La_{0.67-x}Bi_xSr_{0.33}MnO_3$ (x=0, 0.1, 0.2, 0.3, 0.4 and 0.5) prepared by solid state reaction shows the rhombohedral structure up to x = 0.3, which changes to orthorhombic for $x \geq 0.4$. The temperature dependent resistivity and magnetization of $La_{0.67-x}Bi_xSr_{0.33}MnO_3$ (x>0) show the presence of phase separation of ferromagnetic metallic and charge ordered antiferromagnetic insulating phases. Markedly, the field dependant magnetization studies of $La_{0.67-x}Bi_xSr_{0.33}MnO_3$ (x=0.3) show the metamagnetic nature of ferromagnetic metallic state implying the competition of coexisting ferromagnetic metallic and charge ordered antiferromagnetic phases. The electron spin resonance and exchange bias studies of $La_{0.67-x}Bi_xSr_{0.33}MnO_3$ (x=0.4 and 0.5) substantiate the coexistence of ferromagnetic clusters in antiferromagnetic matrix.[1] Notably, two low-temperature upturns observed in resistance of $La_{0.37}Bi_{0.3}Sr_{0.33}MnO_3$, which indicates the existence of two different mechanisms. $La_{0.27}Bi_{0.4}Sr_{0.33}MnO_3$ shows the field induced metallic behaviour due to the melting of charge ordering with applied magnetic field. The large magnetoresistance of ~ 100 % was observed for $La_{0.27}Bi_{0.4}Sr_{0.33}MnO_3$ at ~ 90 K. On the other hand, $La_{0.37}Bi_{0.3}Sr_{0.33}MnO_3$ exhibits a nearly constant large magnetoresistance of ~ 80 % between ~ 30 and 250 K, which decreases outside this temperature range. The observed anomalous low-temperature magnetotransport properties of $La_{0.67-x}Bi_xSr_{0.33}MnO_3$ is shown to arise from the coexisting phases of ferromagnetic metallic and antiferromagnetic charge ordered insulating nature.[2]

H7-11. Superconductivity in Bi/Ni bilayer system:clear role of superconducting phases found at Ni/Bi interface. L. Liu[2,1], Y. Xing[3], D.F. Franceschini[3], I.G. solórzano[2] and *E.B. Saitovitch*[1] *1. CONAM, Centro Brasileiro de Pesquisas Fisicas, Rio de Janeiro, Brazil; 2. DEQM, Pontifícia Universidade Católica do Rio de Janeiro, Rio de Janeiro, Brazil; 3. Instituto de Física, Universidade Federal Fluminense, Niterói, Brazil*

Bi/Ni bilayers with varying Bi and Ni layer thicknesses have been prepared by (a) pulsed-laser deposition at 300 K and (b) thermal evaporation at 4.2 K. Transport measurements as well as high-resolution transmission and scanning transmission electron microscopy, supported by EDXS analysis, reveal that two superconducting intermetallic alloys, namely NiBi and $NiBi_3$, are formed by interdiffusion, if the bilayers are prepared at 300 K. These alloys are responsible for the superconductivity appearing in the Bi/Ni bilayer system. Samples prepared at 4.2 K and annealed at 300 K do not show any superconductivity, as expected in the case interdiffusion does not occur. Therefore, the discussion about the reason for the appearance of superconductivity in the Bi/Ni bilayer system seems to have found a conclusion.

H8-01. Topological order parameters of J_1-J_2 Heisenberg chains of S=1,2 and 3. *S. Fubasami*[1] and Y. Hatsugai[1,2] *1. Graduate School of Pure and Applied Science, University of Tsukuba, Tsukuba, Japan; 2. Division of Physics, University of Tsukuba, Tsukuba, Japan*

Phase diagrams of the integer spin Heisenberg chains with nearest neighbor (J_1) and next nearest neighbor (J_2) interaction are considered for S = 1, 2, 3 and 4. Motivated by the work of topological phase transition of the J_1-J_2-J_3 Heisenberg chains (S = 1)[1], an extension for higher integer S is discussed in this work. By focusing on the quantized Berry phases, sequential topological phase transitions of the J_1-J_2 model are demonstrated and discussed. Introducing local twists for the generic Heisenberg model, the Berry phase is defined for the ground state of the quantum spin system. When the system is invariant for the time reversal even with the twists, the Berry phase is quantized to 0 or π in modulo 2π (Z_2 Berry phases)[2]. Due to this quantization, the Berry phase cannot be modified unless the excitation gap closes. It implies that this Z_2 Berry phase is a topological order parameter. Since an isolated singlet pair of S=1/2 spins gives the Berry phase π, one can consider that this Z_2 Berry phase counts the number of singlet pairs on the twisted bonds[3]. In this study, we calculate the Z_2 Berry phases for the J_1-J_2 Heisenberg chains for S=1,2,3 and 4 numerically by the exact diagonalization. We have obtained series of topological quantum phase transitions by changing J_2/J_1. The results are consistently understood by reconstruction of the spin 1/2 valence bonds. This is a signature of fractionalization in the spin integer systems.

H8-02. Unifying pinch-points and half-moons in spin liquids. *H. Yan*[1], R. Pohle[1] and N. Shannon[1] *1. Okinawa Institute of Science and Technology, Kunigami, Japan*

Pinch-points are arguably the most well-known signature of a U(1) spin liquid. These singular points in structure factors imply divergence-free constraints of the effective magnetic field in the spin system. They are observed in various 2D (Kagome, checkboard etc.) and 3D (pyrochlore etc.) lattice models. Another phenomenon less celebrated, but also widely observed in various Kagome spin liquid models is half-moons in structure factors, i.e., circles with high intensity on opposite sides and low intensity in-between. There has yet to be a decent interpretation of them from a field-theoretic point-of-view like that of pinch-points. We propose a unifying theory for these two phenomena. We show that they arise from the dynamical properties of the divergence-free and curl-free components of the effective magnetic field respectively. While the divergence-free component dynamically decouples and forms a flat-band with pinch-points, the curl-free component carries perpendicular pinch-points and forms a dispersive band due to its non-trivial dynamical couplings. The half-moons are pinch-points on a dispersive band seen on a constant energy cross-section. We also propose that these phenomena can be observed in quantum spin liquid material $Ca_{10}Cr_7O_{28}$.

Three-dimensional view of the dynamical structure factor.

Half moons appear on a constant energy cross section of the dynamical structre factor.

H8-03. Quantum valence bond ice and possible relation to κ-H_3(Cat-EDT-TTF)$_2$. *M.G. Yamada*[1] and Y. Tada[1] *1. the Institute for Solid State Physics, Kashiwa, Japan*

Motivated by the discovery of the coexistence of unfrozen spin and dipole fluctuations in the organic molecular material called κ-H_3(Cat-EDT-TTF)$_2$ [1], we propose a new asymptotically solvable model, where a quantum spin liquid (resonating valence bond) state is accompanied by quantum proton motion, which we call quantum valence bond ice. We can regard this state as a new quantum spin-dipole liquid, where quantum spin fluctuations are purely coming from the coupling to the quantum proton motion. In the classical version of this model, there are macroscopically degenerate ground states, and quantum fluctuations of the proton motion lift the degeneracy. The resulting quantum ground state can be described by Anderson's resonating valence bond state [2] in the perturbative level. Relevance to the experiments of κ-H_3(Cat-EDT-TTF)$_2$ would also be discussed.

H8-04. Low-temperature and high-magnetic-field ESR study of honeycomb-lattice quantum magnet α-$RuCl_3$. *N. Kurita*[1], R. Takeda[1], H. Nojiri[2] and H. Tanaka[1] *1. Tokyo Institute of Technology, Meguro-ku, Japan; 2. Institute for Materials Research, Tohoku University, Sendai-shi, Japan*

Honeycomb-lattice quantum magnet α-$RuCl_3$ has been attracting recent attentions in view of a candidate substance that potentially realizes the Kitaev model [1]. It is known that the Kitaev model is an exactly solvable quantum spin model in which a quantum spin liquid (QSL) ground state emerges in a certain parameter range. In α-$RuCl_3$, $RuCl_6$ octahedra are linked sharing their edges and magnetic Ru^{3+} ions form honeycomb lattice in the ab-plane. Five electrons in the 4d orbitals of Ru^{3+} are in the low-spin state. Thus, low temperature effective spin of Ru3+ is one-half owing to strong crystalline fields from surrounding Cl^- ions and strong spin-orbit couplings [2]. Recently, it has been shown by several experiments that this compound undergoes a field-induced quantum phase transition (QPT) from the zig-zag ordered phase to a QSL phase [3]. In this study, we grew single crystals of α-RuCl3 and performed magnetic susceptibility, specific heat, and electron spin resonance (ESR) measurements under high magnetic fields for elucidating detailed magnetic properties. From the ESR measurement, the g-value of α-$RuCl_3$ for $H\|c^*$ is evaluated to be g_{c^*}=1.72. This value is comparable to g_{c^*}=1.67 obtained in the Ru^{3+}-doped $ScCl_3$ which has a similar crystal structure to that of α-$RuCl_3$. As to the field-induced QPT for $H\|ab$, we observed a softening of an excitation mode at the critical field H_c=7.6 T and a low-lying gapped excitation mode across H_c.

H8-05. Topological Clustering in Frustrated Magnets. *T. Mizoguchi*[1,3], L. Jaubert[2] and M. Udagawa[3] *1. Graduate School of Pure and Applied Science, University of Tsukuba, Tsukuba, Japan; 2. CNRS, University of Bordeaux, Bordeaux, France; 3. Department of Physics, Gakushuin University, Toshima-ku, Japan*

Fractionalization is one of the fundamental properties of magnets with nontrivial topological character. For example in spin ice, fractionalized degrees of freedom take the form of magnetic monopoles [1] which serve as elementary excitations with a conserved quantum number, their magnetic charge. Recently, it has been pointed out that the clustering of such topological charges leads to unconventional collective excitations, dynamical bottlenecks and new classical spin liquids on the pyrochlore [2,3] and kagome [4] lattices with further neighbor interactions and Ising spins. The topological-charge clusters give rise to characteristic patterns in static structure factors, which we named "half moon", distinct form the "pinch points" that serve as indicators of a Coulomb phase. In this presentation, we address the possibility of topological clustering in a more general framework. For this purpose, we adopt the J_1-J_2-J_3 Heisenberg models on kagome and pyrochlore lattices [5], which are natural extension of the aforementioned Ising models [2,3,4]. We studied the static magnetic structure factor by combining a large-N approximation and Monte Carlo simulations, and obtained an adiabatic evolution across a variety of strongly correlated magnetic textures. We further solved the semiclassical Landau-Lifshitz equation, and addressed how the characteristic patterns are observed through dynamical structure factor. We compare the obtained dynamical structure factor with the results of inelastic neutrons scattering spectra [6,7], which indeed signal the presence of nontrivial magnetic clustering.

H8-07. Importance of virtual singlets in RVB theory of quantum spin liquids. *A. Ralko*[1], F. Mila[2] and I. Rousochatzakis[3] *1. Institut Néel CNRS, Grenoble, France; 2. EPFL, Lausanne, Switzerland; 3. University of Minnesota, Mineapolis, MN, United States*

It is well known that the low-energy sector of quantum spin liquids and other magnetically disordered systems is governed by short-ranged resonating-valence bonds. Here, we will show that the standard minimal truncation to the nearest neighbor valence-bond basis fails completely even for systems where it should work the most, according to received wisdom. This paradigm shift is demonstrated for both the quantum spin-1/2 square-kagome [1] and kagome [2] lattices, where the strong geometric frustration prevents magnetic ordering down to zero temperature. In the former, the shortest tunneling events bear the strongest longer-range fluctuations, leading to amplitudes that do not drop exponentially with the length of the loop, and to an unexpected loop-six valence-bond crystal, which is otherwise very high in energy at the minimal truncation level. In the latter, we will show from preliminary results [3] how the virtual singlets help in understanding the complex structure of the spin liquid of the RVB description of spin-1/2 kagome antiferromagnets by evidencing the proximity of a diamond-like crystal and making comparison with DMRG data.

H9-01. Effects of thickness and thermal annealing of $Fe_{20}Co20B_{40}$ thin films on ferromagnetic resonance and microwave propagation properties. *A. Arteaga-Duran*[1], R. Sáenz-Hernandez[1], C. Santillan-Rodriguez[1], M. Botello-Zubiate[1], M.C. Grijalva Castillo[1] and J. Matutes-Aquino[1]
1. Physics of Materials, Centro de Investigación en Materiales Avanzados, S.C., Chihuahua, Mexico

Soft magnetic $Fe_{40}Co_{40}B_{20}$ films for EMI shielding applications with ferromagnetic resonance frequencies of a few GHz and large transmission signal attenuations have been studied as a function of film thickness from 80 to 270 nm, and of thermal annealing from 200 to 450°C under a vacuum below 2 x 10^{-5} Torr. The films were prepared by DC magnetron sputtering. The microwave scattering parameters were measured in the range of 1 – 6 GHz with a HP8753ES Network Analyzer by the line perturbation method, using a coplanar waveguide (CPW) with a characteristic impedance of 50 ohms. The thin films were prepared using 7059 corning glass (permittivity = 5.84) substrates and a target with $Fe_{40}Co_{40}B_{20}$ nominal composition.. Crystallinity of thin films was evaluated by grazing angle x-ray diffraction before and after the thermal annealing. Thickness and elemental composition of films were studied by scanning electron microscopy. The films grew in the amorphous state and they showed increasing signal attenuation with increasing thickness. The thermal annealing in vacuum enhanced the attenuation of electromagnetic waves and avoided the formation of iron oxide at high temperature.

H9-02. Accurate Current Measurements of a High Frequency GaN Inverter for Magnetic Characteristic Evaluation. *W. Martinez*[1] *1. KU Leuven, Diepenbeek, Belgium*

This paper introduces the phase characteristics issue of current sensors by the comparison between iron loss characterization procedures using clamp type current probes and high precision shunt resistances at high carrier frequency excitation with a GANFET inverter [1-6]. *Current Clamp* The selected Hall-effect clamp has a wide bandwidth up to 100 MHz. As the iron loss characterization procedure is estimated up to 1MHz of switching frequency, the bandwidth of the current clamp is enough. Nevertheless, when the phase characteristics are considered, the bandwidth is much different. Fig. 1(a) shows a sketch of the phase characteristics in terms of the switching frequency. *Shunt Resistor* The selected shunt resistance is a high accuracy shunt with a bandwidth up to 2 GHz, a maximum rise-time of 30ns and a maximum power of 3W. Nevertheless, although the magnitude characteristics of this shunt are relatively good until certain hundreds of kHz, the phase characteristics are quite deficient at high frequencies. Fig. 1(b) shows the phase characteristics of the shunt resistant. Moreover, shunt resistances are easy to characterize using a good impedance analyzer. On the other hand, Hall effect current clumps are much more difficult to characterize. Consequently, designing and implementing an additional phase compensator circuit can be relatively easy when the phase characteristics are well known. *Phase Compensator Circuit* The design and implementation of the phase compensator circuit for both sensors will be presented in detail in the final manuscript. RESULTS Fig. 2 shows the iron losses when the current probe and the shunt resistance are used, in the case of the experimental circuit. Fig. 2 also presents the conventional iron loss case of sinusoidal 50Hz excitation. The full procedure of the sinusoidal excitation is described in detail in [7]. The analysis, characterization of both methods and the results will be presented completely in the final manuscript. CONCLUSIONS In this paper, the influence of the current sensor on the magnetic characterization of an electrical steel ring is explored.

H9-03. Optimization of GMI effect and magnetic properties of Co-rich microwires by Joule heating. P. Corte-Leon[1], V. Zhukova[1], M. Ipatov[1], J. Blanco[3], J. Gonzalez[1] and *A. Zhukov[1,2] 1. Phys. Mater., UPV/EHU, San Sebastián, Spain; 2. Ikerbasque, Bilbao, Spain; 3. Dept. Appl. Phys., University of Basque Country, San Sebastian, Spain*

Giant magnetoimpedance (GMI) effect observed in soft magnetic materials is one of the most effective solutions for development of cost effective magnetic field sensors and devices owing to one of the highest magnetic field sensitivities [1,2]. The highest GMI ratio up to 600 % as well as magnetic field sensitivity up to 10%/A/m were experimentally observed in amorphous magnetic wires [1,2]. These achievements allowed to develop a number of extremely sensitive magnetic sensors and magnetometers [3]. It is clear that the performance of magnetic devices can significantly be improved if the used materials will present higher GMI effect. Considering that the predicted theoretical maximum GMI ratio (about 3000%) [1] is few times superior to the experimentally reported it is expected that technology improvement involving development of effective post-processing method will allow achievement of higher GMI ratio. Consequently considerable efforts have been paid to studies of the post-processing on GMI ratio of various magnetic materials, such as wires, ribbons, thin films and multilayers [1,2]. It is expected that Joule heating due to the induced magnetic anisotropy [2] can further improve the GMI effect. Up to know only limited number of experimental results on effect of current annealing on GMI effect are reported [2]. We studied the influence of current annealing on magnetic softness and GMI effect of $Co_{67}Fe_{3.9}Ni_{1.5}B_{11.5}Si_{14.5}Mo_{1.6}$ glass-coated microwires. Current annealed allowed optimization of magnetic softness of $Co_{67}Fe_{3.9}Ni_{1.5}B_{11.5}Si_{14.5}Mo_{1.6}$ microwires: properly current annealed microwires present low magnetic anisotropy field of about 25 A/m and coercivity of 2 A/m (see Fig. 1). We have investigated the GMI response of the current-annealed glass-coated microwire. From the obtained dependence we determined the optimal current annealing conditions and obtained considerable improvement of $\Delta Z/Z_{max}$ –values from 550% to about 650% after appropriate current annealing conditions (see Fig. 2). The analysis of the GMI ratio as a function of the frequency opens new lights to understand the distribution of the magnetic anisotropy inside the microwire.

H9-04. Grading of magnetic anisotropy and engineering of domain wall dynamics in Fe-rich microwires by stress- annealing. V. Zhukova[2], P. Corte-Leon[2], J. Blanco[3], M. Ipatov[2] and *A. Zhukov[2,1] 1. Ikerbasque, Bilbao, Spain; 2. Dept. Phys. Mater., University of Basque Country, San Sebastian, Spain; 3. Dpto. Física Aplicada, University of Basque Country, San Sebastian, Spain*

Magnetic wires present outstanding magnetic properties such as the giant magnetoimpedance (GMI) as well as magnetic bistability and related single domain wall (DW) propagation and hence are quite attractive for a number of technological applications [1,2]. The common viewpoint on remagnetization process of magnetic wires presenting magnetic bistability is that under the effect of external magnetic field the depinning and fast propagation of a single DW along the wire takes place [3]. The controllable and reliable DW dynamics is essentially relevant for development of aforementioned applications like racetrack memories. Therefore a few methods, like creation of notches, injection of DW by local field or controllable DW collision are proposed for controllable pinning of DWs [1-3]. The other effective method for local change of the internal magnetic field can be a spatially varying magnetization in a compositionally graded ferromagnets [4]. However such DW manipulation require use of precise techniques involving nano-manipulation. We studied magnetic properties and domain wall dynamics in Fe-rich microwires subjected by stress-annealing at variable temperature. Hysteresis loops of Fe-rich microwires have been considerably affected by stress- annealing. In stress-annealed Fe- rich microwire we obtained drastic decreasing of coercivity and change of character of hysteresis loop from rectangular to linear (see Fig.1). For stress-annealed under variable temperature Fe-rich microwires we obtained graded magnetic behavior with local hysteresis loops shape and features (coercivity, remanent magnetization) changing along the sample length (Fig.2). By measurements of local nucleation field we observe d that in the sample subjected to local stress-annealing we created the artificial source of domain wall injection allowing

manipulation of the domain wall dynamics. Observed stress-induced anisotropy must be related to internal stresses relaxation after annealing interplay of compressive "back-stresses" arising after stress annealing and axial internal stresses.

H9-05. Numerical analysis of deformation in multi-layered magnetite small-scale sheets under magnetic field. *D. Zhang*[1], W. Guan[1] and M. Yang[1] *1. School of Electrical Engineering, Wuhan University, Wuhan, China*

In this paper, we aim to investigate the applicability of multi-layered magnetite Fe3O4 nano-tubes included material as magnetic controlled moveable small-scale(micrometer)device by using numerical analysis. Magnetic field analysis, magnetic force analysis and structure analysis are carried out one by one for a two-layer small-scale sheet model with different orientations of nano-tubes as shown in FIG.1. The flux distribution, magnetic force distribution, and deformation are calculated and analyzed. Deformation of bending is confirmed to occur in a two-layer plate model under uniform magnetic field. The mechanism of deformation of multi-layered nano-tubes included materials under magnetic field is clarified and thus an improved model is proposed to obtain the expected deformation mode by controlling B[1]. A magnetic controlled movable small-scale device is able to be achieved to improve the capabilities in bio-engineering application, such as magnetic controlled drug delivery etc by controlling the on/off or the direction of the magnetic field simply. The effective permeability u_{eff} of each layer using homogenization method are defined as follows[2]: $u_{eff}=u_e+2u_e((u_i-u_e)/u_i+u_e-f_p(u_i-u_e))$ The magnetic force distribution is calculated by using the nodal force method, the local force F_{mf} is represented as follows[3]:$F_{mf}=\int T_{jk}\partial_j N_{ip}dV, T_{jk}=H_jB_k-\zeta_{jk}\int BdH$ The deformation distribution is obtained by using the following static structure analysis[4]:$Ku=F_{mf}$ In the improved model, the imposed field is changed to z direction and the orientation of nano-tubes in layer 1 is *z* direction and in layer 2 is *x* direction. The flux distribution, magnetic force distribution and the deformation of the improve model is shown in FIG.2. By changing the imposed magnetic field to z direction, the forces on surface at y=100 are increased and this makes the left part bend downward, too. Furthermore, the forces on surface at x=100 of layer 2 are opposite with those of layer 1, thus the expected bending mode can be achieved as seen from FIG.2(c).

H9-06. Nanostructure evolution of co-evaporated FeNi-SiO_2 magnetic nanoparticle film prepared under high magnetic field. *G. Li*[1], Y. Ma[1], s. Liu[1], L. Chang[1] and Q. Wang[1] *1. Key Laboratory of Electromagnetic Processing of Materials (Ministry of Education), Northeastern University, Shenyang, China*

In order to tune the magnetic properties of magnetic film with a small grain size, FeNi-SiO_2 nanoparticle composite films are fabricated by the thermal co-evaporation of FeNi and SiO_2 under high magnetic field (HMF). Then, this study explores effects of phase formation and elemental distribution inside the nanoparticles on magnetic properties. The results show that the spherical FeNi nanoparticles with an average diameter of about 5 nm dispersed uniformly in the insulating SiO_2 matrix, as shown in figure 1. Furthermore, HMF reduces Fe contents due to the different magnitude of magnetization force on evaporated Fe and Ni. This leads to different Fe contents inside each nanoparticle although Fe: Ni atomic ratio remains unchanged in depth. This results in coexistence of bcc and fcc phases in the nanoparticles. HMF enhances magnetic anisotropy in the films. The higher Fe content in the nanoparticles results in a higher saturation magnetization.

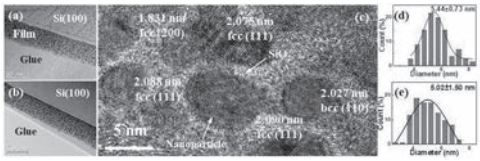

Fig. 1 Cross-section TEM images of the FeNi-SiO_2 nanoparticle films without (a) and with (b) the application of high magnetic field. (c) is high resolution TEM image of (a). (d) and (e) are Gaussian fitting to acquire the statistical particle size distribution from the large-scale TEM images of 0 T and 6 T films.

H9-07. Preparation and characterization of Fe-based amorphous soft magnetic flakes for high performance magnetodielectric inductors. *K. Qian*[1], Q. Li[1], C. Yu[1], A.S. Sokolov[1] and V.G. Harris[1] *1. Electrical and Computer Engineering, Northeastern University, Boston, MA, United States*

The rapid growth of semiconductor industry has made power and thermal management challenges a great concern, especially with the shifting of operation frequencies to higher bands. High performance inductors provide substantial size reduction and effective thermal energy management. A path undertaken here includes the development of high saturation induction, high permeability and soft magnetic flakes. Suspended in a low loss RF thermoset, such flakes can be used in composite inductors [1, 2] operating up to and beyond 200 MHz. Compared to spherical powders, flaky particles with high aspect ratio allow to increase the permeability and natural resonance frequency, exceed the Snoek limit[4], and reduce Eddy current loss. 25 μm spherical amorphous Fe-based soft magnetic powder used in this work was supplied by Carpenter Technology Corporation and boasted one of the world' s highest magnetic flux densities at 1.5 T, as compared to FeSiAl (1.2 T)[5] and NiZn ferrite (0.31 T @ 10 kHz)[6] . Scanning Electron Microscope (SEM) and Vibrating Sample Magnetometer (VSM) analysis of the as-supplied powder can be found in Figures 1(a) and 2. We demonstrate that the spherical particles can be turned into flakes by ball milling. The shape and aspect ratio of the flakes can be control by adjusting the milling speed and time, as well as the composition of the milling balls. To avoid oxygen exposure, the powder was handled in Argon atmosphere in a glove box, milled in toluene, and subsequently dried in vacuum. The balls/powder ratio varied between 2.6-10, balls diameter between 10-4 mm, milling time from 1 to 8 hours. The optimal milling time was found to be 4 hours, and smaller balls (4-6 mm) more efficient, allowing for flakes with aspect rations exceeding 10:1. After ball milling, the coercivity rose from 0.5 Oe to 30 Oe. The change was reversed by post-annealing in flowing N_2 at 693 K for 1 hour. A series of toroids made of the flakes aligned in dielectric hosts was used for the permeability measurements.

H9-08. Unusual influence of a heating rate on soft magnetic properties of $Fe_{81.5}Si_{0.5}B_{4.5}P_{11}Cu_{0.5}C_2$ nano-crystalline alloy. *Y. Zhang*[1], L. Jiang[1], T. Suzuki[1], X. Tong[1] and A. Makino[1] *1. Tohoku University, Sendai, Japan*

Energy conservation is one of the most important issues on a global basis. Soft magnetic alloys have been widely used for power transformers, motors, communications devices, and microelectronics, etc. It is important to improve the efficiency of converting and storing energy using these devices. Soft magnetic material requires high saturation magnetic flux density (B_s) and low coercivity (H_c) which are important factors to decrease the energy loss created by core loss (W) in application of small devices. Among the various Fe-based amorphous nano-crystalline materials based on FINEMET (Fe-Si-B-Nb-Cu) [1], NANOPERM [2] and NANOMET [3] with excellent soft magnetic properties, the Fe-rich (Fe-Si-B-P-Cu) nano-crystalline can be developd, which reduces production cost by eliminating expensive materials such as Nb in FINEMET and Zr, Hf in NANOPERM. Usually, the high Bs and low H_c of NANOMET can be obtained through the hetero-amorphous phase transforming to a uniform α-Fe nano-structure on annealing. A high heating rate of the annealing is necessary to achieve a nano-crystalline alloy in NANOPERM and NANOMET. However, when high heating rate, annealing more than 30 sheets at same time tended to be uncontrollable, during which ribbon stacking density is limited in application [4]. In this work, we obtained the low Hc in $Fe_{81.5}Si_{0.5}B_{4.5}P_{11}Cu_{0.5}C_2$ nano-crystalline ribbon alloy through optimum annealing treatment with low heating rate (10 °C/min). It is reported that small amount of C in Fe-Si-B-P-Cu alloy conduces to improving the glass-forming ability [5] but disrupting the short range order [6] which contributes to the formation of nuclei. The crystallization mechanism during annealing process with high and low heating rate in $Fe_{81.5}Si_{0.5}B_{4.5}P_{11}Cu_{0.5}C_2$ ribbon alloy is analyzed which is different from NANOMET (Fe-Si-B-P-Cu) nano-crystalline with high Fe content. The details of structural, morphological and magnetic properties will be presented.

Strontium hexaferrite is a promising material for recording high-density media, permanent magnets, among other materials that have a hard magnetic behavior, but also are expected to solve problems in materials that operate at high frequencies, provided they have high magnetic saturation combined with a low coercive field. This kind of material recently has also become the focus of nanotechnological applications such as wireless devices (GHz), microwave absorption materials (RAM), biosensor devices and others. Several researchers have extensively studied the substitution of Sr cation by rare earth, in order to change the structural and magnetic properties of hexaferrites. With the intention of altering the particle size, structural, and consequently the magnetic properties of the materials, several synthetic techniques are used, such as hydrothermal process, chemical co-precipitation method, sol-gel, sol-gel autocombustion method, planetary ball mill, solid state reaction, among others. In order to obtain a lower cost for the production of hexaferrite, since the syntheses of this material usually employ high cost or environmentally hazardous reagents, the route used in this work is the proteic sol-gel, which consists of using water of coconut as reagent. In this work it is shown the flow chart for preparation of samples Sr hexaferrite M-Type Sm-doped $Sr_{1-x}Sm_xFe_{12}O_{19}$ ($0.0 \le x \le 0.15$). X-ray diffraction analysis (XRD) showing that the hexaferrite has crystalline single phase belonging to the space group $P6_3/mmc$ was formed for the calcined precursor at 1000 °C/2h, for samples with up to 5% Sm. And the conformation of the formation of the single phase through the techniques: Rietveld refinement and Raman spectroscopy and infrared Fourier transform (FT-IR) spectroscopy.

H9-10. Tunability of magnetostatic and magnetodynamic properties of Fe-Si-B amorphous microwires by stress release. *I. Baraban*[1], A. Litvinova[1] and V. Rodionova[1,2] *1. Laboratory of Novel Magnetic Materials, Immanuel Kant Baltic Federal University, Kaliningrad, Russian Federation; 2. National University of Science and Technology «MISIS», Leninsky Prospect 4, Moscow, Russian Federation*

Amorphous ferromagnetic glass-covered microwires with Fe-based core exhibit the magnetic bistability [1] – prospected for practical applications of microwires themselves and their systems:as a sensor element of physical quantities (temperature, magnetic field, etc.)[2], or as a functional element of a coding systems [3]. The nature of the magnetic bistability of amorphous materials lies in the forming micromagnetic structure by Landau-Lifshitz type [4] during the process of manufacturing microwires by the Ulitovsky-Taylor method [5]. Mechanical stresses σ, associated with the rapid quenching process, with the difference in the coefficients of thermal expansion of the metal and glass and with stress applied by the mechanical stretching are induced in the microwire's core. For forming Landau-Lifshitz type of the structure, when a larger volume of the metal core occupies an axially magnetized domain, it is sufficient to select a highlystrictive material with a positive magnetostriction λ_S as a FeSiB alloy. In this work, we studied the effect of the stressed state of a metal core before and after partial removal of the mechanical stresses of the core by removing the glass coating on the magnetic properties and parameters of the domain wall propagation in microwires with Fe77.5Si17.5B15 composition. Microwires have parameters: d (metal core) from 9 to 13 μm and D (total diameter) from 16 to 35 μm.Hysteresis loops becomes S-shaped after glass removing, the coercive force decreases in 3 times: from 486 to 178 A/m (Fig. 1a). This evaluation indicates a change in the preferential mechanism of the magnetization reversal from the rapid propagation of the domain wall to the rotation of the vector of the magnetic moment as a result of the partial removal of the stresses of the microwire's core. Also, velocity of the domain wall propagation increases and mobility's values change in 5-9 times: from 5.4 to 29.1 $m^2/(s*A)$ (Fig.1b). Micromagnetic structure changes too: the stress components are redistributed along the radius of the metallic core of the microwire, the volume of the region with the axial direction of magnetization decreases and the volume of the periphery with a magnetic moment directed along the radius of the microwire increases.

H9-11. Unusually inverted and conventional volume hysteresis loops and its crossover behavior in $Fe_{73.5-x}Cr_xCu_1Nb_3Si_{13.5}B_9$. *A. Rosales Rivera*[1], I.G. Cely-Orjuela[1], A. Velásquez-Salazar[1], J. López-Tabares[1], N. Salazar-Henao[1] and F. Saccone[2] *1. Laboratorio de Magnetismo y Materiales Avanzados, Universidad Nacional de Colombia, Sede Manizales, Manizales, Colombia; 2. Departamento de Física, Facultad de Ingeniería, Universidad de Buenos Aires, Buenos Aires, Argentina*

The amorphous alloy ribbons system $Fe_{73.5-x}Cr_xCu_1Nb_3Si_{13.5}B_9$ in the range $0 \le x \le 20$ (at. %) is studied by vibrating sample magnetometry (VSM) and magneto-optic Kerr effect (MOKE) measurements, under finite *dc* applied fields (*H*), and X-ray diffraction and Hall effect experiments. The present study shows that the magnetic hysteresis behavior of ribbons volume is strongly different from that found in ribbons near- surface. Indeed, for $0 \le x \le 16$, the hysteresis loop is unusually inverted at ribbons volume with negative remanent magnetization, while is conventional at ribbons near-surface with positive remanent magnetization. For $16 < x \le 20$, the volume axial hysteresis loop becomes in conventional one of a typical ferromagnet with positive remanent magnetization. Likewise, it is found that these ribbons present amorphous and crystalline phases, magnetic anisotropies, non-identical coercive fields at volume and near-surface, several magnetic interactions, and crossover from anisotropic to isotropic behavior as the Cr content is increased. A possible relationship between the features described above and the emergence of the unusually inverted volume axial hysteresis loop is analyzed.

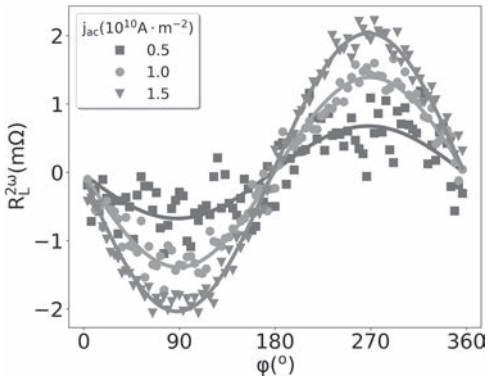
H10-01. Nonreciprocal electrical transport on chiral magnetic order. *R. Aoki*[2] and Y. Togawa[1] *1. Department of Engineering Physics and Electronics, Osaka Prefecture University, Sakai, Japan; 2. Department of Engineering Physics and Electronics, Osaka Prefecture University, Sakai, Japan*



Chirality of materials plays an important role to trigger striking physical responses. In particular, the nonreciprocal electrical transport phenomena observed in a chiral substance has been attracting immense attention [1]. Nonreciprocal electrical transport manifests itself via an electrical magnetochiral (eMCh) effect is in proportion to the inner product between a current *I* and a magnetic field *B*, allowing a direction dependent conductance. The eMCh effect has been observed recently in a chiral magnetic crystal MnSi due to its noncentrosymmetric crystalline structure [2]. Interestingly, chiral magnetic crystals can host many kinds of nontrivial topological spin structures, such as the chiral spin soliton lattice, the chiral conical phase, and the chiral magnetic skyrmion. It has been clarified that the chiral magnetic order influences transport properties through a coupling with itinerant electrons, inducing nontrivial transport phenomena such as discrete magnetoresistance [3] and topological Hall effect. In this respect, a role of the chiral magnetic order on nonreciprocal transport phenomena is quite intriguing. In this study, we have investigated nonreciprocal electrical transport responses in a chiral monoaxial magnet $CrNb_3S_6$, which is a prototype monoaxial chiral magnetic crystal. We observed that the eMCh response appeared over a wide range of temperature region. The eMCh signal was anomalously enhanced in the vicinity of the critical temperature and still existed even in the chiral conical phase of the $CrNb_3S_6$. In the case of multiaxial MnSi, the eMCh signal was largely suppressed in the saturated ferromagnetic state and appeared mainly in the paramagnetic state above the critical temperature, the origin of which was ascribed to chiral spin fluctuations [2]. Our results show that the chiral conical phase can contribute to an enhancement of the eMCh signal in addition to a chiral crystalline media and thereby provide a novel viewpoint to the eMCh mechanism.

H10-02. Effect of dc current on the magnetoresistance of ferrimagnetic insulator/normal metal bilayers. Y. Chen[2], D. Roy[2], E. Cogulu[2], *H. Chang*[1], M. Wu[1] and A.D. Kent[2] *1. Department of Physics, Colorado State University, Fort Collins, CO, United States; 2. Center for Quantum Phenomena, Department of Physics, New York University, New York City, NY, United States*

Normal metals (NM) with strong spin-orbit-coupling have been extensively used as spin current generators and detectors. A variety of materials, structures and techniques have been used to study the physics of spin-charge conversion, interfacial spin accumulation, spin transfer and the dynamical magnetization response. Spin Hall magnetoresistance (SMR) is the dependence of the resistivity on the magnetization direction and associated with the interaction of a spin current with the ferromagnetic (FM) layer. SMR is proportional to the square of the magnetization component transverse to the charge current. Unidirectional magnetoresistance (USMR) has also been observed in NM/FM(metallic) bilayers, such as Pt/Co, as a nonlinear resistance change when either the magnetization or the current direction is reversed. While previous research showed that USMR is either small or absent in NM/Ferrimagnetic insulator (FI) bilayers, important questions remain as to the effects of currents and spin-torques on their linear and nonlinear magnetoresistive response. In this work, we present the effect of dc current on the magnetoresistance in Pt(5nm)/YIG(20nm) bilayers in an in-plane field configuration at room temperature. Both the longitudinal R_L and transverse R_H linear and nonlinear resistive response are measured as a function of the angle ϕ between the ac current and the applied magnetic field H (Fig. 1). Our analysis indicates the spin-Seebeck effect accounts for the main non-linear response $R_L^{2\omega}$, the response at two times the ac frequency ω, consistent with published results. However, when a dc-current is added to the ac-current, several new features are observed. For example, peaks are observed near zero field in the $R_L^{2\omega}$-H hysteresis loops (Fig. 2). These peaks have a strong dependence on the dc-current magnitude and direction. We attribute these effects to modification of the surface magnetic order induced by spin-orbit torques and Oersted fields. These results will be discussed along with models of the underlying physics.

H10-03. Determination of the Néel temperature by the spin Hall magnetoresistance. *T. Iino*[1], T. Moriyama[1], H. Aono[2], Y. Shiratsuchi[2] and T. Ono[3] *1. Kyoto University, Kyoto, Japan; 2. Osaka University, Osaka, Japan; 3. Institute for Chemical Research, Kyoto University, Uji, Japan*

The spin Hall magnetoresistance (SMR) was first discovered in ferromagnetic insulator (FMI) /heavy metal (HM) bilayer systems [1] where the spin Hall effect in HM causes additional spin dependent scattering with the local moments in FMI [2]. SMR has been recognized as one of the convenient methods to electrically detect the magnetic state in magnetic insulators. In this study, we utilize the SMR to electrically detect the magnetic phase transition in a thin film of antiferromagnetic oxide Cr_2O_3 . Pt (t_{Pt} nm)nm) / Cr_2O_3 (20 nm) were deposited on an α-Al_2O_3(0001) substrate by magnetron sputtering. The films were patterned by a photolithography and Ar milling process. In order to increase the signals-to-noise ratio to detect a small resistance change, we adopted the differential resistance measurement technique. We obtained the resistivity ρ as a function of temperature with an external field of 0 ~ 9 Tesla applied perpendicular to the direction of the current flow. Figure 1 shows the magnetoresistance Δρ/ρ as a function of the temperature with various external fields. Change of Δρ/ρ is clearly observed in the vicinity of the Néel temperature T_N ~308 K of Cr_2O_3 [3]. We attribute this resistance change to the SMR picking up the change in the magnetic order across T_N. While the antiferromagnetic Cr_2O_3 moments do not respond to the external field below T_N, the paramagnetic moments above T_N tend to align along the external magnetic field. Since the SMR depends on the relative angle between the current flow and the net magnetization direction, we can identify the magnetic phase transition by the change of the resistance above T_N. We therefore demonstrated that the simple resistance measurement can identify T_N of the oxide antiferromagnet. In the presentation, we discuss in detail the t_{Pt} dependence as well as the field dependence of the resistance change.

Recently, the unidirectional spin Hall magnetoresistance (USMR) has been found in ferromagnetic (FM)/heavy metal (HM) bilayer systems [1]. Magnetoresistive effects, like anisotropic magnetoresistance and spin Hall magnetoresistance are usually symmetric with the current polarity and proportional to M^2. However, for the USMR one can detect a change of the resistance by reversing the current or magnetization direction. This is related to the spin accumulation at the FM/HM interface induced by the spin Hall effect. In addition, it was shown that in FM/HM systems with large spin-orbit coupling, a charge current flowing through the system generates spin-orbit torques (SOTs) that can switch the magnetization of the FM layer [2]. This effect is of large interest as a tool to control the magnetic state of a spintronic device, e.g. in SOT based magnetic random access memories. The USMR can be potentially used in applications for sensing and multi-state memory devices [3]. Here, we present harmonic longitudinal and transverse resistance measurements of Pt/Co, Ta/Co and their multilayer systems. By varying the layer order and stack repetitions, we can extract information about the influence of the stacking order on the USMR and the SOTs. We found that a variation of the FM/HM layer order gives rise to an additional sin2ϕ dependence in the second harmonic longitudinal resistance, which can be explained by a contribution of the planar Nernst effect. Thus, the order of the layer plays a significant role and directly influences the contribution of thermal effects, while keeping the magnitude of the USMR constant. Furthermore, we varied the capping layer to investigate the influence on the harmonic resistance measurements as well as to compare the total saturation magnetization M_s. In addition, we studied HM/FM/HM trilayers by x-ray resonant magnetic reflectometry at the L_3 Pt edge [4,5]. Recently, Peterson et al. [6] found a distinctive influence of the magnetic proximity effect (MPE) on the SOT efficiency in FM/Pt bilayers. Our results reveal the presence of the MPE in both trilayer systems. Further investigations are scheduled to correlate the influence of the MPE on the USMR as well as the SOTs in such systems.

H10-05. Annealing Temperature Effects on Spin Hall Magnetoresistance in Perpendicularly Magnetized W/CoFeB Bilayers. *T. Peterson*[1], P. Sahu[1], D. Zhang[2], D. Mahendra[1] and J. Wang[2] *1. Physics and Astronomy, University of Minnesota, Minneapolis, MN, United States; 2. Department of Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States*

Devices designed with spin Hall materials have been considerably studied as candidates for developing ultrahigh-density and ultralow-energy spin memory and logic devices, such as spin orbit torques magnetic random access memory (SOT-MRAM).[1] SOT devices typically consist of a thin ferromagnetic (FM) layer (e.g. CoFeB) sandwiched between a heavy metal (HM) layer (e.g. W) and an oxide layer (e.g. MgO). The HM layer interface with the FM layer is responsible for the spin Hall effect (SHE), which is favorable for SOT necessary for SOT-MRAM. To decrease the power consumption of SOT-MRAM requires materials large spin Hall angle (SHA) and large effective anisotropy. In addition, for the integration with the existing CMOS technology, spintronic devices are required to sustain operation reliability for processing temperatures as high as 400 °C. [2]. Spin Hall magnetoresistance (SMR) can be used to electrically measure the magnetization direction of a FM and provides a method to non-invasively access fundamental spin transport parameters such as the and spin diffusion

length vin HM and FM bilayers [3]. SMR originates from the simultaneous action of two effects, the SHE and the inverse SHE (ISHE). The SHE causes a conversion of charge current without a polarizing ferromagnet, while the ISHE converts a pure spin current into a charge current. In this work, we studied the SMR of perpendicularly magnetized W/CoFeB bilayer structures annealed at 250-425 °C. The angle dependent magnetoresistance was investigated to track the SMR where an in-plane external magnetic field of 8T is applied. Meanwhile, the sample was rotated in the *yz* plane to isolate the SMR signal from the anisotropic magnetoresistance (AMR). From the experimental results as shown in Fig. 1, we found that the SMR dramatically increases up to the maximum values with the annealing temperatures at 300 °C and 350 °C. When continue increasing the annealing temperature, the SMR decreases, this may be due to the increase and magnetization change.

H10-06. Room Temperature Large Magnetoresistance Effect based on Avalanche Breakdown in Ag/SiO_2/SI-p-Si Schottky junction. X. He[1], *Z. Sun*[1] and J. He[2] *1. State Key Laboratory of Advanced Technology for Materials Synthesis and Processing, Wuhan University of Technology, Wuhan, China; 2. Division of Functional Material Research, Central Iron and Steel Research Institute, Beijing, China*

Magnetoresistance (MR) devices combining high performance and low cost have always attracted a lot of attentions. Up to now, the large MR effect has been observed in nonmagnetic semiconductor based MR devices, such as Si[1-3], GaAs[4] and Ge[5] based devices. In these devices, the MR effect were either due to interface effect[4] or due to body effect[2]. However, separating the interface MR effect from the body effect needs to be further investigated. In this paper, we studied the room temperature MR effect of an Ag/SiO_2/SI-p-Si/SiO_2/Ag device and its MR mechanisms were investigated by separating its surface MR effect and the body effect. As shown in the inset of Figure 1, we used a voltage source to apply voltage V_{43} and an ammeter to measure the current I_{43}. In order to measure the body MR effect, an additional voltmeter V_{12} was applied. The I_{43}-V_{43} curves can be divided into two parts: when V_{43} is smaller than a threshold voltage (V_{th}), the I_{43}-V_{43} curve are linear and the currents are very small. There are very small variation of current under applied magnetic field. When $V_{43}>V_{th}$, the current increases sharply. The currents obviously decrease with increasing the applied magnetic fields, indicating a large MR effect. When V_{43}=20V, the MR[4] reaches about 90%@1T. In Fig. 2, the body MR effect of the SI-p-Si can be independently acquired. We found that the V_{12}-I_{43}curves vary little with the applied magnetic field, and the corresponding largest MR is about 9%@1T@2mA, which is only one-tenth of the total MR effect. Therefore, we conclude that the MR effect in our device originates from the Ag/SiO_2/SI-p-Si Schottky junction. When $V_{43}>V_{th}$, local plasmas due to avalanche breakdown gradually form in the junction, resulting in the increment of the current, which is similar to our previous work[1]. The plasmas can be quenched by the applied magnetic field, resulting in a large MR effect. This work was supported by the National Natural Science Foundation of China (Grant Nos. 11574243 and 11174231).

H10-07. AC Excited Spin Hall Magnetoresistance Sensor with Extremely Simple Structure and Zero DC Offset. *Y. Xu*[1], Y. Yang[1], M. Zhang[1], Z. Luo[1] and Y. Wu[1] *1. Electrical & Computing Engineering, National University of Singapore, Singapore*

Magnetoresistive (MR) sensors are becoming increasingly important for applications in both traditional and emerging industries such as automation, automotive, aerospace, consumer products, robotics, logistics, internet-of-things, autonomous-vehicles, *etc.*, owing to their high sensitivity at low-field. However, most of the commercial MR sensors tend to be more costly than Hall effect sensors, due to their complex magnetic bias structure which is required for output linearization and suppression of noise and DC offset. Recently, we have reported that the coexistence of spin Hall magnetoresistance (SMR) and spin-orbit torque (SOT) in ultrathin NiFe/Pt bilayers allows to realize a SMR sensor with built-in magnetic bias arising from the SOT effective field[1,2]. This significantly simplifies the MR sensor design. Here, we demonstrate that, by using built-in AC excitation and rectification detection, we are able to effectively eliminate the requirements of any linearization and domain stabilization mechanisms separate from the active sensing layer, thereby achieving an all-in-one SMR sensor with only a bare NiFe/Pt bilayer. Despite the simplest possible structure, the fabricated Wheatstone bridge sensor exhibits essentially zero DC offset, negligible

hysteresis, and a detectivity of around 1nT/√Hz at 1Hz. Furthermore, unlike commercial anisotropic magnetoresistance sensor, which can only resolve 180° as an angle sensor, the SMR sensor can detect 360° of angular position. The superior performances together with simplest possible structure for any magnetic sensor will open new opportunities for industrial and consumer product applications, as demonstrated in proof-of-concept experiments on angle, vibration and finger motion detection.

H10-08. Low temperature divergence in the AHE and AMR of ultra-thin Pt/Co/Pt trilayers. *E. Zion[1] 1. Physics, Bar Ilan University, Tel Aviv, Israel*

We study the anomalous Hall effect (AHE) and anisotropic magnetoresistance (AMR) in a series of ultra-thin Pt/Co(x)/Pt trilayers (0.1 nm <x< 0.5 nm). We find that the AHE exhibits a significant increase at low temperatures (T). This increase cannot be attributed to a trivial increase in magnetization or resistivity. A similar T dependence is observed in the AMR measurements. Interestingly, these effects show almost no dependence on cobalt thickness. Our measurements indicate that the deviation from common behavior is related to an additional scattering mechanism that we attribute to an interface induced magnetic proximity effect in the Pt layers, which increases at low temperatures.

ρ_{xy} as function of T, Co thicknesses are marked.

ρ_{xy} in the low T regime for the sample with Co thickness of 0.3 nm, dotted line is the expected extrapolation. Inset: schematic illustration of sample structure and measurement geometry

Session H11
SPIN-CHARGE CONVERSION AND SPIN-ORBIT TORQUE III (Poster Session)

Eric Arturo Montoya, Chair
University of California, Irvine, Irvine, CA, United States

H11-01. Roles of PtMn in spin-orbit torque switching in PtMn/[Co/Pt]$_2$. *M. Yang*[1], P. Lin[1], B. Yang[1], Y. Du[1] and C. Lai[1] *1. Department of Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan*

The perpendicular magnetization can be switched by spin-orbit torque (SOT) with the assistance of an external field. Antiferromagnets (AFMs) exert exchange bias (EB) on adjacent ferromagnets, using which the field-free switching can be achieved in AFM/FM bilayer structures. PtMn known to have a high blocking temperature has been used to demonstrate the field-free switching [1]. Here we demonstrate three different switching modes in AFM/FM by controlling the PtMn state. Three samples with the same film stack Ti(3)/Pt(6)/PtMn(9)/[Co(0.8)/Pt(2)]$_2$/Ti(3) (unit: nm) were sputtered. Sample I was deposited at room temperature. Sample II was deposited with the layers Ti/Pt/PtMn at 400 °C, followed by an in-situ annealing for 1 hour, and then the upper layers (Co/Pt)$_2$/Ti were deposited at room temperature. Sample III follow the same process as sample II but followed by a field annealing process at 250 °C. Samples II and III possessed an $L1_0$ ordered PtMn phase but Sample I showed the disorder phase. Only Sample III has an exchange bias of ~100 Oe. By the lock-in method, we can obtain the longitudinal effective field, as shown in Fig. 1. Judged from the sign of the effective field, we conclude the dominating spin current comes from the top instead of PtMn. The symmetric Co/Pt multilayers have shown a net spin current from top Co/Pt interface [2,3]. The PtMn has the positive spin Hall angle as Pt, that is, the spin current generated from the top Co/Pt interface may be partially cancelled by that produced in PtMn layer. Notice that the effective field is reduced for the sample with $L1_0$ PtMn phase, indicating the SOT generated in PtMn may be enhanced after ordering. The switching curves are shown in Fig. 2. For Sample I, a typical binary switching is observed but Sample II always ends up at a demagnetization state, consistent with a reduced effective field. Sample III shows an unusual switching, for which the switching only occurs from a negative to positive magnetization. The existing perpendicular exchange bias, which favors the positive magnetization state, may be responsible for this switching.

Materials that may exhibit a giant Spin Hall Effect (SHE) have recently received attention due to the possibility of converting an electric current into a spin current without the need of ferromagnets [1]. In addition to the small intrinsic SHE in pure metals, scattering on impurities with strong spin-orbit coupling can contribute to an enhanced SHE. Recent theoretical papers

have proposed that alloys of Bi diluted in a Cu matrix should show giant SHE [2,3]. However, in order to attain high SHE values relatively large Bi concentrations are mandatory[4,5]. In this work we incorporate up to 10% of Bi atoms into the Cu structure by co-evaporation of Bi and Cu atoms in a molecular beam epitaxy system at room temperature. We investigate the spin pumping effect in a series of yttrium-iron-garnet (YIG)–Cu(Bi) bilayers by the measurement of broadband ferromagnetic resonance. We determine the effective spin-mixing conductance as a function of Bi concentration from ferromagnetic resonance measurements on pure YIG layers as well as on Cu(Bi)/YIG bilayers in a frequency range from 2-10GHz. With a Cu(Bi) layer on top of the YIG the Hilbert damping is significantly enhanced (up to 40%) for samples with higher Bi concentrations, as can be seen in the figure. The effective spin-mixing conductance extracted from the ferromagnetic resonance experiments increase with the Bi concentrations up to a value of $G_{eff} = 7.3x10^{18}$ m^{-2}, which is at least twice the value measured in similar Pt/YIG structures. This makes Cu(Bi) a promising material for spintronics applications.

H11-03. Spin torque efficiency in Pt/Co bilayers estimated from spin torque ferromagnetic resonance. *Y. Du*[1], S. Karube[1,2], M. Kohda[1,2] and J. Nitta[1,2] *1. Department of Materials Science, Tohoku University, Sendai, Japan; 2. Center for Spintronics Research Network, Tohoku University, Sendai, Japan*

When an electrical current density (J_e) flows through materials with strong spin-orbit coupling, transverse spin accumulations occur due to the spin Hall effect (SHE). In non-magnetic/ferromagnetic (NM/FM) bilayers, the transverse spin current density (J_s) diffusing into the neighboring FM layer exerts torques on its magnetization. Such charge/spin current conversion is characterized by the spin torque efficiency $\xi_{ST} \equiv (2e/\hbar)J_s/J_e$. The ξ_{ST} can be experimentally measured by methods such as spin torque ferromagnetic resonance (ST-FMR),[1] harmonic response technique, spin Hall magnetoresistance measurement *et al.* In this work, we studied ξ_{ST} in epitaxial (epi-) and polycrystalline (poly-) Pt/Co bilayers using ST-FMR, which takes advantage of the SHE in Pt that induces FMR dynamics with rf input. Thin film stacks of Pt(10)/Co(t_F)/Al_2O_3(2) (thickness in nm, t_F ranges from 2.5 to 9) were deposited onto Si/SiO_x and Al_2O_3(0001) substrates to fabricate poly- and epi- films, respectively. To perform the ST-FMR measurement, samples were patterned into rectangular shapes with ground-signal-ground waveguide. Figure 1 shows the frequency dependence of the ST-FMR signal V_{mix}, which is the d.c voltage across the device, as a function of the external field for poly- sample with $t_F = 3$ nm. By fitting the V_{mix} with symmetric (S) and anti-symmetric (A) Lorentzian function, the effective ξ_{ST} is obtained (Fig. 2) via $\xi_{ST} = (S/A)e\mu_0 M_s t_F t_N/\hbar_bar(1+M_{eff}/H_{res})^{1/2}$,[1,2,3] in which M_s, $t_{F(N)}$, M_{eff} and H_{res} are the saturation magnetization, thickness of FM(NM) layer, demagnetization and resonance field. By plotting the ξ_{ST} as a function of the t_F, the damping-like and field-like spin torque efficiency ξ_{DL} and ξ_{FL} of poly- samples are obtained,[3] to be 0.171±0.014 and 0.016±0.009. On the other hand, for epi- samples, the ξ_{FL} is found to be 0.208±0.056, which is one order of magnitude larger than that of the poly- samples; the ξ_{DL} of epi- samples is found to be 0.331±0.059, which is about 2 times larger. The large enhancement of the ξ_{FL} in epi- samples suggests considerable Rashba spin-orbit coupling at Pt/Co interface.[4,5] Our results show clearly how the change of interface could dramatically change the spin orbit torques in NM/FM bilayers.

H11-04. Inverse Spin Hall Effect and Magnetization Switching in Topological Dirac Semimetals. *T. Misawa*[1] and K. Nomura[2] *1. Institute for Solid State Physics, University of Tokyo, Kashiwa, Japan; 2. Tohoku University, Institute for Materials Research, Sendai, Japan*

We study the spin/charge transport phenomena and magnetization switching in a topological Dirac semimetal attached to a ferromagnetic insulator. Topological Dirac semimetals manifest a large inverse spin Hall effect when a spin current is pumped from the attached ferromagnetic insulator with a precessing magnetization, compared to conventional normal metals. We show that the induced charge current is robust against disorders. This result indicates that the robustness originates to topological nature of the topological Dirac semimetals, such as the helical Fermi arc states at the interface. We also show that an applied electric field in the topological Dirac semimetal generates the spin Hall torque which reverses the magnetization in the ferromagnet.

H11-06. Non-local dipole effects on spin density waves in planar ferromagnets. *P. Sprenger*[1], M. Hoefer[2] and E. Iacocca[2] *1. University of Colorado Boulder, Boulder, CO, United States; 2. Applied Mathematics, University of Colorado at Boulder, Boulder, CO, United States*

Recent theoretical studies have demonstrated the possibility to excite and sustain static chiral textures in trivial ferromagnetic and antiferromagnetic nanowires by exerting spin orbit torques at their extrema [1-4]. The resulting chiral state is a spin density wave (SDW) [1] in which the non-collinear magnetization enforces a non-zero exchange flow that minimizes the exchange energy, similar to a train of wide Néel domain walls with the same chirality. In the ideal scenario of a planar magnet, i.e., with uniaxial symmetry, the exchange energy is effectively canceled and SDWs can be interpreted as a spin superfluid [3]. Superfluidity can be lost in realistic magnets by several effects: spin waves excited on a SDW can enter a supersonic regime relative to the SDW so that vortex-antivortex pairs can ensue and unravel the SDW chirality [1]; and in-plane anisotropy perturbs the spatial profile of the SDW, inducing a finite exchange energy along the SDW [2,4]. However, the effect of non-local dipole arising from the finite thickness d of magnetic films on the spatial profile of the SDW as well as magnetostatic waves has not been considered. Here, we use asymptotic methods to find the spatial profile of a SDW considering non-local dipole fields. We find a correction to the SDW wavevector k_0 that has two terms: a shift proportional to d and a modulation whose amplitude and wavevector are proportional to d and k_0, respectively, shown in Fig. 1. The maximum wavevector is k_0+d/4, in quantitative agreement with previous micromagnetic simulations [1]. Additionally, our analytical approach is amenable to describe the dispersion relation of both magnetostatic and exchange spin waves on the dipole-perturbed SDW in order to predict the stability of SDWs in realistic materials and devices.

H11-07. Determination of Spin Hall Effect and Spin Diffusion Length of Pt by Enforcement of Onsager Reciprocity in the Fitting of Damping and Inverse Spin-Orbit Torque. *T. Silva*[1], A.J. Berger[1], E. Edwards[1], H. Nembach[1], O. Karis[2] and M. Weiler[3] *1. NIST, Boulder, CO, United States; 2. Department of Physics and Astronomy, Uppsala University, Uppsala, Sweden; 3. Physics Department, Technical University of Munich, Garching, Germany*

Understanding the evolution of spin-orbit torque (SOT) with increasing heavy-metal thickness in ferromagnet/nonmagnet (FM/NM) bilayers is critical for SOT-magnetic memory development. However, there is a discrepancy in the dependence of damping enhancement and damping-like SOT on NM thickness. Here, by use of phase-resolved vector network analyzer ferromagnetic resonance (VNA-FMR) measurements [1], we simultaneously extract damping enhancement and damping-like inverse SOT in Py/Pt bilayers as a function of Pt thickness [2]. By enforcing Onsager reciprocity in the data analysis, both the damping enhancement and damping-like inverse SOT can be described by a single spin diffusion length (≈ 4-5 nm), and we unambiguously separate the spin pumping and spin memory loss contributions to damping. Less than 40% of the pumped spins pass through the Ni80Fe20/Pt interface into the Pt. On account of the spin memory loss and corresponding reduction in total spin current available for spin-charge transduction in the Pt, we determine the bulk spin Hall angle = 0.387(8) to be larger than commonly-cited values. These results suggest that Pt can be an extremely useful source of SOT if the FM/NM interface can be engineered to minimize spin loss. Lastly, self-consistent fitting of the damping and SOT data is best achieved by a model with Elliott-Yafet spin relaxation and extrinsic spin Hall effect, where both the spin diffusion length and spin Hall conductivity are proportional to charge conductivity.

Nembach, *et al.*, "Inductive detection of field-like and damping-like AC inverse spin-orbit torques in ferromagnet/normal metal bilayers," arxiv:1611.05798v2 (2017). [2] A. J. Berger, E. R. J. Edwards, H. T. Nembach, *et al.*, "Determination of spin Hall effect and spin diffusion length of Pt from self-consistent fitting of damping enhancement and inverse spin-orbit torque measurements," arXiv:1711.07654v1 (2017).

(a) Final values for dampinglike (DL) inverse spin orbit torque (iSOT) and fieldlike (FL) iSOT for Py(3.5)/Pt(d_{Pt}). The FL iSOT remains constant over the range of studied thicknesses, whereas the DL iSOT increases with a characteristic length scale ~ 5 nm. (b) Gilbert damping for the same sample series (error bars are smaller than symbols). Color coding indicates different contributions to the Gilbert damping. Both the iSOT conductivity and damping are fit to four different models, where spin relaxation is either Elliot-Yafet (EY) or D'yakonov-Perel' (DP), and the spin Hall effect arises from either intrinsic (int) or extrinsic (ext) processes. In both cases EY + ext (black line) provides the best fit, as determined by a χ^2 analysis.

H11-08. Quantifying the spin Hall angle and spin diffusion length in niobium from spin-pumping-induced inverse spin-Hall effect. *K. Jeon*[1,2], C. Ciccarelli[2], H. Kurebayashi[3], J. The combination of spin pumping with inverse spin Hall effect (iSHE) [1,2], spin-to-charge conversion, allows the electrical detection of spin current flow in a ferromagnet (FM)/non-magnet (NM) bilayer. A dynamically injected spin current in the NM layer is scattered through iSHE and converted into a transverse charge current, producing a measurable electromotive force. This approach has been widely employed to investigate the spin-orbit coupling and spin transport parameters, such as spin Hall angle θ_{SH} and spin diffusion length l_{sd}, in a variety of NM materials [1, 3-5]. Several studies exploring the quasiparticle (QP) spin transport in superconductors (SCs) have been achieved using DC (non-)local transport measurements [6]. Interestingly, it has been shown that in all metallic non-local spin-Hall devices with transparent contacts [7], the iSHE mediated by QP in the superconducting state of NbN increases significantly by about 3 orders of magnitude compared

to the normal state. Another recent experiment has reported that for a ferrimagnet insulator YIG/NbN junction with ohmic contacts [8], the iSHE voltage induced by spin Seebeck effect is largely enhanced by a factor of ~2.5 in the vicinity of the superconducting transition. Although more work is certainly needed, these experiments seem to suggest the existence of emergent phenomena arising through the QP spin-orbit coupling. Here, we experimentally quantify the θ_{SH} and l_{sf} values of Nb from spin-pumping-induced iSHE measurements in Nb/$Ni_{80}Fe_{20}$ bilayers by varying the Nb thickness t_{Nb}, comparing to a $Ni_{80}Fe_{20}$/Pt reference sample, and checking an out-of-plane angular dependence. We also studied iSHE as a function of temperature T for different t_{Nb}. Above the critical temperature T_c of Nb, a clear t_{Nb}-dependent T evolution of iSHE is observed whereas below T_c, the iSHE voltage drops rapidly and becomes undetectable at a lower T. This can be understood in terms of the decay of QP charge relaxation length in the superconducting Nb layer. The additional investigation of iSHE in a different sample geometry along with model calculation suggests the necessity of a careful design of the sample/device geometry in spin-pumping-induced iSHE measurements with SCs below T_c.

Recently, a significant amount of work has been done on understanding and utilizing spin Hall effects in paramagnetic heavy metals as means to control magnetic states of ferromagnets [1]. The most basic mechanism relies on inducing torque due to accumulated spin density noncollinear to magnetization. Due to possible symmetry breaking at the interface, additional component to spin torque might appear, which is believed to result from Rashba-Edelstein effect [2,3,4]. We consider, in general, a trilayer system consisting of a $Co_{20}Fe_{60}B_{20}$ ferromagnet sandwiched between two metals with opposite signs of spin Hall angle: W and Pt. Using spin-torque ferromagnetic resonance method (ST-FMR) [5] we measure symmetric and antisymmetric component of the resonance signal (A) as a function of heavy metal thickness. Symmetric part of the signal is known to correlate with damping-like torque while antisymmetric part correlates with field-like torques. Contrary to W/CoFeB bilayer, in the CoFeB/Pt system a sign reversal of the asymmetric component is measured (Fig. 1), which also appears in measurements on the whole W/CoFeB/Pt trilayer. By fitting experimental data with the results of spin drift-diffusion theory we consider different interfacial mechanisms and estimate contributions to field-like torque from interface, spin Hall effect and Oersted field. We particularly estimate real and imaginary parts of spin-mixing conductance as well as spin memory loss due to interfacial spin-orbit phenomena for both W/CoFeB and CoFeB/Pt interfaces. This allows us to predict effective spin Hall angle of examined structures more accurately. Acknowledgments: The project is supported by National Science Centre, Poland, Grant No. 2015/17/D/ST3/00500. L. K. and T. S. acknowledge funding from National Science Centre in Poland as a research project No. 2016/23/B/ST3/01430 (SPINORBITRONICS).

Spin-orbit torque (SOT) induced by spin Hall and interfacial effects in heavy metal(HM)/ferromagnetic(FM) bilayers has recently been employed to switch the magnetization direction using in-plane current injection. In this paper, using Keldysh Green's function approach within first principle method we obtain Kubo-like expressions for the SOT. We decompose the SOT into Fermi sea and Fermi surface as well as Field-Like(FL) and Damping-Like(DL) components. As presented in Fig.[1], we calculate the results versus orientation of the magnetization for different inplane lattice constants and thicknesses of the HM in HM/Co bilayer system with HM=Pd and Pt. We show that the SOT is governed by the electrons on the Fermi surface and verify the DL and FL decomposition of the SOT through their expected angular dependence. We extract the amplitudes of the FL- and DL-SOTs for different thicknesses of the HM, which are in relatively good agreement with the experimental results in Ref.[1] for Pt/Co and Ref.[2] for Pd/Co biayers.

H11-11. Fast and Energy-effective STT Switching in MTJs with Assistance of SOT. *S. Pathak*[1], J. Cha[1], C. Youm[2] and J. Hong[1] *1. Materials Science and Engineering, Yonsei University, Seoul, South Korea, Seoul, The Republic of Korea; 2. Computer Science, Yonsei University, Seoul, The Republic of Korea*

Magnetic Random Access Memory (MRAM) is a promising emerging memory technology because of its various advantages, such as non-volatility, high density and scalability, over other competing memories. In particular, spin-transfer torque MRAM (STT-MRAM) having the building unit of a perpendicular magnetic tunnel junction (p-MTJ) has received a significant attention because it offers reduced write current and strong thermal stability. Despite all these advantages, STT-MRAM also faces various challenges such as, reliability of a tunnel barrier, long write latency and high write power. A novel, spin-orbit torque (SOT) switching is gaining interest in order to overcome those problems. Especially, separate read and write lines in SOT-MRAM promises strong reliability, in addition to fast switching speed due to direct switching faster than precession switching in STT-MRAM. In this presentation, we discuss our simulated results showing the significant improvement of both switching speed and power consumption by using STT write pulse (WP_{STT}) current with additional SOT write pulse (WP_{SOT}) current. We have used OOMMF simulator implemented with an STT-SOT module developed during our study to investigate the switching behavior of a 20 nm cell in a p-MTJ at a WP_{STT} duration of 10 ns (Fig 1). We found that both amplitude and duration of the WP_{SOT} have a great impact on the switching behavior of the free layer in the p-MTJ. For example, we could dramatically reduce the switching time by 80 % and thereby reduce the write power over 60 % as compared to those in the absence of the WP_{SOT} (Fig 2 (a-d)). Even a very weak SOT current density pulse (of the order of 10^2 A/m^2) significantly reduced the critical current density for switching and thereby decreased the power consumption as well. It is worth to be pointed out that the power can be saved further by tuning the WP_{SOT} parameters i.e. amplitude and duration along at the critical current density of WP_{STT}. The reduction is closely related to the details of spin precession during switching under the influence of torque due to WP_{SOT} and WP_{STT}, acting simultaneously.

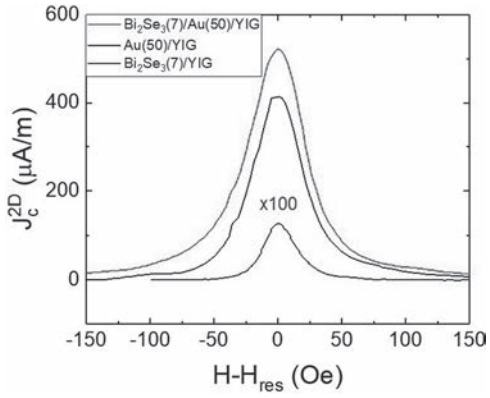
Energy saving and switching time as a function of J_{STT}

H11-12. Spin-Orbit Torques in Fe_xPt_{1-x} Alloys and Fe/Pt Multilayer Heterostructures. Y. Ou[2], *R.C. Tapping*[2], D. Ralph[2] and R. Buhrman[1] *1. Applied & Engineering Physics, Cornell University, Ithaca, NY, United States; 2. Physics, Cornell University, Ithaca, NY, United States*



The efficient manipulation of the magnetization in thin film heterostructures with strong spin-orbit torques (SOTs) offers a number of promising opportunities for spintronics applications. Such SOTs are usually generated by the transverse diffusive spin current that arises via the spin Hall effect (SHE) in an adjacent metallic layer. So far, most efforts studying the use of the SHE to generate SOTs focus on several heavy metal elements and their alloys formed with other non-magnetic elements. To date, the behavior of the SHE in systems where a constituent has a strong magnetic moment, and at temperatures where strong spin fluctuations can arise, has been largely unstudied. In this presentation, we will firstly discuss the results from our recent study of such a system, Fe_xPt_{1-x} alloys, which have a ferromagnetic transition temperature that varies with Fe concentration. The SHE in Fe_xPt_{1-x} alloys has a particularly strong temperature dependence with a sharp peak near the ferromagnetic transition region, i.e. Curie temperature (Tc), as it is approached from above. This strong enhancement of the SHE is attributed to the (near) singularity in spin fluctuation amplitude that is expected to occur in the vicinity of T_C. The peak value of the strength of the SOTs in these Fe_xPt_{1-x} alloys, as quantified by the efficiency of the damping-like spin torque exerted on an adjacent ferromagnetic layer with a much higher ferromagnetic transition temperature, is at least comparable to that from the SHE in beta tungsten. We also observe a strong enhancement of the spin mixing conductance near T_C in these Fe_xPt_{1-x} alloys, which is not expected from the traditional spin pumping theory. These results indicate that a ferromagnetic system with strong spin-orbit coupling and spin fluctuation can serve as a new platform for the fundamental study and potential application of SOTs and spin transport. We will also report on the extension of this study of systems with strong spin fluctuations to super-lattices of Pt/Fe and Pt/Fe_xPt_{1-x} in pursuit of opportunities to further enhance the amplitude of the spin fluctuations and broaden the temperature range in which they are active.

H11-13. Spin Transport and Spin-to-charge Current Conversion in Bi_2Se_3/Au Heterostructure. *Y. Fanchiang*[1], C. Tseng[2], Y. Liu[2], C. Chen[2], J. Lin[3], S. Lee[4], M. Hong[1] and J. Kwo[2] *1. Department of Physics, National Taiwan University, Taipei, Taiwan; 2. Department of Physics, National Tsing Hua University, Hsinchu, Taiwan; 3. Center for Condensed Matter Sciences, National Taiwan University, Taipei, Taiwan; 4. Institute of Physics, Academia Sinica, Taipei, Taiwan*

The dissipationless surface conducting channel with helical spin texture of topological insulators (TIs) has great potential for spintronics application. To date, most experiments on the spin transport of topological surface states (TSSs) focus on systems with TIs in direct contact with a magnetic layer. However, recent study on magnetization dynamics of Bi_2Se_3/YIG shows strong interfacial coupling manifested as large interfacial in-plane magnetic

anisotropy (IMA)[1]. The modulated interfacial magnetic properties could severely disturb spin current generation from TSSs. Hence, in this work we performed ferromagnetic resonant spin pumping in Bi_2Se_3/Au/YIG structures to secure TSS from magnetic perturbations, according to first principle calculations that the helical spin texture is preserved at Bi_2Se_3/Au interface[2]. We then demonstrate that the Au insertion layer effectively weakens the interfacial IMA, indicating that the coupling between Bi_2Se_3 and YIG has been reduced. Moreover, a more efficient spin-to-charge conversion (SCC) is observed in the Bi_2Se_3/Au heterostructure compared to Bi_2Se_3 or Au single layer (Fig. 1). Au thickness dependent measurement suggests that the Bi_2Se_3/Au interface play a role in the enhanced SCC (Fig. 2). The improved SCC in Bi_2Se_3/Au thus provides new direction of tailoring TI hetero-interface for spintronics research.

H12-01. Magnetic characteristics of RPd_2Si_2 (R = Rare earth).
K. Uchima[1], Y. Uwatoko[2] and T. Shigeoka[3] *1. General Education, Okinawa Christian Junior College, Nishihara, Japan; 2. Institute for Solid State Physics, University of Tokyo, Kashiwa, Japan; 3. Physics, Yamaguchi University, Yamaguchi, Japan*

The ternary compounds RM_2X_2 (R = rare earth, M = transition metal, X = Si, Ge and so on), which crystallize in the tetragonal $ThCr_2Si_2$-type crystal structure, have been extensively studied for the last three decades because of their large variety of physical properties [1]. A large number of these compounds show an antiferromagnetic ordering and are Ising-like systems with the easy magnetization axis of the [001] direction (c-axis). Much less study has been made on compounds with the easy magnetization direction in the basal plane [1, 2]. The behavior of magnetic moments having the basal plane anisotropy is interesting. Magnetic study has been planned on the compound series RPd_2Si_2 which has an anisotropy of easy direction in the basal plane using single crystals. The several RPd_2Si_2 compounds, $GdPd_2Si_2$ without crystalline electric field (CEF) effects, heavy-rare-earth compounds RPd_2Si_2 (R = Dy and Tb) and light-rare-earth compounds RPd_2Si_2 (R = Nd and Pr) with CEF effects, have been already investigated, and reported interesting magnetic properties, such as novel magnetic behaviors, peculiar *B-T* magnetic phase diagrams[3, 4] and multi-step metamagnetic behaviors in the basal plane magnetization processes, as well as a strong magnetic anisotropy within the basal plane [5, 6]. In this work, magnetic measurements have been carried out on the $HoPd_2Si_2$ and $ErPd_2Si_2$ single crystal compounds in order to elucidate their magnetic characteristics. Both the compounds are antiferromagnetic at low temperatures, and show multi-step metamagnetic processes on the easy magnetization ones. Then we consider the magnetic characteristics comprehensively through the RPd_2Si_2 compound series. The plot of transition temperature T_N *vs*. de Gennes factor suggests that the RKKY interaction plays a major role in this system, and some other interactions exist. The crystal field effects have been estimated for all the compounds in this system, which indicates the anisotropic magnetic behaviors are able to be almost explained by the CEF effects.

H12-02. Magnetic Structure of a Non-Centrosymmetric $CePtSi_3$.
D. Ueta[1], M. Yoshida[1], Y. Ikeda[2], H. Yoshizawa[1], Y. Liu[3] and T. Hong[3] *1. Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan; 2. Institute for Materials Research, Tohoku University, Sendai, Japan; 3. Neutron Scattering Division, Oak Ridge National Laboratory, Oak Ridge, TN, United States*

Since the discovery of the first heavy electron superconductor $CePt_3Si$ [1] with a non-centrosymmetric crystal structure, the effect of the antisymmetric spin-orbit interaction (ASOI) on superconductivity and magnetism in correlated *f* electron physics has attracted much attention. Here we focus on the non-centrosymmetric $BaNiSn_3$-type compounds $CePdSi_3$ and $CePtSi_3$. The former exhibits successive magnetic transitions, weak ferromagnetism, and unusually complex metamagnetic transitions [2]. The magnetic properties of the later is very similar to those of $CePdSi_3$, but there are some qualitative differences [3]. Unlike a weak ferromagnetic (canted-antiferromagnetic) ground state observed in $CePdSi_3$, a proper antiferromagnetic state may be realized in $CePtSi_3$. Although the origin of this remarkable difference is still unclear, we expect that the Rashba-type ASOI certainly influences their magnetic properties, and the strength of ASOI may cause the difference of magnetic behavior between $CePdSi_3$ and $CePtSi_3$. As the first step of further understanding of the ASOI effect, we performed neutron diffraction experiments using a single crystalline sample of $CePtSi_3$ and examined the magnetic structure. We found that the incommensurate magnetic propagation vector $\tau_1 = (0.27, 0, 0)$ in the phase I (~ 5 K) switches to commensurate vectors $\tau_2 = (0.25, 0, 0)$ and $\tau_3 = (0.25, 0, 1)$ in the phase III (~ 2 K) at zero field. Although the magnetic structure of $CePtSi_3$ in the phase I is a longitudinal spin density wave similar to those in $CeRhSi_3$, $CeIrSi_3$, and $CePdSi_3$, the magnetic structure in the phase III is commensurate, unlike other $CeTSi_3$ (T = Rh, Ir, Pd) compounds.

H12-03. Signature of a Griffiths phase in layered canted antiferromagnet Sr_2IrO_4.
A. Rathi[1,2], P. Rout[1], S. Perween[3,2], R. Singh[4], A. Gupta[1,2], R. Pant[1,2] and G. Basheed[1,2] *1. CSIR-National Physical Laboratory, New Delhi, India; 2. AcSIR, CSIR-National Physical Laboratory (NPL) Campus, New Delhi, India; 3. CSIR-National Physical Laboratory, New Delhi, India; 4. Indian Institute of Science Education and Research, Bhopal, India*

The layered iridate Sr_2IrO_4 has been greatly acknowledged recently, after the prediction of high-T_C superconductivity (HTSC) on doping [1], as in layered cuprates. However, recent studies [2, 3] introduce new complexities, owing to IrO_6 octahedral rotation and minimal electronic correlations, and challenge the believed spin-orbital Mott state [4] and 2D quantum pseudo-spin-1/2 Heisenberg antiferromagnetic excitations [5] in Sr_2IrO_4. Nevertheless, recently observed HTS signatures in surface-doped Sr_2IrO_4 [6] recommend reinvestigation of the system. In this study, we investigated the magnetic interactions in canted antiferromagnet Sr_2IrO_4 (T_N = 221 K). The inverse magnetic susceptibility, $1/\chi$ (T) shows power-law behavior [7], $1/\chi$ (T) α $(T/T_N^R - 1)^{1-\lambda}$ with $\lambda = 0.24$ (< 1) when $T_N < T \leq T_G \sim 285$ K [inset (a)]. This suggests the short-range AFM ordering (sustained by strong basal-plane anisotropy) above bulk T_N – a signature of Griffiths singularity [8]. This has been linked with irregular IrO_6 octahedral rotation in real samples [9] and the competing intralayer canted-AFM (in basal-plane) and interlayer AFM (along c-axis) interactions in Sr_2IrO_4, as in other systems [10]. The non-analytic nature of GP [8] results in unique critical exponent, $\beta = 0.75(1)$ from modified Arrott plot (MAP) method [11] [inset (b)], in corroboration with magneto-caloric study. More importantly, Bray model [12] in GP regime yields $\beta = 0.19$ (1) [Figure 1], in consistent with earlier neutron diffraction and muon spin spectroscopy (μSR) studies [3]. The extracted β value belongs to the 2D XYh_4 universality class [13], where large inplane magnetic anisotropy shifts the β value from 2D XY ($\beta = 0.23$) towards 2D Ising ($\beta = 0.125$) model. Finally, the study discusses the contin-

uous nature of "Slater" metal-to-insulator (MIT) transition [2] in context of GP signatures in Sr_2IrO_4.

H12-04. Phase Diagram for the SU(2) Kondo Lattice Model. *M. Abele*[1] and P.S. Riseborough[1] *1. Physics, Temple University, Downingtown, PA, United States*

A phase diagram for the Kondo lattice model for systems of S=1/2 and J=3/2 total angular momenta is explored under a self-consistent mean-field treatment. The energy of the localized level is fixed by constraint and that of the itinerant band is given by the tight-binding approximation. In the Kondo phase, local moments are hybridized with itinerant ones. In the magnetic phase, spin-density wave solutions are sought without an assumption of commensurate ordering vectors. Calculations are carried out with SU(2) symmetry in a three-dimensional, simple cubic lattice. Finite- and zero-temperature calculations are used to produce a temperature-vs-occupation diagram. As conduction bands become either completely empty or completely filled, the Kondo temperature approaches O K, possibly indicating that Nozieres exhaustion occurs. Moreover, as the these limits are approached, the ordering vector becomes (0,0,0), indicating ferromagnetism. In S=1/2, the antiferromagnetic phase experiences an enhancement at half-filling.

H12-05. Transitions from a Kondo-like Insulator into a Modulated Ferromagnetic Metal in $FeGa_{3-y}Ge_y$. *Y. Zhang*[1,2] *1. Shanghai Jiao Tong University, Shanghai, China; 2. Kyoto University, Kyoto, Japan*

One initial and essential question of magnetism is whether the magnetic properties of a material are governed by localized moments or itinerant electrons. Although ferromagnetism is one of the oldest observed and studied quantum phenomena, well-established theories for ferromagnetism are restricted to two narrow and polar extremes, which are the localized and itinerant-electron regimes. Despite extensive effort has been made to elucidate the magnetic properties in the intermediate range of the two extremes [1-5], a successful theory remains elusive. It is particularly due to the limited diversity of materials for further study, as well as the difficulty in reconciling these polar scenarios [6]. In this work, we expose the case for the weakly ferromagnetic system $FeGa_{3-y}Ge_y$ wherein these two opposite models are reconciled. We follow the phase transitions by increasing the Ge doping of $FeGa_{3-y}Ge_y$, through all of which the magnetic properties are significantly affected. With the electron doping introduced by Ge substitution, the diamagnetic insulating parent compound $FeGa_3$ becomes a paramagnetic metal as early as at $y = 0.01$, and turns into a weakly ferromagnetic metal around the quantum critical point $y = 0.15$. The marginal Fermi-liquid behavior is observed on the verge of the transition. The magnetic properties in the ferromagnetic region crossing over between the localized model and itinerant regimes of $FeGa_{3-y}Ge_y$ are fairly reconcilably interpreted by mainly taking into account the effects of temperature dependent spin fluctuations in general based on the magnetic theories of spin fluctuations. Spin fluctuations may play a key role in approaching a unified theory for localized and itinerant ferromagnets, and $FeGa_{3-y}Ge_y$ seems to be one of the best candidates for probing the unified theory for itinerant magnetism [7].

Rare-earth silicides have received continuous attention over the years due to interesting physical phenomena, such as highly anisotropic magnetic properties associated with the long range Ruderman-Kittel-Kasuva-Yoshida (RKKY) interaction and crystal electric field (CEF). Recently, a new series of rare earth intermetallic compounds $RNiSi_3$ (R = Y, Gd-Tm) were synthesized, based on the compound $YbNiSi_3$.[1] Magnetic susceptibility indicates antiferromagnetic phases at low temperatures (T_N = 2-32 K) with fairly marked anisotropy.[2] However, the detailed magnetic structures still remain to be determined. In this work, the magnetic structure of $GdNiSi_3$ is investigated by resonant magnetic x-ray diffraction, using the X-ray Diffraction and Spectroscopy (XDS) beamline of the Brazilian Synchrotron Laboratory (LNLS). This may be considered the parent compound and the starting point for the understanding of the magnetism of the whole series, since Gd^{3+} shows an isotropic half-filled $4f^7$ shell with negligible influence of spin-orbit

coupling in its magnetic structure, and the RKKY exchange is expected to be the dominant interaction. Our results reveal a commensurate antiferromagnetic structure for this material with propagation vector k=[0 0 0], i.e., the magnetic unit cell coincides with the nuclear one. The temperature, energy, and polarization dependence of the magnetic contribution of the Bragg peaks will be discussed.

H12-07. Designing new magnetic materials in $Ti_3Co_5B_2$ structure-type borides. *P. Shankhari*[1] and B.P. Fokwa[2] *1. Chemistry, University of California, Riverside, Riverside, CA, United States; 2. Chemistry, University of California, Riverside, Riverside, CA, United States*

An emerging pathway in material design is theoretical screening of compounds beforehand the costly and serendipitous trial and error synthesis process. Following this pathway, we recently predicted (and experimentally confirmed) competition between antiferromagnetic and ferromagnetic ground states in a ruthenium rich boride $Hf_2MnRu_5B_2$ ($Ti_3Co_5B_2$-structure type, Figure 1) for the first time.[1, 2] DFT calculations predicted/indicated that the ferromagnetic (FM) and one of the antiferromagnetic models (AFM1) were comparable in energies. Vibrating scanning magnetometry of the compound showed a weak AFM transition at T_N = 20 K under very weak magnetic field (0.005 T) which vanishes at higher fields and ferromagnetic ordering emerges with a positive Weiss constant of 116.7 K, thus confirming the competition between FM and AFM states as predicted. Prior studies on similar Ru-rich compounds were mostly based on compounds which had Fe as the magnetic atom and these compounds had shown predominating antiferromagnetic characteristic.[3-5] The unexpected behavior of $Hf_2MnRu_5B_2$ motivated us to investigate new Mn-based magnetic materials in the $Ti_3Co_5B_2$-structure, an area never explored before. The 5d element Hf was incorporated for the first time in this structure type affecting the itinerant magnetism due to its diffuse 5d-orbitals. Therefore, we started a comparative study of the quaternary compounds $A_2MRu_5B_2$ (A = Zr, Hf; M = Mn, Fe, Figure 1) to get a better understanding of the combined effects of Mn (which has different magnetic ground state than Fe) and Hf on itinerant magnetism. First, we investigated their electronic structure and magnetic interactions through DFT and the successfully synthesized the phases via arc melting and characterized via X-ray crystallography and magnetometry. Our findings reveal that the Fe and Mn based phases behave differently and the enhanced ferromagnetic interaction in $Hf_2MnRu_5B_2$ stems both from effects of Mn and Hf. Additionally a neutron diffraction study is undergoing to understand the magnetic behavior of the compounds in depth

H13-01. Ferromagnetic fluctuations and Superconductivity of UCoGe under Pressure. *M. Manago*[1], S. Kitagawa[1], K. Ishida[1], K. Deguchi[2], N. Sato[2] and T. Yamamura[3] *1. Department of Physics, Graduate School of Science, Kyoto University, Kyoto, Japan; 2. Department of Physics, Graduate School of Science, Nagoya University, Nagoya, Japan; 3. Institute for Materials Research, Tohoku University, Sendai, Japan*

Uranium-based ferromagnetic (FM) superconductors have attracted much attention because of the variety of the unusual features including the coexistence of ferromagnetism and superconductivity [1]. UCoGe is a member of the FM superconductors, and the Ising-type FM fluctuations are considered to be essential for the superconductivity [2]. UCoGe is a unique system in which the SC phase remains even if the FM state is suppressed by hydrostatic pressure [3]. We performed ^{59}Co NMR and nuclear quadrupole resonance (NQR) to reveal how the FM fluctuations are changed under pressure from the microscopic point of view. We revealed that the FM fluctuations at the superconducting (SC) transition temperature T_{SC} are enhanced around the critical pressure P_c and start to decrease at higher pressure. Since T_{SC} is also enhanced around P_c, this result also supports the idea that the superconductivity is mediated by the FM fluctuations. NMR measurements are also performed in the SC state at the paramagnetic (PM) side, and it was found that the decrease of the Knight shift below T_{SC} is much smaller than the total spin part in the field perpendicular to the easy axis. This is a microscopic indication of the spin-triplet superconductivity in the PM side. We will also report the nuclear spin-lattice relaxation rate $1/T_1$ in the SC state at the PM side. This result will give us information about the SC gap structure, as well as how the FM and SC states coexist at ambient pressure.

H13-02. ^{73}Ge-NQR studies of ferromagnetic superconductor UGe_2 under pressure. *Y. Noma*[1], H. Kotegawa[1], T. Kubo[1], H. Tou[1], H. Harima[1], Y. Haga[2], E. Yamamoto[2], Y. Onuki[3], K. Itoh[4], E. Haller[5], A. Nakamura[6], Y. Homma[6], F. Honda[6] and D. Aoki[6] *1. Kobe University, Kobe, Japan; 2. Japan Atomic Energy Agency, Tokai, Japan; 3. University of the Ryukyus, Nishihara, Japan; 4. Keio University, Yokohama, Japan; 5. University of California, Berkeley, CA, United States; 6. IMR, Tohoku University, Oarai, Japan*

UGe_2 is a ferromagnet with the ferromagnetic (FM) Curie temperature T_{Curie} = 52 K at ambient pressure and the T_{Curie} is suppressed to 0 K with increasing the pressure. The superconducting (SC) transition was observed in the pressure range of P = 1 to 1.5 GPa.[1] The magnetization shows the enhancement at T_X in the FM phase.[2] The transition between FM1 with smaller ordered moment and FM2 with larger one is a broad crossover at ambient pressure. However, the crossover region terminates by applying the pressure. The terminal point is called a critical point (CP), above which the FM1-FM2 transition is of a first order. The CP in UGe_2 was reported as T_{CP} = 7 K and P_{CP} = 1.16 GPa. The FM1-FM2 transition disappears above P = 1.2 GPa where the superconducting transition temperature is highest. This suggests the SC is involved in the FM1-FM2 transition in UGe_2. The NMR measurements were performed in UCoGe which is one of the ferromagnetic superconductors. The measurements of the spin-lattice relaxation rate $1/T_1$ in UCoGe indicated that UCoGe possesses the Ising type magnetic fluctuation along the magnetic easy axis (*c*-axis).[3] In addition, it was reported that the anisotropic fluctuation correlates closely with the SC.[4] On the other hand, the details of the magnetic fluctuations in UGe_2 have not been reported. In order to clarify the anisotropy of the magnetic fluctuations in UGe_2, we carried out the ^{73}Ge-NQR measurement under pressure. We measured T_1 and the spin-spin relaxation time T_2 to clarify the anisotropy of the magnetic fluctuations under several pressures. Figure 1 shows the temperature dependences of $1/T_1T$ and $1/T_2$ at P = 0.71, 0.98, and 1.31 GPa. Below T_X, the suppression of $1/T_1T$ is observed at 0.71 and 0.98 GPa. On the other hand, $1/T_2$ is enhanced near T_X. The behaviour of $1/T_2$ shows the large divergence at 0.98 GPa, where is close to P_{CP}. These results suggest that the magnetic fluctuations along *a* axis is enhanced toward the CP. The peak of $1/T_2$ at 1.31 GPa, where the FM1-FM2 transition disappears, is observed at 3 K. We are now measuring T_1 and T_2 at 1.21 GPa to investigate the anomaly of $1/T_2$ at 1.32 GPa.

H13-03. Development of a Low Temperature Magneto-Optic Kerr Microscope to Probe Ferromagnetic Superconductors. *C. Clark*[1] and A. Huxley[1] *1. Physics, University of Edinburgh, Edinburgh, United Kingdom*

Bulk coexistence of ferromagnetism and superconductivity is thought to be the result of long-range magnetic pairing, rather than the conventional phonon mediation. Currently only a handful of ferromagnetic superconductors are known to exist - all of which contain Uranium [1]. Despite nearly 20 years of research, key questions related to the pairing mechanism in these compounds remain unexplained, necessitating the use of more exotic measurement techniques. UGe_2 was the first discovered ferromagnetic superconductor [2] and has a Curie temperature of 53K. Within the ferromagnetic state, UGe_2 additionally has a transition with decreasing temperature from a weakly polarised state (FM1) to a strongly polarised state (FM2). A broad crossover region separates the two polarised states at ambient pressure, which in itself is directly related to the emergence of superconductivity in UGe_2 under pressure [3]. The origin of the FM1-FM2 crossover remains unknown and so investigating this transition will give new insight into the superconducting state in UGe_2. One direct probe of local surface magnetisation, and hence the polarisation of magnetic moments, is the Magneto-Optic Kerr Effect (MOKE) - the rotation of linearly polarised light when reflected from a magnetic surface. Here, we report on the development of a low temperature MOKE microscope using a modulation technique. Both low temperatures and large magnetic fields may be accessed to observe how

magnetisation in UGe_2 evolves in its ferromagnetic state at ambient pressure. Further to this, rastering may be used to build up magnetic domain images, fully illustrating the magnetic microstructure evolution of UGe_2 which will have implications for our understanding of the pairing mechanism.

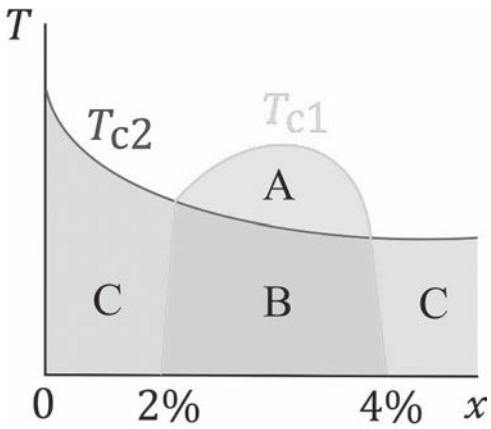
H13-04. Effect of atomic disorder on superconductivity of $Ca_3Rh_4Sn_{13}$.
A. Slebarski[1], M.M. Maska[1], P. Zajdel[1], M. Fijalkowski[1] and J. Goraus[1]
1. Institute of Physics, University of Silesia, Katowice, Poland



Recently, we documented experimentally, that the effect of nanoscale disorder generated by doping of the $Ca_3Rh_4Sn_{13}$ [1] and isostructural $La_3M_4Sn_{13}$ [2] superconductors (M = Rh, Ru, Co) leads to appearance of an inhomogeneous superconducting state, characterized by the critical temperature T^*_c higher than T_c of the bulk phase. Similar interesting behavior has been observed in a number of other strongly-correlated superconductors (see, e.g., [3], [4]), particularly those close to a quantum critical point (QCP), where an increase of T_c was documented by nanoscale electronic disorder. In the critical regime, such a system is at the threshold of an instability, and even a weak perturbation, such as disorder can cause significant macroscopic effects. This is a reason for continuing our research of the atomic scale disorder and its impact on a novel phenomena in $Ca_3Rh_4Sn_{13}$ and similar superconductors. The comprehensive research of the electronic structure, thermodynamic and electrical transport properties reveals the existence of inhomogeneous superconductivity due to structural disorder in $Ca_3Rh_4Sn_{13}$ doped with La ($Ca_{3-x}La_xRh_4Sn_{13}$) or Ce ($Ca_{3-x}Ce_xRh_4Sn_{13}$) with superconducting critical temperatures T^*_c higher than those (T_c) observed in the parent compounds. The T-x diagrams and the entropy $S(x)_T$ isotherms well document the relation between degree of an atomic disorder and separation of the high-temperature T^*_c and T_c - bulk phases. In these dirty superconductors with the mean free path much smaller than the coherence length, the Werthamer-Helfand-Hohenber theoretical model does not well fit the $H_{c2}(T)$ data. We suggest that this behavior can result from two-band superconductivity or from the presence of strong inhomogeneity in these systems. The multiband model very well describes the H-T dependencies, but the present results as well as our previous studies give also arguments for the scenario based on the presence of nanoscopic inhomogeneity of the superconducting state.

H13-05. Magnetic response in multiple superconducting phases of $U_{1-x}Th_xBe_{13}$.
K. Maruo[1] *1. Materials Engineering Science, Osaka University, Toyonaka, Japan*

UBe_{13} is a heavy-fermion superconductor with cubic symmetry. The superconductivity of this material was discovered more than 30 years ago, but its superconducting state has not been elucidated yet. The normal state is known as a non-Fermi liquid, where the specific heat, spin susceptibility and electrical resistivity in the normal state show behavior different from Fermi liquid at low temperature. On the other hand, multiple superconducting phases have been discovered in the superconducting state, where there are at least three superconducting phases when a small amount of Th is substituted for U (Fig.). Recently, new facts about the gap functions of this compound have been revealed by field angle resolved specific heat measurements with a single crystalline $U_{0.97}Th_{0.03}Be_{13}$ [1]. In order to explain these experimental results and the T-x phase diagram, two plausible scenarios have been proposed [2]. One represents each superconducting state by using two-dimensional E_u irreducible representation (degenerate scenario). The gap functions include the uniaxial and biaxial nematic states with the spontaneously broken cubic symmetry and non-unitary tetrahedral (cyclic) pairing state [3]. Another is based on the combination of different one-dimensional representations (accidental scenario). In this research, we theoretically study spin susceptibilities and surface Andreev bound states in these two scenarios of $U_{1-x}Th_xBe_{13}$. The degenerate scenario shows the anisotropy of the spin susceptibility due to the spontaneous breaking of cubic symmetry, while the spin susceptibility of the accidental scenario is fully isotropic. Furthermore, we will clarify the topological aspects of the evolution of the surface Andreev bound states in the accidental scenario. In this presentation, we will report the details of calculation results and discuss a possible way to identify the multiple superconducting phases.

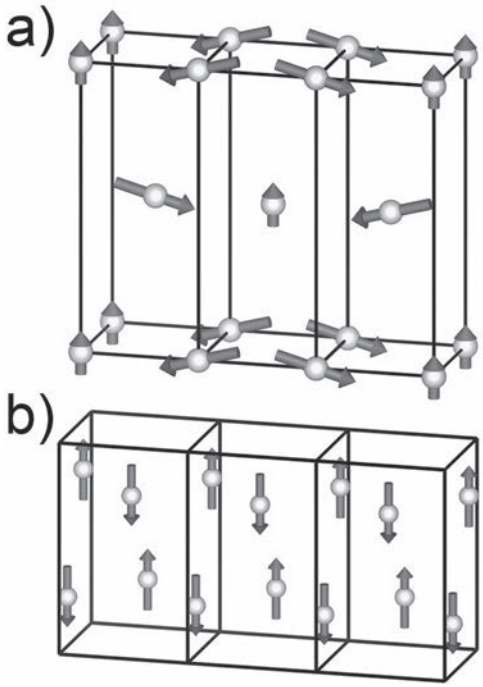
H13-06. ^{9}Be NMR Study of Magnetic Structure in Single Crystalline $SmBe_{13}$.
H. Hidaka[1], Y. Ihara[1], S. Yamazaki[1], N. Miura[1], T. Yanagisawa[1] and H. Amitsuka[1] *1. Department of Physics, Hokkaido University, Sapporo, Japan*



The intermetallic compounds MBe_{13} (M = rare earths and actinides) crystallize in a $NaZn_{13}$-type cubic structure with the space group Fm-3c (No. 226, O_h^6), where M atoms are located at the 8a site without local-inversion symmetry (O). [1] Among them, UBe_{13} is well known as a heavy-fermion superconductor, and a number of studies have been performed in order to unveil the origin of its unconventional superconductivity as well as non-Fermi-liquid behaviour. [2] On the other hand, it has been revealed from previous neutron scattering measurements that most heavy-rare-earth MBe_{13} compounds undergo a helical-magnetic order with propagation vector of $Q \sim$ <0, 0, 1/3> at low temperatures, where magnetic moments lie in the (001) plane. [3] Although light-rare-earth MBe_{13} compounds are also expected to exhibit similar helical-magnetic order, there is no microscopic study on their magnetic structures thus far. We have recently succeeded in growing single crystalline samples of $SmBe_{13}$ by the Al-flux method, and constructed a detailed magnetic phase diagram from several bulk measurements. [4] The magnetic phase diagram of this compound consists of three regions (named low-B, high-B and low-T, and high-B and high-T phases) below the ordering temperature $T_M \sim 8.3$ K. In the present study, we performed ^{9}Be NMR measurements on single crystalline $SmBe_{13}$ at the magnetic field B of ~ 2 T and 5 T in order to investigate the magnetic structure of each phase microscopically. In the low-B phase ($B \sim 2$ T), we found a clear difference in the obtained NMR spectra at 1.8 K between B // <001> and <110>. These obtained spectra cannot be explained by the helical magnetic structure reported in the heavy-rare-earth MBe_{13} systems. We will discuss a possible magnetic structure which can explain the obtained spectra. In addition, NMR spectrum at $T = 2$ K and $B \sim 5$ T suggests that uncompensated "up-up-down"-type antiferromagnetic order occurs in the high-B and low-T phase.

Cerium compounds are very well known to exhibit variety of ground states because of competing inter-site RKKY and local Kondo effect. Specifically group of non-centrosymmetric tetragonal compounds $CeTX_3$ is widely studied due to discovered unconventional superconductivity [1] (for example in $CePt_3Si$, $CeRhSi_3$ or $CeIrGe_3$). Several other members of the group undergoes superconducting transition, except of compounds with Aluminum. The reasons for suppression of superconductivity are not clarified yet and detailed study of magnetic ground state within series is extremely helpful. We have grown [2], analyzed [2] and evaluated magnetic structures of the slightly orthorombic $CePdAl_3$ and tetragonal $CePtAl_3$ [3] by means of neutron single crystal diffraction. Both crystals exhibit long-range magnetic order with transition temperatures 5.6 and 3.4 K respectively (see Fig. 1). We will discuss obtained results and compare them with other know members of the group [4].

H13-08. Thermal Analysis of the Specific Heat of $Pr_{1-x}Nd_xOs_4Sb_{12}$. *S. Hishida*[1], J. Velasquez[1], T. McCullough-Hunter[1], P. Ho[1], M.B. Maple[3] and T. Yanagisawa[2] *1. Physics, California State University, Fresno, Fresno, CA, United States; 2. Department of Physics, Hokkaido University, Sapporo, Japan; 3. Physics, University of California, San Diego, La Jolla, CA, United States*

The filled-skutterudite compounds $PrOs_4Sb_{12}$ and $NdOs_4Sb_{12}$ have attracted interest due to their properties at low temperatures, where they exhibit unconventional heavy-fermion superconductivity (T_c = 1.85 K) and ferromagnetism ($T_{Curie} \approx$ 0.9 K) respectively. Previous studies on the series of compounds $Pr_{1-x}Nd_xOs_4Sb_{12}$ have shown competition between the superconducting and ferromagnetic states and that the two phenomena coexist within the sample for particular concentrations of Nd and Pr. The zero-field heat capacity of single crystal clusters of $Pr_{1-x}Nd_xOs_4Sb_{12}$ was measured in the temperature range from 10 K – 300 K, and the specific heat was analyzed to determine contributions from the lattice and the conduction electrons. The Debye and Einstein models were used in conjunction to account for the lattice contribution, and the Sommerfeld model was used to account for the specific heat of the electrons. A curve fit was applied to the specific heat data in order to extract values for parameters related to these models, including the Debye Temperature, Einstein Temperature, and the electronic specific heat coefficient. These parameters provide information about the lattice stiffness, rattling mode, and electron correlation, respectively. A minimum was observed in the Debye and Einstein Temperatures for Nd concentrations near x = 0.55, which suggests that a form of lattice softening may be taking place around the Nd concentration where the superconductivity disappears. H13-09. Investigation of Broken Time Reversal Symmetry in the Pr-rich side of $Pr_{1-x}Nd_xOs4Sb_{12}$. *P. Ho*[1], D.E. MacLaughlin[2], M.B. Maple[3], L. Shu[4], A. Hillier[5], O. Bernal[1], T. Yanagisawa[6], P. Biswas[5], J. Zhang[4], C. Tan[4], S. Hishida[1] and T. McCullough-Hunter[1] *1. Physics, California State University, Fresno, CA, United States; 2. Physics, University of California, Riverside, Riverside, CA, United States; 3. Physics, University of California, San Diego, La Jolla, CA, United States; 4. Physics, Fudan University, Shanghai, China; 5. ISIS Neutron and Muon Sources, Science & Technology Facilities Council, Harwell, United Kingdom; 6. Physics, Hokkaido University, Sapporo, Japan*

One of the intriguing features that indicate unconventional superconductivity (SC) in the filled skutterudite compound $PrOs_4Sb_{12}$ is the broken time reversal symmetry (TRS)[1]. Previously in our muon spin relaxation (μSR) study on the influence of the Nd^{3+} moment in $Pr_{1-x}Nd_xOs4Sb_{12}$ [2], we found that the magnetism extends deep in the SC state for $0.45 \leq x \leq 0.55$ and a strong μ^+ dynamic rate in x = 0.25 possibly resulting from significant fluctuations of the Nd moment. In our most-recent results of μSR experiments in the samples of x=0.05, 0.1, 0.15 and 0.2, at zero magnetic field, a combined exponential and Gaussian relaxation behavior was found. The exponential depolarization rate (λ) in ZF-μSR has a strong temperature (T) dependence below the SC transition temperature T_c, which may originate from spontaneous supercurrents or spin texture due to broken TRS. In addition, in TF-μSR, a peculiar peak feature appear in λ vs T near T_c for x=0.15 and 0.2, which was not observed in the previous μSR study of $PrOs_4Sb_{12}$. H13-10. Superconductivity in a Multiorbital Model for the Γ_3 Crystalline Electric Field State. *K. Kubo*[1] *1. Advanced Science Research Center, Japan Atomic Energy Agency, Tokai, Japan*

A cubic system with the Γ_3 cubic crystalline electric field (CEF) state is an ideal system to investigate multipole physics, since it does not have dipole but has higher-order multipoles such as quadrupole and octupole. In addition, superconductivity has been observed in PrT_2X_{20} (T = Ir, Rh, X = Zn; T = Ti, V, X = Al) systems with the Γ_3 CEF ground state [1-5]. To approach these phenomena theoretically, we consider a model composed of *f* electrons with the total angular momentum $j = 5/2$. The $j = 5/2$ states split into Γ_7 and Γ_8 levels under a cubic CEF. When we assume an antiferromagnetic interaction between the Γ_7 and Γ_8 orbitals, the f^2 ground state is the Γ_3 state composed of singlets between these orbitals as long as the level splitting is small. Thus, we employ this model as one of the simplest models to describe the Γ_3 state. From this model, we have derived multipole interactions for the Γ_3 systems [6]. In the present study, we investigate superconductivity in the same model. In multiorbital systems, we can expect anisotropic superconductivity originating from the orbital anisotropy. For example, we obtain a *d*-wave spin-triplet state in a model for e_g orbitals on a square lattice [7]. We apply random phase approximation for superconductivity in a multiorbital system [8] to the present model. Then, we have obtained a *d*-wave spin-singlet state. This pairing state is naturally expected from the f^2-Γ_3 CEF ground state. To stabilize such a superconducting state, we do not need particular fluctuations in contrast to the single orbital Hubbard model on a square lattice where superconductivity is expected to be mediated by antiferromagnetic fluctuations. Indeed, multipole fluctuations are weak in the parameter region where the superconductivity takes place. We will discuss the relevance of the present theory to the PrT_2X_{20} superconductors [1-5].

H14-01. Hydrostatic pressure effect in BiS_2 based superconductors $LaO_{0.5}F_{0.5}Bi(S_{1-x}Se_x)_2$. *K. Kondo*[1], S. Watanabe[1], N. Kase[1] and N. Miyakawa[1] *1. Dept. of Applied Phys, Tokyo University of Science, Katsusikaku, Japan*

A BiS_2-based superconductor $LaOBiS_2$ has a layered structure of LaO-blocking and BiS_2-conducting layers. Superconductivity is appeared by electron doping via F substitution at O site with T_c of 2.6 K [1]. By applying hydrostatic pressures, T_c drastically increase from 2.6 to 10.7 K at 0.7 GPa, because a structural phase transition from tetragonal (*P*4/*nmm*) to monoclinic ($P2_1/m$) occurs [2]. The Se-substituted compounds $LaO_{0.5}F_{0.5}Bi(S_{1-x}Se_x)_2$ are known to exhibit bulk superconductivity with the optimum Se content (x = 0.5) at T_c of 4.1 K [3]. The chemical pressure causes this enhancement of superconductivity for $LaO_{0.5}F_{0.5}Bi(S_{1-x}Se_x)_2$. In order to clarify the relationship between the external and chemical pressure, we performed the hydrostatic pressure effect of the compound $LaO_{0.5}F_{0.5}Bi(S_{1-x}Se_x)_2$ in which chemical pressure is applied. Figure 1 displays the temperature dependence of the electrical resistivity of $LaO_{0.5}F_{0.5}BiSSe$ in various pressures. Two drops were observed at 1.43 GPa and superconducting transition width obviously broadened above 1.70 GPa. Applying further pressure up to 2.41 GPa, T_c continued to linearly increase. In addition, AC magnetic susceptibility under pressure showed two transitions at 1.83 GPa simultaneously. It seems to coexist two distinct superconducting phases. The behavior is clearly difference from that of $LaO_{0.5}F_{0.5}BiS_2$, because, single superconducting phase is observed in $LaO_{0.5}F_{0.5}BiS_2$, in the previous report. In this presentation, we will show the results of the pressure effect of other Se substitution and compare with the pressure effect of $RO_{0.5}F_{0.5}BiS_2$ (R = La, Ce, Pr, Nd) in which chemical pressure is applied.

H14-02. Superconductivity in a misfit compound $(PbSe)_{1.12}(TaSe_2)$. X. Yang[1], M. Wang[1], *Y. Li*[1], J. Ma[1], H. Bai[1], Q. Tao[1], C. Dong[2] and Z. Xu[1,3] *1. Department of Physics, Zhejiang University, Hangzhou, China; 2. Institute of Physics, Chinese Academy of Science, Beijing, China; 3. Collaborative Innovation Centre of Advanced Microstructures, Nanjing, China*

We report the discovery of superconductivity with a maximum $T_c \approx 1.28$ K in a new misfit compound $(PbSe)_{1.12}(TaSe_2)$, which consists of a bilayer of distorted rocksalt PbSe alternating with dichalcogenide $TaSe_2$. We found that the Br-doping on the Se site in the PbSe layer is required for the formation of this misfit compound and superconductivity can be tuned by Br content. The large anisotropic parameter of resistivity $\rho_c/\rho_{ab} \approx 100$ and upper critical filed ≈10 are obtained, and the estimated c-axis coherence length is about 6.3 nm which suggests it is anisotropic 3D superconductor. Hall coefficient measurements suggest that the charge transport is dominated by hole-type charge carriers and there is charge transfer from Br-doped PbSe layer to $TaSe_2$ layer. The small normalized specific jump value $\Delta C/\gamma Tc = 1.05$ and electron-phonon coupling constant $\lambda_{ep} \approx 0.61$ indicate a weak-coupling BCS superconductor.

H14-03. Thermodynamic and transport properties of transition-metal doped BiS_2-based superconductors. *N. Kase*[1], K. Kondo[1], M. Koike[1], S. Watanabe[1] and N. Miyakawa[1] *1. Dept. of Applied Physics, Tokyo University of Science, Suginamiku, Japan*

A BiS_2-based compound $LaOBiS_2$ shows superconductivity by electron doping, F and transition metal (Ti, Zr, and Hf)[1,2]. In addition, Se-doping (chemical pressure) is effective to emergence of bulk superconductivity in BiS_2-based compounds[3]. Thus, chemical pressure and carrier doping is significant to occur bulk superconductivity. We focus on co-doping of Se and transition metal to emergence of superconductivity by controlling chemical pressure and carrier doping. We synthesized the polycrystalline samples of transition-metal and Se-doped compounds and succeeded to synsesize the polycrystalline samples with single phase. The temperature dependence of the electrical resistivity of transition-metal doped compounds behaves as insulator. The electrical resistivity increases with doping values of transition metal. With increasing Se-doping, electrical resistivity obviously decreased in the compounds. The behavior is consistent with other Se-doped compounds. In the present situation, no superconductivity is observed above 2.8 K. We expect to observe the occurrence of superconductivity in this compounds by further cooling. Thus, Se doping is effective to metallic transition, and possibly emergence of superconductivity in transition-metal doped compounds. Furthermore, we show Seebeck effect of the transition-metal doped compounds in this presentation.

H14-04. Variational cluster approach to the excitonic condensation and superconductivity. *R. Fujiuchi*[1], K. Sugimoto[2] and Y. Ohta[3] *1. Department of Physics, Chiba University, Chiba, Japan; 2. Center for Frontier Science, Chiba University, Chiba, Japan; 3. Physics, Chiba University, Chiba, Japan*

It is predicted theoretically that the quantum condensation of electron-hole pairs (exciton) can occur in the ground state of a small band-gap semiconductor or a small band-overlap semimetal, the phase of which is called the excitonic insulator [1]. Transition-metal chalcogenides 1*T*-$TiSe_2$ and Ta_2NiSe_5 are promising candidates for the realization of the spin-singlet excitonic phase. Intriguingly, in the phase diagrams of these materials, the superconducting phase is adjacent to the excitonic insulator phase [2,3]. This behavior resembles that of cuprates and iron pnictides, where the superconducting phase is adjacent to the antiferromagnetic phase [4]. Therefore, the superconducting phase in 1*T*-$TiSe_2$ and $Ta_2NiSe_5$is discussed in relation to the excitonic fluctuations [5]. Motivated by such developments in the field, we investigate the two-orbital Hubbard model defined on the two-dimensional square lattice using the variational cluster approximation based on the self-functional theory, whereby we consider the mechanism of the exciton-mediated superconductivity. We calculate the phase diagram of the model in the parameter space of the intra-orbital and inter-orbital Coulomb interactions, and show that the antiferromagnetic Mott insulator state appears in the regime of strong intra-orbital interaction and the band insulator state appears in the regime of strong inter-orbital interaction, and in-between, the spin-singlet s^{+-} superconducting state appears in a weak-correlation regime and the excitonic insulator state appears in a strong-correlation regime. Thus, we discussed the competition between the superconducting and excitonic insulating phases. We also calculate the single-particle spectral function of the model and discuss the band gap formation due to superconductivity and excitonic condensation comparatively.

H14-05. On the enhancement of conventional superconductivity by a controlled incorporation of non-magnetic defects in some classes of crystalline solids. D.A. Chaves[1] and *M. ElMassalami*[1] *1. Fisics dos Solidos, Instituto de Fisica, Rio de Janeiro, Brazil*

Routinely, non-magnetic defects can be incorporated, in a controlled fashion, in a vast number of BCS-type superconductors. Such a process can be effectively used to generate and stabilize certain types of defects which, in turn, can lead to a strong (sometimes an order of magnitude) enhancement in the superconducting transition temperature, T_c [1-7]. It is established that such a T_c enhancement is manifested in diversified classes of defect-bearing superconductors independent of whether these defects are incorporated by implantation, codeposition, alloying, or high-temperature quenching. It was also found out that such a process is independent of whether the matrix is in a thin-film or in a bulk form. More remarkable is the observation that the above-mentioned defect-introducing procedures can lead to a manifestation of superconductivity in pristine matrix that is initially non-superconducting or even non-metallic. For illustration, let us recall the following three exotic examples: (i) Enhancement of T_c of Al (In) thin film when irradiated by proper Al (In) projectiles [6] (emphasizing the minor role, if any, of difference in size or charge carrier donation). (ii) The irradiation-induced superconductivity in non-superconducting matrix such as semiconducting Ge or metallic Pd [7.a] (a pre-existing BCS superconductivity is not required). (iii) The evolution of a dome-like T_c (x) for quenched solid-solutions of non-superconducting constituents e.g. Pd-X [5] and Ge-X [7.b] (X=Cu, Ag, Au). In this work we analyze the common trends of the normal-state and superconducting properties when controlled amount of these defects are incorporated. In particular, we discuss a generalized *x*-*T* phase diagram of these T_c -enhanced defect-bearing systems (x represents defect/disorder content). We also discuss the anomalous case of T_c reduction observed in some irradiated films such as V, Nb, Ta and Pb [8].

H14-06. Enhancement of the superconducting T_c in doped SnTe possibly due to the negative-*U* mechanism. *M. Kriener*[1], M. Kamitani[1], T. Koretsune[1,2], R. Arita[1], Y. Taguchi[1] and Y. Tokura[1,3] *1. RIKEN - Center for Emergent Matter Science (CEMS), Wako-shi, Japan; 2. Department of Physics, Tohoku University, Sendai, Japan; 3. Department of Applied Physics and Quantum-Phase Electronics Center (QPEC), University of Tokyo, Tokyo, Japan*

The simple binary semiconductor SnTe has recently regained a lot of attention when it was identified to be a topological crystalline insulator [1]. SnTe is also a self-doped superconductor with superconducting transition temperatures T_c < ~300 mK [2]. Moreover, it was shown that T_c is enhanced by one order of magnitude when doping In [3-6]. Since the topologically nontrivial surface state survives at small *x* in $Sn_{1-x}In_xTe$ [7], the system attracted even more interest because of the possibility of topological superconductivity. Another intriguing question is what mechanism is responsible for the one-order-of-magnitude enhancement of T_c. In this context Varma proposed the so-called "negative *U* mechanism" which can yield enhanced superconductivity when elements are involved which skip certain valence states as, e.g., In: The formal In^{2+} state in $Sn_{1-x}In_xTe$ is energetically unstable and the "ion" appears as In^{1+}, In^{3+}, or even a mixture of these [8]. One drawback of this system is that at around *x* ~0.5 its structure changes from cubic to tetragonal and the superconductivity is lost. Hence all available experimental studies of the superconductivity in this system are restricted to *x* < ~0.5. We successfully overcame this limitation by employing a high-pressure synthesis method which allows to synthesize the whole solid solution $Sn_{1-x}In_xTe$ in cubic structure and map out the full phase diagram as shown in Fig. 1. We find that T_c takes its maximum around *x* = 0.60. Interestingly just below this point, the superconductivity is strongly and sharply suppressed yielding a two-dome structure. The phase diagram and the possible important role of valence skipping on T_c along with the doping effect on the band-structure will be discussed in detail.

H14-07. Revisit CuCl. *L. Deng*[1], Z. Wu[1], S. Huyan[1], S. Yoshizumi[3], S. Spagna[3] and P. Chu[1,2] *1. Texas Center for Superconductivity at the University of Houston, Houston, TX, United States; 2. Lawrence Berkeley National Laboratory, Berkeley, CA, United States; 3. Quantum Design, Inc., San Diego, CA, United States*

CuCl drew a great deal of attention in the 1970's due to its phase transition under pressure and the possible existence of a small direct bandgap which may favor an excitonic superconducting phase transition. C. W. Chu et al. successfully induced an insulator to metal transition at a pressure of around 40 kbar in CuCl single crystals in 1975 and published a detailed study of CuCl in 1978. Activity around CuCl diminished around the discovery of the high temperature superconductors. Later, the report on possible interfacial superconductivity in CuCl/Si lead to a brief resurgence of CuCl investigation. Recently, CuCl has attracted some additional study. In 2015, Dr. Y. Kopelevich and co-authors reported an electric-field-driven insulator-metal transition in CuCl. To further study magnetic orders, the electrical field effect on the conductivity, and possible superconductivity of CuCl, we carried out a detailed investigation on the CuCl samples under electrical and magnetic fields. Interesting results including electric-field-induced insulator-metal transition, polarity effect, negative differential resistance, magnetic transitions, and phase analysis will be presented and discussed. High resolution X-ray and magnetization measurements under an electrical field are in progress, which will shed light on the understanding of the electrical-field-induced insulator-metal transition and may help to find the hints of possible superconductivity.

H14-08. Spin-Orbit-Coupled Ferroelectric Superconductivity. *S. Kanasugi*[1] and Y. Yanase[1] *1. Physics, Kyoto University, Kyoto, Japan*

In principle, metals cannot exhibit ferroelectricity because dielectric polarization is screened by conduction electrons. However, in 1965, Anderson and Blount predicted the existence of ferroelectric metals (FEMs) in which a ferroelectric (FE) -like structural transition occurs in the metallic state [1]. Since then, for half a century, many experiments have been done to find the FEM, and recently, $LiOsO_3$ was identified as a FEM [2]. Following the discovery of FEM, coexistence of superconductivity and ferroelectricity has also received a lot of attention. A candidate of a ferroelectric superconductor (SC), in which the FE-like order coexists with superconductivity, is $SrTiO_3$ (STO). STO is a quantum paraelectric [3] whose dielectric constant is extremely large at low temperatures, but a pure compound does not exhibit ferroelectricity because the FE order is suppressed by quantum fluctuation. On the other hand, STO exhibits ferroelectricity by substituting Sr with Ca or isotopic substitution of oxygen. Furthermore, it becomes a metal by cation substitution or oxygen deficient. The metallic STO becomes superconducting at a density as low as 10^{17} cm^{-3}. Based on these observations, Rischau et al. [4] performed various measurements for carrier-doped Ca-substituted STO. They mapped out a phase diagram, which shows a coexistent phase of the superconductivity and the FE-like order. This observation has generated a flurry of interest in the relationship between ferroelectricity and superconductivity. In the presentation, we will show results of our theoretical study about coexistence of the superconductivity and the FE-like order based on a model of two-dimensional Rashba SC. In our model, the effect of polar lattice displacement induced by a FE-like structural transition [Fig. 1] is included as a Rashba-type antisymmetric spin-orbit coupling. By calculating the free energy, in which the energy loss of lattice polarization is included, we mapped out phase diagrams. It is shown that the FE superconducting state is stabilized under the applied magnetic field [Fig. 2], and its stability is increased in the low carrier density regime.

H14-09. Unconventional Superconductivity and Interplay between Superconductivity and Magnetism in 2-Dimensional Electron Gases at $SrTiO_3$ Capped $LaAlO_3/SrTiO_3$ (100). Y. Kwak[1], W. Han[2], J. Kim[2] and *J. Song*[1] *1. Physics, Chungnam National University, Daejeon, The Republic of Korea; 2. Korea Research Institute of Standards and Science, Daejeon, The Republic of Korea*

The 2-Dimensional Electron Gases (2-DEGs) observed at the $LaAlO_3/SrTiO_3$ hetero-interface exhibits various intriguing phenomena such as ferromagnetism, superconductivity, and strong spin-orbit coupling. Based on these functionalities, this system has been widely studied for being a low-dimensional ferromagnetic oxide superconducting system with a strong gate-tunable spin-orbit interaction. However, its lack of stability and environmental susceptiveness have been an obstacle to its further

experimental investigations and applications. In this study, we demonstrate that capping the bilayer with $SrTiO_3$ relieves this thickness limit, while enhancing the stability and controllability of the interface. In addition, in the Josephson junction device fabricated by this trilayer system, we found that the $SrTiO_3$-capped $LaAlO_3$ exhibits unconventional superconductivity; the critical current dramatically increases under a parallel magnetic field, and shows a reversed hysteresis contrary to the conventional hysteresis of magnetoresistance. From these observations, we propose the helical superconductivity of the 2-DEGs in $SrTiO_3$ capped $LaAlO_3/SrTiO_3(100)$ trilayer system. This oxide trilayer could be a robust platform for studying the extraordinary interplay of superconductivity and ferromagnetism at the interface electron system between $LaAlO_3$ and $SrTiO_3$.

Session H15
THEORY AND SIMULATION OF MAGNETIC SYSTEMS I (Poster Session)

Thomas Andrew Ostler, Chair
The University of Exeter, Sheffield, United Kingdom

H15-01. Generalised spin-wave simulations by SpinW and developments for the European Spallation Neutron Source. *S. Ward*[1,2] and S. Toth[1] *1. Paul Scherrer Institut, Villigen PSI, Switzerland; 2. European Spallation Neutron Source, Copenhagen, Denmark*

The measurement of spin waves from magnetic crystals has been a long-standing success story of inelastic neutron scattering. The development of linear spin wave theory pre-dates the first neutron scattering measurements and is well developed and suited to the determination of spin waves from magnetic ions with large spins. Recently we have developed spin wave calculation software "SpinW"[1] which can handle the simulation of complex magnetic structures with non-collinear ground states and arbitrary spin exchange matrices, anisotropies, g-tensors and external magnetic field. With an easy to use and flexible 'out of the box' framework we will show how real systems can be modelled and exchange interactions determined. With the new European Neutron Source (ESS) being built, we will describe how SpinW will be used in the context of large scale facilities for on-the-fly data analysis and describe our vision for the neutron scattering community.

H15-02. Lattice Vibrations in the Neutron Scattering by Ferromagnetic Metals. *G.V. Paradezhenko*[1], N.B. Melnikov[1] and B.I. Reser[2] *1. Lomonosov Moscow State University, Moscow, Russian Federation; 2. Mikheev Institute of Metal Physics UB of RAS, Ekaterinburg, Russian Federation*

Polarized neutron scattering experiment is used for studying the magnetic short-range order in metals, which is described by the spin-density correlator. The electron subsystem contribution to the correlator at finite temperatures was calculated in the dynamic spin-fluctuation theory and compared with experimental results (for review, see [1]). The contribution to the correlator from the lattice vibrations is mainly determined by the Debye-Waller factor (DWF) e^{-2W}. Evaluation of the DWF by the well-known formula $2W(\kappa) = \kappa^2\langle u^2\rangle/3$ (κ is the scattering vector) requires cumbersome calculations of the mean-square atomic displacement $\langle u^2\rangle$ in the harmonic or anharmonic approximations. We propose a concise derivation of a DWF expression in the harmonic approximation. The simplification is achieved by using the formula for canonical average of exponentials of operators linear in the atomic displacements. By means of this formula it is easily shown that the displacement has a Gaussian distribution and expression for the DWF is obtained directly without calculating the mean-square displacement [2]. The DWF for ferromagnetic metals is calculated as a function of the scattering vector κ and temperature T [3]. The effect of the DWF substantially depends on κ. For values of κ within the Brillouin zone, we show that the DWF correction is insignificant. In particular, for iron and nickel at the Curie temperature the DWF correction is no more than 3-4%. Hence the DWF can be ignored when studying magnetic characteristics given by an integral over the Brillouin zone (such as the spin-density correlator, local magnetic moment, etc.). Beyond the Brillouin zone, in the range of κ characteristic to polarized neutron scattering experiments, the DWF correction can become substantial. For instance, in the experiment for nickel with the range of κ up to 4 $Å^{-1}$ [4], the DWF correction reaches 20-30% (see Fig. 1). The research was carried out within the state assignment of FASO of Russia (theme 'Electron' No. AAAA-A18-118020190098-5) and was supported in part by the Program of UB RAS (project No.18-2-2-11) and by the RFBR (grant No. 17-32-50014).

H15-03. Short-Range Order in Metals Above the Curie Temperature. *N.B. Melnikov*[1], B.I. Reser[2] and G.V. Paradezhenko[1] *1. Lomonosov Moscow State University, Moscow, Russian Federation; 2. Mikheev Institute of Metal Physics UB of RAS, Ekaterinburg, Russian Federation*

Neutron scattering experiments point to the existence of short-range order (SRO) in ferromagnetic metals above the Curie temperature T_c. However, the estimate of the correlation length 15–20 Å based on the spin-waves interpretation [1] is controversial. We study SRO in the dynamic spin-fluctuation theory (DSFT), which takes into account the quantum character (dynamics) and nonlocality of the spin fluctuations (for review, see [2]). In the DSFT we have obtained explicit expressions for the effective moment $M(q)$, local magnetic moment m_L and spatial spin-density correlator [3, 4]. At high temperatures, the DSFT spin correlator reduces to the Ornstein-Zernike form, the effective moment $M(q)$ is given by the Lorentzian function, and $M(0)$ tends to the effective moment m_{eff} in the Curie-Wiess law. For the itinerant-electron magnets, we derived the relation between effective moment and neutron scattering cross-section. Our theoretical results have been demonstrated by the example of bcc Fe. The effective moment $M(q)$ was calculated as a function of wavevector and temperature and compared with the polarized neutron scattering experiment [1]. The $M^2(q)$ calculated with an appropriate energy window was found to be in good agreement with experiment over a wide temperature range (Fig.1). The spin correlator was calculated as a function of distance and temperature. The calculated local magnetic moment m_L is approximately equal to the experimental value at $T=0$, and its change with temperature is small. The local magnetic moment calculated with an appropriate energy window is in good agreement with experiment. The calculated halfwidth of the normalized

correlation function is up to 4 Å. Thus, the SRO above T_c is limited to small distances and slowly decreases with temperature. The research was carried out within the state assignment of FASO of Russia (theme 'Electron' No. AAAA-A18-118020190098-5) and was supported in part by the Program of UB RAS (project No. 18-2-2-11) and RFBR (grant No. 17-32-50014).

H15-04. Non-monotonic dependence of concentration on magnetic properties of $Ni_2Mn_{1+x}Z_{1-x}$ (Z = In, Sn, Sb) Heusler alloys: a local atomic configuration approach. *K. Zaleski*[1], M. Ekholm[2], B. Alling[2], I. Abrikosov[2] and J. Dubowik[3] *1. NanoBioMedical Centre, Adam Mickiewicz University, Poznan, Poland; 2. Department of Physics, Chemistry and Biology, Linköping University, Linköping, Sweden; 3. Institute of Molecular Physics, Polish Academy of Sciences, Poznan, Poland*

The $Ni_2Mn_{1+x}Z_{1-x}$ Heusler alloys, where Z = In, Sn, Sb, are attractive candidates for shape memory alloys. The effect is directly related to their magnetic properties. We have studied these systems by *ab-initio* calculations and experiments, focusing on magnetic moments and the exchange-bias effect. The calculations indicate that the composition dependence of the total magnetic moment is due to competing ferromagnetic and antiferromagnetic alignment between Mn atoms on different sublattices and with different local environments. This phenomenon can also explain the composition dependence of the exchange-bias effect. K.Z. acknowledges support from Polish National Science Center grant UMO-2016/23/D/ST3/02121. M.E. acknowledges support from the Swedish e-Science Research Centre (SeRC). The calculations were performed on resources provided by the Swedish National Infrastructure for Computing (SNIC) at the National Supercomputer Centre (NSC), Linköping University, Sweden.

H15-05. Giant barocaloric effect and Maxwell relation in spin-crossover system: application in $[Fe(pzt)_6](PF_6)_2$. *P.d. Alho*[1], B.d. Alho[1] and P. von Ranke[1] *1. Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brazil*

Nowadays one of the big challenges of material science and technology consists in the investigations of alternative refrigeration materials to the gas-compression refrigeration systems which have low efficiencies and is not environmental friendly [1]. To overcome these drawbacks, the solid refrigerant materials, appear as an ecologically alternative. From the physical point of view, a good solid refrigerant should present three main requisites for the barocaloric effect potentials [2] ΔT_{ad} and ΔS_T: (1) high values, upon low field variations; (2) large temperature interval around the desired refrigeration temperature and (3) negligible hysteresis losses (reversibility). In this work, we reported the barocaloric effect in $[Fe(pzt)_6](PF_6)_2$ (pzt=1-propyltetrazole) spin crossover compound which crystallizes in triclinic crystallographic structure in which the $Fe^{+2}N_6$ molecules show almost regular octahedral coordination. This compound presents the three

main requisites mentioned above. The obtained refrigerant capacity in $[Fe(pzt)_6](PF_6)_2$ was RC = 1380 J/kg, which is 5 times higher than the giant value reported in $(NH_4)_2SO_4$, upon pressure variation ΔP = 1 kbar [3]. This huge caloric effect was ascribed to the coupling interactions between the crystal lattice (phonons) and the order parameter (γ_{HS}) that describes the molar fraction of high spin molecules ($Fe^{+2}N_6$) - ($t^4_{2g}\, e^2_g$) in $[Fe(pzt)_6](PF_6)_2$. We constructed a proper Hamiltonian to describe the microscopic interactions in $[Fe(pzt)_6](PF_6)_2$ spin crossover compound. A new methodology to obtain the barocaloric effect potentials is presented using a proper thermodynamic Maxwell relation for spin-crossover systems. The experimental results, for the isothermal entropy change, were calculated from the pressure dependence of γ_{HS} data and showed good agreement with our theoretical predictions.

H15-06. Field evolution of topological sectors in a finite Dzyaloshinskii-Moriya antiferromagnetic chain. *J. Chovan*[1,2] and D. Legut[1] *1. IT4Innovations National Supercomputing Center VSB - Technical University, Ostrava, Czechia; 2. Department of Physics, Matej Bel University, Banska Bystrica, Slovakia*

We present a theoretical study of a finite classical Heisenberg antiferromagnetic (AF) chain with strong easy-plane (EP) anisotropy and uniform Dzyaloshinskii-Moriya (DM) interaction [1] in a magnetic field H. The chiral axis is perpendicular to the EP and we assume free boundary conditions (BC). In the bulk limit, the ground state (GS) is a perfect spin spiral rotating in the EP. When H is applied in the EP, the spiral is distorted and its period grows. For strong H, the structure becomes a chiral soliton lattice (CSL) with large commensurate regions separated by narrow domain walls. Above a certain critical field the GS is commensurate [2]. The properties of finite chains with N spins can be controlled by manipulating the topological sector - the number of spiral twists over the chain n, which depends on N and H. Recent experiments on thin films in DM ferromagnets (FM) MnSi and $CrNb_3S_6$ observed H-induced discrete magnetization jumps whose number is size-dependent [3-5]. Such jumps are absent in bulk systems. Theory [5-7] traced the origin of these jumps to transitions between topological sectors, and established that, for given N, n decreases with H in steps of 1. The importance of BC was emphasized. Here, the finite DM AF system is considered for the first time. We numerically determine the GS, its topological sector n and the magnetization M, and monitor its evolution with N and H. We find several novel features not observed in FM systems. In particular, with increasing H: 1) transitions between different n display pronounced even-odd N effects. 2) n not always decreases in steps of 1; with H, n may even increase and then decrease again. 3) the transition to the commensurate state may occur significantly above the bulk critical field. Our results call for further experimental and theoretical studies. H15-07. Ground-State Properties of Spin-1/2 Heisenberg Antiferromagnets with Frustration on the Diamond-Like-Decorated Square and Triangular Lattices. Y. Hirose[1], S. Miura[1], C. Yasuda[2] and *Y. Fukumoto*[1] *1. Tokyo University of Science, Noda, Japan; 2. University of the Ryukyus, Nishihara, Japan*

We study the ground-state phase diagrams and properties of spin-1/2 Heisenberg models on the diamond-like-decorated square [1-4] and triangular lattices. The diamond-like-decorated square (triangular) lattice is a lattice in which the bonds of a square (triangular) lattice are replaced with diamond units. The diamond unit has two types of antiferromagnetic exchange interactions, and the ratio λ of the strength of the diagonal bond to that of the other four edges determines the ground-state properties [1]. For both the diamond-like decorated square and triangular lattices, we obtain three types of ground-state phases: the dimer-monomer state for $2<\lambda$, the macroscopically degenerated tetramer-dimer (MDTD) states, which are equivalent to the dimer covering states of the original lattice [1-3,5], for $\lambda c<\lambda<2$, and the ferrimagnetic state for $\lambda<\lambda c$. By means of the modified spin wave (MSW) method [6] and the quantum Monte Carlo (QMC) method [7], we estimate the ferrimagnetic ground-state energies, for which we can consider the mixed spin-1 and spin-1/2 Lieb-lattice and triangular Lieb-lattice Heisenberg antiferromagnets instead, and obtain the phase boundaries $\lambda c=0.974$ for the square case [8] and $\lambda c=0.988$ for the triangular case. We also calculate the long-range order parameters using the QMC and MSW methods and find a scaling relation where the spin reduction of each sublattice is inversely proportional to the number of sublattice sites [1,8]. We prove this scaling relation by applying an infinitesimal uniform magnetic field and causing spontaneous symmetry breaking. Furthermore, by using the Marshall-Lieb-Mattis theorem and the MSW theory, we focus on the total spin of the ground state and examine the mathematical structure behind the scaling relation for sublattice long-range orders [8].

H15-08. Engineering Surface Critical Behavior of (2+1)-Dimensional O(3) Quantum Critical Points. C. Ding[1], L. Zhang[2] and *W. Guo*[3] *1. School of Science and Engineering of Mathematics and Physics, Anhui University of Technology, Maanshan, Anhui 243002, China, Maanshan, China; 2. Kavli Institute for Theoretical Sciences and CAS Center for Excellence in Topological Quantum Computation, University of Chinese Academy of Sciences, Beijing, China; 3. Physics Department, Beijing Normal University, Beijing, China*

Surface critical behavior (SCB) refers to the singularities of physical quantities on the surface at the bulk phase transition. It is closely related to and even richer than the bulk critical behavior. In this work, we show that three types of SCB universality are realized in the dimerized Heisenberg models at the (2+1)-dimensional O(3) quantum critical points by engineering the surface configurations. The ordinary transition happens if the surface is gapped in the bulk disordered phase, while the gapless surface state generally leads to the multicritical special transition, even though the latter is precluded in classical phase transitions because the surface is in the lower critical dimension. An extraordinary transition is induced by the ferrimagnetic order on the surface of the staggered Heisenberg model, in which the surface critical exponents violate the results of the scaling theory and thus seriously challenge our current understanding of extraordinary transitions.

H15-09. General method for atomistic spin-lattice dynamics with first principles accuracy. *J. Hellsvik*[1,2], D. Thonig[3], K. Modin[4,5], D. Iusan[3], A. Bergman[6], O. Eriksson[7], L. Bergqvist[8] and A. Delin[2] *1. Nordita, Stockholm, Sweden; 2. KTH Royal Institute of Technology, Stockholm, Sweden; 3. Department of Physics and Astronomy, Uppsala University, Uppsala, Sweden; 4. Chalmers University of Technology, Gothenburg, Sweden; 5. University of Gothenburg, Gothenburg, Sweden; 6. Dept. of Physics and Astronomy, Uppsala University, Uppsala, Sweden; 7. Physics and Astronomy, Uppsala University, Uppsala, Sweden; 8. Materials and Nano Physics, KTH Royal Institute of Technology, Kista, Sweden*

We present a computationally efficient general first-principles based method for spin-lattice simulations for solids and clusters. Our method is based on a combination of atomistic spin dynamics [1] and molecular dynamics, expressed through a spin-lattice Hamiltonian where the bilinear magnetic term is expanded to second order in displacement. The effect of first-order spin-lattice coupling on the magnon and phonon dispersion in bcc Fe is reported as an example, and is seen to be in good agreement with previous simulations performed with an empirical potential approach [2,3]. In addition, we also illustrate the abilities of our method on a more conceptual level, by exploring dissipation-free spin and lattice motion in small magnetic clusters (a dimer, trimer and quadmer). Our method opens the door for quantitative description and understanding of the microscopic origin of many fundamental phenomena of contemporary interest, such as ultrafast demagnetization, magnetocalorics, and spincaloritronics [4].

H16-01. Ultrafast Magnetization Dynamics of (Gd,Tb)Co alloys exhibiting Helicity-Independent All-Optical Switching. *A. Ceballos*[1], A. Pattabi[2], C. Simon[1], J. Bokor[2] and F. Hellman[1] *1. UC Berkeley, Berkeley, CA, United States; 2. EECS Dept., University of California, Berkeley, CA, United States*

A single, linearly polarized femtosecond optical pulse can deterministically reverse the magnetization of a ferrimagnetic film within picoseconds. This is known as Helicity-Independent All-Optical Switching (HI-AOS). First demonstrated by Radu *et al.*[1] and Ostler *et al*.[2] in ferrimagnetic GdFeCo, this phenomenon not only seems to defy conservation of angular momentum but also represents the fastest magnetization reversal mechanism known so far. HI-AOS has presently only been demonstrated in ferrimagnetic GdFeCo and GdCo films even though theorists have predicted said effect to be possible in any magnetic material with at least two non-equivalent magnetic sublattices[3]. Thus, other rare-earth transition metal alloys should be the most obvious candidates. However, both our initial internal studies and literature[4], show that Tb-Co films lack HI-AOS across a broad range of compositions, indicating that understanding the exact role of Gd in enabling the switching is paramount for finding new materials with HI-AOS. Here we report the ultrafast magnetization dynamics of (Gd,Tb)Co alloys confirmed by us to exhibit HI-AOS as seen in Fig. 1. Starting with Gd-Co, we have doped with increasing amounts of Tb (keeping the at.% of the rare-earths constant) and have observed HI-AOS in $(Gd_{1-x}Tb_x)_{22}Co_{78}$ films of up to 12% Tb. With a set of films that span x=0 to x=1, we systematically study the evolution of the ultrafast magnetization dynamics as we cover the spectrum from films that exhibit HI-AOS, to those that only demagnetize upon irradiation. Together with monitored changes in the saturation magnetization and anisotropy constant, we aim to elucidate the underlying mechanisms of HI-AOS and determine the parameters that enable HI-AOS.

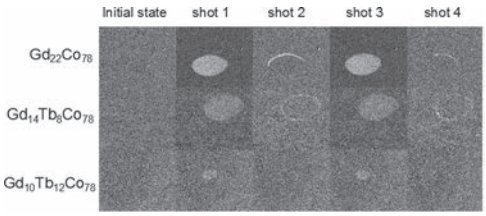

Fig. 1. Magneto optical Kerr effect (MOKE) microscope images of a sequence of HI-AOS events on 10 nm thick $Gd_{22}Co_{78}$, $Gd_{14}Tb_8Co_{78}$ and $Gd_{10}Tb_{12}Co_{78}$ samples. Each shot consists of a single 100 fs laser pulse with an incident fluence of ~ 4 mJ/cm². Each pulse is sourced from a regeneratively amplified Ti Sapphire laser (800 nm central wavelength), at an angle of 40° from the normal of the sample's surface. Dark (light) grey indicates magnetization pointing into (out of) the plane of the sample.

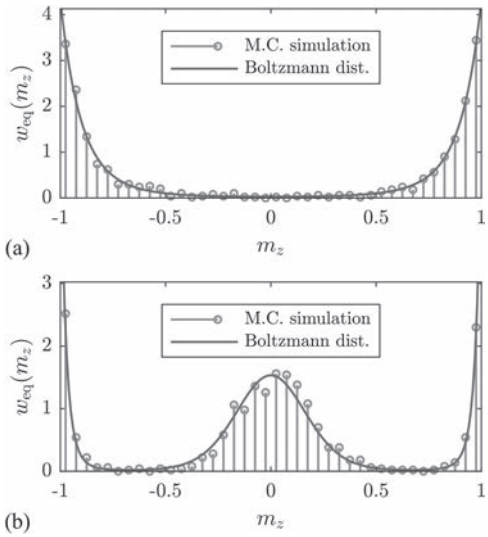
H16-02. Crystal Growth and Spin Reorientation Transition of $Sm_{0.4}Er_{0.6}FeO_3$ Orthoferrite. *A. Wu*[1] *1. Shanghai Institute of Ceramics, CAS, Shanghai, China*



High quality $Sm_{0.4}Er_{0.6}FeO_3$ single crystal has been successfully grown by the floating zone method. Temperature dependence of the magnetizations of Sm0.4Er0.6FeO3 under ZFC process is studied in the temperature range of 4–300 K. Spin reorientation transition between Γ2 (Gz, Fx) and Γ4 (Gx, Fz) is observed in the temperature range of 170–210 K, which is significantly lower than that of $SmFeO_3$, while much higher than that of $ErFeO_3$. A compensation point (35.8 K) corresponding to zero magnetization and a spontaneous magnetization reversal transition at 49.5 K are observed in $Sm_{0.4}Er_{0.6}FeO_3$. Temperature-induced SRT of $Sm_{0.4}Er_{0.6}FeO_3$is systematically studied by Terahertz time-domain spectroscopy (THz-TDS) range from 40 K to 300 K. The temperature dependence of amplitude of AFM mode coincides well with the magnetization measurement which demonstrates that SRT in $Sm_{0.4}Er_{0.6}FeO_3$ can be studied through the amplitude of AFM mode FID emission. The AF mode frequency is almost invariant, while the F mode frequency significantly decreases with increasing temperature, which could be explained by the temperature dependence of anisotropy energy.

H16-03. Reversal time of jump-noise driven magnetization dynamics in nanomagnets via Monte Carlo simulations. *A. Parthasarathy*[1] and S. Rakheja[1] *1. Electrical and Computer Engineering, New York University, Brooklyn, NY, United States*

The conventional way of modeling magnetization dynamics with thermal effects is by including two distinct and disjoint terms in the effective field of the macroscopic equation of motion[1]: (a) a dissipative field,[2] and (b) a random thermal field. While such model is reasonable at nominal temperatures, it becomes inadequate for explaining low temperature (10 mK—10 K) phenomena, such as macroscopic tunneling of magnetization,[3,4] in which the transition rate between two magnetic states is independent of temperature. By modeling the dynamics due to thermal effects using a single random process composed of discontinuous transitions (jumps) with Poisson arrivals, called the jump-noise,[5,6] a unified model applicable over a broad range of temperatures is obtained. The jump noise provides a justification for quantum tunneling of magnetization without invoking quantum mechanics.[4] In this work, we develop improved numerical methods for Monte Carlo simulation of jump-noise dynamics compared to prior works,[7,8] and validate the method by comparing the stationary distribution obtained numerically against the analytic Boltzmann distribution. In accordance with the Néel-Brown[1] theory, jump-noise dynamics display an exponential relaxation toward equilibrium with a characteristic reversal time, which we extract for nanomagnets with uniaxial and cubic anisotropy. We also identify an analytic upper bound on the strength of jump-noise: this bound establishes the regime of small noise in which an equivalent Gilbert damping coefficient can be defined within the classical framework of magnetization dynamics.

It has long been known that ferromagnets undergo a phase transition to the paramagnetic phase when heated above the critical temperature. However, such a transition under strongly out-of-equilibrium conditions, e.g. after excitation of a material by an ultrafast laser pulse, and its role in the process of ultrafast demagnetization [1] is poorly understood. By correlating time- and angle-resolved photoemission (Tr-ARPES) and time-resolved transverse magneto-optical Kerr effect (Tr-TMOKE) measurements, both at EUV wavelengths, we uncover the universal nature of the ultrafast photoinduced magnetic phase transition in Ni [2,3]. Recent work using surface-sensitive ARPES uncovered the presence of critical behavior, where Ni undergoes a magnetic phase transition after the electrons are transiently heated above the Curie temperature [2]. Here, we fully explain the ultrafast magnetic response of Ni over a wide range of laser fluence – from a small reduction of the magnetization at low fluence, to complete quenching at high fluence. Both probe methods exhibit the same universal demagnetization and recovery timescales: first, fast coupling of the laser energy to the spin system within 20 fs; second, demagnetization of the material that occurs within ~200 fs; and third, subsequent recovery of the magnetization on timescales ranging from 500 fs to >70 ps, depending on the excitation fluence. Finally, there is evidence of two competing channels with two distinct timescales in the recovery process that suggest the presence of coexisting phases in the material.

In heat-assisted magnetic recording (HAMR), magnetization is reversed through the combined action of a laser-induced thermal load and an anti-parallel magnetic field[1]. Here, we experimentally and numerically reveal an alternative pathway, using a magnetic field applied perpendicular to the axis of magnetic anisotropy. The laser-induced thermal load destroys the magnetic anisotropy[2], thus triggering large-amplitude precession about the new transient effective field, enabling the magnetization to undergo complete reversal. Compared to HAMR, this pathway is both faster and more energy-efficient. In our experiment, the sample of Bismuth-doped $Y_3Fe_5O_{12}$, featuring out-of-plane magnetic anisotropy, was exposed to a magnetic field with a strong in-plane (H_x) and a weaker out-of-plane component. To trigger magnetization dynamics, the medium was excited by a single intense ultrashort optical pulse. The resulting transient change of the out-of-plane component of magnetization was then probed via the Faraday effect, using a second time-delayed pulse. Shown in Fig. 1 are typical images obtained in our experiment for several time-delays. Despite the intensity distribution of the pump pulse being spatially continuous and Gaussian, our results reveal that we form a "bullseye" pattern of magnetic domains.

The number of rings increases with both the pump fluence and H_x, and are formed within less than 1 ns after the pulse arrival. To study the magnetization dynamics with more detail, we also performed time-resolved trace measurements, the results of which are shown in Fig. 2. At low fluence, incapable of switching the magnetization, we observe several oscillations, persisting for several nanoseconds. However, when the fluence is enough to form a single ring of reversed magnetization, we observe the smooth reversal of magnetization in the absence of ringing, revealing an anomalous increase in the magnetic damping. This is crucial for magnetization to be reversed in the shortest possible time.

H16-07. Lattice dynamics in the helical phase of Dy epitaxial films. *K. Dumesnil*[1], A. von Reppert[2], J. Pudell[2], A. Koc[3], M. Reinhardt[3], W. Leitenberger[2], F. Zamponi[2] and M. Bargheer[2,3] *1. Institut Jean Lamour, CNRS/Université de Lorraine, Nancy, France; 2. Instituite of Physics and Astronomy, University of Potsdam, Potsdam, Germany; 3. Helmoltz Zentrum Berlin, Berlin, Germany*

The ultrafast magnetization dynamics in the ferromagnetic phase of transition metals and lanthanides drives a strong interest to unravel the various mechanisms responsible for the demagnetization process [1]. The remagnetization is another fundamental issue, especially for possible technological applications, which has received less attention. The dynamics in *non-collinear phases*, as observed in many lanthanides, are also relatively unexplored. One can however mention a recent study on the dynamics of the core spins in the Dy helical phase [2], reporting that this dynamics occurs on much longer time scales than the excitation of conduction electrons and differs from that observed in the ferromagnetic phase or in transition metals. Some disorder of the spin system by the way persists more than 10 ns, especially for high fluence excitation. The present work aims in exploring the *lattice dynamics* in the Dy spin-spiral phase resulting from ultrafast optical excitation and associated to spin and phonons dynamics [3]. Temperature- and fluence-dependent Ultrafast X-Ray Diffraction measurements are performed in a 80nm thick Dy epitaxial film sandwiched between Y thin layers. In the magnetically ordered phases of Dy, the energy transferred from the electrons to the spin system leads to a lattice contraction, whereas heating the phonon system leads to an expansion. A careful analytic decomposition of the signals has thus permitted to extract the non-equilibrium spin and lattice dynamics triggered by ultrafast heating of the electron system and to analyze the heat flow among spins and phonons and through the different layers. It appears that the phonon and spin systems are mutually not in thermal equilibrium for several nanoseconds after the optical excitation. A rapid disorder in the spin system, inducing a contractive force, reveals a very strong spin-lattice interaction in the ordered phase. On the other hand, restoring the magnetic order is much slower than the cooling of the lattice, especially around the Néel temperature. This suggests a rather weak spin-phonon coupling for (partially) disordered spins. These results provide important information in the debate about ultrafast angular-momentum transfer to the lattice.

H16-08. All-Optical Observation of Coherent Magneto-Phonon Polariton Dynamics. *C. Berk*[1], M. Jaris[1], W. Yang[1], S. Dhuey[2], S. Cabrini[2] and H. Schmidt[1] *1. UC Santa Cruz, Santa Cruz, CA, United States; 2. Molecular Foundry at Berkeley, Berkeley, CA, United States*

The coupling of the magnon and phonon modes offers an underexplored degree of freedom for the manipulation of magnetic thin film systems. [1] When these modes are resonantly coupled, the dynamics are attributed to the magneto-phonon polariton quasiparticle, where the modes hybridize and display both phonon and magnon character. [2] We report on the direct observation of magneto-phonon polariton dynamics within a single thin (30 nm) Ni square nanomagnet. The confirmation of the hybridized mode is seen in the avoided crossing of the magnetic resonance and the element's mechanical vibration (fig. 1). The dispersion and coupling of these modes have been predicted, [2] however, this is the first experiment to spectroscopically resolve the avoided crossing, the hallmark of coherent coupling, in this type of system. The dynamics were measured using two-color Time-Resolved MOKE Spectroscopy. The absorption of the pump pulse has two effects on the nanostructure. First, the magnetization dynamics are triggered by the quasi-instantaneous thermalization which spontaneously demagnetizes the sample. Simultaneously, thermal expansion activates vibrational resonances in the nanostructure. An external applied field is used to tune the magnetic resonance, and when the magnetic resonance is close to the mechanical resonance an enhancement of the magnetic signal is seen along with the repulsion of the two modes (fig.1). The coupling energy, $\Delta\kappa$, is measured to be 3.3 μeV from the frequency splitting of the two modes on resonance (fig. 2).

Ultrafast spin dynamics occurs in a variety of magnetic materials subject to femtosecond laser excitation. The sub-picosecond manipulation of the magnetization and the subsequent evolution of the material's degrees of freedom has been studied for more than two decades and is usually described from the perspective of quasi-equilibrium, averaged dynamics where only perturbative scattering processes are considered, e.g. the three temperature model with separate electron, spin, and lattice thermal baths [1]. However, the rapid evolution of the spatially varying magnetization after ultrafast demagnetization has largely been neglected until now [2]. Here we use soft X-ray magnetic scattering at the LCLS to probe the temporal evolution of the spin-spin correlation function following femtosecond laser heating of GdFeCo ferrimagnetic alloys. We find that subsequent to the initial ultrafast demagnetization and all-optical magnetic switching, the magnetization evolves at picosecond timescales through the coalescence of magnons into transient solitons. This process is confirmed by multiscale modeling that includes atomistic and micromagnetic components. Magnon coalescence is observed as a scattering feature centered at q = 0 whose linewidth narrows at picosecond timescales, see Fig. 1a, interpreted as the coalescence of magnons into randomly distributed, spatially localized bound states that can be identified as either magnon drops, topological skyrmions, or both [3]. The observed experimental and numerical magnon coalescence follows a temporal power law, see Fig. 1b, and is analogous to the phase ordering kinetics in binary fluids and superfluids when subject to rapid annealing through a phase transition. Our results suggest that the equilibrium magnetization state after femtosecond laser heating, e.g., skyrmions in materials with Dzyaloshinskii-Moriya interaction, may be tailored by patterning features or controlling the microscopic structure of the irradiated magnetic materials.

Institute for Molecules and Materials, Radboud University, Nijmegen, Netherlands*

Magnetic semiconductors are an excellent playground to reveal the role of intra- and interband electronic transitions in optically induced spin dynamics. Here we report about spin dynamics in ferromagnetic InMnAs semiconductor thin films excited by ultrashort far-infrared (THz) and mid-infrared pulses. We perform measurements for two considerably different pump photon energies: mid-infrared pump with a photon energy of 500 meV and terahertz pump with a photon energy of about 5 meV. The ultrafast response of the medium to such an excitation is measured with the help of a probe pulse with a photon energy of 1.5 eV, employing the magneto-optical Kerr effect. In the measurements an external magnetic field was applied at an angle to the film normal. For both pump photon energies we experimentally reveal partial demagnetization of about 50 % followed by spin oscillations at the frequency of the ferromagnetic resonance. The frequency of the oscillations is in the GHz range and has a linear dependence on the external magnetic field. In both cases the oscillations are independent of the pump polarization, suggesting that the mechanism responsible for the excitation is due to demagnetization or a change of the strength of magnetic anisotropy already present in the medium. It is interesting to note that pump pulses with photon energies which differ by two orders of magnitude trigger qualitatively similar spin dynamics. Despite the qualitative similarities, we also observe that THz pump pulses with fluence of 0.1 mJ/cm2 trigger spin dynamics of the same amplitude as mid-infrared pulses having a 100 times lower fluence. This indicates that intraband transitions play a decisive role in the optically induced spin dynamics.

I1-01. Spin-Orbit Torques: Discoveries, Advances and Possibilities.
R. Buhrman[1] *1. Applied Physics, Cornell University, Ithaca, NY, United States*

The discoveries early in this decade establishing that robust spin-orbit torques (SOT) can be exerted on the magnetic structure of a ferromagnetic thin film by charge flow in a thin film bilayer consisting of that ferromagnet and a heavy metal layer opened up a broad new exciting area of nanomagnetism research for fundamental studies and potential spintronics applications. Since then there have been many highly notable developments, including: (1) major advances in the understanding of the different possible origins of SOT and their range of characteristics; (2) the identification of new classes of materials that can provide strong spin currents and different types of SOT; (3) the demonstration of new concepts and approaches to effectively utilize SOT in a variety of ways for efficiently manipulating magnetism at the nanoscale; and (4) marked progress in both understanding and controlling the physics that degrade spin currents in heterostructures, and in enhancing through materials engineering the strength of SOT of conventional heavy metal systems. Due to the very broad scope of the current SOT research field, in this presentation I will focus largely on a selection of some of more recent developments in the first and last of these topic areas, particularly those that arguably show promise for possibly enabling a successful SOT technology in the relatively near term. Then in the last part of my presentation I will discuss some recent progress that has been made towards the effective demonstration of fast, reliable, low pulse current SOT switching of three terminal magnetic tunnel junction devices

J1-01. Heusler Alloy/III-V Semiconductor Lateral Spin Valves.
T.A. Peterson[1], C. Liu[1], S. Patel[2], A.P. McFadden[2], C.J. Palmstrom[2,3] and *P.A. Crowell*[1] *1. Physics and Astronomy, University of Minnesota, Minneapolis, MN, United States; 2. Electrical and Computer Engineering, University of California, Santa Barbara, Santa Barbara, CA, United States; 3. Materials, University of California, Santa Barbara, Santa Barbara, CA, United States*

Improvements in the performance of III-V semiconductor-based lateral spin valves over the last decade have been made through a combination of a better understanding of their physics as well as the integration of different magnetic materials, including Heusler alloys. I will discuss recent experiments on epitaxial Heusler-alloy /III-V heterostructures, including the demonstration of room-temperature operation [1], measurements of the spin relaxation rate, and the implementation of a new detection technique based on ferromagnetic resonance [2]. These devices, based on the $Co_2Mn_xFe_{1-x}Si$-family of Heusler alloy materials, have exploited both their high spin polarization and low magnetization damping. I will discuss limits on both of these quantities, with some emphasis on extrinsic sources of Gilbert damping in epitaxial films, including two-magnon scattering. Returning to low temperatures, we are addressing physics in the regime of large spin accumulations, and in particular the dependence on channel-doping near the metal-insulator transition. Supported by the National Science Foundation through DMR-1708287 and C-SPIN, a STARNET center of SRC and DARPA.

J1-02. Neuromorphic computing by artificial neural network with analog spin-orbit torque device. *S. Fukami*[1] *1. Tohoku University, Sendai, Japan*

Representing the human brain in computers is one of the focuses of interest in recent electronics as the brain is a model system that can readily accomplish complex tasks at small power consumption level, in contrast to conventional von Neumann computers. Such fields, referred to as the neuromorphic computing, have shown rapid progress and gathered growing attention for these years. An artificial neural network offers a promising platform for highly intelligent neuromorphic computing. A key ingredient for the network is an artificial synapse that has analog and nonvolatile memory functionalities and learning capability as in the real synapse in the human brain. Here I show a spintronics device that can serve as an artificial synapse meeting these requirements. I will first describe an analog spin-orbit torque (SOT) switching device consisting of an antiferromagnet-ferromagnet bilayer structure used for the artificial synapse [1]. The mechanism of analog operation [2] and control of state by short pulses with the duration down to 1 ns will be described. Secondly, a proof-of-concept demonstration of an artificial neural network with 36 SOT devices will be shown [3]. An associative memory operation is performed, where the developed system successfully associates memorized clean patterns with noisy inputs using the Hopfield model.

The author thanks H. Ohno, S. Sato, Y. Horio, H. Akima, W. A. Borders, A. Kurenkov, R. Itoh, C. Zhang S. DuttaGupta, and H. Sato for fruitful discussion and technical support. J1-03. Neuromorphic computing with spintronic nanodevices.
J. Grollier[1] *1. Unité Mixte CNRS/Thales, Palaiseau, France*

Today, neural networks are everywhere: they are the virtual assistants in our smartphones, they are powering our search engines and they are the key to big data classification. They can even beat humans at image recognition or at strategy games such as Go. However neural networks are still running as software on our current computers, consuming tens of kilowatts and working rather slowly. In comparison, the brain from which they are inspired, operates with 20 W and can realize incredibly complex tasks in fractions of seconds. Building chips more closely inspired from the brain architecture is the path to cognitive computing at low energy cost. Applications of such chips span from embedded automatic pattern recognition for big data management, going through unmanned vehicle control to bio-medical prosthesis. The challenge of fabricating brain-inspired hardware relies in the ultra-high density networks that have to be built, out of complex processing units interlinked by tunable connections providing memory. Magnetic nanodevices can be a key technology in this context thanks to their ability to provide massive access to memory, their multiple and tunable functionalities, their non-linear dynamics and compatibility with CMOS [1]. In this talk I will give an overview of recent advances in the field of hardware brain-inspired computing. I will show how magnetic nanodevices can be used for brain-inspired computing, and discuss the working principle of neuromorphic models that can be implemented in Spintronics. Finally, I will show our first results of cognitive pattern recognition with magnetic oscillators [2,3].

Physics, Informatics and Mathematics, Università di Modena e Reggio Emilia, Modena, Italy

This presentation will highlight recent progress towards the development of lanthanide molecular magnets for potential quantum information processing (QIP) applications [1]. Bottom-up synthetic chemistry approaches to such technologies are particularly attractive because they enable systematic control of the spin states of metal ions (the quantum bits, or qubits), in this case a lanthanide. Moreover, molecular functionalization provides a means for engineering interactions between spin qubits, as well as for tethering molecules to surfaces or between the electrodes of a field-effect device. After a brief introduction, I will describe results of continuous-wave (cw) and pulsed electron paramagnetic resonance (EPR) studies of related families of lanthanide molecules that are of interest for QIP. The first example involves a Ho^{III} ion ($4f^{10}$, total angular momentum ground state $J = L + S = 8$) encapsulated within a $(W_5O_{18})_2$ polyoxometalate cage [1,2]; the resulting magnetic anisotropy gives rise to a pair of low-lying $m_J = \pm 4$ singlets that are further split by a strong hyperfine interaction with the $I = 7/2$ nuclear spin. I will then show how small distortions away from a near perfect D_{4d} local site symmetry can give rise to EPR transitions that are immune to dipolar field fluctuations (noise) associated with the surrounding electron and nuclear spins. These so-called 'clock transitions' (named after the principle that gives atomic clocks their exceptional phase stability) result in unusually long coherence (T_2) times [2]. I will also show that one can harness both electron and nuclear spin degrees of freedom for QIP by driving long-lived electron/nuclear clock transitions at microwave frequencies [3]. The second example involves a bis-phthalocyanine radical coupled to a Tb^{III} ion, revealing a highly anisotropic signal that is attributed to the radical, suggesting a significant coupling to the lanthanide spin [4]; the radical EPR spectrum would be expected to be essentially isotropic otherwise. This work is important given the recent demonstration that radical bearing ligands provide a means of addressing the electron and nuclear quantum states of lanthanide ions integrated into single-molecule devices.

Single molecular toroics are an emerging class of coordination complexes that exhibit spin vortex chiral ground states due to non-collinear arrange-

ments of local magnetic moments. While *ab initio* methods have proven indispensable for predicting local magnetic moments in polynuclear lanthanide complexes, unequivocal experimental determination of local magnetic moments has proven more challenging. Typically, angular dependent single crystal magnetization would be considered a good method to obtain detailed anisotropy information. However, periodicity resultant from the cluster symmetry has hindered the use of this method for the study of many complexes including Dy_3 [1]. In this work we consider a snub square molecular complex, Dy_8 [2] (Fig. 1). Multiple orientation single crystal magnetization, measured at 0.3 K, reveal the orientation of local moments, via the identification of two field-induced ground-state crossings that exhibit different angular phases (Fig. 2). These measurements, with a simple Ising model, are used to identify a zero toroidal ground state in Dy_8, highlighting the robustness of vortex chirality within larger Dy based molecular lattices. J2-04. Spin Liquid States in Spin-Frustrated Systems of Organic Radicals. *K. Awaga*[1] *1. Nagoya University, Nagoya, Japan*

Geometrical spin frustration has been investigated extensively in the past two decades, and the formation of a quantum spin liquid state, predicted by the resonating valence bond (RVB) theory, has attracted much attention. It is preferable to elucidate the spin-frustrated systems of organic Heisenberg spins, because their spin isotropy is ideal for the study of quantum spin liquids. In this presentation, we report two kinds of organic spin-frustrated systems. (i) In the crystals of *m*-MPYNN●X (*m*-MPYNN=*m*-*N*-methylpyridinium nitronylnitroxide and X= I, BF_4, ClO_4, etc.), *m*-MPYNN (*S*=1/2) exists as a ferromagnetic dimer and the *S*=1 dimers form a 2D Kagome lattice with spin frustration. The low-temperature magnetic and thermal measurements reveal a spin-liquid ground state, which exhibits the fractional plateaus in the magnetization curve at 1/2 and 3/4 of the saturation magnetization [1]. (ii) In the crystals of $(TBA)_{1.5}$[(−)-NDI-Δ] (TBA= tetrabutylammonium and NDI= naphthalene diimide), (−)-NDI-Δ forms a K_4 structure due to its triangular molecular structure and an intermolecular π-π overlap between the NDI moieties. This lattice is identical to the hyper-kagome lattice of *S*=1/2 Mott dimers (Fig. 1). The low-temperature magnetic and thermal measurements reveal the presence of a spin liquid state with a large residual paramagnetism and a large heat capacity that can be fitted to the power law of $T^{0.62}$ [2].

Photon Science Division, Paul Scherrer Institute, Villigen, Switzerland; 6. Department of Physics, ETH Zürich, Zürich, Switzerland*

Quantum spin clusters, and in particular finite chains or rings, provide a platform for the experimental study of many-body entanglement. Here we show theoretically how they can be used to investigate the so-called "entanglement transition" – a qualitative change between two different types of spin-spin entanglement as an applied magnetic field is raised [1]. For infinite chain compounds, the entanglement transition will be complicated by the proximity of the quantum phase transition corresponding to the melting of magnetic order by quantum fluctuations. In a small cluster the latter transition does not occur. We address a simple model of a single-molecule nano-magnet featuring a ring of N interacting spins in a transverse applied magnetic field, and consider the experimental implications of the entanglement transition [2]. The Hamiltonian we consider is the general spin-1/2 anisotropic antiferromagnetic Heisenberg model with local variation of the easy axes to take into account the symmetry of the molecule. From numerical diagonalization for N=4,6,8,10,12 we calculate the magnetisation, low-energy gap and neutron-scattering cross-section. We find that there are N/2 level crossings between the ground state and first excited state as the field is increased, with zeros in the energy gap and magnetisation jumps at the crossings. The last level crossing corresponds to the entanglement transition in which, for all N, the ground state is fully factorised into a product wave function, that is, it shows no entanglement. Our most important result is that at each crossing there is a rearrangement of spectral weight in the spin-spin correlation function, with a dramatic change on going through the entanglement transition. We find there is a large shift in spectral weight from the vicinity of antiferromagnetic peaks to ferromagnetic peaks as the nature of the entangled state changes through the factorisation field. The signatures of the entanglement transition are detectable at temperatures as high as 5% of the antiferromagnetic interaction strength between spins, and are most pronounced for the smaller rings. Neutron scattering experiments should therefore be able to detect the entanglement transition.

J3-01. Quantum Kagome Spin Liquids: a Local View. *P. Mendels*[1], F. Bert[1], P. Khuntia[2], E. Kermarrec[1], Q. Barthélémy[1] and M. Velazquez[3]
1. Lab. Physique des Solides, Univ. Paris-Sud, Univ. Paris-Saclay, Orsay, France; 2. IIT Madras, Madras, India; 3. ICMCB, Bordeaux, France

The antiferromagnetic kagome lattice decorated with quantum spins has been considered since the late 90's as the best candidate for stabilizing a quantum spin liquid in dimension higher than one. From a theoretical point of view, the simple Heisenberg case remains a standing problem, not solved yet. Experimental realizations have remained scarce for long until the discovery of Herbertsmithite $ZnCu_3(OH)_6Cl_2$ in 2005 [1]. Others followed [2] which sometimes differ by the scheme of couplings, like in kapellasite. I'll briefly introduce them in my talk. Herbertsmithite features a perfect kagome geometry, with dominant first neighbor interactions, and was first in this geometry not to show any freezing at any temperature [3]. For most of these kagome antiferromagnets, there are deviations to the ideal case, either magnetic defects or anisotropy which for typically, $T < J/10$ in herbertsmithite (i) can mask the signatures of the kagome physics at low-T in most experimental techniques, (ii) may induce deviations from the pure Heisenberg model [4]. These difficulties can be circumvented by using local techniques such as NMR. This path was initiated long ago in my group in the study of $SrCr_8Ga_4O_{19}$ [5]. Working on high quality single crystals considerably improves the accuracy of NMR measurements [6] and its ability to address fundamental issues such as the existence of a gap or not and the class of models relevant to describe the ground state of spin liquids. In the case of herbertsmithite which I'll describe first, even in NMR, the greatest challenge to reach firm conclusions about the low-T kagome physics is still to discriminate between what belongs to kagome Cu's and what is the counterpart induced by defects. The latter contribution can be mapped out in detail and the ^{17}O NMR spectral signature of kagome Cu's can then be isolated. Neither in our shift measurements nor in our relaxation studies, any hint of a gap is found down to 1.2 K, ie 0.007 J. On the contrary, we conclude that the susceptibility is finite and independent of the field in the range 3.1 - 12 Teslas [7] at variance with the results from ref. [6]. We will also address some issues resulting from defect physics at low-T revealed by a recent combined torque and high field ESR [8] measurements on our samples. Next, I'll shortly review the two recent hyperkagome materials, featuring a structure built from corner sharing triangles in 3D. I'll stress the results from and NMR and μSR experiments (i) on $Na_4Ir_3O_8$ where spin-orbit is at play and Na deintercalation further offers an interesting avenue for doping [9,10] (ii) on $PbCuTe_2O_6$ [10].

Lett. 115, 047201 (2015).; [10] P. Khuntia, F. Bert, P. Mendels et al, Phys. Rev. Lett. 116, 107203 (2016).

Comparison between the ^{17}O NMR powder spectrum (broad line) on herbertsmithite and that obtained from a single crystal (sharp lines). While there is a unique O site in the structure, both spectra reveal the existence of defects. The set of 5 intense lines corresponds to O sites far from defects and tracks the intrinsic susceptibility of the kagome planes while the set of less intense lines corresponds to two types of defects the susceptibility of which is Curie-like and very different from the intrinsic one. Note that both intrinsic (M) and extrinsic (D) signals are also revealed in the powder spectrum but are less resolved.

J3-02. Dynamics and spectral functions of quantum spin models. *F. Pollmann*[1], R. Verresen[1] and R. Moessner[2] *1. Technical University of Munich, Garching, Germany; 2. Max Planck Institute for the Physics of Complex Systems, Dresden, Germany*

Dynamical response functions provide insight into the excitations above highly-entangled ground states. It is a challenging problem to obtain these in spatial dimensions higher than one. In this talk, we introduce a matrix-product state based method to efficiently study the dynamics of general two-dimensional lattice Hamiltonians. Aside from discussing the general method, we illustrate this for anti-ferromagnetic Heisenberg models on square and triangular lattices, as well as the Kitaev-Heisenberg model—the latter hosting spin liquid phases. The excitations of these models are shown to exhibit anomalous and exciting behavior. An important question in this context is the interactions of magnons and whether this leads to decay.

J3-03. The Mother of All States on the Kagome Quantum Antiferromagnet. H. Changlani[2,1], D. Kochkov[1], K. Kumar[1], *B. Clark*[1] and E. Fradkin[1] *1. Physics, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 2. Physics, Johns Hopkins University, Baltimore, MD, United States*

Quantum spin systems on geometrically frustrated lattices often have a large number of competing phases. This is particularly true on the kagome lattice which appears to support, as a function of various Hamiltonian coupling constants, both a variety of ordered states as well as quantum spin liquids [1]. In this work, we give a source for the wide panapoly of such phases. We report [2] on the existence of a macroscopically degenerate ground state manifold in a simple Hamiltonian: the nearest neighbor antiferromagnetic XXZ model on the kagome lattice, with the ratio of Ising to antiferromagnetic transverse coupling of Jz=−1/2 (the XXZ0 point [3]). Due to the exponential degeneracy at this point, various perturbations can generate a wide variety of phases. We explore one class of such phases proximate to XXZ0. We show that in the plane of coupling constants defined by Jz and the second nearest neighbor coupling constant, J2, that there are five phases proximate to XXZ0. Four of these phases including a spin liquid, q=0 state and sqrt(3) x sqrt(3) phase are adiabatically connected to the Heisenberg line. In addition, we give numerical evidence that there is a transition very close to J2=0 extending from Jz=-0.5 to Jz=1.0.

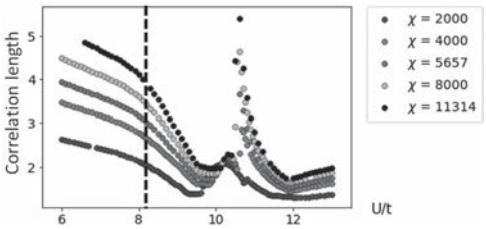
Example three-coloring state on the kagome lattice.



The phase diagram in the Jz – J2 plane on the 36d lattice showing five phases. Star symbols correspond to location of fidelity dips and the error-bars indicate the uncertainty in the location of the phase boundaries (when scanned in the J2 direction) and correspond to the grid-spacing used for the computation of the fidelity. The black hexagon (at Jz ≈ 0.5, J2 ≈ 0.10) is a kink in the second derivative of the fidelity; beyond the corresponding Jz the fidelity dip is not noticeable and the phase boundary is just an extrapolation. The diamonds are colored based on the structure factor at the M point (S(M)) and squares are colored based on the structure factor at the K point (S(K)).

J3-04. Indications of a Spin Liquid Phase in the Triangular Lattice Hubbard Model from Density Matrix Renormalization Group Calculations. *A. Szasz*[1,2], J. Motruk[1,2] and J. Moore[1,2] *1. Physics, University of California, Berkeley, Berkeley, CA, United States; 2. Lawrence Berkeley National Laboratory, Berkeley, CA, United States*

Experimental studies have found signatures of a quantum spin liquid phase in organic crystals whose physics is believed to be described by the Hubbard model on the triangular lattice at half filling[1]. Several theoretical studies, including with the density matrix renormalization group (DMRG) on finite systems[2], confirm the appearance of a possible spin liquid phase between the metallic and magnetically ordered phases of this model. However, the precise nature of the phase is still not completely clear. In this work, we use infinite-system DMRG (iDMRG) on a cylinder geometry in a mixed real- and momentum-space basis to further investigate the ground state phase diagram of the Hubbard model on the triangular lattice, with a focus on the purported spin liquid regime. By computing the correlation length (Figure 1), the spin structure factor (Figure 2), and the entanglement as a function of U/t, we identify three distinct phases: a gapless metallic phase at low interaction strength, a gapped spin-ordered phase at high interaction strength, and a gapped nonmagnetic insulating phase between them. We find an exact two-fold degeneracy in the entanglement spectrum of the intermediate phase which, combined with the gapped nature of the phase, is consistent with a Z_2 spin liquid.

[1] Y. Zhou, K. Kanoda, and T.-K. Ng, Rev. Mod. Phys. 89, 025003 (2017) [2] T. Shirakawa, et al, PRB 96, 205130 (2017)

Correlation length as a function of interaction strength in the Hubbard model, U/t. Each line corresponds to a particular number of states χ kept in the DMRG simulations, controlling the precision of the results. The peak at U/t≈10.6 indicates a second order phase transition between two gapped phases. Finite entanglement scaling (not shown) reveals that the system is gapless (metallic) to the left of the dashed line and gapped to the right.

The maximum value of the spin structure factor S(q) shows a sharp increase at U/t≈10.6, revealing that the peak in the correlation length (Figure 1) corresponds to a spin-ordering transition. The insets show S(q) at representative values of U/t on either side of the transition. To the right of the transition, the weight in S(q) is concentrated at specific points in the Brillouin zone.

J4-01. Magnetic Nanoparticles in Borate Glasses: Theory, Experiment, Modelling, Application Prospective. *J. Kliava*[1], I. Edelman[2], O. Ivanova[2], R. Ivantsov[2] and E. Petrakovskaja[2] *1. LOMA, Université de Bordeaux, Talence, France; 2. Kirensky Institute of Physics, FRC KSC SB RAS, Krasnoyarsk, Russian Federation*

The interest in nanostructures including magnetic nanoparticles is supported by the perspectives of their application in modern high-technology devices. In particular, considerable attention is paid to magnetic nanoparticles arising in glasses doped with paramagnetic additives. As a rule, high contents of these additives are necessary for the formation of magnetic particles in the glass. Meanwhile, borate glasses provide an exception to this rule; indeed, in these glasses, during synthesis and subsequent thermal treatment, magnetic nanoparticles are formed already at low doping levels, ca. 1 mass % [1]. Due to the occurrence of magnetic nanoparticles such glasses acquire the characteristics of magnetically-ordered materials (e.g., a non-linear magnetic field dependence on magnetization with hysteresis and saturation) while keeping transparency in visible and near-infrared spectral ranges and demonstrating strong magneto-optical effects. Such amazing nanomaterials – "transparent magnets" – are first-rate candidates for using in new magneto-optical data storage and spin electronics devices. A compendium of experimental data will be presented describing qualitative behaviour and quantitative characteristics of borate glasses of various compositions, with low contents of paramagnetic dopants and co-dopants - mainly 3d and 4f ions - prepared under different synthesis conditions and containing magnetic nanoparticles. The main attention will be paid to magneto-optical and electron magnetic resonance studies yielding consistent complementary data [2]. Assisted with computer simulations of experimental spectra, these studies have allowed to elucidate the mechanisms of nanoparticles formation, to identify the nature of the nanoparticles arising in the glasses and to establish correlations between their structure and morphology on the one hand and the resulting physical characteristics of nanoparticle-containing glasses on the other hand [3-7]. The modelling of magnetic properties of nanoparticles as well as some new effects related to their size, surface state and interparticle interactions will be described.

J4-02. Key role of the Co cations on the destabilization of the collinear magnetic order in Co-ferrite nanoparticles with tunable structural defects. A. Fraile Rodríguez[1,2], C. Moya[1,2], M. García del Muro[1,2], S. Avula[3], C. Piamonteze[3], X. Batlle[1,2] and *A. Labarta*[1,2] *1. Física Matèria Condensada, Universitat de Barcelona, Barcelona, Spain; 2. Institut de Nanociència i Nanotecnologia (IN2UB), Barcelona, Spain; 3. Swiss Light Source, Paul Scherrer Institut, Villigen PSI, Switzerland*

Co-ferrite ($CoFe_2O_4$) nanoparticles (NP) are versatile materials due to their high values of the magnetocrystalline anisotropy, saturation magnetization, and magneto-optical coefficients. However, owing to their spinel structure, structural defects within each NP may destabilize the ferrimagnetic (FiM) collinear order due to the competition between the inter- and intra-sublattice superexchange interactions. Recently, we showed that stoichiometric, monodisperse 8 nm $CoFe_2O_4$ NP, chemically synthesized with a progressive degree of structural disorder, can exhibit phenomena ranging from bulk-like FiM order to glassy magnetic behavior for NP with relatively few structural defects [1,2]. The actual microscopic mechanisms underlying this strong magnetic degradation are not clear yet since this is not shown by other FiM NP such as magnetite. In this work, we address this issue by using complementary local probes: element-and site-specific X-Ray Magnetic Circular Dichroism (XMCD) measurements on monodisperse 8 nm NP combined with high-resolution transmission electron microscopy characterization of individual NP. The total magnetic moment obtained by XMCD sharply decreases from the $CoFe_2O_4$ bulk value as the structural disorder increases. By comparing the experimental XMCD to ligand field multiplet simulated spectra, the cation occupancies (Co^{2+} and Fe^{3+}) for each site (tetrahedral – Th– and octahedral – Oh –) are quantified. Element-specific XMCD hysteresis loops at all the cationic sites show a progressive decrease in squareness, and increase in both closure field and high-field susceptibility as the NP become more structurally defective, suggesting the loss of collinear FiM order. However, the Co^{2+} Oh sites are significantly more affected by the breaking of superexchange paths, due to the structural defects, than the rest of the cations. Measurements with different probing depths show similar results on the whole NP volume. Our results show the key role of the Co^{2+} Oh cations on the destabilization of the collinear order in Co-ferrite NP with tunable structural defects.

We investigate the influence of carbon nanotubes (CNT) aligned array on the magnetic properties of ensemble of densely packed (10^{10} cm^{-2}) Co nanoparticles (NP) (20 nm) embedded inside CNT. Each CNT contains only one nanosized Co. Samples are synthesized by chemical vapor deposition activated by current discharge plasma and hot filament (DC HF CVD) [1,2]. Co NP is initially formed on a Si/SiO_2 substrate from an ultrathin Co film (4.5 nm). The metal reduction and the formation of an array of Co NP is done in thermally and plasma-activated mixture of H_2 and NH_3 at 973K during 15 min. By means of nuclear magnetic resonance spin-echo and electron diffraction we prove the existence of both *fcc* and *hcp* Co. The DC HF CVD vertically aligned array of CNT growth is carried out with a mixture of C_2H_2 and H_2 at p = 15 mbar for 6 minutes. Co NP are anisotropic, with the long axis parallel to the CNT one and the aspect ratio in the range 4-10. It is established that the reference Co NP ensemble and Co NP embedded inside CNT behave differently in a magnetic field. In the former case Co NP are strongly coupled by the dipole-dipole interaction (DDI). As a result, the easy axis plane is oriented parallel to the substrate. For Co-CNT samples Co NP are magnetically isolated. The reason for suppressing the contribution of the DDI is the magnetic anisotropy [3]. It increases significantly because of the peculiar morphology of Co embedded in CNT and stresses caused by them. We evaluate the values of shape, magnetocrystalline and magnetoelastic anisotropy constants [4]. The magnetoelastic anisotropy is estimated for both observed crystalline structures of Co, *fcc* and *hcp*. It is demonstrated that due to the presence of the *hcp* crystalline phase, stresses could reach significant values (≈ 10 GPa) to lead to the noticeable magnetoelasticity (≈ 5.5×10^5 J/m^3). However, such internal elastic stresses cause the deformation of the CNT lattice only in the range of 0.5 – 2 % [5]. The influence of stresses onto magnetic structure of Co inclusions is investigated by the micromagnetic simulations, which help us to determine that the presumable direction of the hexagonal axis of *hcp* Co is oriented perpendicular to the CNT axis.

J4-04. Jahn-Teller distortion and magnetoelastic coupling in tetragonal (Cu,Co)Fe_2O_4 particles. *H. Latiff*[1], M. Kishimoto[1], J. Inoue[1], E. Kita[1] and H. Yanagihara[1] *1. Institute of Applied Physics, University of Tsukuba, Tsukuba, Japan*

The large magnetoelastic effect exhibited by $CoFe_2O_4$ can induce a large magnetic anisotropy (MA) in the presence of strain, as demonstrated in epitaxially strained thin films [1-2]. The presence of high MA in nanoparticles are desirable for many applications. The introduction of lattice distortion in nanoparticles was demonstrated by exploiting the Jahn-Teller (JT) effect of Cu^{2+} in (Cu,Co)Fe_2O_4 [3]. Here, we report the effect of Co content on the JT distortion and coercivity in $Co_xCu_{1-x}Fe_2O_4$ particles prepared by the coprecipitation and flux method (x=0–0.2). The precipitate obtained from coprecipitation was mixed with KBr and heated at 850 °C for 3 h (flux method). After removing the KBr, the particles were heat-treated in air at 900 °C for 2 h, followed by furnace cooling. The as-fluxed particles were mostly single phase cubic spinel for all compositions. After heat-treatment, distinct JT distortions (c/a>1) were confirmed from the single phase tetragonal spinel of x=0–0.1 samples. As Co increases to x=0.2, no distinct global JT distortion were confirmed from the XRD powder patterns (Fig. 1). From the magnetic measurements, the saturation magnetization, M_s varied proportionally with x from 25 to 37 Am^2/kg. The coercivity, H_c showed a distinct increase after heat-treatment compared to that of the as-fluxed state, due to local and global distortion, in which magnetic anisotropy is triggered by the magnetoelastic effect of the Co^{2+} in the presence of the JT distortion. After heat-treatment, the Co content dependent H_c showed a maximum value for x=0.1, where $\mu_0 H_c$ = 220 mT (Fig. 2). As x increases, the decrease in Cu content suppresses the JT effect while the anisotropy sites from the magnetoelastic effect of Co^{2+} increases. A maximum in magnetic anisotropy, K may be realized by balancing the Cu:Co content so that Cu is sufficient to facilitate JT distortion while Co provides the anisotropy sites. Based on these results, a simple phenomenological theory of the JT distortion and magnetoelastic coupling in tetragonal (Cu,Co)Fe_2O_4 particles is discussed.

J4-05. Single Phase Manganese Ferrite Nanoparticles Prepared by High Temperature Decomposition. *E. Oxford*[1], A.M. Abdelgawad[2], T. Sibley[2] and S. Majetich[1,2] *1. Physics, Carnegie Mellon University, Pittsburgh, PA, United States; 2. Materials Science and Engineering, Carnegie Mellon University, Pittsburgh, PA, United States*

We have previously demonstrated through electron energy loss spectroscopy (EELS) mapping that a popular method for synthesizing monodisperse $MnFe_2O_4$ nanoparticles [1] actually produces cores that are mostly magnetite plus a non-stoichiometric Mn ferrite shell [2]. The core-shell particles showed strong spin canting, but the underlying mechanism could not be uniquely established [2]. There is a need for single phase manganese ferrite nanoparticles in order to determine whether the canting arises from the Dzyaloshinskii-Moriya interaction on the Mn^{2+} B sites. Here we describe how to make uniform $MnFe_2O_4$ particles and characterize their properties. The core-shell phenomenon we observed was caused by the 60°C difference between the decomposition temperatures of the two precursors. We addressed this issue by injecting a mixture of the precursors into the reaction at 300°C, well above both decomposition temperatures. In the original preparation, atomic absorption spectroscopy (AAS) results indicated an Fe:Mn molar ratio of 4.75:1 in 7.0±1.4 nm particles because the Mn precursor did not fully decompose. Here we find a 2.70:1 molar ratio, which is much closer to the desired 2:1 ratio than that observed in the core-shell particles. Figure 1 shows a transmission electron microscopy (TEM) image of the 7.22±0.98 nm particles. Figure 2 shows an alternating gradient force magnetometer (AGM) magnetization at room temperature. The specific saturation magnetization of 80.2 emu/g was calculated using the moment at 13 kOe and the particle concentration found in the AAS measurements. This measurement approaches the emu/g found in bulk $MnFe_2O_4$, indicating that the Mn could not be in a separate phase from the Fe, as was the case with the core-shell particles. EELS maps and SANS data for the new particles will be compared with those of the core-shell particles.

Ferromagnetic Ni_2MnGa-based magnetocaloric materials are subject of study due to their relevant properties for some technological fields such as magnetic refrigeration and energy harvesting. However, the search for materials with low cost and large magnetocaloric effect (MCE) under small magnetic fields remains necessary to develop the technology. Here, we present the magnetic and thermal properties of the polycrystalline $Ni_2Mn_{0.7}Cu_{0.3}Ga_{0.84}Al_{0.16}$ Heusler alloy. The alloy was fabricated using conventional arc melting and annealed for structure stabilization. Calorimetric measurements show a magneto-structural transition (MST) in two steps, in both, heating and cooling curves, as seen in Fig. 1. The energy associated to the transition on cooling is 6235 J kg^{-1} and the transformation temperature is around 297 K, resulting in a zero magnetic field entropy change (ΔS) of -21 J/K $g^{-1}K^{-1}$, induced by temperature. The MST was considered to be reproducible, within 0.17 K and for 60 cooling-heating cycles, the difference of energy released by the sample in the MST is always less than 1.4%. Isofield and isothermal magnetization measurements were performed. At 20 mT, a large magnetization change is observed at 295K on cooling, and 305K on warming, corresponding to martensite-ferromagnetic to austenite-paramagnetic phase. Isothermal magnetization measurements up to 9T allowed us to calculate the field dependence of transition temperature to be 1K/T. Results for the MCE were obtained from heat flow measurements. In a magnetic field change of 2T, the material presents a magnetic entropy change – 21 J Kg^{-1} K^{-1} with adiabatic temperature change of 1.3 K, resulting in a relative cooling power (RCP) of 27.3 J Kg^{-1}. The RCP is increased for the magnetic field change of 5T (ΔS = - 30 J Kg^{-1} K^{-1} and ΔT_{AD}= 4.3 K), which is 43% higher than the material without Al. The results show that Al based Heusler alloys can open a new path for research towards to produce cheaper materials with high magnetocaloric properties.

J5-02. Tuning of magnetic properties of Heusler-type glass-coated microwires. *A. Zhukov*[1,4], V. Zhukova[2], M. Ipatov[3] and J. del Val[2] *1. Phys. Mater., UPV/EHU, San Sebastián, Spain; 2. Dept. Phys. Mater., Univercity of Basque Country, UPV/EHU, San Sebastian, Spain; 3. Dept. Phys. Mater., University of Basque Country, UPV/EHU, San Sebastian, Spain; 4. Ikerbasque, Bilbao, Spain*

Studies of Heusler alloy have attracted considerable interest owing to a number of interesting features such as large magnetic field-induced strain, the ferromagnetic shape-memory effect, magnetic field induced martensitic transition, a substantial magnetocaloric effect (MCE) and the half-metallic behaviour [1]. The conventional method for preparation of Heusler alloys is arc-melting followed by long high temperature annealing [1,2]. High MCE observed in Heusler-type alloys is fairly attractive for magnetic refrigeration [1,2]. For increasing of the heat exchange rate the use of either thin wires or thin films is beneficial [1,2]. Hence, recently we performed few attempts to

prepare Heusler-type microwires using Taylor-Ulitovsky method [1]. The main peculiarity of the glass-coated microwires is the appearance of strong internal stresses (of the order of 100 - 1000 MPa) distributed in complex way within the microwires, i.e. much higher than the stress induced by the magnetic field in Ni-Mn-Ga bulk alloys (1- 7 MPa) [1]. Therefore proper stress relaxation is needed for observation of aforementioned versatile properties of Heusler alloys. In present paper we report on our last results on NiMnGa microwires. As-prepared Ni-Mn-Ga microwires at room temperature exhibit a very weak magnetization, M/M_{5K}. As-prepared samples additionally present magnetoresistance, MR, effect and considerable dependence of M/M_{5K}(H) dependences (particularly M/M_{5K}-values) on magnetic field values related to the magnetic and atomic disorder. We observed the hysteresis in M/M_{5K}(T) and temperature dependence of resisivity in as-prepared and annealed samples. Annealing of the samples resulted in a drastic change of magnetic properties: a ferromagnetic ordering with Curie temperature near room temperature. The most relevant feature of observed $M/M_{5K}(T)$ dependences for the NiMnGa microwire annealed at 923 and 973 K (for 2 h) is that they clearly show the hysteretic anomalies typical for the martensitic transformation. Moreover we observed change of hysteresis loops around 260 K. Consequently we report on first order phase transition in properly processed Heusler-type glass-coated Ni_2MnGa microwires.

J5-03. Entropy Changes and Caloric Effects in $YbInCu_4$. *N.A. De Oliveira*[1], P. von Ranke[1] and A. Troper[2] *1. Instituto de Física, Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brazil; 2. Centro Brasileiro de Pesquisas Físicas, Rio de Janeiro, Brazil*

The magnetocaloric effect (barocaloric effect) is the heating/cooling of magnetic materials upon magnetic field (pressure) variation. These caloric effects, which are the basis of magnetic refrigeration, are characterized by the entropy change in an isothermal process and by the temperature change in an adiabatic process upon the variation of the corresponding external agent [1]. Despite the efforts done and the achievements obtained so far, the search for new materials with large caloric effects is still a challenge for this area of research. Experimental data [2] of magnetic susceptibility show that the compound $YbInCu_4$ exhibits a valence transition around a temperature T_V. In fact, it has an itinerant behavior at low temperature and a local magnetic moment profile at temperatures larger than the valence temperature T_V. Moreover, experimental data also show that this critical temperature T_V can be controlled by magnetic field and pressure. Therefore, it is expected that this kind of transition from an ordered phase of local moments to a disordered phase of electron gas produce large entropy change. Based on these comments, in this work we theoretically discuss the entropy changes and the magnetocaloric and the barocaloric effect in $YbInCu_4$. In order to do this, we use a two subband model in which a strongly correlated narrow band is coupled with a wide conduction electrons band. In the model, the charge transfer is controlled by the energy bandwidth and the hybridization parameter. The entropy and the caloric functions are calculated using the standard relations [1]. Our theoretical results, show that the magnetocaloric effect occurs in a very small temperature interval while the barocaloric quantities exhibit sizeable values in a larger range of temperatures. This outstanding finding, which need experimental data to be confirmed, show that the change of valence induced by magnetic field and/or applied pressure gives rise to large entropy change and therefore is worth of further investigations.

J5-04. The partial phase diagram of $Mn_xFe_{2-x}P_{1-y}Si_y$. *X. You*[1], M. Maschek[1], N. van Djik[1] and E. Brück[1] *1. Delft University of Technology, Delft, Netherlands*

Magnetocaloric materials (MCMs) show great potential for utilization in magnetic refrigeration and energy conversion [1]. A thermomagnetic motor (TMM) prototype, built by Swiss Blue Energy, is able to convert low-temperature waste heat to mechanical energy, which may be utilized directly or converted into electricity [2]. In order to get high efficiency appropriate magnetocaloric materials should be used. These materials should exhibit strong magnetization changes with low hysteresis. In contrast to refrigeration applications, energy conversion with MCMs requires a low latent heat for high efficiencies. Materials with suitable Curie temperatures and small hysteresis can be found in the quaternary $(Mn,Fe)_2(P,Si)$ system. The phase diagram of $Mn_xFe_{2-x}P_{1-y}Si_y$[3] was investigated in a wide compositional range ($0 \le Mn \le 2$, $0.33 \le Si \le 0.6$), in order to find suitable compositions for magnetic energy conversion. Polycrystalline samples of $Mn_xFe_{2-x}P_{1-y}Si_y$ have been prepared by ball-milling. After ball-milling, the samples were sintered at 1373 K for 25 h then quenched into water. In general, the transition temperature increases with increasing Fe and increasing Si content. The experimental phase diagram allows us to identify proper candidates for magnetic energy conversion in the thermomagnetic motor. The current working temperature range of the thermomagnetic motor is between 20 °C (293 K) an 60 °C (333 K) with an optimal T_C of *40 °C* (313 K). Promising candidates for TMMs application with a low hysteresis can be found in Fe-rich P-rich part ($Mn<0.7$, $Si<0.4$) and Mn-rich Si-rich part ($Mn>1.1$, $Si>0.5$) of the phase diagram.

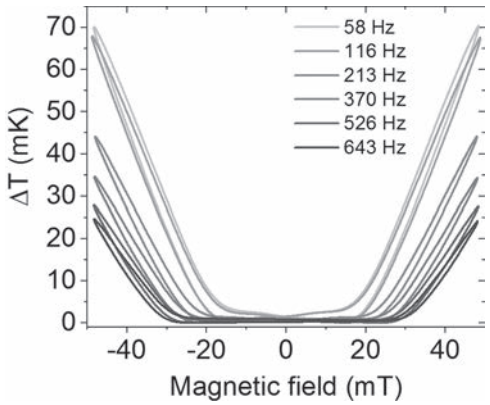
Lappeenranta University of Technology, Lappeenranta, Finland; 5. Louisiana State University, Baton Rouge, LA, United States*

The magnetic, and magnetocaloric properties of $Ni_{45}Mn_{43}CoSn_{11}$ was measured using a direct method for magnetic field changes up to 14 T, heat capacity measurements, and magnetization with hydrostatic pressure applications. A large reversible magnetocaloric effect resulted in a ΔT_{ad} of about =–11 K and 5 K for a magnetic field change of 14 T in the vicinity of magnetostructural (T_A~260 K) and magnetic (T_C~320K) transition, respec-



tively. The impact of thermomagnetic history on ΔT_{ad} at high magnetic fields has been revealed. Significant changes in the relaxation time of ΔT_{ad} depending on the type of phase transitions, magnetization, and demagnetization cycle are discussed. The mixed effects of pressure and magnetic field on the transition temperature is discussed. J5-06. Dynamics of the magnetocaloric effect in oscillating fields up to 1kHz. *J. Döntgen*[1], J. Rudolph[1] and D. Hägele[1] *1. Ruhr-Universität Bochum, Bochum, Germany*

One of the key challenges in the research of magnetocaloric materials is a reliable determination of the adiabatic temperature change ΔT. We have developed a novel method for direct measurements of ΔT that allows the investigation of the magnetocaloric effect on length- and time-scales inaccessible by traditional calorimetry [1]. Our technique is based on the application of temporally oscillating magnetic fields and detection of the resulting change of the thermal radiation emitted by the sample. We achieve a unique combination of a sensitivity of better than 1 mK, a time-resolution of 10 μs, and magnetic field modulation frequencies exceeding 1 kHz. The fast field modulation allows to study also thin films and small volume samples despite the fast heat diffusion in small structures. We show measurements on Gd films with thicknesses down to only 1.4 μm, which are the first systematic investigations of the magnetocaloric effect in such thin films [2]. Measurements at different field modulation frequencies give access to high-frequency dynamics of the magnetocaloric effect. Frequency dependent measurements in a 2 mm thick Gd sample show a remarkable decrease of the ΔT peak amplitude for increasing modulation frequency. We further present measurements on a single 60 μm thick melt-spun ribbon of amorphous $Fe_{80}B_{12}Nb_8$ and on a $La(Fe,Si)_{13}$-type compound as a first-order phase-transition material, where we find a peculiar magnetic-field dependence of ΔT (see Fig. 1) [3]. These observations suggest an interplay between magnetic and thermal sample properties that cause a complex frequency-behavior and cannot be explained by mere heat diffusion processes.

J6-01. The Bloch Point Pair-mediated Vortex Core Reversal. *H. Han*[1], S. Lee[1], D. Jung[1], N. Kim[1] and K. Lee[1] *1. School of Materials Science and Engineering, Ulsan National Institute of Science and Technology, Ulsan, The Republic of Korea*

A lot of attention has been focused on the magnetic vortex structure [1,2] owing to its unique topological characteristics including high thermal stabilities as well as various dynamic modes such as gyration of vortex core (VC), radial and azimuthal spin wave modes [2-4]. In particular, the reversal of VC orientation is very interesting topological behavior since it must be accompanied by changing of local topological number through the vortex-antivortex pair creation and annihilation process [1,2]. During the reversal process, it has been known that a single point singularity, a Bloch point (BP), should be injected from the surface and it moves to the opposite surface [5]. In this work, we report a novel vortex core reversal mechanism - a BP pair-mediated VC reversal by the resonant excitation of a three-dimensional spin-wave mode, an oscillation of the VC volume. Unlike the vortex-antivortex-pair-mediated mechanism [1,2], the BP pair is formed in the middle of single VC structure, not surface during the reversal process as seen in Fig.1. Our works provide a new method to realize ultrafast VC reversal, it helps to develop a spintronic device such as vortex-based memory devices.

Energy efficient control of magnetism is fundamental for the development of spintronic devices. This is enabled e.g. in multiferroic materials, exhibiting more than one ferroic order where one of these can be controlled by another [1]. As an example, this allows one to modify the magnetization with an electric field [1,2]. Large effect of electric field on magnetic properties have been realized via the so called magneto-elastic effect (ME) – i.e. the effect of lattice strain on magnetic anisotropy [3-6]. While the quasi-static behavior of the ME effect has been thoroughly analyzed and can be well described by a simple magneto-static model [4,7], there are only a few experimental studies of the effect of ME coupling on the dynamical behavior of the magnetization [5,6]. Here we report on the electric field control of magnetic vortex core gyration dynamics via a ME effect in magnetostrictive microstructures fabricated on top of a piezoelectric substrate. Modulated by piezoelectric strain, the ME anisotropy modifies the magnetic configuration of the microstructures (Fig. 1) and also influences the vortex core trajectory (Fig. 2), which we determine by time-resolved photoemission electron microscopy combined with x-ray magnetic circular dichroism (XMCD-PEEM). A comparison with micromagnetic simulations is presented, to quantitatively ascertain the dynamical effect of the ME coupling (Fig. 1).

Materials Science and Engineering, MIT - Massachusetts Institute of Technology, Cambridge, MA, United States; 4. Univ Gothenburg, Göteborg, Sweden*

Phase-locked spin torque vortex oscillators (STVOs), formed from multiple nano-contacts (NCs) on a spin-valve mesa, are anticipated to exhibit enhanced microwave power and phase stability compared to an individual STVO. The Oersted field produced by the DC current in each NC leads to the formation of a vortex, while the spin-torque sustains vortex gyration.[1,2] While the microwave emission due to the gyration can be characterized by electrical measurements, the magnetization dynamics beyond the perimeter of the NC cannot. In this work pairs of STVOs with NCs of 100 nm diameter and centre-to-centre separation ranging from 200 nm to 1100 nm have been studied, with a combination of electrical measurements and time-resolved scanning Kerr microscopy (TRSKM) being used to explore the microwave emission and associated magnetization dynamics as a function of NC separation. The character of the spectrum was found to change markedly as the NC separation was reduced. At the smallest separation of 200 nm, splitting of the STVO frequency was observed over a significant range of DC current. To explore the splitting further TRSKM was used to image the magnetization dynamics. The Kerr images acquired for the NC pair with 200 nm separation reveal significant differences in the spatial character of the magnetization dynamics when compared to those observed previously for a pair with 900 nm separation, for which the dynamic interaction is expected to be weaker. For a separation of 900 nm, localized regions of magnetization dynamics were observed close to each NC, each region having similar spatial character to that found within single NC devices, suggesting that a separate vortex had formed at each NC.[3] However for a pair of NCs with 200 nm separation, no evident change in contrast was observed to span the region occupied by the NCs, even though large amplitude dynamics were observed some microns from the NCs. We speculate that these dynamics are due to the oscillation of anti-vortices (AV) that were pushed away from the NCs, pinned by stray DC electromagnetic fields from the device contact pads, and then excited by the stray RF Oersted field.

J6-04. Control of the skyrmion Hall angle by combining spin-Hall effect, breathing mode and in-plane field. *R. Tomasello*[1], A. Giordano[1], V. Puliafito[2], S. Chiappini[3], M. Carpentieri[4] and G. Finocchio[1] *1. Department of Mathematical and Computer Sciences, Physical Sciences and Earth Sciences, University of Messina, Messina, Italy; 2. Department of Engineering, University of Messina, Messina, Italy; 3. Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy; 4. Department of Electrical and Information Engineering, Politecnico of Bari, Bari, Italy*

Magnetic skyrmions show promising features to be exploited for the design of computational paradigms, magnetic storage and programmable logic [1]. The first room-temperature evidences [2] have led to open questions on spin-Hall effect (SHE)-driven skyrmion dynamics that have to be understood. In particular, this motion is characterized by an in-plane angle with respect to the direction of the applied current, i.e. the skyrmion Hall angle (SHA) Φ_{SkH}, which has been found to be independent of the current in theoretical calculations [1]. By contrast, experiments [2] have shown a dependence on the current ascribed to pinning due to local defects or to the combination of SHE-field-like torque and internal deformations of the skyrmion, such as a breathing mode due to thermal fluctuations [4] and/or disordered physical parameters [5]. Here, we have performed full micromagnetic simulations of a ferromagnet coupled to a heavy metal, in order to achieve an appreciable interfacial Dzyaloshinskii-Moriya interaction [1]. We have conceived a numerical experiment where, at zero temperature, we can control the excitation of the breathing mode by applying an ac perpendicular-polarized current [6]. We also apply an in-plane current j_{HM} into the heavy metal, which gives rise to the SHE, and an in-plane external field H_y to control the SHA. An out-of-plane field H_z=25mT is also applied. Our results (see Fig. 1) show that the SHA depends on current only under the simultaneous presence of H_y and breathing mode. Our micromagnetic results are confirmed by analytical calculations based on the formulation of a time-dependent generalized Thiele's equation [3] where it is assumed that the magnetization texture depends on time to reproduce the dynamics of the breathing mode. Our theoretical achievements can be very important for the fundamental understanding of origin of the current dependence of the skyrmion Hall angle.

J6-05. The skyrmion-bubble transition in a ferromagnetic thin film. A. Bernand-Mantel[1], *L. Camosi*[1], A. Wartelle[1], N. Rougemaille[1], M. Darques[1] and L. Ranno[1] *1. Institut Neel-CNRS, Grenoble, France*

Magnetic skyrmions and bubbles, observed in ferromagnetic thin films with perpendicular magnetic anisotropy, are topological solitons which differ by their characteristic size and the balance in the energies at the origin of their stabilisation. However, these two spin textures have the same topology and a continuous transformation between them is allowed. In the present work, we derive an analytical model to explore the skyrmion-bubble transition. We evidence a region in the parameter space where both topological soliton solutions coexist and close to which transformations between skyrmion and bubbles are observed as a function of the magnetic field. The nanoscale size and non-trivial topology of skyrmions make them particularly attractive for information technologies. The recent observations of skyrmions at room temperature and their fast displacement with low electrical currents [1], has triggered a revival of the quest for a memory based on topological solitons, taking the form of a skyrmion racetrack memory [2]. Magnetic bubbles and skyrmions are close relatives as they can share the same topology. However, their characteristic size differs and while classical bubbles present a long lifetime at RT, much shorter lifetimes were found for skyrmions of a few nanometers in recent experimental and theoretical. The case of intermediate-size solitons is more favorable, as stable room-temperature topological solitons with sizes of a few hundred to a few tens of nanometers have been reported in multilayers and even in a single ferromagnetic layer. These topological solitons are sometimes called skyrmion bubbles when the demagnetising energy plays a role in their stabilization. In this context, the necessity to clarify whether a fundamental difference exist between skyrmions and bubbles appears. In previous works, the difference between magnetic bubbles with a large number of collinear spins in their center and skyrmions with a compact core has been described [3]. In the present work [4], we have developed an analytical topological soliton model containing expressions of the long range demagnetising and exchange curvature energies, two key ingredients to stabilize bubbles and skyrmions in ferromagnetic thin films. This allowed us to construct a skyrmion and bubbles phase diagram (see figure) and explore quantitatively the possible transitions between them. The observed skyrmion-bubble transition present similarities with the liquid-gaz transition, in particular a critical point is present above which the transformation between both spin textures becomes continuous. While distinct characteristics of skyrmions and bubbles remain, their common nature as topological solitons is emphasised.

J7-01. Noncentrosymmetric 2D Superconductors with Spin-Valley Locking. *Y. Iwasa[1,2] 1. Department of Applied Physics, The University of Tokyo, Tokyo, Japan; 2. CEMS, RIKEN, Wako, Japan*

Noncentrosymmetric superconductors have attracted much attention due to their unique properties, as exemplified by the single-triplet parity mixing, when there are sizable spin-orbit interactions. Here we discuss on a new class of noncentrosymmetric superconductor, which has an ultrathin two-dimensional (2D) structure. In the past decade, technological advances of materials fabrication have led to discoveries of a variety of highly crystalline 2D superconductors at heterogeneous interfaces, field effect devices and in ultrathin films [1]. These systems are offering opportunities of searching for superconductivity at higher temperatures as well as investigating the intrinsic nature of 2D superconductors, which are distinct from the conventional 2D superconductors with the amorphous or granular structures, which were extensively investigated in the last century. Thus the new 2D superconductors could be a new plat form of physics of 2D superconductivity, which allows us to investigate the impact of the broken inversion symmetry on superconductivity. There are two possibility of broken inversion symmetry in 2D superconductors. First, inversion symmetry in the out-of-plane direction is inherently broken, if ultrathin superconductors are fabricated at the interface and/or induced by the field effect. Another possibility is the case where the in-plane inversion symmetry is broken. In this talk, we focus mainly on the latter, specifically monolayer or quasi-monolayer transition metal dichalcogenide (TMD), the structure of which is trigonal. Importantly, owing to the spin-orbit interaction, the conduction band spins undergo so-called a spin-valley locking, where spins are out-of-plane polarized and the polarization direction is dependent on the conduction band valleys. Discussion will given on the enhanced in-plain upper critical field (Pauli paramagnetic limit) [2] and the nonreciprocal transport [3]. The latter is the diode like transport where the electrical resistance of matters differs dependent on the direction of current.

Thales Research and Technology, Palaiseau, France*

The recent discovery of graphene, and other 2D materials, has opened novel exciting opportunities in terms of functionalities and performances for spintronics devices. While to date, it is mainly graphene properties for efficient spin transport which have been put forward, we will present here experimental results on another avenue for 2D materials in spintronics. We will show that a thin graphene passivation layer, directly integrated by low temperature catalyzed chemical vapor deposition (CVD), can prevent the oxidation of a ferromagnet [1]. This in turn enables the use of novel humide/ambient low-cost processes for spintronics devices, which would usually lead to oxidation during the fabrication and thus a quenching of the spintronic performances. We will illustrate this property by demonstrating the use of ozone based ALD processes to fabricate efficient spin valves protected with graphene [2]. Importantly, the use of graphene on ferromagnets allows to preserve a highly surface sensitive spin current polarizer/analyzer behavior and adds new enhanced spin filtering property [1][2]. Finally, we will present results concerning another 2D material isomorph to graphene: the atomically thin insulator hexagonal boron nitride (h-BN). Characterizations of complete spin valves making use of monolayer h-BN tunnel barriers grown by CVD will be presented [3]. These different experiments unveil promising uses of 2D materials for spintronics [4].

J7-03. Induced spin-orbit coupling in silicon thin films by bismuth doping. *F. Rortais[1], S. Lee[3], R. Ohshima[2], S. Dushenko[1], Y. Ando[4] and M. Shiraishi[5] 1. Department of Electronic Science and Engineering, Kyoto University, Kyoto, Japan; 2. Department of Electronic Science and Engineering, Kyoto University, Kyoto, Japan; 3. Department of Electronic Science and Engineering, Kyoto University, Kyoto, Japan; 4. Department of Electronic Science and Engineering, Kyoto University, Kyoto, Japan; 5. Department of Electronic Science and Engineering, Kyoto University, Kyoto, Japan*

Spin injection in silicon has already been demonstrated in degenerate and non-degenerate doping concentrations, reaching long spin lifetime of nanoseconds [1]. To achieve a silicon spintronics device, the manipulation of

spins is required but the intrinsic spin-orbit coupling of silicon is too small to manipulate spins by using a gate voltage. In this study, we used bismuth atoms to increase the spin-orbit coupling in the silicon thin films. Silicon-on-insulator substrate (SiOI) highly phosphorus-doped ($1.0x10^{20}$ cm-3) was implanted with bismuth ions. To achieve a homogeneous doping profile of $5.0x10^{19}$ cm-3 as in figure 1, we used 4 steps of bismuth ions implantation at different energies and doses summarize in inset of figure 1. An annealing of 600°C during 30 minutes under neutral atmosphere was done to electrically activate the bismuth dopants. This thin film but also a reference substrate (only phosphorus doped) were patterned in Hall bar devices to evaluate the impact of bismuth doping on electrical and spintronics proprieties. At low temperature on the substrate only phosphorus doped, we observed weak localization effect with a strong decrease of conductance close to zero magnetic field (Figure 2.a). But after bismuth implantation, at low temperature we observed positive magnetoconductance correction, characteristic of weak antilocalization effect (Figure 2.b). We use Hikami-Larkin-Nagaoka (HLN) model to fit the magnetoconductance signal [2]. We deduced a spin orbit coupling length of 50 nm at 2 K and 10 μA. We determined the dependence of spin orbit coupling length in function of temperature and gate voltage. The observation of weak antilocalization after bismuth implantation implies the presence of significant spin orbit coupling in this silicon thin films. This result paves the way toward an efficient electrical spins manipulation and a silicon spintronics device.

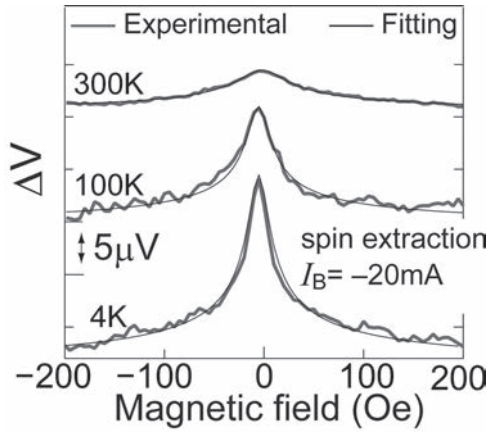
J7-04. Efficient spin transport through a SiO_xN_y tunnel barrier in ferromagnet/ SiO_xN_y / n^+-Si junctions compatible with the Si-CMOS technology. *R. Nakane*[1], S. Sato[1], T. Hada[1] and M. Tanaka[2] *1. EEIS, The University of Tokyo, Tokyo, Japan; 2. EEIS, The University of Tokyo, Tokyo, Japan*



Recent progress in spin injection/extraction into/from Si has been made by using ferromagnet/MgO/Si junctions as spin injectors/detectors [1-3]. However, growing high-quality MgO on Si is very difficult, prohibiting efficient spin injection/extraction. For device applications, SiO_xN_y is much more favorable as a tunnel barrier, because it can be formed by direct oxi-nitridation of Si, it is compatible with the Si-CMOS technology, and a low interface state density at SiO_xN_y/Si may allow us to achieve high spin injection/extraction efficiency. In this study, we demonstrate that a Fe/Mg/SiO_xN_y/Si junction works well as a spin injector/extractor, although SiO_xN_y is amorphous and the spin-filter effect of MgO is absent. Using a n^+-Si(001) substrate (8×10^{19} cm^{-3}), we prepared three-terminal devices having a tunnel junction Al/Mg(1nm)/Fe(3nm)/Mg(1nm)/SiO_xN_y(1nm)/Si with 17.8μm in diameter, where SiO_xN_y was formed by oxi-nitridation of the Si surface with RF plasma and the metallic multilayer was deposited using molecular beam epitaxy. Fig. 1 shows the device structure and setup for three-terminal Hanle measurements with a perpendicular magnetic field. Unlike the widely-used device structure formed on a silicon-on-insulator substrate, our device structure is free from the channel confinement effect [3], thus we can accurately estimate the spin polarization P_S and spin lifetime t_S of electrons in Si. In this study, we estimate P_S and t_S by experimental Hanle signals with the fitting function we derived [3]. Clear spin-extraction Hanle signals were obtained in the temperature range of 4 - 300 K, as shown in Fig. 2. The temperature dependence of t_S was consistent with the theory of impurity-dominated spin scattering [4], and relatively high P_S and t_S were obtained: P_S = 16% and t_S = 5.6 ns at 4 K, and P_S = 7.5% and t_S = 2.7 ns at 300 K. Since these are comparable to the best values obtained in ferromagnet/MgO/Si junctions, it was found that the spin filtering MgO is unnecessary and a low interface state density at the SiO_xN_y/Si may be important. Therefore, the Fe/Mg/SiO_xN_y/Si junction is highly promising for Si-based spin transport devices.

RIKEN CEMS, Wako, Japan*

We investigate Aharonov-Casher (AC) spin interference [1], [2] in an array structure of InGaAs-based mesoscopic rings under different orientations of the in-plane magnetic field. Anisotropic Al'tshuler-Aronov-Spivak (AAS) oscillations (Fig. 1) and AC spin interference amplitude (Fig. 2) depending on the in-plane field direction are observed, manifesting the coexistence of Rashba and Dresselhaus spin-orbit interactions (SOIs). The anisotropy shows either maximum or minimum under the in-plane field angle at $\phi = \pi/4$ or $\phi = 3\pi/4$ with respect to [100] direction. The anisotropy is reversed by varying the Rashba SOI α while the sign of the Rashba SOI is unchanged (Fig. 2). According to a perturbation theory developed here, the Rashba SOI can change AC resistance anisotropy via spin dynamic and geometric phases while the direction of in-plane Zeeman field modifies spin dynamic phase. Therefore, anisotropy measurements in an AC spin interferometer can be used to reveal signatures of spin dynamic and geometric phases. By comparing the experimental results with 2D numerical simulations [3], an additional anisotropy reversal is observed. This additional anisotropy reversal is attributed to sign reversal of renormalized Dresselhaus SOI.

J8-01. High-field and high-pressure phase diagram of $CeRhIn_5$ probed by dilatometry. *P. Rosa[1] 1. Condensed Matter and Magnet Science, Los Alamos National Laboratory, Los Alamos, NM, United States*

The heavy-fermion antiferromagnet $CeRhIn_5$ exhibits remarkable behavior when subjected to either high magnetic fields or high applied pressures. From the superconducting dome around a putative unconventional quantum critical point at 2.3 GPa to the recently discovered XY nematic phase at H ~ 30T, this material hosts important open questions. In this talk, I will address these questions via high-resolution thermal expansion and magnetostriction measurements at extremes. Optical fibers containing fiber Bragg grating (FBG) sensors are used to measure the length change in millimiter-sized single crystals subjected to DC fields to 45 T. An FBG optical apparatus for measuring thermal expansion under applied hydrostatic pressures to 2.5 GPa will also be presented. Our results support a scenario in which anisotropic hybridization sets the stage for electronic nematicity and quantum criticality in $CeRhIn_5$.

J8-02. Squeezing out hidden-order in URu_2Si_2 under combined pressure and magnetic field. *W. Knafo[1], S. Araki[2], D. Braithwaite[3], D. Aoki[4], G. Knebel[3], G. Lapertot[3] and J. Flouquet[3] 1. LNCMI Toulouse / CNRS, Toulouse, France; 2. Department of Physics, Okayama University, Okayama, Japan; 3. INAC, Université Grenoble Alpes and CEA, Grenoble, France; 4. IMR, Tohoku University, Oarai, Japan*

A long-standing mystery is that of the hidden order phase which develops below T_0 = 17.5 K in URu_2Si_2 [1] . This metal is subject to competing magnetic interactions, as illustrated by the presence of gapped magnetic fluctuations, i.e., signatures of magnetic exchange, with the wavevectors k_0 = (0 0 1) and k_1 = (0.6 0 0) [2]. These fluctuations are precursors of long-range order, which can be stabilized either under pressure p (antiferromagnetism with wavevector k_0) [3] or under a magnetic field H ∥ c (spin density wave with wavevector k_1) [4,5]. An itinerant origin of magnetism is suggested by Fermi surface nestings with the same wavevectors k_0 and k_1 [6]. In this work, we present a systematic (p, H,T) investigation of the three-dimensional electronic and magnetic phase diagram of URu_2Si_2, using novel instrumentation allowing the combination of pressures up to 4 GPa and magnetic fields up to 60 T [7]. At the highest pressure, our transport data support that the field-induced hidden order (see [8]) is squeezed out, and the system undergoes a direct antiferromagnetism to polarized-paramagnetism transition. The extracted phase diagram results from the competition between hidden order, spin-density wave, antiferromagnetism, and polarized paramagnetism, and reveals a subtle competition between the magnetic interactions. It constitutes a new constraint for models aiming to describe the hidden-order in URu_2Si_2.

INAC/PHELIQS, CEA-Grenoble, Grenoble, France*

The elastic properties of URu_2Si_2 in the high-magnetic field region above 40 T, over a wide temperature range from 1.5 to 120 K, were systematically investigated by means of high-frequency ultrasonic measurements under the pulsed magnetic fields up to 68 T with pulse duration of about 150 ms at the Dresden High Magnetic Field Laboratory (HLD). The present study is motivated by a expectation that temperature dependence of the symmetry-breaking ultrasonic modes provides information on the bare 5*f*-electrons character with a broken of the unidentified electronic phase transition, so called 'hidden order', and weakened hybridization [1, 2]. We found contrast behaviors that appeared in three different transverse modes (as shown in Figs. 1); both Γ_4 (B_{2g}) and Γ_5 (E_g) symmetry modes of C_{66} and C_{44} show elastic softening which is enhanced above 30 T, respectively, while the characteristic softening of the Γ_3 (B_{1g}) symmetry mode (C_{11}–C_{12})/2 is suppressed in high magnetic fields. These results underscore the presence of a hybridization-driven Γ_3 (B_{1g}) lattice instability [3] in the HO phase, and in the strong *c-f* hybridization region at low-magnetic fields in URu_2Si_2. However, the enhanced softening of C_{44} and C_{66} for H ∥ [001] at high magnetic fields cannot be fully explained by using existing crystalline-electric field (CEF) schemes applied to the quadrupolar susceptibility in a local $5f^2$ (J = 4) configuration, for example; ($\Gamma_1^{(1)}$ - Γ_2 - Γ_3), or ($\Gamma_5^{(1)}$ - $\Gamma_1^{(1)}$ - Γ_2), or ($\Gamma_1^{(5)}$ - $\Gamma_5^{(2)}$ - Γ_2), or (Γ_3 - $\Gamma_1^{(1)}$ - Γ_2), and so on. Thus, the origin of the softening in these transverse modes still remains an open question. Instead, we analyzed the softening of (C_{11}–C_{12})/2 in low-magnetic field region by using the phenomenological theory for the band-Jahn-Teller effect.

J8-04. Heisenberg Ising-Kondo Necklace model with transverse field for heavy-fermion compound URu_2Si_2. S. Rufo[1] and *M. Continentino*[1]
1. Theoretical Physics, Brazilian Center for Research in Physics, Rio de Janeiro, Brazil

In this work, we introduce the Heisenberg Ising-Kondo Necklace with transverse field as a possible model to describe the heavy-fermion compound URu_2Si_2. This compound presents many open questions, like the transition to the hidden order phase(HO) at T_o=17.5K and discussions about the localization degree of the Uranium ions. Thus, studies about these questions remain a very attractive research issue nowadays. Our Hamiltonian proposal includes elements that comes from crystal field process and Ruderman-Kittel-Kasuya-Yosida(RKKY) interaction arguments for URu_2Si_2, beside a spin-spin approach. The main idea behind this treatment is allow the transverse field, that *a priori* acts only in the localized moments, to influence the conduction-electrons via the RKKY interaction. For this, one additional transverse field is considered for the conduction-electrons. The spin wave theory was applied starting from a canted antiferromagnetic(AF), as a classical reference state due the transverse field, and from magnetization analysis we build the quantum phase diagram. In reason these considerations, we was able to establish that the phase diagram must have two regimes: the strong and weak J_K, where the quantum fluctuations are only derived by the Kondo interaction(J_K) and transverse field(Γ), respectively. Our results reveal a quantum second order phase transition from an canted AF to Kondo-singlet(KS) in a strong J_K, and a transition from canted AF to a paramagnetic phase(P) in a weak J_K. Furthermore, a reentrance effect was also observed and attributed to the presence of a first-order phase transition point, which connects the two the J_K regimes. This is a very important result and allow us to link the ordered canted AF phase with the mixture Hidden Order/Large Moment Antiferromagntic(HO/LMAF) phase proposed by experimental studies for compound URu_2Si_2, once a fist-order phase transition is expected between HO and LMAF.

J9-01. Interplay of heavy-fermion quantum criticality and unconventional superconductivity. *F. Steglich*[1] *1. MPI Chemical Physics of Solids, Dresden, Germany*

Unconventional superconductivity often occurs near quantum critical points (QCPs) in antiferromagnetic (AF) heavy-fermion metals, such as the exemplary materials $CeCu_2Si_2$ and $YbRh_2Si_2$. The nature of the pairing symmetry of $CeCu_2Si_2$ which is a prototype for heavy-fermion superconductivity near a *conventional*, three-dimensional spin-density-wave, QCP has been the subject of recent controversy. To resolve this issue, a fully gapped $d + d$ band-mixing pairing state was proposed for $CeCu_2Si_2$ [1], which yields excellent fits to both superfluid-density [1] and specific-heat [2] results, as well as accounting for the sign change of the superconducting order parameter along the incommensurate nesting wave vector inside the dominating heavy-fermion band [3,4]. No superconductivity had been detected down to 10 mK near the field-induced *unconventional,* Kondo-destroying, QCP in $YbRh_2Si_2$ [5-7], which raised the question about the generality of the *quantum critical paradigm ("AF QCPs in clean, stoichiometric heavy-fermion metals give rise to unconventional superconductivity")*. However, recent results of magnetic and calorimetric measurements on $YbRh_2Si_2$ at ultra-low temperatures and low magnetic fields reveal the onset of hybrid AF order dominated by the Yb-derived nuclear spins slightly above 2 mK as well as heavy-fermion superconductivity at $T_c = 2$ mK [8]. This nuclear order was concluded to suppress the primary electronic AF order, which forms at $T_N = 70$ mK, and to allow heavy-fermion superconductivity to develop, most likely, with the aid of critical fluctuations associated with the QCP [8]. These results demonstrate a new way to approach the QCP in $YbRh_2Si_2$ and provide further support for the *quantum critical paradigm* to hold. Work done in collaboration with G.M. Pang, M. J9-02. Phonon Thermal Transport Near the Structural Quantum Critical Point in $(Ca_xSr_{1-x})_3Rh_4Sn_{13}$. *M. Sutherland*[1], X. Chen[1], K. Yoshimura[2], M. Imai[2], B. Chen[2], J. Yang[2], D. Tompsett[3] and S.K. Goh[4] *1. Physics, Cambridge University, Cambridge, United Kingdom; 2. Kyoto University, Kyoto, Japan; 3. University of Bath, Bath, United Kingdom; 4. Chinese University of Hong Kong, Hong Kong, Hong Kong*

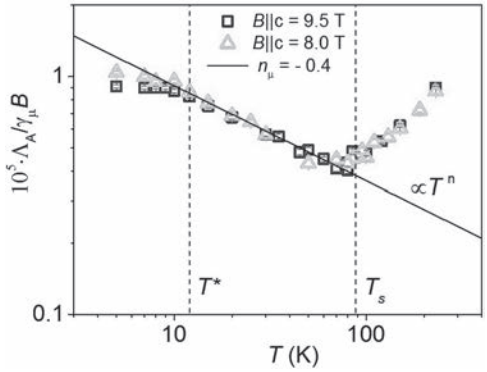
The quasi-skutterudite family $(Ca_xSr_{1-x})_3Rh_4Sn_{13}$ has a structural phase transition that can be tuned towards zero temperature by chemical substitution. The resulting soft phonon mode gives rise to an enhanced superconducting transition temperature. By studying the transport of heat in these materials at temperatures T<1K, we reveal an anomalous temperature dependence of the phonon contribution to thermal conductivity, with $\kappa \propto T^{1.6}$ near the critical concentration rather than the T^3 expected in the boundary scattering regime. We investigate models that might account for this, including boundary effects, phonon-phonon scattering and scattering by intrinsic quasi-static spatial disorder. By comparing heat capacity and transport date with DFT calculations of the phonon spectrum, we conclude that the anomalous temperature dependence of the phonon thermal conductivity is best described by scattering from an intrinsic spatial disorder that sets in near the critical concentration, and comment on the significance for superconductivity in this system.



a) The exponents from power law fits to the phonon thermal conductivity of $(Ca_xSr_{1-x})_3Rh_4Sn_{13}$ below T~1 K, plotted against the substitution fraction *x*. The power law reaches a minimum close to where the structural phase transition is suppressed to zero, with a value that is well below the expected T^3 boundary scattering behaviour. Different surface treatments do not affect the result. (b) The variation in the structural transition temperature T^* and the superconducting transition temperature T_c across the same substitution regime.

A nematic transition preceding a long-range spin density wave antiferromagnetic phase is a common feature of many parent compounds of Fe based superconductors. However, in the FeSe system with a nematic transition at $T_s \approx 90$ K no evidence for long-range static magnetism is found down to very low temperatures. The lack of magnetism is a challenge for the theoretical description of FeSe. We investigated high-quality single crystals of FeSe using high-field (up to 9.5 Tesla) muon spin rotation (μSR) measurements [1]. The μSR Knight shift and the bulk susceptibility linearly scale at high temperatures but deviate from this behavior around $T^* \sim 10 - 20$ K, where the Knight shift exhibits a kink. In the temperature range $T_s < T < T^*$ the muon spin depolarization rate shows a quantum critical behavior $\Lambda \propto T^{-0.4}$ (Fig.1). The observed critical scaling indicates that FeSe is in vicinity to an itinerant antiferromagnetic quantum critical point. Below T^* the quantum critical behavior breaks down. We argue that this breakdown is caused by a temperature induced Lifschitz transition.

J9-04. Vestiges of Superconducting Vortices in the Insulating State of an Oxide Interface. *E. Maniv*[3], M. Mograbi[1], P.K. Rout[1], D. Graf[2], J.H. Park[2] and Y. Dagan[1] *1. Physics, Tel Aviv University, Tel Aviv, Israel; 2. National High Magnetic Field Laboratory, Tallahassee, FL, United States; 3. Physics, University of California, Berkeley, Berkeley, CA, United States*

In disordered two-dimensional (2D) superconductors an insulating state can be induced either by applying a magnetic field, H, or by increasing disorder. The difficulty in characterizing the insulating state and its origin stems from the lack of a continuous mapping of the superconducting to insulating phase diagram in a single sample. Here we use the two-dimensional (2D) electron liquid formed at the interface between the two insulators (111) $SrTiO_3$ and $LaAlO_3$ to study the superconductor to insulator transition. By use of electrostatic gating and magnetic fields, the sample is tuned from the metallic region, where supeconductivity is fully manifested, deep into the insulating state. Through examination of the field dependence of the sheet resistance and comparison of the response to fields in different orientations we show that vortex-like fluctuations are responsible for the transition in this material and that these fluctuations persist deep into the insulating state.

J10-01. Majorana quantization and half-integer thermal quantum Hall effect in a Kitaev spin liquid. *Y. Kasahara*[1] *1. Kyoto University, Kyoto, Japan*

Kitaev quantum spin liquid (QSL) displays the fractionalization of quantum spins into Majorana fermions [1]. In magnetic fields, the emergence of Majorana edge current is predicted to manifest itself in the form of a finite thermal Hall effect [1,2], a feature commonly discussed in topological superconductors. Here we report on thermal Hall conductivity κ_{xy} measurements in α-$RuCl_3$, a prime candidate for realizing Kitaev spin model on two-dimensional (2D) honeycomb lattice. In zero field, α-$RuCl_3$ is in a spin-liquid state below $J_K/k_B \sim 80$ K and exhibits antiferromagnetic order at $T_N \sim 7$ K. In magnetic field perpendicular to the 2D honeycomb planes, positive κ_{xy} develops gradually upon cooling below $\sim J_K/k_B$. We find the thermal Hall responce in the spin-liquid state of α-$RuCl_3$ at $T_N < T < J_K/k_B$ is essentially different form other insulating magnets. Meanwhile, the magnitude of thermal Hall signal as well as its sign and its T-dependence above T_N are well reproduced by the Monte Carlo calculation for 2D pure Kitaev model with a weak magnetic field [2]. These results suggest the presence of quasiparticle excitations inherent to the Kitaev spin liquid in α-$RuCl_3$ [3]. The application of a parallel magnetic field melts the AFM order, leading to a field-induced spin-liquid state at lower temperatures. To study the thermal Hall effect in this field-induced spin liquid state, we measured κ_{xy} in magnetic fields tilted away from the *c* axis within the *ac*-plane. In this configuratin, the Hall response is determined by magnetic field perpendicular to the 2D planes and T_N is suppressed by the parallel fields. We find that, in the field-induced spin-liquid state at low temepratures, κ_{xy}/T shows a plateau behavior as a function of applied magnetic field. The 2D thermal Hall conductance κ_{xy}^{2D}/T per honeycomb plane attains a quantization value of $(\pi/12)(2\pi k_B^2/h)$, which is exactly half of κ_{xy}^{2D}/T in the integer quantum Hall effect. This half-integer thermal Hall conductance provides direct evidence of topologically protected chiral edge currents of charge neutral Majorana fermions, particles that are their own antiparticles, which possess half degrees of freedom of conventional fermions. At high field, the quantization disappears and κ_{xy}^{2D}/T goes to zero rapidly, indicating a crossover from topologically non-trivial QSL to trivial high-field state [4].

J10-02. Probing spinon nodal structures in Kitaev spin liquids. *N. Perkins*[1], G. Halasz[2], J. van den Brink[3] and B. Perreault[4] *1. Physics, University of Minnesota, Minneapolis, MN, United States; 2. KITP, Santa Barbara, CA, United States; 3. IFW Dresden, Dresden, Germany; 4. Univeristy of Minnesota, Minneapolis, MN, United States*

The quantum spin liquid (QSL) state of matter is very difficult to detect experimentally because it lacks a local order parameter to which common probes couple directly. The three defining characteristics of a QSL are a topological ground-state degeneracy, long-range entanglement, and a fractionalization of the fundamental spin degrees of freedom. While the first two are not easily accessible by experiment, fractionalized excitations can be detected by means of thermodynamic and dynamical scattering measurements. Here we propose that resonant inelastic X-ray scattering (RIXS) is an effective probe of the fractionalized excitations in 2D and 3D Kitaev spin liquids, which are quintessential examples of the QSL state [1,2]. We find that RIXS channels, the spin-conserving and the non-spin-conserving RIXS channels do not interfere and give completely different responses. The spin-conserving channel picks up exclusively the Majorana sector with a pronounced momentum dispersion. In all Kitaev spin liquids, as a signature of symmetry fractionalization, the spin-conserving response is strongly suppressed around the center of the Brillouin zone. The non-spin-conserving RIXS channels additionally create immobile fluxes, and the response becomes only weakly momentum dependent.

J10-03. New physics in the field-induced ground state in Kitaev candidate alpha-$RuCl_3$. *A. Banerjee*[1], P. Lampen-Kelley[2], C. Balz[1], M. Lumsden[3] and S.E. Nagler[1] *1. Neutron Sciences Directorate, Oak Ridge National Laboratory, Knoxville, TN, United States; 2. Material Science and Engg, University of Tennessee, Knoxville, TN, United States; 3. Oak Ridge National Laboratory, Oak Ridge, TN, United States*

The Kitaev model on a honeycomb lattice predicts a special quantum spin liquid (QSL) ground state with excitations resembling Majorana Fermions and gauge flux excitations [1]. These emergent features are exciting prospects to both basic physics and applications towards a lossless technology for quantum qubits [2]. In the magnetic Mott insulator alpha-RuCl3 despite a long-range ordered ground state, our inelastic neutron scattering measurements revealed a continuum of fractionalized excitations [3] resembling predictions from Majorana Fermions [4, 5], confirming that the material is proximate to a QSL. In a 8T magnetic field the long-range order vanishes revealing a true QSL with gapped excitations [6, 7] raising hopes of a state where non-Abelian excitations can reside. This opens prospects for future experiments which can directly probe the signatures of quantum coherence in this material. I will describe the ongoing neutron scattering, THz, susceptibility [8] and transport measurements ongoing to understand these phenomena.

K1-01. Evidence for Spin-Transfer Torque Induced by Spin-Triplet Supercurrents. *Y. Sun*[1], L. Li[1], Y. Zhao[2] and X. Zhang[2] *1. Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2. King Abdullah University of Science and Technology, Thuwal, Saudi Arabia*

Cooper pairs in superconductors are normally spin singlet (spin antiparallel). Nevertheless, recent studies suggest that spin-triplet Cooper pairs (spin parallel) can be created at carefully engineered superconductor/ferromagnet interfaces. If Cooper pairs are spin-polarized they would transport not only charge but also a net spin component, but without dissipation, and therefore minimize the heating effects associated with spintronic devices. Although it is now established that triplet supercurrents exist, their most interesting property – spin – is only inferred indirectly from transport measurements. In conventional spintronics, it is well known that spin currents generate spin-transfer torques that alter magnetization dynamics and switch magnetic moments. The observation of similar effects due to spin-triplet supercurrents would not only confirm the net spin of triplet pairs but also pave the way for applications of superconducting spintronics. In this talk, we present strong evidences for spin-transfer torque induced by triplet supercurrents in superconductor/ferromagnet/superconductor Josephson junctions. Below the superconducting transition temperature T_C, the ferromagnetic resonance field at X-band (~ 9.0 GHz) shifts rapidly to a lower field with decreasing temperature due to the spin-transfer torque produced by AC triplet supercurrents. In contrast, this phenomenon is absent in ferromagnet/superconductor bilayers and superconductor/insulator/ferromagnet/superconductor multilayers. These results are consistent with theoretical predictions for ferromagnetic Josephson junctions with precessing magnetization where a high frequency AC triplet supercurrent is induced between two superconductor/ferromagnet interfaces. The observation of spin-transfer torque associated with triplet supercurrents opens a door toward the potential applications of superconducting spintronics.

K1-02. Probe of Spin Dynamics in Superconducting NbN Thin Films via Spin Pumping. *Y. Yao*[1] *1. School of Physics, International Center for Quantum Materials, Beijing, China*

The emerging field of superconductor (SC) spintronics has attracted intensive attentions recently. Many fantastic spin dependent properties in SCs have been discovered, including large magnetoresistance, long spin lifetimes and the giant spin Hall effect, etc. Regarding the spin dynamics in superconducting thin films, few studies has been reported yet. Here, we report the investigation of the spin dynamics in a *s*-wave superconducting NbN film via spin pumping from an adjacent insulating ferromagnet GdN film. A profound coherence peak of the Gilbert damping of GdN is observed slightly below the superconducting critical temperature of the NbN, which agrees well with recent theoretical prediction for *s*-wave SCs in the presence of impurity spin-orbit scattering[1]. This observation is also a manifestation of the dynamic spin injection into superconducting NbN thin film. Our results demonstrate that spin pumping could be used to probe the dynamic spin susceptibility of superconducting thin films, thus pave the way for future investigation of spin dynamics of interfacial and two dimensional crystalline SCs.

K1-03. Superconducting spin transport via induced triplet states by spin-orbit coupling. *K. Jeon*[1,2], C. Ciccarelli[2], A. Ferguson[2], H. Kurebayashi[3], L.F. Cohen[4], X. Montiel[5], M. Eschrig[5], J. Robinson[1] and M. Blamire[1] *1. Materials Science and Metallurgy, University of Cambridge, Cambridge, United Kingdom; 2. Physics, University of Cambridge, Cambridge, United Kingdom; 3. London Centre for Nanotechnology and Department of Electronic and Electrical Engineering, University of College London, London, United Kingdom; 4. The Blackett Laboratory, Imperial College London, London, United Kingdom; 5. Physics, Royal Holloway, University of London, London, United Kingdom*

Direct spin transport studies in superconductors (SCs) have traditionally involved quasiparticle (QP) injection at bias voltages around the superconducting gap energy [1]. A number of exotic properties have been observed: enhanced spin relaxation time, spin and charge decoupling, and a giant spin-orbit interaction [1,2]. Equilibrium (zero-bias) studies of the Josephson effect in SC/FM/SC (FM: ferromagnet) junctions and the critical temperature T_c modulation in FM/SC/FM and SC/FM/FM' superconducting spin valves have demonstrated that engineered magnetically-inhomogeneous (spin-mixing) SC/FM interfaces can generate long-range triplet pairing states which explicitly carry spin [2,3]. However, direct measurement of triplet spin transport through singlet SCs has not so far been achieved. A time-dependent ferromagnetic magnetization (or FMR: ferromagnetic resonance) generates a spin angular momentum flow into adjacent materials, so-called spin pumping, and the transport and relaxation of spin currents from the FM in turn affect its magnetization dynamics via an enhancement in the effective Gilbert damping [4,5]. Because conventional (spin-zero) singlet pairing blocks spin transport, spin pumping efficiency is expected to decrease below T_c of a coupled (singlet) SC [6]. Here we present the results of a systematic set of temperature-dependent FMR measurements on Nb/$Ni_{80}Fe_{20}$/Nb trilayers with various Nb thicknesses and show that, as expected, the spin transfer from the precessing $Ni_{80}Fe_{20}$ into Nb layers through quasiparticle (QP) excitation (*i.e.* diffusive penetration of spin-polarized QP) is blocked at a low temperature by the superconductivity; we then extend the FMR measurements to Pt/Nb/$Ni_{80}Fe_{20}$/Nb/Pt structures in which the Pt provides an effective spin sink with strong spin-orbit coupling (SOC). Where Pt (or other large SOC spin sinks) are present, a substantially increased FMR damping for Nb layer thicknesses of the order of the coherence length ξ_{sc} is interpreted as evidence for the generation of superconducting spin currents [3,7,8]. We also present our latest result that superconducting spin transport can be modulated by interfacial-exchange-coupling-induced spin-splitting in the Pt layer.

We investigated the field of applicability of spin pumping as a probe of linear spin fluctuations. The spin pumping mechanism implies the injection of a spin current from a ferromagnetic spin-injector into an adjacent layer called the spin-sink, resulting in the loss of spin angular momentum.[1] The non-local contribution to the spin-injector damping is directly connected to the dynamical transverse spin susceptibility of the spin-sink.[2,3] Since the dynamical transverse spin susceptibility enhances around most ordering transitions, spin pumping should generically translate into a maxima in the temperature-dependence of spin-injector damping for fluctuating spin-sinks of all magnetic and electrical kind. We will discuss temperature-dependent relaxation in NiFe films and how it was affected by spin fluctuations in adjacent spin-sinks made of all kinds of ordering states: ferromagnetic (Tb), antiferromagnetic (IrMn exchange biased, IrMn not biased, NiO, NiFeOx, $BiFeO_3$), and superconducting (NbN). We will also discuss to what extent the effect is independent on the metallic (Tb, IrMn), insulating (NiO, NiFeOx, $BiFeO_3$), and superconducting (NbN) electrical nature of the spin-sink, i.e. to what extent the physical origin of the phenomenon disregards whether the spin current probe involves electronic or magnonic transport.[4]

We report on the temperature dependence of the ferromagnetic relaxation in $TiO_2(110)/VO_2/Ni_{80}Fe_{20}$/Al thin film structures using broadband ferromagnetic resonance (FMR). Figure 1(a) shows the Resistance temperature behavior of an exemplary $TiO_2(110)/VO_2$(50nm) system, determined from a 4-point R(T) measurement. We can confirm that the VO_2 resistance is on the order of ~10^5 Ω for the 300 K measurement and drops to 65 Ω at 385K. Broadband FMR measurements were performed on $TiO_2(110)/VO_2$(15 nm)/ $Ni_{80}Fe_{20}$(t)/Al(3nm) structures, t=6nm, 20nm at 300K and 385K to determine the effective Gilbert damping parameter. As shown in Figure-1(b) the damping parameter of the system increases as the VO_2 layer goes through Insulator -Metal Transition. We show that the observed temperature dependence of the effective Gilbert damping parameter can be explained by spin pumping [1,2] into the VO_2 layer, when taking into account the change of the spin mixing conductance at the VO_2/ $Ni_{80}Fe_{20}$ interface. This temperature dependent damping enhancement is removed upon insertion of a 3 nm Ru seed layer between the Py and VO_2 layers and is more pronounced for the 6nm $Ni_{80}Fe_{20}$ as compared to the 20nm $Ni_{80}Fe_{20}$ sample. This further confirms the change of interfacial spin mixing conductance as the reason behind the temperature dependence of the damping. A similar behavior of the damping parameter is reported in $Ni_{80}Fe_{20}$/Gd structures upon paramagnetic-ferromagnetic phase transition in Gd[3]. This work was supported by NSF-DMREF#1235396 Grant.

Understanding spin-pumping at the interface between low-damping magnetic insulators and normal metals with large spin-orbit coupling (e.g. Pt) is crucial to the development of "pure" spin current spintronic devices. We present the spinel-ferrite magnetic insulator $(Ni,Zn)(Al,Fe)_2O_4$ (NZAFO) as a new low-loss spin current source. Broadband ferromagnetic resonance (FMR) spectroscopy shows a Gilbert damping parameter of 0.003 for 20 nm thick single-layer NZAFO. In NZAFO/Pt bilayers the damping parameter increases to 0.009 and is accompanied by a voltage peak at resonance, suggesting significant spin-pumping from the NZAFO to Pt with a spin-mixing conductance of 2×10^{14} $\Omega^{-1}m^{-2}$. To investigate the contribution of anisotropic magnetoresistance (AMR) due to proximity induced magnetism in the platinum later, we perform angular-dependent magnetoresistance (ADMR) measurements and find that, while present, AMR is about three times weaker than the spin-Hall magnetoresistance (SMR) characteristic of spin-pumping. To further address this issue, we insert copper spacer layers at the NZAFO/Pt interface with intentions to suppress any proximity-induced magnetism in the Pt. Similar damping enhancement and FMR-driven voltage are observed in these samples, and ADMR results demonstrate a decrease in prominence of AMR with increasing copper thickness (with a 5nm copper spacer AMR is four times weaker than SMR). These results suggest that the observed voltage peak at ferromagnetic resonance is indeed due to the inverse spin-Hall effect from spin-pumping across the NZAFO/Pt interface, with a minimal contribution from proximity-induced magnetism.

A low power switchable magnetic ordering would present a leap forward in efficiency from today's current hungry memory and logic electronics. Films of FeRh have long been known to exhibit a unique magnetostructural antiferromagnetic (AF) to ferromagnetic (FM) transition slightly above room temperature (~360K) which coincides with a ~1% volumetric expansion. Recently, works by us and others have shown that strain can be used to modify the temperature at which this transition occurs by both active[1,2], and passive[3,4], mechanisms. Controllability of the transition has also been recently realized with thickness[7], and varying degrees of chemical[8], and irradiation[6,7], induced disorder. Here I will show our recent work in achieving controllability of the metamagnetic transition, as well as detail our recent discovery of He-ion implantation induced magnetic order multilayering and a surface mesoscopic spin glass state[6].

Proximity effects induce various kinds of phase transitions in nanoscale heterostructures. A paradigmatic example is the observation of superconducting correlations in a normal conductor by proximity to a superconductor. However, the occurrence of a true magnetic phase transition induced by proximity has never been investigated to our knowledge in a quantitative manner. In this work, we report the observation of a second-order phase transition induced by a magnetic proximity effect in a Ni(4nm)/FeF_2(70 nm) bilayer. We show that FeF_2, an antiferromagnet (AF) with strong uniaxial anisotropy, induces a unidirectional growth anisotropy in the ferromagnetic (FM) Ni layer. Since the two layers are negatively exchange coupled through the interface the emergence of magnetic domains in the AF at the Néel temperature (T_N) causes the formation of reversed domains in the Ni [1]. We combine photoemission electron microscopy (PEEM) with X-ray magnetic circular dichroism (XMCD) to obtain layer-resolved information of both the Ni domains and the uncompensated Fe moments at the interface, which are responsible for the reversed Ni spins [1]. As we cool down below T_N, the initial Ni saturated state splits into a branched pattern of small, inverted domains with magnetization along the FeF_2 easy axis [1], signaling the onset of a magnetic transition. We define the order parameter *m* as the normalized fraction of inverted Ni domains. The lateral correlation length ξ of the latter is determined by fitting the pair-correlation function of the PEEM images. We find that *m* increases monotonically from zero below T_N while ξ follows an asymptotic behavior centered at T_N, both features characteristic of a second-order phase transition. In addition, the two parameters exhibit critical behavior around T_N with exponents β=0.33±0.06 and ν=0.7±0.3. Our results strongly indicate that the formation of inverted FM domains follows a second-order phase transition triggered at T_N by a proximity effect with the AF layer. K2-03. Tuning the magnetic anisotropy of NiPtMnGa by substitution and epitaxial strain. *H.C. Herper*[1] and A. Grünebohm[2] *1. Dept. of Physics and Astronomy, Uppsala University, Uppsala, Sweden; 2. Faculty of Physics, University of Duisburg-Essen, Duisburg, Germany*

Large magneto crystalline anisotropies (MCA) are of high technical relevance for permanent magnets and memory devices with high density (suppression of the superparamagnetic effect). Large MCA has been reported for the low temperature L10 phase of Ni2MnGa [1] and both, Mn and Pt substitution can stabilize this phase at higher temperatures. It has been reported that Pt substitution may result in a degeneration of the MCA despite the large spin-orbit coupling in this heavy 5d-element due to structural relaxations [2]. The MCA has been studied for a combination of epitaxial strain and Mn and Pt substitution in a broad concentration range based on density functional theory methods, see Figure 1. A combination of VASP [3] and the fullpotential RSPt [4] code have been used throughout the calculations. A k-point meshes (RSPt) up to 54*54*54 have been adopted to determine the anisotropy energies. We show that one can stabilize both, large uniaxial and easy-plane anisotropies, depending on the value of strain and the Pt concentration, see Figure 2. We acknowledge financial support by StandUp for energy (Sweden) and the Deutsche Forschungsgemeinschaft (GR 4792/1-2).

K2-04. Interplay between Strain-Stabilized Ferromagnetism and Charge Transport in Epitaxial $LaCoO_{3-\delta}$ Thin Films. *V. Chaturvedi*[1], J. Walter[1], A. Paul[1], J.S. Jeong[1], A.J. Grutter[2], B.J. Kirby[2], J. Borchers[2], A. Mkhoyan[1], T. Birol[1] and C. Leighton[1] *1. Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, MN, United States; 2. NIST Center for Neutron Research, National Institute of Standards and Technology, Gaithersburg, MD, United States*

$LaCoO_3$ (LCO) has been extensively studied due to its thermally-assisted spin-state crossover of Co^{3+} ions, deriving from the very small difference between crystal field splitting and Hund's exchange energies. Bulk LCO is thus a diamagnetic insulator below ~30 K, above which a spin-state crossover is initiated. Recently, ferromagnetic (FM) order in epitaxial LCO thin films[1], in stark contrast to the bulk, has gathered substantial attention. While stabilization of a finite spin-state and FM interactions under tensile strain are known to play a role, no consensus has emerged as to the origin of the FM under epitaxial tension. Additionally, due to the insulating nature of this strain-stabilized FM, relatively little attention has been paid to electronic transport. In this work, we present a systematic study of epitaxial LCO films grown under both tensile and compressive strain, emphasizing not only magnetism but also transport. Based on X-ray diffraction, atomic force microscopy, and scanning transmission electron microscopy (STEM), the films are phase-pure, smooth, epitaxial, and fully strained to the substrates, from -1.5 to 2.5% lattice mismatch. STEM reveals oxygen vacancy ordering, with orientation controlled by strain-state, similar to Sr-doped LCO[2]. Tensile films exhibit ferromagnetism with saturation magnetization 1-1.5 μ_B/Co and Curie temperature ~80 K, consistent with prior work (Fig. 1). Polarized neutron reflectometry has also been performed, from which magnetization depth profiles have been extracted. Most notably, transport, which is semiconducting in all cases (Fig. 2), reveals an unanticipated correlation between strain-state and majority carrier type, supported by density functional theory calculations suggesting significant changes in conduction band structure under strain. Magnetoresistance reveals similarly contrasting behaviour under tension *vs.* compression, providing important clues on the origin of FM in this material.

K2-05. Magnetic Imaging of Phase Domain Development in Laterally Confined FeRh. *R.C. Temple*[1], T.P. Almeida[2], J. Massey[1], K. Fallon[2], R. Lamb[2], S.A. Morley[1,3], S. McVitie[2], T.A. Moore[1] and C.H. Marrows[1] *1. School of Physics and Astronomy, University of Leeds, Leeds, United Kingdom; 2. School of Physics and Astronomy, University of Glasgow, Glasgow, United Kingdom; 3. Physics Department, University of California, Santa Cruz, CA, United States*

The binary equiatomic alloy FeRh with B2 chemical ordering has a magnetostructural phase transition at an unusually high temperature of approximately 370 K. This is a first order transition from an antiferromagnetic (AF) to a ferromagnetic (FM) state. The transition temperature can be manipulated through magnetic field, strain, chemical doping and spin-polarised currents [1]. Due to this high flexibility this material has been extensively investigated in recent years for its potential technological applications in heat-assisted memory recording [2], antiferromagnetic memory [3] and electric field control of magnetic order [4]. Here we have imaged the phase transition in laterally confined nanopatterned islands using x-ray photoemission electron microscopy. While the transition in the bulk form of the material is relatively well understood the effects of lateral confinement on the structure are not well studied. Here we image the FM phase domains during heating and cooling through the transition in square islands of FeRh material ranging from 5 μm to 500 nm in width, above and below the typical final domain size. In the 5 μm structures shown in Fig. 1 this domain development during heating is shown to proceed in three distinct modes: nucleation, growth, and coarsening, each with subsequently greater energy costs. At edge of the larger islands and uniformly in the 500 nm structures the transition temperature was found to 30 K lower than the central regions. The magnetic transition is highly sensitive to small rearrangement of the crystalline order [5]. The modification to the transition temperature is found to be caused by a combination of strain relief and side wall damage during the mask transfer process. These issues will need to be taken into account in order to advance towards future patterned devices.

K2-06. Control of Domain Size and Morphology in Non-Collinear Artificial Spin Systems. *J. Lehmann*[1], A. Bortis[1], P. Derlet[2], C. Donnelly[2], N. Leo[2], L. Heyderman[2] and M. Fiebig[1] *1. Department of Materials, ETH Zurich, Zurich, Switzerland; 2. Paul Scherrer Institute, Villigen PSI, Switzerland*

In ferromagnetic and ferroelectric materials the interplay of volume and surface energy terms determines the configuration of domains[1]. The question of how microscopic coupling mechanisms affect size and morphology of domains, domains walls and phase transitions in long-range ordered systems with zero net magnetization is much less understood but of great fundamental and technological interest[2]. The formation, final configuration and stability of spontaneous order is a result of the energy minimization of various contributions with different strength and range. Knowledge about the correlation dynamics that drive the transition to long-range order provides an essential basis for the control of desired emergent properties. Here, we investigate the formation of domains in a model system consisting of planar dipolar-coupled single-domain ferromagnetic building blocks[3]. These are arranged on a square lattice such that a unit cell yields a vortex-like compensated magnetization and the as-grown state consists of domains with uniform magnetic handedness. By varying the distances of magnetic nanoislands, we can independently tune the interaction strengths for the inter- and intra-vortex coupling. By magnetic force microscopy and statistical methods, we examine a general phase diagram that links the ratio of two distinct coupling strengths to the correlation length. In the case of a single dominating coupling, we observe a percolation transition that is characterized by the existence of magnetically compensated meta-molecules. In thermal equilibrium, long-range order exists for both phases but differs in the anisotropy and effective magnetic charge of a domain wall. For contributions with equal strength, large domains are observed. Our results demonstrate the control of domain size and domain-wall geometry in artificial nanomagnetic crystals. This work reveals an approach for modelling and tailoring ordered systems and provides insight into the formation of domains in materials with zero net magnetization[4].

K3-01. Ultrafast and Very Small: Discover Nanoscale Magnetism With Picosecond Time Resolution Using X-Rays. *H. Ohldag*[1] *1. SLAC National Accelerator Laboratory, Menlo Park, CA, United States*

Today's magnetic device technology is based on complex magnetic alloys or multilayers that are patterned at the nanoscale and operate at gigahertz frequencies. To better understand the behavior of such devices one needs an experimental approach that is capable of detecting magnetization with nanometer and picosecond sensitivity. In addition, since devices contain different magnetic elements, a technique is needed that provides element-specific information about not only ferromagnetic but antiferromagnetic materials as well. Synchrotron based X-ray microscopy provides exactly these capabilities because a synchrotron produces tunable and fully polarized X-rays with energies between several tens of electron volts up to tens of kiloelectron volts. The interaction of tunable X-rays with matter is element-specific, allowing us to separately address different elements in a device. The polarization dependence or dichroism of the X-ray interaction provides a path to measure a ferromagnetic moment and its orientation or determine the orientation of the spin axis in an antiferromagnet. The wavelength of X-rays is on the order of nanometers, which enables microscopy with nanometer spatial resolution. And finally, a synchrotron is a pulsed X-ray source, with a pulse length of tens of picoseconds, which enables us to study magnetization dynamics with a time resolution given by the X-ray pulse length in a pump-probe fashion. The goal of this talk is to present an introduction to the field and explain the capabilities of synchrotron based X-ray microscopy, which is becoming a tool available at every synchrotron, to a diverse audience. The general introduction will be followed by a set of examples, depending on the audience, that may include properties of magnetic materials in rocks and meteorites, magnetic inclusions in magnetic oxides, interfacial magnetism in magnetic multilayers, and dynamics of nanostructured devices due to field and current pulses and microwave excitations.

K3-02. Insights into Magneto-Electric Coupling using X-ray Photoemission Electron Spectro-Microscopy. *R.V. Chopdekar*[1] *1. Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA, United States*

Ferromagnetic-ferroelectric (FM-FE) heterostructures have been studied as a route to obtain strong room-temperature magneto-electric interactions not commonly found in single-phase materials.[1] In such composites it is critical to understand the role of charge- and strain- mediated interactions at interfaces of the constituent phases, and spatially resolved probes such as x-ray photoemission electron microscopy (XPEEM) at the Advanced Light Source PEEM3 beamline can observe such interface interactions at the scale of a single FE or FM domain. Polarization-dependent soft x-ray spectro-microscopy as a function of temperature and applied electric and magnetic fields can offer unique insights into coupling at heterointerfaces with sub-100 nm resolution by exploiting the x-ray linear dichroism (XLD) and magnetic circular dichroism (XMCD) effects. In this talk, I will present a detailed analysis of the magneto-electric coupling in model artificial multiferroic systems (e.g. FM layers grown on FE single crystals) using XLD- and XMCD-PEEM imaging. While the 3D vector orientation of FM domains can be mapped with XMCD imaging at different azimuthal orientations, anisotropic strain interactions between FE and FM phases can be mapped by XLD imaging in an analogous fashion.[2,3] The anisotropic nature of the strain imprinted by the FE induces a local variation of the magnetic anisotropy of the FM phase due to a large magnetoelastic coupling coefficients in FM oxides such as $CoFe_2O_4$ or $La_{0.7}Sr_{0.3}MnO_3$, and by varying applied electric fields or changes in temperature we can observe both the FM domain structure and imprinted strain state evolve due to such pertubations.[2] Furthermore, we can compare spatially averaged electric-field dependent magnetometry to spatially resolved XMCD images in applied magnetic fields, and directly correlate a giant anisotropy rotation and change of anisotropy symmetry to the local tuning of magnetic anisotropy at the scale of single FE and FM domains.[3] Thus, XLD- and XMCD-PEEM imaging offer a facile method to visualize electric-field induced FM domain rotation and domain wall propagation while simultaneously mapping the local strain imprinted into the FM layer by the underlying FE phase.

K3-03. The SQCRAMscope: Scanning Quantum Cryogenic Atom Microscope. *S. Taylor*[1], F. Yang[1], J. Palmstrom[1], S.D. Edkins[1], I.R. Fisher[1] and B. Lev[1,2] *1. Applied Physics, Stanford University, Palo Alto, CA, United States; 2. Physics, Stanford University, Palo Alto, CA, United States*

Microscopic imaging of local magnetic fields provides a window into the organizing principles of complex and technologically relevant condensed matter materials. However, a wide variety of intriguing strongly correlated and topologically nontrivial materials exhibit poorly understood phenomena outside the detection capability of state-of-the-art high-sensitivity, high-resolution scanning probe magnetometers. We have recently introduced the Scanning Quantum Cryogenic Atom Microscope (SQCRAMscope), a quantum-noise-limited scanning probe magnetometer that can operate from room-to-cryogenic temperatures. By employing a magnetically levitated atomic Bose-Einstein condensate (BEC) that can be scanned near the surface of a cryogenically cooled material, the microscope achieves unprecedented DC-field sensitivity at micron-scale resolution. We present recent work advancing the capabilities of this new magnetometry technique and will mention its application to imaging transport in pnictide superconductors through the electron nematic transition.

K3-04. Visible light detection and imaging of magnetic field in the microwave regime with a combination of magnetic losses material and thermofluorescent molecules. H. Ragazzo[2], S. Faure[3], J. Carrey[3], F. Issac[2], D. Prost[2] and *J. Bobo*[1] *1. CEMES CNRS, Toulouse, France; 2. DEMR, ONERA, Toulouse, France; 3. LPCNO, Toulouse, France*

Characterization of the electromagnetic field emitted by various sources (antenna, radar...) is an important issue, either for civil or defense applications. The measurement of electromagnetic field may be performed either by local probes or by thermography imaging, in particular with an infrared camera. The latter method, called EMIR (ElectroMagnetic InfraRed) has been developed several years ago. [1] We have recently successfully implemented this technique in the domain of visible light thanks to the combination of a film sensitive to either electric field (slightly conductive film) or magnetic field (insulating film with ferromagnetic particles) and a polymer coating doped with fluorescent molecules with an emission depending on temperature, indeed a thermofluorescent sensor. This novel technique for electromagnetic field imaging is patented. [2] We present our recent results obtained imaging the microwave magnetic field emitted in the near field of a zeroth order resonator antenna (ZOR) [3]. The sensing film is a stack of FLEX TOKIN magnetic absorber, already tested by EMIR infrared thermography in our group [4]. A 20 micrometer film composed of a mixture of rhodamine B (RhB) in a cellulose acetate matrix was spin-coated on the FLEX surface. RhB, in ethanol solution has a thermofluorescence coefficient of ~2%/K at room temperature (Fig. 1) at its maximum of fluorescence of 595 nm. Excitation light is delivered by an array of blue 470 nm LEDs. 4.29GHz Microwave excitation of the ZOR device is amplitude modulated at 0.5 Hz in order to cancel any thermal drift and convection of the thermofluorescence image. Low frequency excitation modulation also allows noise cancellation via image pixel demodulation post processing. In Fig. 2 we present the deduced temperature mapping of the sensing film placed 2 mm above the ZOR patch antenna. The emitted magnetic field is proportional to the square root of ΔT. Up to our knowledge this is the first observation of a microwave magnetic field by thermofluorescence.

K4-01. Bilinear magneto-electric resistance as a probe of spin textures.
P. He[2], S. Zhang[3], G. Vignale[4] and *H. Yang*[1] *1. National University of Singapore, Singapore; 2. National University of Singapore, Singapore; 3. Material Science Division, Argonne National Laboratory, Lemont, IL, United States; 4. University of Missouri, Columbia, MO, United States*

The symmetry breaking introduced via this coupling has gained significant attention in recent years due to emergent unique topologies of spin textures, in both real and momentum space. These topologies range from the traditional surface states found in topological insulators as well as magnetic skyrmions and various other non-collinear spin textures. The topological protection associated with these states has suggested that their manipulation may be utilized as the building blocks of next-generation spin-based logic and memory devices. Probing the spin texture of these states is of critical importance for the realization of various devices, however the main technique available so far is the spin- and angle-resolved photoemission spectroscopy. In this work, we reveal a close link between the spin texture and a new kind of magneto-resistance, which depends on the relative orientation of the current with respect to the magnetic field as well as the crystallographic axes, and scales linearly with both the applied electric and magnetic fields [1]. This bilinear magneto-electric resistance (BMER) can be used to map the spin texture of various materials including topological insulators by simple nonlinear transport measurements. For a prototypical Bi2Se3 single layer, we can map both the in-plane and the out-of-plane components of the spin texture. The latter is arising from hexagonal warping. Theoretical calculations suggest that the bilinear magneto-electric resistance originates from the conversion of a non-equilibrium spin current into a charge current under the application of the external magnetic field. The BMER effect can be modulated by tuning various parameters such as the film thickness, temperature, electrostatic gating, etc. We anticipate the BMER may also exist in materials with giant Rashba spin splitting at surface (interface) or bulk, as well as two-dimensional transition metal dichalcogenides with spin-polarized states, which may in turn help to estimate the spin-polarization direction of the states contributing to the transport.

K4-02. ***Electrical detection and transport properties of magnetic skyrmions at room temperature.*** *D. Maccariello*[1], W. Legrand[1], N. Reyren[1], K. Garcia[1], K. Bouzehouane[1], S. Collin[1], V. Cros[1] and A. Fert[1] *1. Unité Mixte de Physique CNRS-Thales, Univ. Paris-Sud, Université Paris-Saclay, Palaiseau, France*

Magnetic skyrmions are whirling spin configurations that can be stabilized in magnetic materials in which a chiral interaction is present[1]. Their limited size together with their robustness against the external perturbations make them very promising for technological applications from the data storage to neuro-inspired skyrmion based devices[2]. So far, only low temperature measurements, mainly in magnetic materials with B20 crystals, have demonstrated the skyrmions contribution to the electrical transport[3]. However, these low temperatures reduce the achievable applications of magnetic skyrmions in real devices. We engineer magnetic multilayers in form of stacks composed of ultra-thin magnetic layers in contact with heavy material thin films in which is possible to the stabilize sub-100nm magnetic skyrmions at room[4]. In these multilayers, skyrmions can be nucleated by applying current pulses in tracks[5]. Using the combination of Magnetic Force Microscopy (MFM) imaging and concomitant Hall resistivity measurements (Fig1) we demonstrate the electrical detection of isolated skyrmions in magnetic multilayers at room temperature (RT)[6]. In Fig.2, we show the variation of the transverse resistivity ρ_{xy} associated to the appearance of one isolated skyrmion in the Hall cross region of a nanostructured track. This observation allows us to estimate, for the first time, the room temperature variation of the Hall resistivity $\Delta\rho_{xy}$ associated to a single skyrmion in multilayers, which is mainly dominated by anomalous Hall effect. Beside the detection of isolated skyrmions, we also present the early results of a comprehensive characterization of the both longitudinal and transversal resistivity in microstructured multilayers hosting high densely packed skyrmion lattices. The RT observation of skyrmions and their electrical detection can be a robust basis for the development of skyrmion-based devices, as well as a new path for further fundamental studies on their very rich physics.

K4-03. Magnetoresistance in Hybrid Pt/$CoFe_2O_4$ Bilayers Controlled by Competing Spin Accumulation and Interfacial Chemical Reconstructions. H.B. Vasili[2], M. Gamino[1], J. Gazquez[1], F. Sanchez[1], M. Valvidares[2], P. Gargiani[2], E. Pellegrin[2] and *J. Fontcuberta*[1] *1. Institut de Ciència de Materials de Barcelona, Bellaterra, Spain; 2. CELLS-Divisió Experiments, ALBA Synchrotron Light Source, E-08290 Cerdanyola del Vallès, Spain*

Pure spin currents are seen as an alternative for low energy consuming spintronics. In a particular realization, a ferromagnetic insulating oxide layer (FMI) is covered by a non-magnetic metallic layer (NM) forming NM/FMI stacks. Current-induced spin flow in the NM layer is reflected back at the FMI interface or diffuses across (G) it, depending on the magnetitzacion of FMI at the interface. In Pt/$CoFe_2O4$ bilayers anisotropy of G and discrepant magnetic field dependences of the spin magnetoresistance (SMR) and the FMI film magnetization have been observed [1, 2]. Additional open questions are the occurrence or not of magnetic proximity effect (MPE) in the Pt layer, where conflicting results have been reported [3,4], and the understanding of its origin. Here, we address some of these pivotal questions. We focus on Pt(4 nm)/$CoFe_2O_4$(28 nm)//$MgAl_2O_4$(001) devices with emphasis on the impact of the temperature deposition of the sputtered Pt layer on the magnetic and magnetotransport properties. We characterized the magnetic response by conventional magnetometry, angular dependent magnetoresistance measurements (ADMR) and spectroscopic and atomic-scale compositional analysis by using STEM-EELS. We performed exhaustive XMCD X-ray absorption experiments at Pt edges. It turned out that simultaneous XMCD exploration of the (Co, Fe) edges on the very samples was crucial to unravel relevant information. Two main conclusions emerge [5]. If Pt is grown at room-temperature, the ADMR is largely dominated by spin current-related effects; the XMCD at Pt edges do not show any magnetic signature and the XMCD of (Fe,Co) edges have the characteristic features of insulating CoFe2O4. However, when Pt is grown at higher temperature the ADMR data clearly indicate the emergence of a ferromagnetic metallic contribution that is fully confirmed by the observation of XMCD at Pt. Significant changes are visible on the of (Fe,Co) XMCD spectra and the STEM-EELS spectra reveal Pt/(Co,Fe) interfusion at the Pt/CFO interface. These results show that alloying at interfaces can be very relevant and may provide a simple explanation for some lossely described MPEs.

Using the spin Hall effect (SHE) or the Inverse the spin Hall effect (ISHE), an effective generation and detection of the spin currents at ferromagnet (FM)\Heavy metal (HM) interfaces have been explored intensively for future spintronic device applications [1]. The efficiency of spin current transport at the interface is determined by spin mixing conductance, the key factor governing spin Hall magnetoresistance (SMR). It is generally accepted the important role of FM\HM interfaces in determining the spin mixing conductance. However, direct observation of the impact of interface geometry on spin mixing conductance is still lacking. In this work, we systematically investigated the interface roughness effect on the SMR for Fe_3O_4\Pt heterostructures. Prior to Pt deposition, the different levels of surface/interface roughness ranging from 0.4 to 1.1 nm were provided by using different film growth techniques and changing the growth conditions. The films were prepared by oxide-MBE and RF-magnetron sputtering technique under different deposition parameters on substrate and substrate temperature, and then followed by vacuum annealing. The careful analysis of the surface structure of Fe_3O_4 was performed using atomic force microscopy. Our results reveal that the electrical properties of the Pt Hall bar strongly depend on the interface geometry of Fe_3O_4\Pt. As the interface roughness increases, we observed strong enhancement of spin-mixing conductance that is extracted from the SMR effect measured at low temperature (77 K lower than the Verway transition temperature of magnetite). To our best knowledge, it is the first experimental observation of the roughness-induced enhancement of the efficiency of the spin current transport across the FM\HM interface. Our results provide further insights into this phenomenon to develop highly effective SHE devices.

K4-05. Evaluation of bulk-interface contributions to Edelstein magnetoresistance at metal/oxide interfaces. *J. Kim*[1], Y. Chen[1], S. Karube[2], S. Takahashi[3], K. Kondou[4], G. Tatara[5] and Y. Otani[6,1]
1. RIKEN, Wako, Japan; 2. Institute for Solid State Physics, University of Tokyo, Wako, Japan; 3. Institute for Materials Research, Tohoku University, Sendai, Japan; 4. RIKEN-CEMS, Wako, Japan; 5. RIKEN CEMS, Wako, Japan; 6. ISSP, University of Tokyo, Kashiwa, Japan

Recently a novel magnetoresistance (MR) generated by the spin/charge current interconversion have been reported. The novel MRs are named spin Hall MR and Edelstein MR following by their origin [1,2]. As shown in a previous report, the novel MR provides an alternative and simple method for the conversion efficiency as well as it assists to reveal veiled properties on the spin transport [3]. Here we observed the Edelstein MR, and derived a characteristic spin transport generally shown nearby two dimensional interfaces, e.g. the Rashba and the topological interfaces [4]. In particular, our study provides a practical way to understand an enormous difference of the conversion efficiency between the charge-to-spin and the spin-to-charge conversion at the topological interfaces.. We prepared Hall bar devices on the top of a CoFe (5 nm)/Cu (0~30 nm) /Bi_2O_3 (20 nm) thin films where the Cu/Bi_2O_3 interface indicates the Rashba splitting [5]. The Edelstein MR measurement was carried out with applying 60 kOe external field in the physical property measurement system (PPMS). The observed Edelstein MR for the several thicknesses of the Cu layer is shown in Fig. 1. In order to extract a property of the spin transport from the Edelstein MR, we developed a general analytical model. In the model, we adopted a spin relaxation process which indicates where the accumulated spins at the Rashba interface will proceed (Fig. 2) [6]. Here the spin relaxation process is described by characteristic times τ_i and τ_b which represent a spin relaxation time inside and outside the Rashba interface, respectively. An analysis based on the developed model indicates only 34 % of the spins at the Rashba interface reaches to the ferromagnetic layer. We also recognized the ratio is almost insensitive to temperature. Further information will be given during the conference.

K5-01. Magnetic Nanostructured Materials for Non-biomedical Applications. *A.A. El-Gendy*[1] *1. Physics, University of Texas at El Paso, El Paso, TX, United States*

Magnetic nanostructured materials (MNMs)are involved in all the advanced technology nowadays. While you are reading this abstract maybe few minutes ago you have checked your phone, or you may even be reading this chapter on your tablet or laptop. It is curious that while you try to learn about MNMs, you are surrounded by them. MNMs are used in a wide variety of devices including electronic devices, motors and generators, hard disk drives, magnetic refrigeration and even in general home appliances (e.g. washing machines). Therefore, small is beautiful and powerful. Magnetic nanoparticles can be classified to soft or hard magnetic materials. Soft magnetic materials such as Fe, Co, Ni or their alloys can be used for magnetocaloric effect for magnetic refrigeration as well as medical applications. The other type of the magnetic nanoparticles, which is the focus of this talk, is hard magnetic materials. Co_xC, Mn_xGa, and $CoFe_xC$ nanoparticles are good examples of hard magnets, which have the property of storing magnetic energy even after removing the magnetic field. Such property are commonly used for fabrication of permanent magnets. The main advantage of such particles is due to the higher magnetic anisotropy which can act as good candidate for new generation of magnetic data storage. Magnetic characterization of the novel carbide phase ($CoFe_2C$) revealed thermal stability up to 790 K for particles with a domain size as small as 5 nm and have giant MCE of 4.6×10^6 J/m^3, which is ten times larger than that of Co nanoparticles. Such colossal anisotropy leads to a thermally stable long-range magnetic order. Therefore, the talk focusses on the synthesis of Co_xC, Mn_xGa, $CoFe_xC$ magnetic nanoparticles and their potential for industrial applications.

K5-02. Thermo-magnetic field driven magnetic fluid propulsion engine. *V.H. Dave*[1], H.A. Virpura[1] and S.P. Bhatnagar[1] *1. Department of Physics, Maharaja Krishnakumarsinhji Bhavnagar University, Bhavnagar, India*

The magnetic fluid contains the magnetic nanoparticles of an average size of 10-12nm stabilized in some carrier liquid [1]. Different types of magnetic fluid have been prepared as per their requirement in various applications. Novel properties of magnetic fluids have been explored in the area of Engineering, material research, optical, technological, and biomedical applications [2]. One of the types is temperature sensitive magnetic fluid whose magnetization changes notably with temperature. When such fluid is exposed to a thermal gradient and uniform magnetic field, it loses its magnetization as it reaches the curie temperature. Fluid flow occurs when this hot fluid is displaced by the higher magnetization fluid. It depends on the change in magnetization of magnetic material with a temperature i.e. pyromagnetic coefficient. The motion of fluids helps to dissipate the heat at a far place. After losing heat in the surrounding, the same fluid will return to its higher magnetization and cycle can continue. The idea was first proposed by Rosensweig [1] and later many scientists have tried to design but achieved low efficiency and low flow rate compared to our experiment [3-6]. We are presenting the thermal field and magnetic field driven magnetic fluid engine with a reservoir for the first time. The magnetic property of the magnetic fluid, distribution of temperature and area and intensity of magnetic field play a vital role in the motion of the fluid. The reservoir design helps to establish a proper temperature gradient inside the system as well as it gives visual flow measurement of magnetic fluid.

K5-03. Spark plasma sintering of ferrite-based hybrid magnets: towards rare-earth-free magnets for energy storage. *P. Jenus*[1], A. Kocjan[1,3], C. Sangregorio[2], M. Petrecca[4] and S. Kobe[1] *1. Department for Nanostructured Materials, Jozef Stefan Institute, Ljubljana, Slovenia; 2. ICCOM – CNR and INSTM, Sesto Fiorentino, Italy; 3. Jozef Stefan International Postgraduate School, Ljubljana, Slovenia; 4. Department of Chemistry, University of Florence, Sesto Fiorentino, Italy*

In the last years, much effort has again been devoted to the research of ferrite-based permanent magnets, due to the so-called rare-earth crisis. [1, 2] In particular, a quest to enhance ferrites' BH_{max}, is still underway. Large BH_{max} values are found in magnets combining substantial magnetisation at remanence (M_R) with high coercivity. Both parameters are influenced by materials properties, such as crystalline and shape anisotropy and particle' size. Here, the influence of composition, particle size, sintering conditions and exposure to the external magnetic field before compaction on microstructure and consequently magnetic properties of strontium ferrite (SFO)-based hybrid composites will be presented. Powders' mixtures consisted of commercial SFO powder consisting of micron-sized, isotropic particles, or hydrothermally (HT) synthesised SFO with hexagonally-shaped platelets with a diameter of 500 nm and thickness up to 50 nm, and a soft magnetic phase in various ratios. Powders were sintered with spark plasma sintering (SPS) furnace. Starting powders and hybrid magnets were examined by means of phase composition (XRD) and microstructure (TEM, SEM). Their magnetic properties were evaluated with vibrating sample magnetometer and permeameter. Depending on the concentration and composition of soft phase the M_R of the composite can be altered. Application of external magnetic field before the consolidation induces the anisotropy in commercial, and HT synthesised SFO, leading to the increase in the M_R of hybrid magnets. Moreover, sintering with SPS promotes the alignment of HT synthesised

SFO particles in the direction of the applied pressure, which is also the direction of SFOs' easy axis and thus the enhancement in M_R is perceived leading to the M_R/M_S higher than 0.8. Besides, after SPS almost no grain growth was observed, which is beneficial for exploiting advantages of nano-sized-induced phenomena also in bulk sintered samples. K5-04. From the Lab to the Factory: "Closing the Loop" through Recycling by Tuning Microstructural and Magnetic Properties in Sr-Ferrite Powder. *A. Bollero*[1], J. Rial[1], M. Villanueva[1], A. Seoane[2], J. Almunia[2] and R. Altimira[2] *1. Division of Permanent Magnets and Applications, IMDEA Nanoscience, Madrid, Spain; 2. Ingeniería Magnética Aplicada IMA S.L., Barcelona, Spain*

Sr-ferrite ($SrFe_{12}O_{19}$) is a permanent magnet (PM) widely used in many energy and transport technological applications such as low field and power applications, high-frequency systems, sensors... [1]. Recycling of the residues generated in the manufacturing process is beneficial from an environmental point of view but also economically to reduce costs at the company, while guarantying sustainability by closing the loop in production. This study shows two fundamental and technological highlights: (i) Possibility of tuning microstructural and magnetic properties, making possible the upgrade of a low-to-high quality ferrite powder. (ii) Successful recycling of industrial ferrite powder residues (Fig. 1). Rapid-milling [2,3] of commercial Sr-ferrite for 1.5 min, followed by calcination in air, has resulted in a coercivity of 2.7 kOe, which is well above 0.9 kOe measured for the starting commercial powder [4]. This increase results from a homogeneous microstructure and a reduced grain size of 60 nm. The acquired knowledge has been transferred to the post-processing of Sr-ferrite residue produced in magnets manufacturing. Residues were collected in the PM factory from a line of cutting machines used to shape ferrite magnets [4]. Grinding and calcination of this residue resulted in a recycled ferrite with coercivity and remanence superior to those of the starting material (Fig. 2a). Heat treatment of the latter improves its properties but to a much lower extent than for the recycled, thus proving that the enhanced properties cannot be attributed solely to thermal effects, but mainly to nanostructuration and homogenization through grinding (Fig. 2b). A coercivity value 3.5 times larger than the starting brand new ferrite, and a 25% increase in remanence (Fig. 2a), makes the recycled material and upgraded ferrite product to re-enter the production line (Fig. 1).

K5-05. Electric polarization influence on magnetic properties of Multiferroic Composites type PMN-PT/$CoFe_2O_4$. A.J. de Oliveira[1], *K.R. Jimenez*[1], F.L. Zabotto[1], D. Garcia[1] and A. Gauzzi[2] *1. Physics Department, Federal University of São Carlos, São Carlos, Brazil; 2. IMPMC, Sorbonne Université-CNRS-IRD-MNHN, Paris, France*

The multiferroism is characterized by the existence of two or more ferroic orders in materials. A particular class is that of magnetoelectric (ME) materials where the combination of ferromagnetic and ferroelectric orders occur due to coupling between the magnetic and electric phases through magnetic and electrical fields. One way of obtaining multiferroic materials is the production of composite that combine ferroelectric and ferromagnetic materials. The use of magnetostrictive materials as ferromagnetic phase in composites is very important because the mechanical stress applied in ferroelectric phase induces the appearance of magnetoelectric effect [1,2]. In this work we present a studied of the electric polarization influence on the magnetic properties in PMN-PT/$CoFe_2O_4$ of the 0-3 type magnetoelectric particulate. The samples were prepared by solid-state reaction method in concentration 80/20 in two condition sintering time of 1 hour (A1) and 10 hours (A10) at temperature of 1050 °C [3]. The samples were characterized on the two conditions of the remanent electric polarization {0, +20} kV/cm under electric field applied at room temperature (RTP) and 80 °C (TP). Our results showed that the saturation magnetization decreases with the electric polarization in ~2% RTP and ~5% TP to the field magnetic parallel to poled axis and increases ~4% (RTP) and ~6% at 80 °C to the field magnetic perpendicular to poled axis, but the coercive field did not change. For the magnetoelectric responses occurred the same effect was observed. In specific heat as a function of applied magnetic measurements with electric polariztion present changes associated with interaction between phonons of the ferroelectric and ferrimagnetic phases. These effects could be due to magneto-elastic effect and strain interfacial mediated coupling

between constituted phases, on magnetic moments for two samples by electric polarization states T_a and T_p, it as observed in others can be considered as quasi-intrinsic magnetoelectric coupling effect in mMultiferroics bulks materials 0-3 particulates.

K6-01. Emergent Dynamic Chirality in a Thermally Driven Artificial Spin Ratchet. *S. Gliga*[1] *1. School of Physics and Astronomy, University of Glasgow, Glasgow, United Kingdom*

The study of emergent phenomena in two-dimensional artificial spin ices is presently the focus of intense research. Artificial spin ices are composed of geometrically frustrated arrangements of lithographically patterned single-domain nanomagnets and have so far mainly been used to investigate fundamental aspects of the physics of frustration [1,2]. Recently, it has become clear that artificial spin ice has the potential to become a class of functional material with technological applications. I will present a spin ice based active material – consisting in a repeating pattern of chiral units (shown in Figure 1) – in which energy is converted into unidirectional dynamics, thus functioning like a ratchet [3]. Measurements combining photoemission electron microscopy (PEEM) with X-ray magnetic circular dichroism (XMCD) show that following saturation by an external field, thermal relaxation proceeds through the rotation of the average magnetization in a unique sense (Figure 2). Our micromagnetic simulations demonstrate that this emergent chiral behavior is driven by the topology of the magnetostatic field at the boundaries of the nanomagnet array, resulting in an asymmetric energy landscape. This opens the possibility of implementing a Brownian ratchet [4], which may find applications in nanomotors, actuators or memory cells. I will also discuss alternative routes towards applications that aim to combine artificial spin ice lattices, which were found to display localized spectral features based on the presence topological defects such as monopoles [5], and magnonics, in which propagating spin waves in patterned magnetic thin films are manipulated, potentially leading to the creation of metamaterials for spin waves [6]. Finally, I will show that recent experimental advances in magnetic x-ray based nanotomography [7] have opened new perspectives for functionalizing artificial spin ices in three dimensions. SG is funded by the European Union's Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No. 708674.

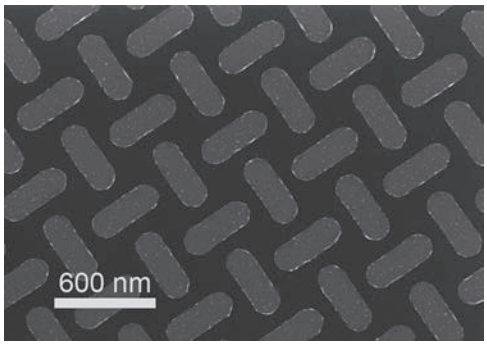

Figure 1: Scanning electron microscopy image of a region of the investigated system.

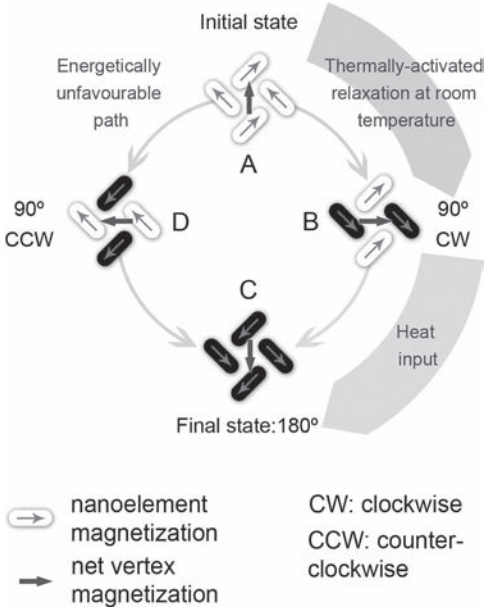

Figure 2: Schematic evolution of the net magnetization at individual vertices within the array. The thermal relaxation at room temperature from state A, following saturation, takes place stepwise via a clockwise rotation of the net magnetization by 90 degrees to state B and is indicated by the blue arrows. When the system is subsequently heated above room temperature in the presence of a weak bias field, the average magnetization can locally rotate further (orange arrows) to state C. Considering the evolution from state A, state D statistically occurs with very low probability.

Magnon spintronics aims at developing novel functional devices that combine magnonic and electronic spin transport phenomena. In particular, magnetic metamaterials such as artificial spin ice and magnonic crystals offer unique possibilities in magnon spintronics since they allow for tailoring the magnonic properties by design. Artificial spin-ice systems are lithographically defined nanomagnets that mimic effects of frustration, which are characterized by competing interactions that cannot all be simultaneously minimized. We recently succeeded in measuring the high-frequency response of a metallic artificial square spin-ice lattice made of $Ni_{80}Fe_{20}$ [1]. The nano-scaled bar magnets were patterned using electron beam lithography and measured using broadband ferromagnetic resonance spectroscopy. We observe a rich mode spectrum over the full frequency/field range as shown in Fig. 1, and find an excellent qualitative agreement to a semianalytical model and micromagnetic simulations. We furthermore find indications that it might be possible to determine the spin-ice state by this type of resonance experiments. These results are a first step towards the understanding of artificial geometrically frustrated magnetic systems in the GHz-regime. We also explored the possibility to detect and drive spin dynamics in rectangular, connected artificial spin ices made of bilayer $Ni_{80}Fe_{20}$/Pt by spintronics effects. We showed that Oersted-field driven spin dynamics in these kinds of nanostructured bilayers can be measured by spin pumping and inverse spin Hall effect [2]. On the other hand, we demonstrated very recently that spin dynamics in artificial spin ices can be excited by spin-torque ferromagnetic resonance [3]. Here, the dynamics is determined by the design of the lattice. Figure 2 shows a comparison of the experimental spectrum and the predicted resonance modes at 6 GHz. We correlate dynamic spin-torque ferromagnetic resonance results to magnetotransport studies. Our experimental findings are described using a simulation approach based on the anisotropic magnetoresistance that reveals the importance of the correlated response of the magnetic system. Our results open up the possibility of designing reconfigurable microwave oscillators and magnetoresistive devices based on connected networks of nanomagnets, which might also provide desirable functionalities, e.g., for neuromorphic computing. Work at Argonne was supported by the US Department of Energy, Office of Science, Materials Science and Engineering Division.

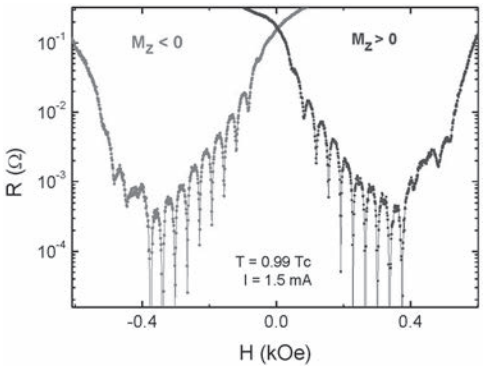
K6-03. Magnetic States In Nanomagnets Probe By Superconducting Vortex Dynamics: From Vortex To Spin-ice States. *J. Vicent*[1,2], V. Rollano[2], J. del Valle[1], A. Gomez[3], E.M. Gonzalez[1,2], M. Velez[4], F. Valdes-Bango[4], C. Quiros[5] and J. Martin[6] *1. Fisica Materiales, Universidad Complutense, Madrid, Spain; 2. IMDEA-Nanociencia, MADRID, Spain; 3. INTA-CSIC, Torrejon de Ardoz, Spain; 4. Universidad de Oviedo, Oviedo, Spain; 5. Física, Universidad de Oviedo, Oviedo, Spain; 6. Fisica, Universidad de Oviedo, Oviedo, Spain*



Nowadays, magnetism and superconductivity competition has turned around and these two antagonist phenomena are seen as a good example of cooperative long range order effects. The so-called magnetic-field-induced superconductivity is a crystal clear example (1). In this talk, we will address the interplay between magnetic states in nanomagnets and superconducting vortex dynamics. Superconducting vortices moving on array of nanomagnets show distinct features that allow discriminating among different magnetic states at the nanoscale. The only requirement is a periodic arrangement of the nanomagnets. These periodic pinning wells can slow down the superconducting vortex lattice motion and many peculiar effects occur as reconfiguration of the superconducting vortex lattice (2) or ratchet effect (3). Furthermore, magnetic nanodevices can be fabricated based on the superconducting vortex dynamics in these superconducting/magnetic hybrids (4). In our case, the hybrid samples are arrays of nanomagnets embedded in superconducting Nb films. Nanostructures of Py, Pd/Co multilayers, $NdCo_5$, Co, Fe and Ni have been fabricated with different shapes, see an example in Figure 1. The hybrid samples are patterned to a cross-shaped bridge which allows magnetotransport measurements with the applied magnetic field applied perpendicular to the film, see an example in Figure 2. Different remanent magnetic states can be obtained in these nanomagnet arrays: magnetic vortex state, in-plane and out of plane magnetization, fractal, labyrinth or aligned stripe domains. The distribution of stray fields (5) is the clue to understand the superconducting vortex responses. Moreover, superconducting vortices can discriminate magnetic domain sizes in the range

of the nanometers. In this framework, we also explore superconducting vortex dynamics moving on frustrated nanomagnets. Frustrated magnets are systems in which magnetic moments interact through competing exchange interactions that cannot be fulfill at the same time; among them we can underline the well-known spin-glass systems. One of them is spin-ice system fabricated with nanomagnets which are geometrically frustrated following the so-called in-out ice rules (6). In the last years artificially spin-ice and seudospin-ice systems have received a lot of attention (7). In closing, the interaction of superconducting vortices with the stray fields coming from different remanent magnetic states shows different responses that allow knowing the magnetic state of the nanomagnets. We show that superconducting vortex core is the crucial parameter, since the temperature dependence of the superconducting coherence length governs the superconducting/magnetic interaction, in such a way that topological magnetic defects can be single out by superconducting vortices on the move.

K7-01. Atomic-Scale Magnetometry of Dynamic Magnetization. J. van Bree[1] and *M.E. Flatte*[2] *1. Institute for Molecular Engineering, University of Chicago, Chicago, IL, United States; 2. Physics, Univ Iowa, Iowa City, IA, United States*

We propose a novel scheme for sensing magnetic properties of materials using the energy stored in the magnetic field of a nearby (scanning) probe [1]. In conventional scanning probe magnetometry a sample perturbs a probe through a magnetic field external to its volume, limiting it to samples with static moments. In our proposed scheme we overcome this limitation by reversing the perturbation; the probe's magnetic field generates a response of the sample, which acts back on the probe and changes its energy. This back action is effectively the probe experiencing a scaled mirror image of itself in place of the sample, see Figure 1. Taking a nitrogen vacancy (NV) spin center in diamond as the probe, we show theoretically this back action effectively changes the fine structure splitting of the spin ground state, see Figure 2. Existing sensitive measurement techniques using coherent detection schemes [2] would then permit detection of the magnetic response of paramagnetic and diamagnetic materials. Not only would this technique extend the class of materials that can be sensed compared to conventional magnetometry, we also show it could be used to measure the thickness of magnetically dead layers with better than 0.1 Å accuracy. This work has been supported by an AFOSR MURI and a Rubicon Grant from NWO.

FeRh is a material that shows a spontaneous change in its magnetic order at above room temperature from antiferromagnetic to ferromagnetic. As well as having this interesting phase transition, in the ferromagnetic phase the magnetization remains moderate meaning it can be used in magnetic devices. Whilst many researchers have proposed ways to exploit the presence of the phase transition for technological devices, significant challenges remain. This is because when the material is fabricated into the ultrathin regime to be integrated into devices, the phase transition temperature is often destroyed or shifted to temperatures. Recent advances have shown that it is possible to grow FeRh on MgO substrates in the ultrathin regime and preserve the phase transition[1]. However, for future hybrid storage devices, the lack of thermal stability FeRh provides is a significant drawback. Therefore, there have been several works looking at combining FeRh with FePt[2], however, the ultrathin regime has never been achieved. In the present work we present spin model calculations[3,4] investigating the effect of the size and sign (AFM or FM) of the interface exchange that can be modified depending on the strain at the interface due to lattice mismatch[1]. Our results reveal that there is a strong dependence of the phase transition temperature on the thickness of both FeRh and FePt layers. This thickness dependence leads to strong variations in the ability to switch and the switching times after laser excitation. Fig. 1 shows the equilibrium magnetization as a function of temperature using a model of atomistic spin dynamics as developed in Ref.[3]. The FePt shows a normal magnetization curve whilst the FeRh is overall ferromagnetic below and above the transition that is induced due to the exchange from the FePt. The amount of FM order below the transition is strongly dependent on the size of the exchange and the number of FePt and FeRh planes. Fig 2. shows the variation of the transition temperature with the number of FeRh and FePt unit cells in the case where they are equal and antiferromagnetically coupled.

K7-03. Determination of the magnetic switching attempt frequency for magnetite nanoparticles. *R. Moreno Ortega*[1] and R.F. Evans[1]
1. Department of Physics, University of York, York, United Kingdom

The Arrhenius-Neel law equation [1,2] describes the typical time scale for which the magnetisation of a nanoparticle switches between two different equilibrium directions, overcoming the energy barrier ΔE that exists between them due to the thermal fluctuations of the magnetisation present at finite temperature T [3,4]. The attempt frequency γ_0 is an important parameter as it is one of the parameters that defines the power dissipation under oscillating magnetic fields [5] for magnetite nanoparticles in hyperthermia. Its dependence on the intrinsic and extrinsic magnetic parameters, such as the anisotropy energy or the applied magnetic field, was determined analytically by Brown for the regime of a single domain particle with uniaxial anisotropy [2,4], however it is usually considered to be constant. In this work, using atomistic spin simulations [6], we determine the value of γ_0, simulating the time evolution of the magnetisation in magnetite nanoparticles under the effect of superparamagnetic fluctuations at room temperature, for different particle sizes with cubic anisotropy, as shown in Fig. 1. From the magnetisation dynamics we obtain the typical switching frequencies corresponding to each particle via a Fast Fourier Transform (FFT) showing a strong evolution with the particle volume as expected. We also calculate the corresponding energy barrier ΔE for each particle in order to fit the value of γ0 via the Arrhenius-Neel equation as a function of the particle size and elongation. This provides new insight into the intrinsic heat generating properties of magnetite nanoparticles and the influence of the shape anisotropy on the magnetization dynamics.

K7-04. Vector Hamiltonian approach for nonlinear dynamics of nano-scale magnetic systems. *V. Tyberkevych*[1], A.N. Slavin[1], G. Rowlands[2], P. Artemchuk[3] and O. Prokopenko[3] *1. Department of Physics, Oakland University, Rochester, MI, United States; 2. Quantum Information Processing, BBN Technologies, Cambridge, MA, United States; 3. Faculty of Radio Physics, Electronics and Computer Systems, Taras Shevchenko National University of Kyiv, Kyiv, Ukraine*

Analytical methods of study of nonlinear magnetization dynamics were extremely successful in explaining a number of dynamic phenomena in bulk and thin-film magnetic systems. Unfortunately, these methods can not be applied to *nano-scale* systems with non-uniform magnetization profile and/or significant influence of boundary effects. Therefore, dynamics of nano-scale systems is almost always studied using numerical simulations, which are time consuming and lack clarity of analytical methods. Here, we report on development of a new *hybrid* approach to nonlinear dynamics in nano-scale magnetic systems. Our approach can be applied to inhomogeneous systems and combines strong sides of both numerical and analytical techniques. Namely, numerical methods are used to find the *linear* frequencies and profiles of spin wave modes. All the *nonlinear* parameters (e.g., nonlinear frequency shift) are calculated as "overlap integrals" of the linear mode profiles. The nonlinear dynamics of the magnetic system can be studied either analytically or numerically using simplified equations for spin wave amplitudes. As an example application of our method, Fig. 1 shows results of simulations of nonlinear ferromagnetic resonance (FMR) of a nano-scale permalloy element (80 nm x 40 nm x 5 nm), namely, frequency dependence of the susceptibility $\chi_{yy}=\mu_0\langle M_y\rangle/b_{rf}$ for different driving fields b_{rf}. As one can see, our approach gives excellent quantitative description of nonlinear FMR. The noticeable differences appear only at the unrealistically large driving field b_{rf}=2.51 mT, at which precession angles exceed 90°. Fig. 1 shows FMR of the lowest spin wave mode (frequency 4.1 GHz), which is strongly non-uniform edge-localized mode. Surprisingly, the nonlinear frequency shift for this mode turned out to be positive (resonance frequency increases with increase of b_{rf}), as opposed to negative nonlinear shift of a uniform mode in an in-plane magnetized element. This unexpected behavior is correctly described by the developed approach.

FMR curves of a nano-scale magnetic element for different driving microwave fields b_{rf}. Points – full-scale micromagnetic simulations, lines – semi-analytical calculations based on the vector Hamiltonian approach.

Institut de Physique et Chimie des Matériaux de Strasbourg, Université de Strasbourg, Strasbourg, France; 6. Department of Physics, University of Warwick, Coventry, United Kingdom*

Understanding the role of the Dzyaloshinskii-Moriya interaction (DMI) for the formation of helimagnetic order as well as the emergence of skyrmions in magnetic systems that lack inversion symmetry, has found increasing interest due to the significant potential for novel spin based technologies. Candidate materials to host skyrmions include those belonging to the B20 group such as FeGe, know for stabilising Bloch-like skyrmions, interfacial systems such as cobalt multilayers or Pd/Fe bilayers on top of Ir(111), known for stabilising Néel-like skyrmions, and, recently, alloys with a crystallographic symmetry where anti-skyrmions are stabilised. Micromagnetic simulations have become a standard approach to aid the design and optimisation of spintronic and magnetic nanodevices and are also applied to the modelling of device applications which make use of skyrmions. Several public domain micromagnetic simulation packages such as OOMMF [1], MuMax3 [2] and Fidimag [3] already offer implementations of different DMI terms. It is therefore highly desirable to propose a so-called micromagnetic standard problem that would allow to benchmark and test the different software packages in a similar way as it is done for ferromagnetic materials without DMI. Here, we provide a sequence of well-defined and increasingly complex computational problems for magnetic materials with DMI. Our test problems include 1D, 2D and 3D domains, spin wave dynamics in the presence of DMI, and validation of the analytical and numerical solutions including uniform magnetisation, edge tilting, spin waves and skyrmion formation. This set of problems can be used by developers and users of new micromagnetic simulation codes for testing and validation and hence establishing scientific credibility. This work is financially supported by the EPSRC Programme grant on Skyrmionics (EP/N032128/1), EPSRC's Centre for Doctoral Training in Next Generation Computational Modelling (EP/L015382/1) and EPSRC's Doctoral Training Centre in Complex System Simulation (EP/G03690X/1), and the OpenDreamKit–Horizon 2020 European Research Infrastructure project (676541).

K8-01. Weyl-Kondo Semimetal in Heavy-Fermion Systems. *H. Lai*[1]
1. Physics and Astronomy, Rice University, Houston, TX, United States

The study of strongly correlated and topologically nontrivial insulators goes back in decades to quantum Hall systems. In contrast, topological conductors with strong correlations have yet to be identified. Heavy fermion semimetals are a prototype of strongly correlated systems and, given their inherently strong spin-orbit coupling, present a natural setting to make progress. We have advanced a Weyl-Kondo semimetal phase [1] within a three-dimensional lattice model that breaks the inversion symmetry. The quasiparticles near the Weyl nodes develop out of the Kondo effect, as do the surface states that feature Fermi arcs. This has allowed us to propose a key thermodynamic signature of the Weyl-Kondo semimetal phase, viz. the specific heat C going as T cubed with a prefactor enhanced by as much as 9 orders of magnitude compared to the expected value for weakly correlated systems. This thermodynamic signature has been realized in the recently discovered heavy fermion semimetal $Ce_3Bi_4Pd_3$ [2]. Our findings provide the much-needed theoretical foundation for the experimental search of topological conductors with strong correlations, and open up a new page for systematic studies of such quantum phases that naturally entangle multiple degrees of freedom.

K8-02. Weyl fermions in the heavy-fermion semimetal YbPtBi.
C. Guo[1], F. Wu[1], Z. Wu[1], M. Smidman[1], C. Cao[2], Y. Liu[1], F. Steglich[3] and H. Yuan[1] *1. Center for Correlated Matter, Zhejiang University, Hangzhou, China; 2. Department of Physics, Hangzhou Normal University, Hangzhou, China; 3. MPI Chemical Physics of Solids, Dresden, Germany*

Topological insulators [1] and gapless Dirac and Weyl semimetals[2-4] have been extensively studied in weakly correlated electron systems. Consequently, it is of great interest to study Weyl fermions when the electronic correlations are strong. Here, we report band structure calculations, angle resolved photoemission spectroscopy(ARPES), magnetotransport and calorimetric measurements of the canonical heavy fermion semimetal YbPtBi [5, 6], From the calculations and ARPES measurements, we find that the band structure hosts triply degenerate points, which will generate Weyl nodes in an applied magnetic field. For 20K - 170K, the chiral anomaly is detected in the magnetotransport measurements, but this contribution becomes negligible at lower temperatures when the electronic correlations become stronger. However, the topological Hall effect still provides evidence for a Berry curvature caused by the seperation of Weyl points in momentum space, and the specific heat also shows the expected signature of Weyl nodes [7]. These results suggest that YbPtBi is a Kondo Weyl semimetal, where the bands hosting Weyl points are renormalized at low temperatures due to the Kondo interaction. Our findings open up the opportunity to explore the interplay between topology and strong electronic correlations.

K8-03. Tuning spin-orbit coupling in heavy fermion systems: Discovery of the Weyl semimetal $Ce_3Bi_4Pd_3$. *S. Dzsaber*[1], L. Prochaska[1], A. Sidorenko[1], G. Eguchi[1], R. Svagera[1], M. Waas[1], A. Prokofiev[1], Q. Si[2] and S. Paschen[1,2] *1. Institute for Solid State Physics, Vienna University of Technology, Vienna, Austria; 2. Rice University, Houston, TX, United States*

Strongly correlated electron systems are a treasure trove for exotic quantum phases and fluctuations, frequently featuring new functionalities of interest for technological exploitation. This richness derives from the multiple degrees of freedom at work in these systems, and the interactions between them. Particularly versatile for discovery are settings where the balance between different interactions can be readily tipped, as is the case in the heavy fermion materials. They have shown exceptional tunability, via changing the balance between the RKKY and Kondo interaction, by the application of external parameters such as pressure or magnetic field. These can drive a given material through various anomalous magnetic, superconducting, and Kondo screened phases, as well as strange metal states. Here, we introduce a new dimension to this field: The systematic tuning of spin-orbit coupling (SOC) [1]. We realize it by substituting heavy Pt by much lighter Pd in the non-centrosymmetric Kondo insulator $Ce_3Bi_4Pt_3$. We show that the substitution series is iso-structural, iso-electronic, and iso-size, allowing for the varying SOC strength to take the dominating role in the tuning. Our thermodynamic, magnetic, and transport measurements reveal a surprising transformation from a Kondo insulator to a strongly correlated semimetal phase. Most interestingly, the correlated semimetal $Ce_3Bi_4Pd_3$ displays thermodynamic signatures of a recently predicted new phase, the Weyl-Kondo semimetal [2]: The low-temperature electronic specific heat coefficient C_{el}/T of $Ce_3Bi_4Pd_3$ is linear in T^2 – a sign of a linear electronic dispersion – with a slope that corresponds to an ultralow quasiparticle velocity (about 1/1000th of the Fermi velocity of a simple metal) [1]. Other peculiar properties of this new phase will also be discussed. We expect this new direction to stimulate further research in the vastly open field of strongly correlated topology.

K8-04. Topological bulk superconductivity of spin-3/2 carriers in a doped Luttinger semimetal. *A. Nevidomskyy*[1], B. Roy[1,2], S. Ghorashi[3,4] and M. Foster[1] *1. Physics and Astronomy, Rice University, Houston, TX, United States; 2. Max Planck Institute for Physics of Complex Systems, Dresden, Germany; 3. Physics, University of Houston, Houston, TX, United States; 4. Texas Center for Superconductivity, Houston, TX, United States*

We study topological Cooper pairing in the doped Luttinger semimetal model, which describes effective spin-3/2 carriers near a quadratic band touching and captures the low-energy properties of a number of materials, from half-Heusler compounds, to pyrochlore iridates, to grey-tin. We show that by virtue of projecting onto the Fermi surface at finite doping, local (momentum independent) electron interactions give rise to the momentum-dependent *d*-wave pairing. Of these, the complex *d*+i*d* pairings have the lowest energy and are characterized by nodal Weyl points of the Bogoliubov quasiparticles. This nodal structure results in the topologically protected Majorana surface arcs, whose signatures should be observable in anomalous thermal Hall and spin Hall conductivities. Presence of Weyl nodes in the bulk also results in the quadratic in energy density of states (DoS ~ E^2) at low energies in the clean limit, which we show transforms into linear-in-energy DoS in the presence of disorder. The latter is consistent with the *T*-linear dependence of the penetration depth in the half-Heusler YPtBi, identified as a candidate nodal topological superconductor, and we predict further experimental signatures in specific heat, thermal conductivity and NMR relaxation rate. We also consider the possibility of odd-parity, fully gapped *p*-wave superconductivity, which if realized, will manifest itself by a gapless Majorana fluid with cubic dispersion appearing at the surface. We show that disorder on such a surface drives it into a critically delocalized phase, with universal DoS and multifractal scaling consistent with a class of conformal field theories $SO(n)_v$ where v denotes the winding number and n counts replicas. Since such theories are known to be stable against the effects of interparticle interactions, our results imply that surface states enjoy robust topological protection, with quantized thermal conductivity. This is contrary to the naive expectation of a surface thermal metal, and implies that the topology tunes the surface renormalization flow to criticality in the presence of disorder.

Los Alamos National Laboratory, Los Alamos, NM, United States*

$CeIrIn_5$ hides a puzzle since its discovery in 2001(*1*). The superconducting transition of this heavy fermion metal is clearly evidenced by a textbook-like specific heat anomaly and the sharp onset of diamagnetism at T_c~400mK. At the same time, high purity single crystals systematically show a transition to a zero-resistance state at substantially higher temperatures, up to T_c*~1.2K. This discrepancy has been extensively studied in the 2000's, for example by Josephson tunneling(*2*) or systematic chemical disorder(*3*). The predominant explanations include local strain around extrinsic defects, akin to the 3K phase in Sr_2RuO_4, or intrinsic superconductivity confined to the crystal surface. We have fabricated transport devices from high purity single crystals using Focused Ion Beam (FIB) machining to investigate the nature of the resistive anomaly on the μm length scale. The normal state transport properties of the devices quantitatively reproduce the measurements on macroscopic crystals. Pronounced Shubnikov-de Haas oscillations are observed in the microstructures, and the frequencies agree quantitatively with the well-studied de Haas-van Alphen spectrum of macroscopic crystals. The superconducting state that unfolds in transport around T_c*, however, appears highly unusual. We have performed an extensive suite of experiments, including more than a dozen different structures and complementary experimental approaches. The robust experimental results suggest an intriguing type of superconductivity: The material consistently transitions to a robust, zero resistance state at temperatures around T_c*, *however only for currents along the crystallographic c-direction.* The in-plane transport, along the crystallographic a-direction, follows the typical T^2 temperature dependence of the Fermi liquid without even the slightest anomaly at T_c*. Only at significantly lower temperatures, at the T_c~400mK observed by magnetic measurements, the material fully exhibits zero resistance along all directions. We discuss possible origins of such an unusual superconductivity, including intrinsic and extrinsic mechanisms, and explore the potential for new quantum applications.

We investigate co-existing (intertwined) superconducting and magnetic orders in Nd-doped $CeCoIn_5$, which was shown by neutron scattering to exhibit two distinct spin-density-wave (SDW) phases within its superconducting state [1] (see schematics in Fig. 1b), using thermal conductivity in a rotating magnetic field. Pure $CeCoIn_5$ is an ultimate example of such interaction, where magnetic order, present in a high-field and low-temperature (HFLT) of the superconducting phase, disappears together with superconductivity at a superconducting critical field [2,3] (see Fig. 1a). Magnetism in $CeCoIn_5$, therefore, needs superconductivity for its very existence, presenting a clear-cut example of two orders that are intimately intertwined [4]. Recent thermal conductivity measurements revealed the simultaneous formation of a third intertwined order in HFLT phase, which was putatively identified as a *p*-wave pair density wave (PDW) [5] (Fig. 1). The low-field phase of Nd-doped $CeCoIn_5$ is most likely induced by impurities [6], and it is *suppressed* by magnetic field, whereas the high-field phase is *induced* by magnetic field [1]. Our measurements of thermal conductivity (see Fig. 2) show that, in spite of the vastly different origins of magnetism in these two phases, both phases possess a third order, which we identify as a superconducting *p*-wave Cooper-pair-density-wave (PDW), in addition to SDW and *d*-wave superconducting orders. There are, therefore, three intertwined orders in each of the phases. These results indicate that the appearance of the *p*-wave PDW, whenever SDW and *d*-wave orders are present, is a general phenomenon, regardless of the origin of the SDW order within the superconducting state.

The $CeMIn_5$ family (M=Co, Rh, In) are considered to be archetypal heavy fermion systems, exhibiting, among other things, unconventional superconductivity, non-Fermi-liquid behaviour, antiferromagnetism, metamagnetism and quantum criticality in closely connected phase diagrams that can be complementarily tuned by the application of magnetic field, pressure and chemical substitution. The richness of these systems, and the accessibility of the relevant parts of their phase diagrams to most of our primary experimental techniques, has provided a wealth of information about the role and consequences of strong electron correlations in metals. There are still many unanswered questions, however, particularly about the mechanism of superconductivity and the influence of various types of quantum phase transitions, to which further investigation of these materials can provide answers. I will present our study of $CeIrIn_5$, through measurements of high field magnetic torque, thermoelectric power, magnetisation and the de Haas-van Alphen effect. Features in torque and thermoelectric power, and a change in the observed de Haas-van Alphen frequencies identify a field-induced Lifshitz transition at ~ 28 T [1]. Previous work also reported features in torque and resistivity in this field range, but considered them to be associated with a metamagnetic transition [2]. Our measurements of longitudinal magnetisation show no anomaly up to 33 T, and rule out associated metamagnetism. We have very recently extended this work by performing torque and magnetic susceptibility measurements on $CeIr(In_{(1-x)}Cd_x)_5$ samples, and find that the Lifshitz transition moves to higher magnetic field with Cd-doping. We also observe superconductivity at significantly higher Cd-doping than previously reported [3]. It has been proposed, on the basis of earlier suggestions of a metamagnetic transition, that metamagnetism in $CeIrIn_5$ is evidence of a valence crossover, and that critical valence fluctuations strongly influence the low temperature behaviour in this material, including having a substantial role in the pairing mechanism for superconductivity [4]. Our results call for a re-evaluation of this discussion, and I will discuss some of the implications.

K9-04. FFLO state in $CeCu_2Si_2$ revealed by ^{63}Cu-NMR. *S. Kitagawa*[1], G. Nakamine[1], K. Ishida[1], J. Hirale[2], C. Geibel[2] and F. Steglich[2] *1. Physics, Kyoto University, Kyoto, Japan; 2. Quantum Matter, Max Planck Institute for Chemical Physics of Solids, Dresden, Germany*

The first heavy-fermion superconductor $CeCu_2Si_2$ discovered in 1979[1] was considered to be a nodal unconventional superconductor from the experiments on polycrystalline samples[2]. However, recent specific heat[3] and thermal conductivity measurements[4] on a superconductivity dominant (*S*-type) single crystal of $CeCu_2Si_2$ down to 40 mK strongly suggested that $CeCu_2Si_2$ possesses more than two full gaps, the size of which are quite different with each other. In addition, it was shown that the superconductivity of $CeCu_2Si_2$ is robust against the impurities introduced with an electron irradiation, which contradicts with the s_{+-}-wave model but consistent

with the multi-band s_{++} wave model. At present, the identification of the superconducting (SC)-gap symmetry is an important issue in $CeCu_2Si_2$. As for the parity of the superconductivity, the decrease of the Knight shift in the SC state[5] and the strong suppression of $H_{c2}(T)$ in any magnetic field direction[6] indicate a spin-singlet pairing. The strong suppression of $H_{c2}(T)$ indicates that the Pauli pair-breaking effect seems to be dominant. However, the clear first-order phase transition has not been observed, but it was suggested that the multiband character of superconductivity may suppress the first-order transition[6]. The conditions for the realization of the FFLO state seems to be satisfied in $CeCu_2Si_2$, but an experimental evidence of the FFLO state has not been reported so far. This is because experimental probes to detect the FFLO state is limited. We have performed ^{63}Cu-NMR/NQR measurements in order to investigate the magnetic and SC properties on an *S*-type single-crystal $CeCu_2Si_2$[7]. The nuclear spin-lattice relaxation rate $1/T_1$ at zero field is almost identical to that in the previous polycrystalline samples down to 130 mK and slightly deviates downward from that below 120 mK. $1/T_1$ in the SC state can be fit with the two-gap s_{+-}-wave rather than the two-gap s_{++}-wave model down to 90 mK. Under magnetic fields, we found the anomalous enhancement of $1/T_1T$ just below $H_{c2}(T)$ for magnetic field parallel or perpendicular to *c* axis. From the analogy of the results on κ-(BEDT-TTF)$_2$Cu(NCS)$_2$[8], we suggest that the FFLO phase is formed in $CeCu_2Si_2$.

K9-05. Anomalous temperature dependences of lower critical field in heavy-fermion superconductors $PrOs_4Sb_{12}$ and $CeCu_2Si_2$. J. Juraszek[1], A. Rudenko[1], L. Bochenek[1], D.G. Franco[2], S. Seiro[2,3], C. Geibel[2], M. Konczykowski[4] and *T. Cichorek*[1] *1. Institute of Low Temperature and Structure Research, Polish Academy of Sciences, Wroclaw, Poland; 2. Max-Planck-Institute for Chemical Physics of Solids, Dresden, Germany; 3. Institute for Solid State Physics, IFW, Dresden, Germany; 4. Laboratoire des Solides Irradiés, École Polytechnique, CNRS, CEA, Université Paris-Saclay, Palaiseau, France*

The filled-skutterudite compound $PrOs_4Sb_{12}$ with a cubic crystal structure is a heavy-fermion superconductor (T_c = 1.85 K) that displays several features indicative of a non-singlet superconducting order parameter [1,2]. The local magnetic induction was measured using micro Hall sensors down to T = 8 mK at which temperature the ac electrical current as small as 10 nA was injected to both reference and sample sensors. Similarly to the previous magnetization studies on a bulk sample [3], we have observed a sudden increase of the lower critical field H_{c1} below about $T/T_c = 0.35$ for several further single crystals of $PrOs_4Sb_{12}$. Note that anisotropy effects must be of minor significance because no anomaly has been detected in $H_{c1}(T)$ of the related compound $LaOs_4As_{12}$ (T_c = 3.2 K) down to $T/T_c = 0.1$. Therefore, we associate the unusual behavior of $H_{c1}(T)$ to a kink structure in the superfluid density at low temperatures due to different contributions from two (or multiple) bands [4]. Open question remains the symmetry of a minor gap in $PrOs_4Sb_{12}$, since no obvious trend to a saturation of $H_{c1}(T)$ was found in the limit $T = 0$. Motivated by the recent reports on unexpected deficiency of nodal quasi-particles [5] and fully gapped superconductivity [6] in a prototypical heavy-fermion $CeCu_2Si_2$, we used a Hall-probe magnetometer to study an "S"-type single crystal (T_c = 0.6 K) that is located near a magnetic instability but without magnetic ordering. Remarkably, we found that in- and out-of-plane $H_{c1}(T)$ dependencies show a pronounced enhancement of the lower critical field deep in superconducting state below about $T/T_c = 0.43$. We note that while this bears striking resemblance to the multiband superconductor $PrOs_4Sb_{12}$, no anomaly in $H_{c1}(T)$ down to $T/T_c = 0.15$ was found for the heavy-fermion superconductor $CeCoIn_5$ (T_c = 2.3 K) [7] with a layered crystal structure and in the vicinity of zero-temperature magnetic instability.

In this talk, I shall give an overview of the fledgling field of topological magnon materials highlighting some of the new physics that should be expected in such systems compared to their electronic cousins. The main part of the talk will show recent results on the well-known Shastry Sutherland magnet strontium copper borate (SCBO). In a theoretical study [1], it was proposed that the triplon excitations in this material - the analogue of magnons in dimerized magnets such as this - may carry nonzero Chern number and may be field-tuned through a topological transition. I shall present inelastic neutron scattering data on SCBO taken on the LET spectrometer at ISIS neutron and muon source that reveals, in considerable detail, the evolution of the triplon modes in small magnetic fields. The data contains, in addition, a new low-lying mode that is interpreted as a bound state of triplons. By treating the interactions between the triplons theoretically it is possible to provide a thorough quantitative picture of the experimental findings from which one can conclude that SCBO is an example of a topological magnon insulator. I shall finish with some words on developments since the completion of this work and an outlook.

Department of Applied Physics, Tohoku University, Sendai, Japan*

$SrCu_2(BO_3)_2$, which shows multi-step magnetization plateaus at low temperature, has attracted much attention since the discovery by Kageyama *et al*. [1]. It is a unique 2 dimensional orthogonal dimer antiferromagnet with the singlet ground state and a spin gap, and Miyahara *et al.* suggested that it is equivalent to the Shastry-Sutherland Model [2]. Moreover, as the ratio α=J'/J, where J' and J are inter-dimer and intra-dimer exchange interactions, respectively, is 0.64 for $SrCu_2(BO_3)_2$ at the ambient pressure and it is close to the critical ratio α_{c1}=0.677 between the dimer and the plaquette phases suggested by the theory [3], various pressure measurements have been performed to find the pressure induced phase transition [4-6]. However, the experimental results are still controversial because it is difficult for the conventional magnetic measurements to distinguish the dimer and the plaquette phases, which have non-magnetic ground states. Therefore, we have developed a new hybrid-type pressure cell for our high-pressure THz ESR, which enables to study the first excited states, and extended our pressure from 1 GPa [6] to 2.5 GPa [7] and applied to $SrCu_2(BO_3)_2$ single crystal. As THz ESR at 2 K can observe the spin gap between the ground and the first excited states directly due to the existence of the Dzyaloshinski–Moriya interaction, we have clearly shown that the spin gap still exists at 2 GPa [8]. This is in contrary to the previous suggestion that the spin gap disappears at 2GPa by the X-ray measurement under high pressure [4]. Moreover, our results suggest that the pressure induced quantum phase transition is the first-order transition because the pressure dependence of the spin gap suddenly change at 1.85 GPa [8]. By comparing our pressure dependence THz ESR results with the calculated excitation energies obtained from an exact diagonalization, we determined the precise pressure dependence for inter- (J') and intra-dimer (J) exchange interactions considering the Dzyaloshinski–Moriya interaction. Thus this system undergoes a first-order quantum phase transition from the dimer singlet phase to a plaquette singlet phase above the ratio $(J'/J)c = 0.660 \pm 0.003$ [8].

The spin-dimer antiferromagnet $SrCu_2(BO_3)_2$ was investigated in great detail over the past two decades, as it represents the most prominent realization of the Shastry-Sutherland lattice model [1]. In this material, electronic spins of Cu^{2+} ions within the $Cu_2(BO_3)_2$ layers form a lattice of mutually orthogonal spin-singlet dimers with significant interdimer interaction, giving rise to pronounced magnetic frustration. At high magnetic fields, triplet states with reduced kinetic energy condense, resulting in a field-driven sequence of magnetic superlattices with corresponding plateaus of the macroscopic magnetization [2]. For the exploration of these superlattice structures up to the present static-field limit of about 45 T, nuclear magnetic resonance (NMR) spectroscopy as a local probe technique has provided invaluable microscopic information [3]. To access the full sequence of plateaus up to 1/2 of the saturated magnetization, fields in excess of about 84 T are needed. With the technical advances achieved during the past decade in dedicated user facilities, these fields are nowadays available by non-destructive, pulsed techniques. We will discuss recent developments of NMR spectroscopy performed in these ultrahigh magnetic fields and, specifically, present new pulsed-field NMR data of $SrCu_2(BO_3)_2$ [4,5].

K10-04. Spin-Orbit Dimers and Non-Collinear Phases in d^1 Cubic Double Perovskites. *J. Romhanyi*[1], L. Balents[2] and G. Jackeli[3,4] *1. Theory of Quantum Matter Unit, Okinawa Institute of Science and Technology, Onna-son, Japan; 2. University of California, Santa Barbara, Santa Barbara, CA, United States; 3. Max Planck Institute for Solid State Research, Stuttgart, Germany; 4. Institute for Functional Matter and Quantum Technologies, University of Stuttgart, Stuttgart, Germany*

Novel quantum phases of matter arising in heavy transition metal compounds due to the strong relativistic spin-orbit coupling have attracted a lot of interest recently. Current experiments on the molybdenum [1-3] and osmium [4-6] based double perovskites, suggest that unusual ordered and disorder quantum states are hosted by these materials. We formulate and study a microscopic spin-orbital model for a family of cubic double perovskites with d^1 ions occupying frustrated fcc sublattice. Relying on variational approaches and a complimentary analytical analysis, we find a rich variety of phases, emerging from the interplay of Hund's coupling and spin-orbit interaction. The phase digram contains non-collinear ordered states, with or without net moments, and, remarkably, a large window of magnetically disordered spin-orbit dimer phase [7]. We discuss the physical origin of the unusual amorphous valence bond state experimentally suggested for Ba_2BMoO_6 (B=Y,Lu), and predict possible ordered patterns in Ba_2BOsO_6 (B=Na,Li) compounds. Additionally, we provide a theoretical background for the available experimental observation in these materials [7]. The proposed physical picture applies to a broad family of heavy transition metal compounds and helps uncovering the origins of magnetism in spin-orbit assisted Mott insulators.

L1-01. Size effects on magnetic property and crystal structure of Mn_3O_4 nanoparticles in mesoporous silica. *T. Tajiri*[1], K. Sakai[2], H. Deguchi[2], M. Mito[2] and A. Kohno[1] *1. Faculty of Science, Fukuoka University, Fukuoka, Japan; 2. Graduate School of Engineering, Kyushu Institute of Technology, Kitakyushu, Japan*

Spinel oxide Mn_3O_4 has geometrical frustration derived from the antiferromagnetic interactions between the B sites of spinel oxide. Mn_3O_4 exhibits interesting phenomena such as magnetodielectric, magnetoelastic and magnetocaloric behaviors, and successive phase transformation owing to the strong coupling among spin, orbital and lattice degrees of freedom. As temperature decreases, the magnetic phase for Mn_3O_4 bulk crystal changes from paramagnetic phase to Yafet-Kittel phase at T_N = 42 K, successively to an incommensurate phase at T_1 = 40 K, and finally to a commensurate phase at T_2 = 34 K. The magnetic properties for the Mn_3O_4 nanoparticles are expected to be different from those for bulk crystal owing to the modulation of magnetic frustration and lattice distortion in the nanoparticles. We investigated both the magnetic property and crystal structure for the Mn_3O_4 nanoparticles with particle size of 7-25 nm systematically. The Mn_3O_4 nanoparticles were synthesized in pores of mesoporous silica. Powder X-ray diffraction patterns for the nanoparticles corresponded to the same tetragonal symmetry as bulk crystals at room temperature. As particle size decreases down to 11 nm, the lattice constant *a* was almost constant value, whereas the lattice constant *c* decreased. Below 11 nm, both *a* and *c* increased monotonically with decreasing particle size. Temperature dependences of the DC susceptibility for the nanoparticles indicated existence of the three transition temperature, T_N, T_1, and T_2, which depended on the particle size. The magnetic transition temperatures exhibited rapid reduction below 11 nm. There was no clear distinction between T_1 and T_2 below 8 nm, which suggests the disappearance of the incommensurate or commensurate phase for nanoparticles below 8 nm. The coercive field obtained from the magnetization curves decreased rapidly below 11 nm, while it retained an almost constant value above 12 nm. These experimental results indicate the existence of strong correlation between magnetic property and crystal structure, and the changes in the magnetic properties and magnetic phase diagram for the nanoparticles are attributed to the modulation of the crystallographic structure.

L1-02. Probing the Variability in Oxidation States of Magnetite Nanoparticles by Single-particle Spectroscopy. *A. Fraile Rodríguez*[1,2], C. Moya[1,2], M. Escoda-Torroella[1,2], A. Romero[1,2], A. Labarta[1,2] and X. Batlle[1,2] *1. Física Matèria Condensada, Universitat de Barcelona, Barcelona, Spain; 2. Institut de Nanociència i Nanotecnologia (IN2UB), Universitat de Barcelona, Barcelona, Spain*

Magnetite (Fe_3O_4) nanoparticles (NP) are versatile building blocks in many applications due to their good magnetic performance, ease of production and functionalization by chemical routes, and low toxicity [1,2]. However, controlling the electronic and magnetic properties of iron oxide NP remains a challenge because of their crucial dependence on composition, structure, surface chemistry, and interparticle interactions. The difficulty to disentangle all of these factors limits the ability to quantify their actual effects on the functional response of the NP. In this work, we address this issue by studying with single-particle sensitivity the electronic and chemical properties of size- and shape-selected Fe_3O_4 nanoparticles by means of X-ray photoemission electron microscopy. The local X-ray absorption spectra reveal that the oxidation states and cation distribution of the individual NP may show a striking local variability even when the average structural and magnetic parameters of monodisperse ensembles appear homogeneous and size-and sample-independent. Our results show the key role of the oleic acid concentration during the synthesis reaction on the formation and distribution of the Fe phases within the individual NP. When the concentration of oleic acid is high enough, the NP are composed of a Fe_3O_4 core surrounded by a thin oxidized shell of γ-Fe_2O_3. In contrast, at low concentration, the NP are inhomogeneous with small inclusions of FeO and Fe phases due to the uncontrolled reduction of Fe^{3+} [3]. This work highlights that a deeper knowledge of the formation pathways, phase coexistence and surface chemistry of magnetic nanoparticles is still required to improve the understanding over electronic and magnetic phenomena at the nanoscale. This work was supported by Spanish MINECO (MAT201568772-P and PhD contract BES-2016-077527), Catalan DURSI (2014SGR220) and EU-FEDER funds.

An overwhelming amount of research on magnetic nanoparticles (MNPs) is focused on *Fe-oxides* mainly due to their promising biomedical applications [1]. By contrast, research on *4f-based* metallic nanoparticles is a surprisingly missing gap by the scientific community. In this sense, those nanoparticle systems offer advantages which are overlooked: possibility of controlling the magnetic structure within the core by modification of the *RKKY* interactions, stability of the selected crystallographic structure at the nanoscale, high moment and its easy variation by including amount of *Y, La*, and study of crystal field excitations (CEF) [2]. We have carried out a comprehensive work by selecting well-known bulk (binary) *4f-alloys* and reducing the particle size to the nanometric scale (8±1 nm). This process is guaranteed by the high-energy (*CW* containers and balls) inert-atmosphere (*Ar*) milling process, which provides huge quantities (up to 14 g) of nanometric alloys (difficult by other conventional routes) with a reasonable size distribution [3]. Lately we have been investigating $TbCu_2$ with a superantiferromagnetic behavior, with a Néel temperature T_N = 43 K and a freezing temperature of *Tf* = 17 K, as detected by DC-magnetization and AC-susceptibility. The alloy presents a metamagnetic behavior which is still visible in nanometric state and a high magnetic anisotropy which prevents the observation of saturation in *M(H = 8 T)* curves [4]. In this contribution we offer unique results by small-angle neutron scattering (SANS) and inelastic neutron scattering (INS). In SANS we observe a magnetic peak around q = 1.14 $Å^{-1}$ corresponding to nanometric correlations of the magnetic moments. This peak is visible below T_N and disappears at *Tf*. The INS neutron spectra show a complicate CEF scheme with the presence of peaks (E = -4.5 meV), which are broadened in the nanometric state (see Fig. 1). This has been evaluated for the first time in MNPs.

L1-04. Magnetic states of nanostructures containing Ni^{2+} ions at the surface of SiO_2 nanospheres. *P. Tiberto*[1], G. Barrera[1], G. Alberto[2], G. Martra[2] and P. Allia[3] *1. INRIM, Torino, Italy; 2. Chemistry, Università di Torino, Torino, Italy; 3. DISAT, Politecnico di Torino, Torino, Italy*

In recent years, magnetism has been greatly influenced in his foundations and applications by the advent of ultra-small magnetic particles prepared by efficient techniques. In this work, ultra-small magnetic particles containing Ni^{2+} ions were grown at the surface of SiO_2 spheroidal nanoparticles (typical diameter: 50 nm) starting from $NiCl_2$ solutions. Depending on preparation details, two samples characterized by magnetic sub-nanostructures or lamellar sub-nanoparticles (Fig. 1) at the SiO_2 nanosphere surface were obtained. The decorated SiO_2 nanospheres were submitted to physico-chemical characterization at room temperature and to magnetic characterization from 2 to 300 K. These systems provide the opportunity to get a comprehensive picture of the transition from quantum to classical magnetic regime when the temperature is increased. In both samples, a magnetically blocked phase is observed at low temperature. Below 5 K, discontinuities in isothermal magnetization loops (Fig. 2, left panel) and magnetic relaxation effects (Fig. 2, right panel) suggest the onset of coherent quantum tunneling of nanoparticle magnetization (QTM) [1,2]. Relaxation effects are described by a field- and temperature-dependent magnetic viscosity $S_V(H,T)$; the total spin number of magnetic units is estimated by fitting the isothermal $S_V(H)$ curve to a model for an assembly of particles with random anisotropy axes [3]. Phonon-assisted QTM plays an increasingly important role with raising temperature and the quantum regime gradually merges with the classical behavior. Above the blocking temperature the magnetic units behave as classical superparamagnetic particles. At higher temperature, when the intra-particle ferromagnetic order disappears, the Ni^{2+} ions respond individually to the magnetic field.

L1-05. Probing Core and Shell Contributions to Exchange Bias in Co/Co_3O_4 Nanoparticles of Controlled Size. D. De[4,3], *O. Iglesias*[1,2], S. Majumdar[3] and S. Giri[3] *1. Dpt. Condensed Matter Physics, University of Barcelona, Barcelona, Spain; 2. Institut de Nanociència i Nanotecnologia UB, Barcelona, Spain; 3. Solid State Physics, Indian Association for the Cultivation of Science, Kolkata, India; 4. Physics Dept., Neotia University, Neotia, India*

Coupling at the interface of core/shell magnetic nanoparticles is known to be responsible for exchange bias (EB) and the relative sizes of core and shell components are supposed to influence the associated phenomenology [1,2]. In this work [3], we have prepared core/shell structured nanoparticles with a total average diameter around ~27 nm and a wide range of shell thicknesses through the controlled oxidation of Co nanoparticles well dispersed in an amorphous silica host. Structural characterizations give compelling evidence of the formation of Co_3O_4 crystallite phase at the shells surrounding the Co core. Field cooled hysteresis loops display nonmonotonous dependence of the exchange bias H_E and coercive H_C fields, that become maximum for a sample with an intermediate shell thickness, at which lattice strain is also maximum for both phases. The EB effects persist up to temperatures above the ordering temperature of the oxide shell. Results of our atomistic Monte Carlo simulations [4] of particles with the same size and composition as in experiments are in agreement with the experimental observations and have allowed us to identify a change in the contribution of the interfacial surface spins to the magnetization reversal, giving rise to the observed maximum in H_E and H_C. (*Work supported by Spanish MINECO (MAT2015-68772-P), Catalan DURSI (2014SGR220) and EU FEDER funds (Una manera de hacer Europa) also CSUC for supercomputer facilities.)*

L1-06. Magnetic Properties of Aerosol $Fe_{87.5}Cr_{12.5}$ Ferrite Nanoparticles Generated by Spark Discharge. *C.E. Bulbucan*[1], C. Preger[2], A. Virdian[1], M.E. Messing[2] and R. Westerström[1] *1. Synchrotron Research Division, Lund University, Lund, Sweden; 2. Solid State Physics, Lund University, Lund, Sweden*

Here we present a structural and magnetic characterization of aerosol $Fe_{87.5}Cr_{12.5}$ ferrite nanoparticles. The particles were produced by a spark discharge generator (SDG) [1] with the capability of producing particles with a narrow size distribution (<10%) and good control of the surface coverage. High-Resolution Transmission Electron Microscopy (HRTEM) reveals similar lattice parameters as magnetite spinel structure (Fe_3O_4) and Pair Distribution Function (PDF) measurements point in the same direction. XPS studies indicate the presence of a mixture of maghemite Fe_2O_3, magnetite Fe_3O_4 and Cr_2O_3. Furthermore, TEM analysis shows homogeneously mixed particles with the 87.5 to 12.5 Fe-Cr ratio. Magnetic properties of different coverages and particle sizes were studied by the use of SQUID magnetometry. The low coverage systems (with 3% coverage) of 10 nm particles exhibit SPM behaviour with a blocking temperature T_B=58K (see Fig. 1) and no coercivity present at room temperature (i.e. above T_B). 'Medium' coverage samples account for a mixture of SPM and super spin glass (SSG) behaviour. In the case of high coverage systems with cluster formation, inter-particle interactions seem to govern the samples' magnetic response. At a particle size of 30 nm, hysteresis is still detected at temperatures up to 400 K (see Fig. 2).

L1-07. NiO nanoparticles for diluted magnetic semiconductor by co-doping of transition metal ions. *Y. Ichiyanagi*[1,2], K. Fujiwara[1], T. Oka[1], T. Ide[1], A. Oshima[1], T. Hashimoto[1], D. Aihara[1] and K. Kanda[1]
1. Department of Physics, Yokohama National University, Yokohama, Japan; 2. Osaka University, Osaka, Japan

Diluted magnetic semiconductors (DMSs) are attracting attention because of their potential application to spintronics devices, and oxide semiconductors have been extensively studied recently. In this study, Ti ion and transition metal ions such as Fe, Mn, Co do-doped NiO nanoparticles were synthesized in order to improve both electrical conductivity and magnetization value. $Ni_{0.965}Ti_{0.01}M_{0.025}O$ (M = Ti, Co, Mn, Fe) nanoparticles were nanoparticles about 4 nm in size are produced by our original wet chemical method. Single phase NaCl structure in amorphous SiO_2 was confirmed by X-ray diffraction patterns. The magnetization curves for all the co-doped nanoparticles indicated ferromagnetic behavior with slight hysteresis at 5 K. Magnetization values were increased compared with pure NiO nanoparticles. Blocking temperature T_B increased from T_B = 38 K to 48 K by Ti ion doping, and electrical conductivity increased in $Ni_{0.965}Ti_{0.035}O$ sample. The local structures were qualitatively analyzed by XAFS measurements, and no metal oxide impurities were confirmed in obtained samples. Electronic states of these samples were also clarified by X-ray absorption near edge structure analysis.

L1-08. Enhanced thermal stability and magnetic properties in Ni substituted MnZn-Ferrite nanoparticles. *M. Shanigaram*[1], P. Mondal[1], K. Srikanti[2] and V. Srinivas[3] *1. Physics, Indian Institute of Technology, Madras, Chennai, India; 2. Centre for Automotive Energy Materials, ARCI, Chennai, India; 3. Department of Physics, Indian Institute of Technology Madras, Chennai, India*

As prepared (*AP*) MnZn ferrite (MZF) nanoparticles (NPs) are generally annealed at moderate temperatures, to curtail the grain growth and to minimize the strain/ disorder effects on physical properties. However, annealing at moderate temperatures (~600°C) in air results in development of impurity phases (a-Fe_2O_3) in MZF, which leads to the deterioration of magnetic properties [1, 2]. Although Mn triggers the evolution of impurity phase it's presence in MZF enhances soft magnetic behavior. On the other hand, no impurity phase appears in $NiFe_2O_4$ under similar conditions and exhibits superior magnetic properties at higher frequencies. Therefore Ni substituted in MZF ($Mn_{0.6-x}Zn_{0.4}Ni_xFe_2O_4$ (x=0-0.6)) has been investigated in the present study to (i) minimize secondary phase (ii) enhance magnetic properties of MZF. The *AP* Ni-MZF NPs exhibit essentially single spinel phase. However, impurity phase (a-Fe_2O_3) appeared along with ferrite phase when annealed at 600 °C in air. The fraction of impurity phase appear to be weaker compared to that observed in the case of MZF series. On the other hand x=0.4 composition identified to be single phase with indiscernible impurity phases in XRD patterns (Fig. 1). Fig. 2 a lower magnetization (M) (41.5 emu/g) is observed in *AP* sample compared to the 1200 °C (73 emu/g) annealed sample, which can be attributed to the presence of high strain and disorder in *AP* particles for x=0.4. The 600 °C air annealed samples exhibits higher magnetization (50 emu/g) compared to MZF (3 emu/g) and Zn replaced Ni-MZF (28 emu/g) samples. Interestingly, the volume fraction of ferrite phase increases with annealing temperature (700 °C to 1200 °C). This in turn increases the M (60-73) values approaching the bulk value [3]. Structural and magnetic data corroborate well and suggest that by controlling the impurity phases in MZF by choosing suitable composition and annealing temperature one can achieve superior magnetic properties. A detailed analysis of structural and the magnetic data will be presented.

L1-09. Thermal stability and magnetic properties of Ni-nanoparticles prepared by chemical reduction methods. *S. Vishvakarma*[1] and V. Srinivas[1] *1. Department of Physics, Indian Institute of Technology Madras, Chennai, India*

Study of magnetic nanoparticles (NPs) has been the subject of recent interest owing to their potential applications. It is well known that the structural and magnetic properties are sensitive to the synthesis process conditions. It was suggested that residual impurities may appear when reducing agent like $NaBH_4$ is used, while Ni particles with fewer impurities may be synthesized using polyols but the product particle size tends to be large due to weaker reducing ability of polyols. A modified polyol method has been adopted to synthesize Ni NPs [1, 2]. Therefore, in the present study we report on thermal stability and magnetic properties of Ni NPs prepared by two different methods viz. $NaBH_4$ reduction (S1) and polyol (S2) methods. Fine particles of Ni were synthesized with $NiCl_2.6H_2O$, NaOH and $NaBH_4$ as precursors. The X-ray diffraction patterns of as-prepared sample synthesized by S1, S2 methods show the FCC reflections without any impurity (Fig.1). While NiO peaks are observed in air annealed sample (at 600^0C for 1 hour) synthesized by Polyol, which are absent in air annealed sample synthesized by S1 method. The saturation magnetization (M_S) of as prepared samples is low and could be attributed to strain and disorder(Fig.2), while samples annealed in Argon atmosphere show enhancement in M_S values. Interestingly samples prepared with $NaBH_4$ reduction method and annealed in Argon atmosphere show higher M_S values. On the other hand air annealed S2 sample showed superparamagnetic nature at room temperature while S1 sample remained in ferromagnetic state. Therefore, comparison of these results suggest that Ni particles prepared by $NaBH_4$ reduction method appear to be thermally stable and exhibit superior magnetic properties compared to the samples prepared by polyol method. These contrasting results will be discussed in details along with microstructure and a structural model will be proposed to explain the magnetic anomalies observed.

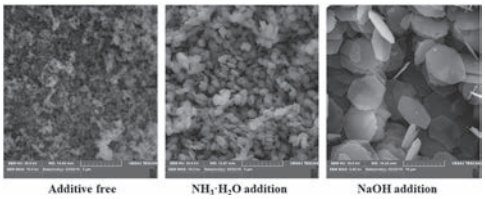
L1-10. Synthesis of Giant Single-Crystal Hematite Hexagonal Nanoplates : Elaborate Analysis of Microstructure, Size and Static Magnetic Properties. *F. Chen*[1], J. Liu[1], H. Luo[1], X. Wang[1], Y. Nie[1], Z. Feng[1], R. Gong[1] and Z. Zhang[2] *1. School of Optical and Electric Information, Huazhong University of Science & Technology, Wuhan, China; 2. School of Optical and Electronic Information, Wuhan, China*



Iron oxide polymorphs (α-Fe_2O_3,β-Fe_2O_3, γ-Fe_2O_3 and ε-Fe_2O_3) have attracted a great deal of interest for both their unique physical properties as well as their potential as enabling materials in such applications as memory devices, photocatalysts, supercapacitors, and biomedical materials [1]. It is well demonstrated that the properties of iron oxide nanoparticles rely greatly on not only the chemical components and crystal structure, but also the morphology, inherent anisotropy and surface activity. Among various the iron oxide polymorphs, the investigation of magnetic properties in α-Fe_2O_3 nanoparticles is of great importance due to the morphology-dependent Morin, Neel and blocking temperature [2]. In this work, giant single crystal α-Fe_2O_3 hexagonal nanoplates have been produced. We focus on the influences of reaction conditions and additives on the morphology, and the relations between the morphology and static magnetic properties in

α-Fe_2O_3. The giant hexagonal nanoplates have been produced by one-pot hydrothermal method. Iron trichloride, ethanol and potassium acetate were used as starting materials without further purification. Particularly, sodium hydroxide and ammonium hydroxide, as PH and hydrolysis control agent, were also added in part of samples. All of the samples present a single phase rhombohedral structure of the R-3c space group (Shown in Fig. 1). It can be found that all the nanoparticles show typical hexagonal flaky shapes due to the confine of the <0001> direction caused by CH_3COO^- (Shown in Fig. 2). Furthermore, the diameters of the nanoplates significantly increase due to the addition of $NH_3{*}H_2O$ and NaOH. It can be inferred that the addition of NaOH, which is a strong basic electrolyte, can inhibit the hydrolysis of CH_3COO^-, so that more acetate anions can further confine the growth along the <0001> direction and promote that along the ab-plane. Magnet hysteresis loops of all the samples were measured, indicating the existence of weak-ferromagnetic property at room temperature and a distinct increase of coercivity caused by the significant expansion of specific surface area which will lead to the enhancement of shape anisotropy.

Magnetotactic bacteria are microorganisms able to align in and navigate along the geomagnetic field thanks to the presence of a chain of magnetic nanoparticles, called magnetosomes. The high control imposed in their synthesis bestows exceptional properties on magnetosomes compared to artificially synthesized counterparts, being good candidates for biomedical applications[1]. Aiming to further increase their potential applications, different authors have focused on modifying the main properties of magnetosomes by doping them with new elements[2-4]. Among them, Co-doping stands out leading to drastic changes in the magnetic response even at low contents. In this work, we provide experimental and theoretical findings concerning the role of Co in the magnetic properties of magnetosome chains synthesized by the bacterium *Magnetospirillum gryphiswaldense,* which mineralize 45 nm sized cubo-octahedral magnetite (Fe_3O_4) magnetosomes[5]. Growing this microorganism in a Co-rich medium, Co-doped magnetite is obtained. By means of Transmission Electron Microscopy (TEM), Energy-Dispersive X-ray Spectroscopy (EDS), X-ray Absorption Near Edge Structure (XANES) and X-ray Magnetic Circular Dichroism (XMCD), we evidenced the incorporation of Co2+ (1%) in substitution of Fe2+ in octahedral sites. DC magnetic measurements reveal strong changes in coercivity and remanence. The hysteresis loops have been modelled with a modified Stoner-Wohlfarth approach in which the anisotropy energy is given by the sum of the cubic magnetocrystalline contribution and a uniaxial contribution resulting from the competition between the particle shape anisotropy and the magnetic interactions between nearest neighbors in the chain. Fig. 1 shows the thermal evolution of the anisotropy constants for both anisotropy contributions, for undoped and Co-doped magnetosomes. In contrast to undoped magnetosomes, whose effective anisotropy is uniaxial from 300 to 5 K, the effective anisotropy of Co-doped magnetosomes changes notably with temperature. It varies from uniaxial from 300 to 150 K, through biaxial down to 100 K, to triaxial below 100 K.

Magnetosprillum gryphiswaldense bacteria (MSR-1) synthesize cubo-octahedral shaped magnetite (Fe_3O_4) nanoparticles, called magnetosomes, with a mean size of 45 nm-diameter with potential applications in different areas and especially in biomedicine [1-2]. In order to further expand the range of applications of magnetosomes, in the last few years different research groups have focused on modifying their magnetic properties by doping them with 3d transition metals such as Co or Mn [3-5]. Magnetite presents an inverse spinel structure essentially composed of Fe^{2+} ions in octahedral sites and Fe^{3+} ions split between octahedral and tetrahedral positions. Thus, the physical and magnetic properties of doped-magnetosomes depend on the cation valences and cation distribution of the dopant element among the octahedral and tetrahedral places of the magnetite spinel structure. X-ray magnetic circular dichroism (XMCD) is a powerful element-specific and magnetic sensitive technique which provides valuable structural and magnetic information. In this work we present XMCD spectra and element-specific hysteresis loops carried out at Fe and Mn/Co L_3 absorption edges in Mn and Co-doped magnetosomes, respectively (Fig.1). XMCD evidences the incorporation of both elements within the spinel structure. In Mn-doped magnetosomes, Mn occupies tetrahedral position of Fe^{3+} and shows a divalent oxidation (Mn^{2+}). Both Fe and Mn hysteresis loops look alike highlighting a perfect coupling (Fig.1a). On the contrary, Co-doped magnetosomes, also in a divalent Co^{2+} state, preferentially occupies Fe^{3+} octahedral sites. The presence of Co^{2+} within the magnetosome structure leads to a notably increase of the coercive field. The difference between hysteresis loops at Fe and Co absorption edges probably points an inhomogenous distribution of the Co^{2+} within the magnetome (Fig.1b).

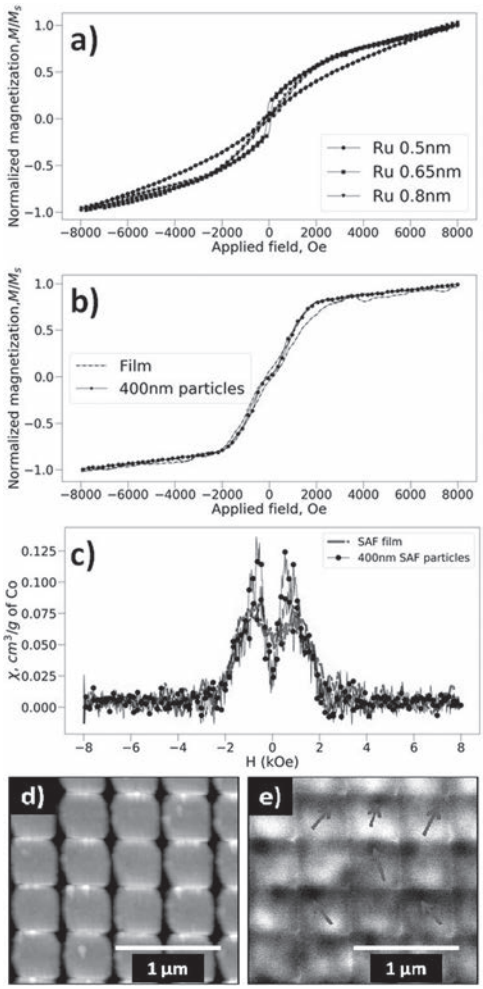
L1-13. Investigation of the optical and magnetic properties of $Bi_xBa_{1-x}fe_{12}O_{19}$ nano composites. *H.M. Basma*[1], H. Rahal[1], M. Mansour[1] and R. Awad[1] *1. Physics, Beirut Arab University, Debbiyeh, Lebanon*

$Bi_xBa_{1-x}fe_{12}O_{19}$ nano composites with $0 \le x \le 0.2$ wt. % were prepared by chemical co-precipitation method. The structure and morphology of the samples was revealed using powder X-ray diffraction (XRD) and transmission electron microscope (TEM). The optical properties of the prepared samples were investigated using room temperature Fourier transform infra-red spectroscopy (FT-IR), ultraviolet-visible (UV-Vis) absorption spectroscopy and Raman spectroscopy. The lattice parameters, crystalline size, functional group of chemical bonds and energy band gap were evaluated and discussed as a function of the content x. Furthermore, room temperature magnetic hysteresis (M-H) allowed the calculation of several magnetic parameters including the saturation magnetization (M_s), the coercivity (H_c), the retentivity (M_r), the anisotropy constant (K_a) and the magnetic moment (μ_m). The variation of these parameters as a function of the content x was also discussed.



L1-14. High Magnetic Moment Metal-Polymer Nanoparticles with Superparamagnetic-Like Characteristics. *I. Nekrashevich*[1], D. Litvinov[1] and L. Chang[2] *1. Materials Engineering, University of Houston, Houston, TX, United States; 2. Electrical and Computer Engineering, University of Houston, Houston, TX, United States*

A high-throughput top-down nanomanufabrucing approach for making metal-polymer nanoparticles with tunable magnetic properties using nanoimprint lithography is reported and magnetic properties characterized. The nanoparticles comprise of a layered structures that includes a Co/Ru/Co synthetic antiferromagnet (SAF) and a polymethyl methacrylate (PMMA) or a hydrogen silsesquioxane (HSQ) layer. The Co/Ru/Co structure deposited by magnetron sputtering was tuned to achieve antiferromagnetic coupling between Co layers, desired magnetic susceptibility, and saturation magnetization. Ultra-high density positive tone thermal nanoimprint lithography molds designed to maximize the depth and minimize the thickness of imprint trenches in nanoimprint resist (PMMA or HSQ) were fabricated. The molds were used to pattern large arrays of 200 nm x 200 nm, 400 nm x 400 nm, and 600 nm x 600 nm SAF nanostructures with superparamagnetic-like magnetic characteristics. The nanostructures were released from the wafers into an aqueous suspensions using by dissolving the sacrificial underlayers, Cu for SAF/PMMA nanoparticles and PMMA for SAF/HSQ nanoparticles. Highly tailorable control of the magnetic properties of SAF multilayers incorporated into the nanoparticles enables superparamagnetic-like behavior with high volume susceptibility, zero remanence, and high saturation magnetization. The polymer layer incorporated into the design was selected for the ease of fabrication, but also to enable Janus nanoparticle design.

The specific absorption rate (SAR) value, defined as the power transformed into heat per unit of mass of MNPs, is one of the most relevant parameters in magnetic hyperthermia experiments. In general, calorimetric methods are used to measure *SAR* of samples with magnetic nanoparticles, even though there are many factors that can affect the value of SAR measured in this way [1]. Alternatively, *SAR* can also be measured by AC magnetometry [2]. In this technique, *SAR* is directly obtained from the area of the AC hysteresis loop of the samples when they are excited by an AC magnetic field. This hysteresis loop area is directly related with the dynamic magnetization of the MNPs, information that calorimetry technique do not provide. In this work, we present a home-made electromagnetic applicator which incorporates an AC magnetometer. The electromagnetic applicator is based on a variable parallel LCC resonant circuit fed by a linear power amplifier that generates homogeneous magnetic fields up to 40 $kA.m^{-1}$ in a frequency range between 100 kHz-1MHz. The AC magnetometer consists in two oppositely wounded pick up coils and it is integrated in the electromagnetic applicator as shown in figure 1 [3]. The usefulness of the technique can be seen in our study on the evolution of *SAR* of iron oxide cubic nanoparticles as function of their size, α, when it is between 10-100 nm. Calorimetric methods indicate a sudden increase in the *SAR* values when α is around 30 nm, but cannot explain the reason behind it. The AC magnetometry measurements performed with our device show a sudden change in the shape of the hysteresis loops when α is close to 30nm (figure2). It has been demonstrated by TEM images that these shape-change is related with chain-like arrangements of nanocubes at this size [4]. Therefore, we prove that our system provides more information than calorimetric methods by explaining the increase of *SAR* in this type of experiments.

L2-01. The correlation between magnetic dead layer and perpendicular magnetic anisotropy in MgO/CoFeB/Ta top structure. S.H. Shen[1], *D.S. Lee*[2], C.W. Cheng[1], W.J. Chan[1] and G. Chern[1] *1. Physics Department, National Chung Cheng University, Chia-Yi, Taiwan; 2. Electrical Engineering Department, Da-Yeh University, Changhua, Taiwan*

MgO based CoFeB structure is one of the typical layered structures with strong perpendicular magnetic anisotropy (PMA). However, the physical properties depend critically upon the sequence of the metal protection layer and the top structure is especially sensitive to the thickness of the meal layer. In this report the cap layer effect on PMA in top structures of Si(substrate)/MgO/CoFeB (1- 1.7 nm)/Ta (1-5 nm) is systematically investigated. An inverse correlation between the interface anisotropy constant (Ki) and the thickness of magnetic dead layer (MDL) is identified. The Ki decreases from 2.2 to 1.4 erg/cm^2 while MDL increases from 0.1 to 0.6 nm, both showing a nonlinear dependence upon the Ta thickness with an abrupt change at Ta ~ 1.5 nm. These observations indicate that the cap layer effect on both PMA and MDL originates from the chemical deterioration at MgO/CoFeB and CoFeB/Ta interfaces by Ta diffusion.

L2-02. Effects of MgO Sputtering Power and Thermal Annealing on Perpendicular Magnetic Anisotropy Properties of Pt/Co/MgO Trilayers. *H. Gweon*[1] and S. Lim[1] *1. Materials Science and Engineering, Korea University, Seoul, The Republic of Korea*

The perpendicular magnetic anisotropy (PMA) properties of Pt/Co/MgO trilayers are investigated as a function of the MgO sputtering power (P_{MgO}) and its thickness (t_{MgO}), both of which are important parameters affecting the degree of oxygen interpenetration into the underlying Co layer during sputtering. A strong PMA is achieved at small values of P_{MgO} and t_{MgO}, where the oxygen interpenetration into Co is expected to be small. The results for the PMA and saturation magnetization indicate that the range of oxygen interpenetration is quite extended in such a way that it affects the Pt/Co interface as well as the Co/MgO one.[1] The PMA properties of as-deposited samples are improved by post-annealing for temperatures (T_a) up to 400°C examined in this study, presumably due to the diffusion of the interpenetrated oxygen atoms toward the Co/MgO interface. A very large PMA energy density (K_{eff}) of 1.99 × 10^7 erg/cm^3 is achieved in a structure of Pt/Co (0.6 nm)/MgO (2 nm), which is deposited under P_{MgO} = 1.10 W/cm^2 and then annealed at 400°C. In Pt/Co/MgO trilayers, the contribution to the total PMA from the bottom Pt/Co interface is significantly greater than that from the top Co/MgO interface at intermediate T_a. However, the relative contribution is reversed at the highest T_a examined in this study, 400°C. These results shown in Fig. 1 indicate that as the T_a increases, the quality of the Pt/Co interface deteriorates owing to the intermixing of Pt and Co, whereas the quality of the Co/MgO interface improves as oxygen atoms are diffused toward the Co/MgO interface.[2] This research was supported by the Creative Materials Discovery Program through the National Research Foundation of Korea (No. 2015M3D1A1070465)

(Here, t_{Co}^{eff} indicates the effective Co thickness) (c) Results for interfacial PMA energy per area (K_i) as a function of T_a for stacks of Pt/Co/MgO at P_{MgO} = 4.39 W/cm^2 (circles), Pt/Co/MgO at P_{MgO} = 1.10 W/cm^2 (squares), and Pt/Co/Cu (diamonds). For comparison, the results are also shown for the stacks of Cu/Co/Pt (triangle) and Cu/Co/Cu (pentagon) in the as-deposited state.

L2-03. Investigation of localized spin wave eigen-modes in a triangular magnet by micro-focused Brillouin light scattering. *B. Cho*[1] *1. Gwangju Institute of Science and Technology (GIST), Gwangju, The Republic of Korea*

Nanoscale magnetic elements have received intensive attention over the last decade as promising candidates for nonvolatile and high density memory devices, magnetic sensors, and logic elements. So far, the majority of research has been focused on spin-wave study in various shapes of confined structures, such as ellipses, wires, rectangles, squares, disks, and rings. However, a triangular magnetic element, which has the most deviation from an ellipsoid than the other shapes, is expected to exhibit strongly localized spin waves near its edges and apex, which is hard to be detected due to the small intensity of the spin wave excitation. Thus, a meaningful study of localized spin waves in a triangular pattern was carried out by numerical calculation. In this study, localized spin wave modes, which are thermally excited at a specific position in a triangular magnetic element, are investigated using micro-focused Brillouin light scattering in two saturated states, the buckle and Y-states, with an applied magnetic field of 0.24 T parallel and perpendicular to the basal edge, respectively. The measured frequency spectrum at a specific beam spot position, rather than an integrated spectrum, is analyzed by comparing it with the simulation data at a precisely selected position within the beam spot area. The analyzed results are used to plot a two-dimensional intensity map and simulation spatial profile to verify the validity of the analysis. From the analysis process, two localized spin wave modes in a triangular magnetic element are successfully identified near the apex region in the buckle state and near the basal edge region in the Y-state.[1]

L2-04. Thermally induced anisotropy transition in Gd-Fe thin film structures. E. Kirk[3], C. Bull[2], J. Raabe[3], S. Finizio[4], T. Thomson[2], *G. Hrkac*[1] and L. Heyderman[3] *1. Engineering, Mathematics and Physical Sciences, University of Exeter, Exeter, United Kingdom; 2. School of Computer Science, University of Manchester, Manchester, United Kingdom; 3. Paul Scherrer Institut, Villigen PSI, Switzerland; 4. SYN, Paul Scherrer Institut, Villigen PSI, Switzerland*

The development of advanced magnetic based processing, sensing and recording technologies has opened a demand for magnetic thin film with added functionality. In particular, temperature can be used as a thermodynamic variable to change the magnetic state. Here we demonstrate that thin films of FeGd can exhibit a thermally induced anisotropy transition allowing the easy axis to be switched from perpendicular to in-plane. FeGd films were sputter-deposited on 200 nm thick Si_3N_4 membranes and capped with Ta to inhibit oxidation. The film structure was Si_3N_4/FeGd(40nm)/Ta(10nm). Vibrating sample magnetometry measurements show a sharp two step switching behavior that changes with temperature, figure 1a. Hysteresis loops were measured at 295 K, 270 K, 250 and 240 K demonstrating an increase in coercivity with decreasing temperature together with the emergence of a two-step reversal process, which can be explained by an induced perpendicular anisotropy in the FeGd sample. X-Ray characterization (XRD and XRR) indicate a change in density and composition as function of film thickness. Comparing perpendicular (θ-2θ) and in-plane XRD data indicate the presence of structure in the x-z plane assuming z represents the perpendicular direction. The θ-2θ scan showed only an amorphous structure. To understand these results we performed micromagnetic simulations. The simulated and measured magnetic data are in agreement if we assume a small columnar structure inside the otherwise amorphous FeGd film, see figure 1b. TEM measurements are currently underway to support the XRD and model data. This thermally induced anisotropy transition can be exploited not only by sensor applications but also can add functionality in a hybrid magnetic structure.

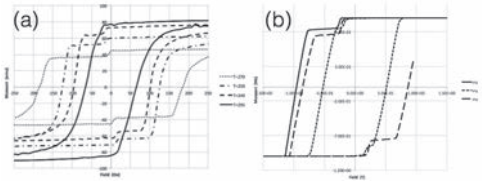

Fig. 1. (a) shows hysteresis loops of Gd-Fe 40nm films at different temepratures. (b) shows hysteresis loops of 40nm Gd-Fe films with embedded columnar structures that are responsible for the induced anisotropy, represented by the two-step reversal.

L2-05. Uniaxial Magnetic Anisotropy of bct FeCo-based Alloy Films. *T. Hasegawa*[1], M. Sakamoto[1], T. Niibori[1], Y. Nakamura[1], M. Oikawa[1], Y. Takemasa[1] and D. Yamamoto[1] *1. Department of Materials Science, Akita University, Akita City, Japan*

The development and use of hard magnetic materials with large uniaxial magnetic anisotropy (K_u) and high saturation magnetization (M_s) in areas such as high-density magnetic storage, spintronic devices, and permanent magnets are being strongly considered. Although FeCo alloys with the bcc structure exhibit the highest M_s among all transition metal alloys, their low K_u and coercivity (H_c) make them unsuitable for these applications. However, recent first-principles calculations have predicted large K_u for the FeCo with the bct structure[1]. In this work, the correlation between the K_u and the tetragonal distortion as the lattice parameters ratio (c/a) in FeCo-based alloy films was studied. A large K_u was observed in FeCo(Al) films with 2–3nm in thickness. The K_u is plotted as a function of the c/a ratio in Figure 1. The maximum K_u value of 2.1 x 10^7 erg/cm^3 is observed at around c/a = 1.2 as expected by the previous first-principles calculations. Since the interfacial magnetic anisotropy (K_i) of the FeCo/Rh is experimentally and theoretically[2] considered to be negligible, the magnetic anisotropy induced by the tetragonal distortion seems to be predominant. Next, in order to evaluate the hard magnetic properties of the bct FeCo(Al), circular dot (diameter: D) patterns were fabricated. Figures 2(a)-(c) and 2(d)-(f) show the SEM and demagnetized MFM images of the nanopatterned bct FeCoAl films with t = 2.0 nm and D = 100, 50, and 30 nm, respectively. The hysteresis curve of the nanopatterned films was measured, and the magnetic easy axis was perpendicular to the film plane in all the nanopatterned samples. The H_c increased with decreasing dot pattern size, and it reached 4 kOe at D = 30 nm[3]. Therefore, the bct FeCo(Al) exhibits high potentials for future applications requiring high K_u and M_s, such as high-performance permanent magnets and data storage devices. This work was supported by KAKENHI (JP15H05518) and NEDO.

L2-06. Disentangling and quantifying temperature-driven symmetry-breaking effects in magnetic nanostructures with competing magnetic anisotropy contributions. *J.F. Cuñado*[1,2], P. Perna[1], A. Bollero[1], R. Miranda[2,1] and J. Camarero[2,1] *1. IMDEA Nanociencia, Madrid, Spain; 2. Universidad Autónoma de Madrid, Madrid, Spain*

Disentangling and quantifying complex magnetic anisotropy landscapes in magnetic nanostructures is a great challenge when different anisotropy contributions are present. We have recently showed how to take advantage of our vectorial-MOKE magnetometer (called TRISTAN [1]) to investigate Fe/MgO(001) model system with competing collinear biaxial and uniaxial magnetic anisotropy contributions, disentangling the temperature evolution of the two contributions by temperature dependent full angular range measurements [2]. We also pointed out the importance of making a crosscheck between different magnetic parameters to avoid misinterpreta-

tions. Anisotropy constants and domain wall energy barriers have been now quantified as a function of temperature [3], by using two different theoretical models for the reversal of the magnetization: the model for collective rotation and switching of the magnetization (Stoner-Wohlfarth [4]), best suited for magnetic nanoparticles, and the pinning model (in particular Cowburn model [5]) for nucleation and domain wall motion at propagative regime, best suited for extended systems, as is the case in Fe/MgO thin film. Each one is applied in the region of the reversal where they work correctly for this kind of extended system, i.e., in the reversible and irreversible regions of the magnetization reversal, respectively. This allows us to simultaneously quantify both (uniaxial and biaxial) anisotropy constants. Full angular range vectorial resolve magnetometry is critical for this purpose. Here we review our experimental set-up (figure 1), explain the aforementioned method for quantifying anisotropy constants in Fe/MgO(001) system (figure 2), and show quantitative values of relevant magnetic parameters and their functional temperature dependence.

L2-07. Modulation of magnetic anisotropy in CoPt thin films by local and fast heat induced by surface acoustic waves. *B. Casals*[1], N. Statuto[2], R. Cichelero[1], F. Sanchez[1], A. Hernández-Mínguez[3], J. Hernàndez[2], G. Herranz[1] and F. Macià[1] *1. Magnetic Materials and Functional Oxides, ICMAB-CSIC, Bellaterra, Spain; 2. Condensed Matter Physics Department, University of Barcelona, Barcelona, Spain; 3. Paul-Drude-Institut für Festkörperelektronik, Berlin, Germany*

Surface acoustic waves (SAWs) are used as filters and oscillators in mobile telephones. SAWs are also considered as an efficient route towards low-energy control of nanomagnetic devices. For instance, SAWs can be used in spintronics to generate spin-pumping in ferromagnetic structures as well as to modulate dynamically spin states in spintronic devices [1, 2, 3]. Interestingly, the shear strains associated to SAW propagation can induce local heating that eventually is used to control magnetic states. Here we report an experimental study on scanning thermal microscopy that analyzes propagation and spatial distribution of the heat generated by SAWs on the surface of $LiNbO_3$ crystal. Our study reveals that heat generated by SAWs is directional and causes local temperature increases up to 10 K. We tested the effects of the SAW-induced heat dissipation in Co/Pt nanostructures having small magnetostriction and with a Curie temperature that can be engineered by film's thickness. We show that the effect of the fast and local heating can be used to variate the magnetic properties of the nanoelements. Our work provides interesting perspectives towards control magnetic nanodevices.

L2-08. Tailoring magnetic properties of TMR sensors via oblique-incidence deposition of CoFeB. *S. Willing*[1,2], K. Schlage[1], T. Gurieva[1] and R. Roehlsberger[1,3] *1. Photon Science, Deutsches Elektronen-Synchrotron (DESY), Hamburg, Germany; 2. Physics, Hamburg University, Hamburg, Germany; 3. The Hamburg Centre for Ultrafast Imaging, Hamburg, Germany*

Over the last years, CoFeB has developed into one of the most used magnetic materials for tunneling magnetoresistance (TMR) applications. In combination with MgO, the CoFeB crystallizes during a so-called solid-state epitaxy process and develops highly spin-polarized bands. To exploit the TMR effect in a CoFeB-MgO-CoFeB stack, the relative orientation of magnetization in the two CoFeB electrodes needs to change in external magnetic fields. In practice, often one of the magnetic layers is pinned in an exchange bias structure. Recently, we showed that oblique-incidence deposition (OID) is an easy and flexible technique to tailor the magnetic properties of ultra-thin films by inducing additional shape anisotropy [1]. By using the two angular degrees of freedom during sputter deposition, the orientation of magnetization as well as the coercive field can freely be tuned in every single magnetic layer (see Fig. 1). In this contribution, we present the interdependencies of film thickness, layer structure, annealing process, polar deposition angle and resulting magnetic properties in single CoFeB layers. Beyond that, we will show how OID can be used to custom-design TMR-stacks for the first time in a simple and convenient fashion.

[1] K. Schlage, L. Bocklage, D. Erb, J. Comfort, H.-C.Wille, and R. Röhlsberger, Spin-Structured Multilayers: A New Class of Materials for Precision Spintronics, Adv. Funct. Mater.26, 7423 (2016).

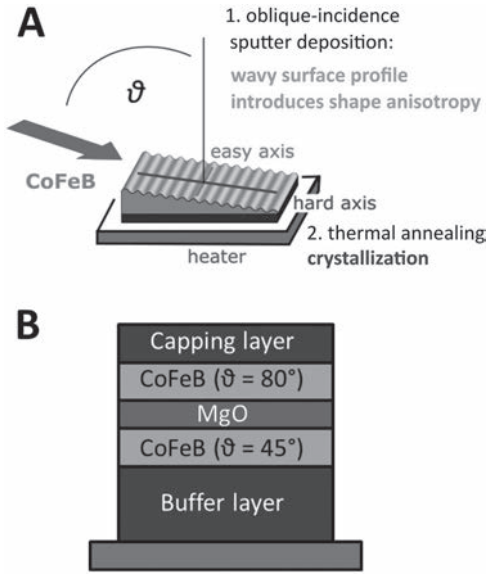

Fig. 1: Sample systems. (A) CoFeB thin films sputtered under oblique incidence exhibit a wavy surface profile that defines the direction of the magnetization axes as well as the coercivity. (B) Typical TMR stack prepared via OID. The polar deposition angle in both CoFeB layers was varied to tailor an asymmetric switching behavior. The resulting measurements can be seen in Fig. 2.

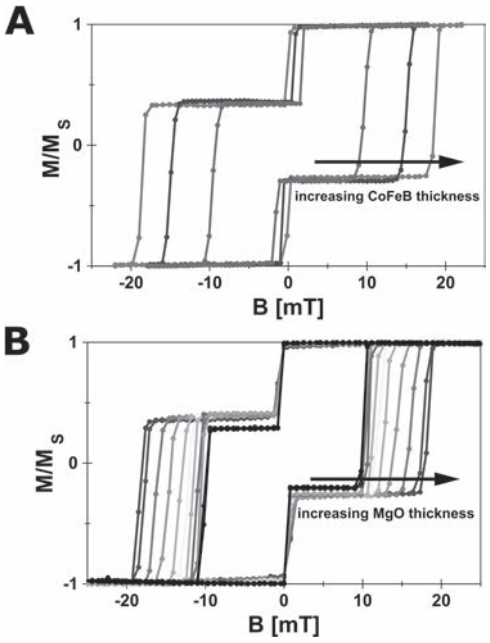

Fig. 2: Three easily accessible parameters adjust TMR properties in CoFeB-MgO-CoFeB stacks. (A) The polar deposition angles and layer thicknesses of the magnetic electrodes define the different coercive fields that result in the tailored double-switching behavior seen in the magnetization measurements. (B) The thickness of the tunnel barrier additionally defines the strength of interaction between the two magnetic electrodes which can also be seen in a shift of the switching field.

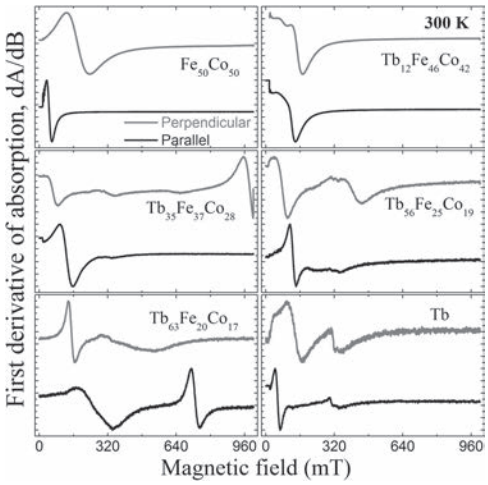
L2-09. Focused ion beam direct writing of magnetic patterns with controlled structural and magnetic properties. *M. Urbánek*[1], L. Flajsman[1], V. Krizakova[1], M. Horký[1], J. Gloss[2], M. Schmid[2] and P. Varga[2,1] *1. Brno University of Technology, Brno, Czechia; 2. TU Wien, Vienna, Austria*



Focused ion beam irradiation of metastable $Fe_{78}Ni_{22}$ thin films grown on Cu(100) substrates [1] is used to create ferromagnetic, body-centered-cubic patterns embedded into paramagnetic, face-centered-cubic surrounding. The structural and magnetic phase transformation can be controlled by varying parameters of the transforming gallium ion beam. The focused ion beam parameters as ion dose, number of scans, and scanning direction can be used not only to control a degree of transformation, but also to change the otherwise four-fold in-plane magnetic anisotropy into the uniaxial anisotropy along specific crystallographic direction. This change is associated with a preferred growth of specific crystallographic domains. The possibility to create magnetic patterns with continuous magnetization transitions and at the same time to create patterns with periodical changes in magnetic anisotropy makes this system an ideal candidate for rapid prototyping of a large variety of nanostructured samples. Namely spin-wave waveguides and magnonic crystals can be easily combined into complex devices in a single fabrication step.

L2-10. Effect of anisotropy on Magnetic and Ferromagnetic Resonance Studies on Tb-Fe and Tb-Fe-Co thin films. R. P[1] and *G. Markandeyulu*[1] *1. Physics, Indian Institute of Technology, Chennai, India*

Rare earth-transition metal thin films are known for their applications in high density data storage, due to the existence of uniaxial perpendicular magnetic anisotropy (PMA) at room temperature. In the present work, Tb-Fe and Tb-Fe-Co films were prepared by magnetron co-sputtering technique and the effect of anisotropy (magnetic) on magnetization and ferromagnetic resonance (FMR) signals were carried out. The films $Tb_{25}Fe_{75}$ and $Tb_{31}Fe_{69}$ were found to have PMA and the film $Tb_{11}Fe_{89}$ has planar anisotropy. The film $Tb_{44}Fe_{56}$ has PMA at 300 K, and planar anisotropy at 25 K due to the domination of the strain anisotropy at low temperatures. The saturation magnetization decreased with increasing Tb content upto the compensation composition and above this composition, increased due to the antiparallel orientation of Fe/Co moments with Tb moments. In Tb-Fe-Co, all the films were observed to exhibit planar anisotropy at 25 K, due to the increase of strain induced anisotropy as a result of large magnetostriction at low temperatures leading to the development of in-plane anisotropy. PMA was observed in the films $Tb_{35}Fe_{37}Co_{28}$, $Tb_{56}Fe_{25}Co_{19}$ and $Tb_{63}Fe_{20}Co_{17}$ at 300 K, due to the dominant R-T (Tb-FeCo) exchange interaction. The compensation composition (x_{comp}) was observed to lie between $Tb_{31}Fe_{69}$ and $Tb_{44}Fe_{56}$ films and between $Tb_{35}Fe_{37}Co_{28}$ and $Tb_{56}Fe_{25}Co_{19}$. The compensation temperatures (T_{comp}) and Curie temperatures (T_C) were found to be above room temperature as also has been observed from the Hall resistivity studies in Tb-Fe and Tb-Fe-Co films. FMR spectra were recorded for Tb-Fe and Tb-Fe-Co films, with the external DC magnetic field applied in-plane and out-of-plane of the films. The regions with different anisotropy fields in the film surface give rise to different ferromagnetic resonances. The localized anisotropy due to Tb sublattice, resulting in non-uniform demagnetizing fields is responsible for the same. Magnetization and FMR studies clearly indicated the dominance of Tb anisotropy due to the strong spin orbit interaction of Tb ions, at low temperatures.

L2-11. First-principles Study of Perpendicular Magnetocrystalline Anisotropy on Co/Ni Multilayers. *T. Nguyen*[1,2], K. Nakamura[2,3] and T. Oguchi[1,2] *1. Institute of Industrial and Scientific Research, Osaka, Japan; 2. MaDIS-CMI2, National Institute for Materials Science, Ibaraki, Japan; 3. Physics Engineering, Mie University, Tsu, Japan*

Materials with perpendicular magnetocrystalline anisotropy (MCA) in a film form have attracted attention for possible applications to spintronic devices such as high-density, high-thermal stability, and nonvolatile memories. Co/Ni multilayers (ML) with large perpendicular MCA [1], high spin polarization [2], and low damping constant [3] is a promising candidate for spin-transfer torque random access memory. Co/Ni ML have been intensively studied as it is easy to tune the magnetic properties by varying the thickness of sub-layers and the number of bilayer stacking. One way to adjust the magnetic properties is to tune the atomic-layer alignment of these ML. However, the dependence of MCA of Co/Ni ML on atomic-layer alignment has been not investigated yet. In this study, we investigate the microscopic mechanisms of MCA in Co/Ni ML thin films by tuning atomic-layer alignment using density-functional-theory full-potential linearized augmented plane wave calculations. Spin-orbit coupling (SOC) is treated within the second-variation method and MCA energy is estimated by the force theorem. The MCA energy of possible atomic-layer alignments of Co/Ni ML with hcp-like (ABAB) and fcc-like (ABCABC) stacking are examined. The present results predict that large perpendicular MCA can be achieved by tuning the atomic-layer alignments in Co/Ni ML. Both hcp-like and fcc-like stacking prefer the perpendicular magnetization direction while the hcp-like stacking is more stable. The large perpendicular MCA arises from SOC between occupied and unoccupied Ni $d_{yz,xz}$ states near the Fermi level. Thus, a promising 3*d* transition-metal film for magnetic tunnel junctions with giant perpendicular MCA and preferred stacking stability is demonstrated.

L2-12. Dynamic and symmetry effects in magnetic nanostructures. J. Fernández Cuñado[2,1], P. Perna[2], J. Diez[1,2], A. Gudin[2], P. Olleros[2], A. Bollero[2], R. Miranda[1,2] and *J. Camarero*[1,2] *1. Universidad Autónoma de Madrid, Madrid, Spain; 2. IMDEA Nanociencia, Madrid, Spain*

The study of the dynamic and the symmetry of the magnetic properties is an important issue in Nanomagnetism today, from both fundamental and technological point of views, triggering the search for materials with tailored properties. For instance, magnetization reversal features (i.e., relevant mechanism, reversal times, reversal fields) determine how the magnetization preserves its state in powerful permanent magnet applications, based on nanograin ferromagnetic structures consolidated in bulk systems, as well as how the information can be read and written in spintronic devices, based on multilayered thin film nanoarchitectures. We have recently shown how critical are both dynamic and symmetry effects at the nanoscale via systematic studies on model magnetic nanostructures [1-3]. These include both basic scientific understanding and novel instrumentation development [1], to perform detailed angular-dependent studies over nine decades of applied magnetic field sweep rate, from 10^{-4} T/s to 10^{+4} T/s, and in a broad temperature range, from 5 K to 500 K. The magnetic nanostructures investigated range from the simplest magnetic symmetry system (ferromagnetic films with well-defined uniaxial magnetic anisotropy) to more complex magnetic heterostructures with competing magnetic anisotropies with spin reorientation transitions, driven either intrinsically (originated from a different temperature-dependent behaviour of the competing anisotropies or by a phase transition) or extrinsically (i.e., via field cooling procedure). Among others, two recent scientific highlights: i) The emergence of Stoner-Wolfharth astroid in ferromagnetic thin films at dynamic regime [2]; and ii) The symmetry-breaking effects in systems with competing anisotropies [3]. This fundamental understanding opens additional avenues to develop future advanced devices based on magnetic nanostructures with tailored (dynamic) effective magnetic symmetry.

L3-01. Magnetoelastic resonance sensor for water-cut applications. *L. Swanepoel*[1,2], A. Kaidarova[2], A. Almansouri[2], M. Khan[2], J.H. Müller[1] and J. Kosel[2] *1. Mechanical Engineering, Stellenbosch University, Stellenbsoch, South Africa; 2. CEMSE, King Abdullah University of Science and Technology (KAUST), Thuwal, Saudi Arabia*

The measurement of the water fraction in oil (i.e. water-cut) is of critical importance in numerous applications. In the oil and gas industry, for example, knowledge of the amount of water production in crude oil is necessary before any remedial action can be taken. To date, cost-effective, reliable and compact downhole measurement technologies capable of full range water-cut measurements are not available. Due to the power and space constrictions involved in those measurement systems, low energy consumption and hardware scalability are important factors to consider. A low-power, low cost, wireless and non-corrosive full range water cut sensor is presented. The resonance sensor is based on magnetoelastic technology that has been implemented by an amorphous ribbon and electromagnetic interrogation. The magnetoelastic ribbon's resonant frequency is dependent on the vibrational damping effect of the surrounding medium, which, in turn, is determined by the dynamic viscosity of the medium. This enables distinguishing water and oil phases. Measurements were performed using an impedance analyzer in combination with a 350-turn coil (Figure 1), which enabled a low-power operation using only 50nW – 125nW. The sensor had a resonance frequency around 54 kHz in oil and a resonant frequency shift to 57 kHz in water (Figure 2). The vibrational response of the sensor enables characterizing the full water-cut range from 0% - 100%.

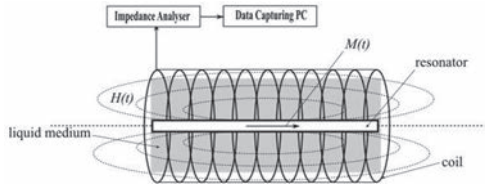

Figure 1: Schematic showing the experimental setup used to measure the resonant frequency of the resonating sensor (resonator).

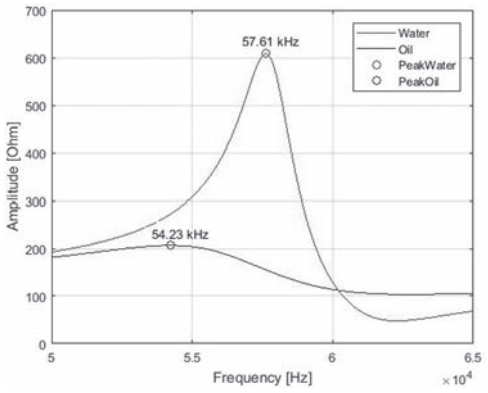

Figure 2: Impedance- frequency response curves for the sensor in water and in oil, respectively. The two resonant peaks in oil and water are indicated.

L3-02. Magnetic Sensing of Residual Stress and Cold Work in a Biometallic Ti-6Al-4V Alloy. *H. Carreon*[1], S. Barriuso[2], J. Gonzalez-Carrasco[2], J. Ocaña[3] and M. Carreon[1] *1. Universidad Michoacana, Morelia, Mexico; 2. Centro Nacional de Investigaciones Metalúrgicas, Madrid, Spain; 3. Universidad Politécnica de Madrid, Madrid, Spain*

Efforts to enhance the ossteointegration, fixation and stability of Ti-base implants have been addressed by inducing a rough surface that increases the surface area available for bone/implant apposition. In this paper, we present the results of all the material properties (bulk and surface) that change significantly during two different surface treatments such as grit blasting and laser peening in a biometallic Ti-6Al-4V alloy, in order to establish how they affect the recorded magnetic signatures and to verify that the residual stress and cold work effects dominate the outcome of the magnetic measurements. However, since the ratio of residual stress to cold work is primarily determined by the material and the specific surface treatment used, we demonstrated that the magnetic technique still offers the unique capability of nondestructively monitoring thermomechanical relaxation below the treated surface only calculating the normal and tangential magnetic fields produced by the resulting thermoelectric currents induced by an external temperature gradient.

L3-03. An Improved Method for Measuring the Magnetic Properties of Silicon Steel with Double Sheets at High Frequency. Y. Li[1], R. Chen[1] and *C. Zhang*[1] *1. Hebei University of Technology, Tianjin, China*

A single-yoked SST with asymmetrical structure of magnetic circuit has been developed for measuring the magnetic properties of silicon steel. However, the asymmetry of the magnetic circuit would increase the leakage magnetic flux and cause the testing error[1]. In order to improve the measurement accuracy, the traditional single sheet tester(SST) forms the magnetic circuit with double yokes and a single silicon steel sheet. This method avoids the calculation of the effective magnetic circuit when testing magnetic field intensity *H*, but also has the problem of poor repeatability[2] [3]. There are two methods of double-yoked SST to test magnetic field intensity *H,* the H-coil method requires integration of the induction signal and magnetic signal, compared to the magnetizing current method has better noise suppression ability[4]. But the testing error of the magnetic field intensity *H* increases with the increase of the height of the induction coil window attached to the surface of the sample. In order to overcome this shortcoming, this paper presents an improved SST of double-yoked and double sheets. The magnetic field intensity *H* and magnetic flux density *B* inside the sheet are measured by induction coil, which is placed in a small chamber and located between the double silicon steel sheets. The electromagnetic simulation shows that the magnetic field between the two sheets is much more uniform than that on other side of the silicon steel sheet. The main structure of the tester consists of two symmetrical U type nanocrystalline core as main exciting cores, the two testing sheets with the same size, material and cutting direction, pairs of excitation windings that wounded around the lateral yoke of magnetic core. The maximum working frequency of this test method can achieve 50kHz much higher than 10 kHz that achieved in the Ref[3]. The comprehensive measurement and analysis have been carried out in this paper. The improved double sheets tester can accurately measure *B* and *H* in the silicon steel sheets in a wide frequency range up to 50kHz.

L3-04. 3D magnetic properties measurement of silicon steel under biased magnetic excitation along laminated direction. *C. Zhang*[1], X. Yan[3], Y. Li[1], Q. Yang[1] and J. Zhu[2] *1. Hebei University of Technology, Tianjin, China; 2. School of Electrical Engineering, University of Technology Sydney, Sydney, NSW, Australia; 3. School of Electrical Engineering, Hebei University of Technology, Tianjin, China*

Rotational flux in the plane of steel laminations causes iron losses which far exceed than that of alternating flux [1]. Traditional testing methods such as Epstein Frame detected only in one direction or one plane may lead to inaccurate predictions of iron loss [2-3]. This paper analyzes the dynamic magnetic hysteresis properties of grain oriented silicon steel by using the novel 3-D testing system under alternating, 2-D rotational and complex 3-D magnetization, in which the laminated direction of the steel sample is loaded by a static magnetic field. The magnetic properties such as *B-H* hysteresis and corresponding core losses properties under different incentive models at 50 Hz are analyzed. A novel 3-D magnetization testing system, which consists of 3-D magnetic properties tester, imbedded PID controller, impedance machine, precondition circuit, digital feedback system and DC source, is established in measurement experiment [4]. The cube sample 27zh59 is placed in the sensor box. Several typical magnetization models including alternating, rotational and complex 3-D excitation have been carried out in the experiment. The magnetic properties such as *B-H* hysteresis loops, corresponding core losses and loci of vector *B* of grain oriented silicon steel are measured by using the novel 3D testing device. The alternating excitation is built up by giving a unidirectional sinusoidal excitation of voltage, while for the 2-D rotating excitation, the trajectory of magnetic flux density(B) is kept as circular by controlling a set of signal equation group [5-6]. To study the effect of DC bias along laminated direction on the magnetic properties of the sample, DC current excitation of 0-5 A is applied in the lamination direction. The experimental results show the magnetic anisotropy of oriented silicon steel. It can be found out that the magnetization in the rolling direction is much stronger than that of transverse direction, the static magnetic field loaded in the stacking direction will make the magnetization process in sheet plane more difficult and increase the iron loss.

L3-05. Ultrahigh Anisotropic Magnetoelectric Sensor Based on FeCoSiB/AlN Thin Film Composites. *J. Ouyang*[1], W. Wang[1], B. Tong[1], Y. Zhang[1], B. Zhu[1], S. Chen[1] and X. Yang[1] *1. School of Optical and Electronic Information, Huazhong University of Science and Technology, Wuhan, China*

The magnetoelectric sensor has the advantages of high sensitivity, low noise, et al. But the anisotropy error, which means the unwanted output perpendicular to the sensitive axis, seriously affected the accuracy of the magnetoelectric sensor. Dong et al.[1] and our group[2] find that the anisotropy error is related to the shape of the piezoelectric material and the magnetostrictive material respectively. In order to obtain very high magnetoelectric anisotropy, ultrafine strip FeCoSiB magnetostrictive film was prepared on AlN piezoelectric film utilizing RF magnetron sputtering and lift-off process. Fig. 1 shows the preparation process of FeCoSiB/AlN magnetoelectric

sensor. (a) Step 1: Si/SiO_2 substrate cleaning; (b) Step 2: RF magnetron sputtering for AlN film; (c) Step 3: KMPE3130B type negative photoresist spin-coated; (d) Step 4: Exposure and development; (e) Step 5: RF magnetron sputtering for FeCoSiB film; (f) Step 6: lift-off for photoresist and FeCoSiB film. The relationship between the size of FeCoSiB magnetostrictive film and magnetoelectric anisotropy was studied by finite element method. In order to confirm the theoretical results, FeCoSiB/AlN thin film composites were prepared with FeCoSiB strip width of 5 μm, 10 μm, 20 μm, 25 μm, 50 μm, 100 μm, 150 μm and 200 μm. Magnetoelectric sensor samples of 10 μm, 20 μm and 50 μm were then tested as shown in Fig. 2. The sample with DC magnetic field biased was rotated in the AC magnetic field (1 kHz), the output of the sensor was connected to the charge amplifier and the spectrum analyzer for magnetoelectric measurement. The results showed that the magnetoelectric anisotropy was enhanced with increasing length-width ratio, and the test values were in agreement with the theoretical values. When the strip width of FeCoSiB film was 10 μm, the magnetoelectric anisotropy of the sensor could reach about 1200, which was ten times higher than the reported results [1,2].

L3-06. Measurement of Magnetic Properties of Electrical Materials Considering The Effect of Temperature. Y. Li[3], M. Yang[1,3], *C. Zhang*[2,3] and Q. Yang[3,4] *1. School of Electrical Engineering, Hebei University of Technology, Tianjin, China; 2. Hebei University of Technology, Tianjin, China; 3. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Tianjin, China; 4. Tianjin Key Laboratory of AEEET, Tianjin, China*

In this paper, a method to measure the magnetic properties of electrical materials is proposed, which is based on the method of magnetic properties of magnetic materials. With the development of the manufacturing technology of electrical equipment, the measurement accuracy of magnetic characteristic parameters of electrical materials with critical components is particularly important. At present, the known world's leader magnetic properties measurement method is only the measurement of magnetic properties of magnetic materials at room temperature [1], and do not consider the influence of the environmental factors applied by the materials on its own characteristics [2]. Therefore, the data measured at present cannot completely reflect the magnetic properties of materials in normal operation of equipment, which will lead to a great difference between the calculation results of electrical equipment and parameters in actual conditions, resulting in unnecessary losses. [3-5] This paper proposes the measurement of magnetic properties of electric materials considering temperature effect. The corresponding magnetic characteristic curves are measured at different temperatures. The hysteresis losses are analyzed, and the reasons for the macroscopic change are explained from microcosmic perspective [6]. The heating method is made by heating the magnetic ring of different materials with constant temperature box to meet the requirement of temperature value. The measuring device remains at room temperature to avoid the measurement error caused by the temperature influence of the measuring device. The effects of the parameters on the magnetic properties of the materials are compared with the temperature, the type of material and the frequency. By using the magnetic curve and hysteresis loop drawn, the loss difference of magnetic materials at different temperatures is further analyzed. The experimental results confirm that under the same conditions, with the increase of temperature, the permeability and hysteresis loss of magnetic materials will gradually decrease, and the coercive force will increase correspondingly. In this paper, the influence of these changes on the performance of electrical equipment is briefly analyzed.

L3-07. Optimization Design of Vibration and demagnetization Reduction by Winding Method of Electric Compressor Motor for Automotive Air Conditioning. *J. Lee*[1], M. Kim[1], s.h. Jung[1] and D. Kang[1] *1. Electrical Energy Engineering, Keimyung University, Daegu, The Republic of Korea*

Recent developments in the eco-friendly vehicle, EV &HEV, are being studied to increase fuel economy and driving efficiency in a variety of ways. In particular, the air compressor is component directly connected to the engine by a belt, which increased the load on the engine. Recently, research for improving the efficiency of a vehicle have been developing BLDC motor driven compressor and considered as the most suitable model to satisfy the characteristics of electric compressors. In addition, since it is possible to reduce the size, the cost and mounting space can be reduced.[1], [2] In this paper, BLDC is applied to electric compressor. Two models of distribution winding and concentration winding were compared. In this paper, analyse the Irreversible demagnetization and vibration properties of permanent magnets in rotor.[3] [4] In general, since permanent magnet materials are used, a comparative analysis of concentrated winding and distributed winding of irreversible demagnetization has not been studied in the past. Therefore, the irreversible demagnetization characteristics compared in this paper will provide very useful information to the designers using the two winding methods in the future. The method of estimating irreversible demagnetization increases the applied current based on the rated current. Since vibration characteristics are very important in the main specifications of vehicle electrical products, vibration characteristics and noise characteristics are analyzed by the two winding methods.[3],[4],[5],[6] The electromagnetic vibration source was analyzed and the mechanical vibration characteristics were simulated. Then, the software used was ANSYS Mechanical with ANSYS EM and Workbench. In addition, vibration characteristics according to each winding method were changed according to irreversible demagnetization characteristics of permanent magnets. Finally, the optimum model

of distribution winding and concentration winding is directly produced and tested to analyze and evaluate demagnetization characteristics. In this paper, analyze the vibration characteristics and plan to publish the results in the final paper to ensure the reliability of the analytical data.
