Cubic Rare-earth compounds $PrTr_2Zn_{20}$ (*Tr* = Ir and Rh) and $PrTr_2Al_{20}$ (*Tr* = Ti and V) have extensively investigated because they show a wide variety of novel phenomena associated with multiple degrees of freedom of 4f electrons [1-3]. The crystalline electric field (CEF) ground state of these compounds is Γ_3 doublet which have not magnetic dipole but quadrupole and octopole. Because the number of such compounds is limited, to explore new cubic Pr compound with Γ_3 doublet CEF ground state have been highly desirable. We have recently focused on an isostructural $PrRu_2Zn_{20}$ which shows a structural transition at T_s = 150 K[4]. Since the site symmetry of Pr ion is lowered by the structural transition, the multipole degrees of freedom are quenched. First principles calculation and inelastic x-ray scattering measurements pointed out that the structural transition is attributed to the low-energy vibration of Zn atom at 16c site (Zn(16c)) encapsulated by R_2Zn_{12} cage with large space [5, 6]. It has also been reported that in Sn- and In- substituted RT_2Zn_{20}, Zn(16c) are preferentially replaced by In and Sn[7, 8]. In general, atomic radius of In and Sn are larger than that of Sn. Therefore, it is expected that the structural transition in $PrRu_2Zn_{20}$ can be suppressed by the In- and Sn- substitutions because cage free space is reduced. In this study, we have synthesized the single crystalline samples of Sn- and In- substituted $PrRu_2Zn_{20}$ by the flux- and melt-growth-methods. The x-ray diffraction measurements revealed that the obtained samples have cubic $CeCr_2Al_{20}$-type structure, and lattice parameters are increased by the Sn- and In- substitutions. No structural transition is observed by the specific heat and electrical resistivity measurements. The magnetic susceptibility shows a Van-Vleck paramagnetic like behavior below 10 K, which is a

hallmark of nonmagnetic CEF ground state of Pr ion. In addition, the magnetic contribution of specific heat increases upon cooling even below 3 K, indicating that the CEF ground state is degenerated. These results suggest that the CEF ground state of Sn- and In-substituted $PrRu_2Zn_{20}$ is Γ_3 doublet.

Graduate School of Science and Engineering, Ehime University, Matsuyama, Japan*

The cage compounds $LaRu_2Zn_{20}$ and $PrRu_2Zn_{20}$ with the cubic $CeCr_2Al_{20}$-type structure show a structural phase transition at T_s = 150 and 138 K, respectively [1]. The Zn atom at the 16*c* site is accommodated in a polyhedral cage consisting of 2 Pr atoms and 12 Zn atoms at the 96*g* site, and the large amplitude atomic motion (the so-called rattling motion) of the Zn atom at the 16*c* site was proposed. The origin of the phase transition was reported to originate from a structural instability induced by the rattling motion [2]. In the present work, elastic properties of the non-magnetic compound $LaRu_2Zn_{20}$ have been investigated by using the ultrasonic technique in order to examine the contribution of 4*f*-electrons to the structural transition. The temperature dependences of the elastic moduli in $LaRu_2Zn_{20}$ increase monotonically with decreasing temperature above T_s. At T_s, an abrupt elastic hardening accompanied by hysteresis is observed in all moduli, indicating that the phase transition is of the first-order. The elastic hardening in $LaRu_2Zn_{20}$ is not caused by 4*f*-electrons of the rare-earth ions. In the isomorphic compound $PrRu_2Zn_{20}$, three-fold superlattice reflection spots appear below T_s [3]. A similar structural modulation is expected in $LaRu_2Zn_{20}$.

U11-05. Magnetic properties of new compound $SmTr_2Sn_2Zn_{18}$ (*Tr* = Co, Rh, and Ir). *Y. Matsumoto*[1] and T. Kuwai[1] *1. Graduate School of Science and Engineering, University of Toyama, Toyama, Japan*

In recent years, the intermetallic compounds with the $CeCr_2Al_{20}$-type structure (so-called 1-2-20 family) have been largely attractive because the anomalous physical phenomena are observed such as the superconductivity caused by the quadrupole fluctuations (PrV_2Al_{20} and $PrTi_2Al_{20}$)[1], the heavy-fermion (HF) caused by the magnetic frustration (YMn_2Zn_{20}) [2], the HF with extremely large specific heat coefficient ($YbCo_2Zn_{20}$)[3], etc. In samarium intermetallic compound, $SmTr_2Al_{20}$ (*Tr* = Ti, V, Cr, and Ta) exhibit the HF behavior with the antiferromagnetic-like order at low temperatures [4, 5]. The HF and the order state of $SmTr_2Al_{20}$ are insensitive to the external magnetic field. Recently, the low-temperature properties of new 1-2-20 family $RTr_2Sn_2Zn_{18}$ (*R* = La, Ce, Pr, and Nd, and *Tr* = Co and Fe) have been reported [6]. Substitution of Zn atoms on the 16c site by Sn occurs for these compounds. It is worth to search for $SmTr_2Sn_2Zn_{18}$ to find the new physical phenomena. We have successfully grown the single-crystalline $SmTr_2Sn_2Zn_{18}$ (*Tr* = Co, Rh, Ir) by the flux method. The crystal structure and composition were characterized by the powder X-ray method and an electro-prove micro-analyzer (EPMA), respectively. The specific heat (*C*) was measured at temperatures down to 0.4 K using a physical property measurement system (PPMS; Quantum Design). We also investigated the magnetic properties by a magnetic property measurement system (MPMS; Quantum Design) from 300 to 2 K. It is found that the *C* of $SmTr_2Sn_2Zn_{18}$ has a peak at 5.3 K (*Tr* = Co), 5.5 K (*Tr* = Rh), and 6.4 K (*Tr* = Ir), respectively. The temperature dependence of magnetic susceptibility has a maximum almost corresponding to the each temperature of the peak in *C*, indicating that the antiferromagnetic-like order takes place. The corresponding $SmTr_2Zn_{20}$ compounds are an paramagnet (*Tr* = Co) [7], an antiferromagnet with antiferromagnetic transition temperature T_N = 2.4 K (*Tr* = Rh) [8], and T_N = 1.3 K (*Tr* = Ir) [9], respectively. The differences of ground state between $SmTr_2Sn_2Zn_{18}$ and $SmTr_2Zn_{20}$ system would be caused by the chemical pressure effect and the difference of the number of conduction electrons.

The class of compounds known as so-called 1-2-20 systems, crystallizing in a cubic $CeCr_2Al_{20}$ – type crystal structure exhibits a wide variety of strongly correlated electron phenomena including multipolar ordering, the related Kondo effect and super heavy fermion behavior. In particular, magnetically robust heavy fermion state formed in some Sm-based 1-2-20 systems is one of the interesting and central issues to be studied in the strongly correlated electron systems. $SmPt_2Cd_{20}$ is known to undergo phase transition below 0.64 K without the presence of a magnetic anomaly in its magnetic susceptibility. The low temperature Sommerfeld specific heat coefficient C_{4f}/T is estimated to be 4.5 J/(mol K^2), strongly indicating the development formation of heavy fermion particles. [1] However, the mechanism responsible for the enhancement of effective mass is still a puzzle. On the other hand, hyperfine coupling between an electronic and a nuclear spin would be rather enhanced, with the consequence the heavy fermion state contains a large contribution from the nuclear state of Sm. We performed ultrasound measurements on $SmPt_2Cd_{20}$ in the extremely low temperature ranges covering the area mentioned above. The nature of the low temperature elastic properties and electronic states involving the ground state multiplets of Sm ions will be discussed.

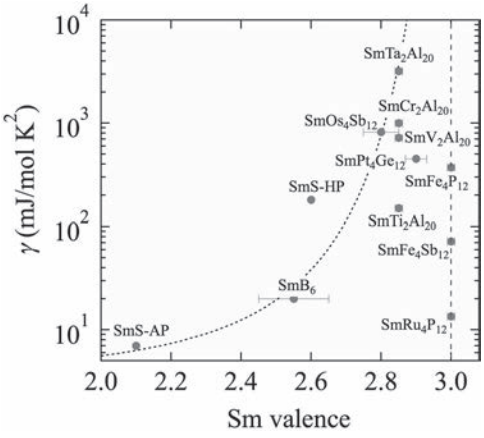
U11-07. Unusual Magnetic-Field-Insensitive Heavy Electron State in $SmTr_2Al_{20}$ (*Tr* = Ti, V, Cr, and Ta). *R. Higashinaka*[1], A. Yamada[1], T. Matsuda[1], Y. Aoki[1], M. Mizumaki[2], S. Tsutsui[2], T. Uruga[2], K. Nitta[2] and T. Ina[2] *1. Department of Physics, Tokyo Metropolitan Univ., Hachioji, Japan; 2. Japan Synchrotron Radiation Research Institute (JASRI), Sayo, Japan*



$LnTr_2X_{20}$ (*Ln* = rare earth, *Tr* = transition metal, *X* = Zn, Al, and Cd) crystallizing in the $CeCr_2Al_{20}$-type cubic structure with the space group *Fd-3m* show wide variety of strongly correlated electron phenomena, which are expected to be realized by a interplay between strong *c-f* hybridization and crystalline electric field effects. Among $LnTr_2X_{20}$, Sm-based compounds have attracted much attention since $SmTr_2Al_{20}$ (*Tr* = Ti, V, Cr and Ta) shows an unconventional field-insensitive phase transition and heavy fermion state[1-3]. These compounds show a Kondo-like -log*T* dependence in the resistivity below 50 K, indicating the strong *c-f* hybridization, and show field-insensitive phase transitions at T_x = 6.5 (Tr = Ti), 2.9 (V), 1.8 (Cr), and 2.0 K (Ta). Moreover, below the phase transition temperature, these compounds show unusual H-insensitive HF behaviors with large Sommerfeld coefficient of γ = 0.15 (*Tr* = Ti), 0.72 (V), 1.0 (Cr), and 3 J/(K^2 mol-Sm) (Ta). The CEF ground state of these Sm compounds is expected to be a Γ_8 quartet of the *J* = 5/2 multiplet[1-3]. Since the size of the ordered moment is

extremely suppressed compared with that expected for a Γ_8 ground state, the multipolar degrees of freedom included in the Γ_8 state are expected to play some role in this field-insensitive ordered state. Magnetic susceptibilities of these compounds show weak temperature dependences, which are evidently different from both of those for free Sm^{2+} and Sm^{3+} ions, and the X-ray absorption spectra for all *Tr* show that Sm ions are in mixed-valence state with the average Sm-ion valence of 2.87 with no significant *T* dependence down to 3 K[4-6]. These results suggest a possibility that valence fluctuation also plays a role for the field-insensitive nature. We discuss all these experimental results on $SmTr_2X_{20}$ and recent progress of theoretical works considering valence fluctuation[7].

CeT_2X_{20} (T: transition metals, X=Al, Zn, Cd) crystallizes in the cubic $CeCr_2Al_{20}$ type structure. In this system, the ground state of 4*f* electron in Ce atom strongly depends on X atom. For example, CeT_2Al_{20} (T=Ti, V, Cr) shows the paramagnetic ground state with a temperature independent and small magnetic susceptibility [1]. $CeIr_2Zn_{20}$ and $CeRu_2Zn_{20}$ exhibit the intermediate valence state and heavy-fermion state, and show a broad maximum in the magnetic susceptibility [2,3]. The localized character of the 4*f* electrons is suggested in CeT_2Cd_{20} (T=Ni, Pd, Pt), showing the Curie-Weiss type magnetic susceptibility at low temperatures [4,5]. The hybridization effect between 4*f* and conduction electrons tends to be weak in order of X=Al, Zn, and Cd. In the present study, we controlled the hybridization strength between 4f and conduction electrons in the intermediate valence compound $CeIr_2Zn_{20}$ by substituting Cd for Zn, in order to research the quantum critical phenomena in CeT_2X_{20} system. On the other hand, the ground state of CeT_2Cd_{20} has not been clear yet. We also show the ground state for X=Cd compound. Single crystals of $CeIr_2(Zn_{1-x}Cd_x)_{20}$ and $CePt_2Cd_{20}$ were grown using Zn-Cd and Cd self flux method, respectively. By substituting Cd for Zn in $CeIr_2Zn_{20}$, the hybridization effect is found to be reduced and the electronic state approaches the quantum critical point from the experimental results of the magnetic susceptibility, specific heat, and resistivity. $CePt_2Cd_{20}$, which corresponds to a limit of x=1, exhibits a magnetic transition at very low temperature. Substituting Cd for Zn, the characteristic temperature $T_{\chi max}$ where the magnetic susceptibility shows the broad maximum decreases from about 100 K for $CeIr_2Zn_{20}$ to 30 K for x=0.4. The reduction of $T_{\chi max}$ corresponds to a suppression of the hybridization effect. The specific heat measurement revealed that the γ increases as function of x and reaches to 400 mJ/K^{2}mol. The temperature dependence of the electrical resistivity ρ of $CeIr_2Zn_{20}$ shows a shoulder-like structure at 150 K. With increasing x, the temperature where ρ shows the shoulder decreases and the value of A increases up to the order of 0.1 μΩcm/K^2 for x=0.4.

U11-09. Antiferromagnetic transitions of Kramers doublets in caged cubic compounds NdT_2Zn_{20} (T = Co, Rh, and Ir). *R. Yamamoto*[1], T. Onimaru[1], R.J. Yamamda[1], Y. Yamane[1], K. Umeo[2], Y. Shimura[1] and T. Takabatake[1] *1. Graduate School of Advanced Sciences of Matter, Hiroshima University, Higashi-Hiroshima, Japan; 2. Natural Science Center for Basic Research and Development, Hiroshima University, Higashi-Hiroshima, Japan*

A family of caged compounds RT_2X_{20} (R: rare-earth, X: Al, Zn and Cd) crystalize in the cubic $CeCr_2Al_{20}$ type structure. The coordination for the R ion by 16 X atoms allows the 4*f* state to interact strongly with conduction electrons. For example, PrT_2X_{20} with non-Kramers Pr^{3+} ions of the $4f^2$ configuration exhibits a variety of phenomena due to a quadrupole Kondo effect [1]. Less studies have been performed for NdT_2X_{20} with the Kramers Nd^{3+} ions of the $4f^3$ configuration. Under the cubic crystalline electric field (CEF), $NdIr_2Zn_{20}$ has the Kramers Γ_6 doublet ground state, which undergoes an antiferromagnetic (AFM) transition at 0.65 K [2]. Interestingly, a recent theory predicts a two-channel Kondo effect to manifest itself in the Γ_6 doublet [3]. In the present work, we focus on NdT_2Zn_{20} (T = Co and Rh) which are isoelectronic to $NdIr_2Zn_{20}$. In the previous work for T = Co [4], the CEF effect was not fully considered and no phase transition was observed down to 2 K. To compare the CEF level scheme and ground state properties among T = Co, Rh, and Ir, we have grown single crystalline samples and measured the magnetic, transport, and thermal properties down to 0.37 K. The magnetic susceptibility $\chi(T)$ for T = Co and Rh follows the Curie-Weiss law for 10-300 K with the effective magnetic moments of 3.92 and 3.80 μ_B/Nd, respectively. The magnetic specific heat C_m data for the two compounds show a broad maximum at around 15 K, which could be fit by a Schottky model with a Γ_6 doublet ground state and the Γ_8 quartet lying at around 40 K. On cooling, the data of $C_m(T)$ for T = Co and Rh exhibit sharp peaks at T = 0.52 K and 0.92 K, respectively, which coincide with the drop in the

electrical resistivity. With applying magnetic fields, the shift of the peak of C_m to lower temperatures indicates the AFM nature of the magnetic phase transition. However, for the three compounds, the magnetic entropy S_m at T_N is only 50% of $R\ln 2$ although the release of $R\ln 2$ is expected for the magnetic order of the Γ_6 doublet. The reduction of S_m at T_N may result from short-range magnetic correlations and hybridization of the Γ_6 doublet with conduction bands.

Department of Physics and Astronomy, Rice University, Houston, TX, United States*

The search for novel phases with non-trivial topology has recently broadened to encompass also heavy fermion materials. Both topological Kondo insulators and Dirac- and Weyl-Kondo semimetals have been proposed [1-3]. It is of great interest to explore whether and how materials may be systematically tuned between phases distinguished by symmetry-breaking or metal-insulator transitions [4], but also by distinct topological character, and under which conditions quantum criticality appears at such transitions. A first experiment on a heavy fermion material along this line has recently demonstrated a Kondo insulator to semimetal transformation in noncentrosymmetric $Ce_3Bi_4(Pt_{1-x}Pd_x)_3$, upon varying the spin-orbit coupling strength via the substitution level x [5]. The semimetallic end compound $Ce_3Bi_4Pd_3$ shows thermodynamic signatures of the recently predicted [3] Weyl-Kondo semimetal [5]. Here we investigate the noncentrosymmetric compound $CeRu_4Sn_6$ [6,7], another candidate correlated Weyl semimetal [7,8]. Our study of quasi-elastic magnetic neutron scattering, magnetic susceptibility, and magnetic Grüneisen ratio on single crystals in a wide range of temperature and magnetic field indicates the presence of quantum criticality in $CeRu_4Sn_6$. Most notably, we observe energy over temperature and temperature over field scaling, with anomalous critical exponents. We acknowledge financial support from the Austrian Science Fund (FWF projects P29296-N27 and I2535-N27).

U12-02. Characterization of substituted $YbNi_4P_2$ and $YbRh_2Si_2$ single crystals. *K. Kliemt*[1], P. Denck[1], C. Butzke[1], J. Banda[2], M. Brando[2] and C. Krellner[1] *1. Institute of Physics, Goethe-University Frankfurt, Frankfurt, Germany; 2. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany*

We present the single crystal growth and the characterization of two similar heavy-fermion quantum-critical systems, the ferromagnet $YbNi_4P_2$ and the antiferromagnet $YbRh_2Si_2$. The tetragonal heavy-fermion compound $YbNi_4P_2$ is a rare ferromagnet with a very low Curie temperature $T_C = 0.17$ K. T_C can be suppressed by substituting P by As which results in the presence of a ferromagnetic (FM) quantum critical point (QCP) at about 10% of As-substitution [1,2]. Moreover, in the stoichiometric compound, multiple Lifshitz transitions have been observed recently at very small fields, between 0.5 and 12 T [3]. Here, we present the first characterization of $YbNi_4(P_{1-x}As_x)_2$ single crystals [4,5] with $0 \le x \le 1$ by electrical transport, heat capacity and magnetization measurements. We also discuss the effect that substitution on the Yb site by smaller atoms like hafnium and scandium might have on T_C. The prototype heavy-fermion system $YbRh_2Si_2$ is situated extremely close to an unconventional antiferromagnetic (AF) QCP. The AF ordering temperature ($T_N = 70$ mK) can be lowered by chemically-induced negative pressure [6] or by the application of a small magnetic field $B_c = 60$ mT, applied within the basal plane of the tetragonal structure [7]. Recently, superconductivity was discovered within the AF phase below 2 mK [8]. Here, we report on the first growth of large $YbRh_2Si_2$ single crystals from a self flux using the Czochralski method and of their characterization.

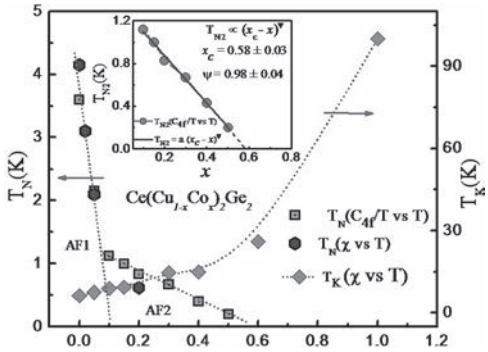
The heavy-fermion superconductor $CeCoIn_5$ (the $HoCoGa_5$-type tetragonal structure) has been attracting continuous interest because of its anomalous superconducting properties coupled with the quantum critical fluctuations. It exhibits a superconductivity below T_c=2.3 K, whose stability against the magnetic field B is governed by the strong Pauli paramagnetic effect. In addition, the non-Fermi-liquid (NFL) behavior appears in various bulk quantities at around the upper critical field H_{c2}=5 T, strongly suggesting that the magnetic quantum critical fluctuations play a crucial role in the anomalous nature of the superconductivity. In the mixed compound $CeCo_{1-x}Ni_xIn_5$, we have recently found that the superconductivity is monotonically suppressed by doping Ni, and then, the NFL behavior appears even in the absence of magnetic field at the critical Ni concentration: x=0.25 [1]. We consider that this situation is useful to precisely investigate the physical properties of the quantum critical fluctuations because of few restrictions on the experimental conditions. In this presentation, we show the details of the NFL characteristics observed in magnetization and specific heat of $CeCo_{1-x}Ni_xIn_5$. At x=0.25, it is revealed that temperature variation of magnetization divided by magnetic field, M/B, shows an unusual power-law dependence T^p with p~ -0.18 at B=0.1 T, and it changes into conventional Fermi-liquid (FL) behavior (M/B ~ constant) with further increasing B. Similar features are also observed in the specific heat; the specific heat divided by temperature, C/T, follows a -logT function in the wide temperature range at B=0, and



becomes nearly T-independent by applying B. The NFL-to-FL crossover temperature approaches zero as magnetic field is reduced to zero, suggesting a presence of the quantum critical point at around zero field in Ni-doped $CeCoIn_5$, in contrast to the field-induced quantum critical behavior at $\sim H_{c2}$ in pure $CeCoIn_5$ [2,3]. We also briefly show our recent muon spin relaxation measurement for x~0.25 in this presentation.

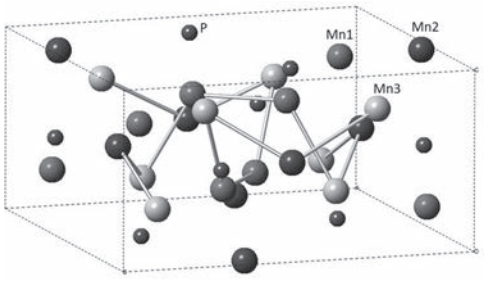
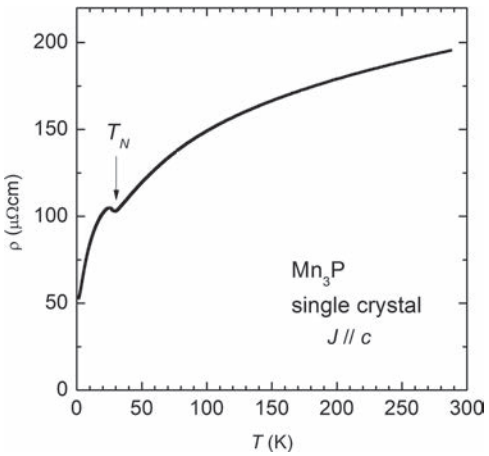
U12-04. Non-Fermi-liquid behavior at anti-ferromagnetic quantum critical point in heavy fermion system $Ce(Cu_{1-x}Co_x)_2Ge_2$. *R. Tripathi*[1], D. Das[1,3], C. Geibel[3], S.K. Dhar[4] and Z. Hossain[2] *1. Physics, Indian Institute of Technology, Kanpur, India; 2. Physics, Indian Institute of Technology, Kanpur Nagar, India; 3. Physics of Quantum Materials, Max-Planck-Institute for Chemical Physics of Solids, Dresden, Germany; 4. Condensed Matter Physics & Materials Science, Tata Institute of Fundamental Research, Mumbai, India*

Polycrystalline samples of $Ce(Cu_{1-x}Co_x)_2Ge_2$ were investigated by electrical resistivity $\rho(T)$, magnetic susceptibility $\chi(T)$, and heat capacity $C_p(T)$ measurements from 0.4 K to 300 K. The long-range antiferromagnetic (AFM) ordering (T_N) is suppressed by non-iso-electronic Cobalt (Co) doping at a critical value of the concentration x_c = 0.60, where non-Fermi liquid (NFL) behavior is observed. At the critical concentration x_c, NFL behavior is characterized by a -log T contribution to the $C_p(T)$ down to 0.4 K as well as deviations from T^2 behavior in the electrical resistivity. In the phase diagram of $Ce(Cu_{1-x}Co_x)_2Ge_2$ we have observed a 2-dimensional nature of quantum critical fluctuation separating AFM and non ordered states[Fig.1]. However, we have not seen any superconducting phase in the quantum critical regime down to 0.4 K.

The manuscript is under review in PRB.



Variation of AFM ordering temperature T_N (left panel) and Kondo temperature T_K (right panel) as a function of Co doping x. Inset shows T_{N2} vs x data fitted with $T_{N2} = a\,(x_c - x)^\psi$ (solid line) in the range $0.1 \le x \le 0.5$, expected for 2D quantum critical fluctuations.



U12-05. Quantum criticality of antiferromagnet Mn_3P under pressure. *H. Kotegawa*[1], K. Uda[1], Y. Kuwata[1], H. Tou[1], H. Sugawara[1], T. Sakurai[1], H. Ohta[1] and H. Harima[1] *1. Kobe University, Kobe, Japan*

Recent discovery of superconductivity in MnP at a magnetic phase boundary has motivated the exploration of quantum phase transition in Mn-based systems.[1] However, Mn-based compounds generally tend to have strong magnetic interaction and the ground states of most of Mn-based compounds are magnetically-ordered state with a large magnetic moment. In this presentation, as a rare example, we will show that a magnetic quantum phase transition occurs in Mn_3P under a relatively lower pressure. Mn_3P crystalizes in a tetragonal structure as shown in Fig.1 and the space group is *I-4*. The Mn ions have three inequivalent sites, and the space inversion symmetry is lacking. The antiferromagnetic transition occurs at T_N = 30 K, [2] but a magnetic structure has not been clarified yet. We synthesized single crystals of Mn_3P using a flux method. Figure 2 shows temperature dependence of resistivity at ambient pressure. The resistivity shows a clear hump below T_N and possesses the relatively high residual resistivity, indicative of a gap formation by the antiferromagnetic transition. This behavior resembles that of α-Mn.[3] By applying pressure, the transition is gradually suppressed, accompanied by the decrease in the residual resistivity, and the ordered state disappears at 1.5 GPa. In the vicinity of quantum critical point, the behavior in resistivity is similar to those of heavy fermion systems, and the A coefficient in resistivity shows quite high value among d electron systems. We will discuss the quantum criticality of Mn_3P from the resistivity data and show results of NMR measurements.

Renewed and intensified attention is being paid to heavy fermion systems since the discovery of a quantum critical point (QCP) in many of them. The hybridization of localized f-states and conduction band states is very sensitive to electron distribution around the magnetic ions – a well-known manifestation of this phenomenon is the continuous drive of the transition temperature between the magnetically ordered state and paramagnetic state to T = 0 K. This behaviour is long known and well documented within the Doniach phase diagram [1]. The cerium and uranium compounds (Yb to lesser extent) are extensively investigated close to QCP where physical phenomena are mainly driven by quantum fluctuations and characteristically a non- Fermi liquid behaviour is evoked. $CePd_2Ga_3$, a Kondo lattice

ferromagnet (T_K = 4 K and T_C = 6 K), has been synthesized (in polycrystalline form) more than two decades ago [2]. Earlier results indicate possibility of the intermediate AF/complex magnetic phase with increased pressure in the vicinity of presumable QCP [3]. To shed light on the high pressure behaviour we prepared single crystalline samples of $CePd_2Ga_3$ by Bridgman method in high-frequency induction furnace. Our results confirms the ambient pressure ferromagnetic ground state with strong planar anisotropy, however, magnetic and transport measurement does not show any presence of the AF/complex magnetic phase. Our results shows the monotonous decrease of the Curie temperature with increasing pressure, critical pressure of the magnetism suppression being estimated to 5.5GPa.

UTX (T – transition metal, X- p-metal) compounds are in the center of research due to coexistence of superconductivity and ferromagnetism in UCoGe [1] and URhGe [2]. The appearance of the superconductive dome in the generalized phase diagram is related to the presence of the quantum phase transition (QPT). In pure enough materials phase diagram with discontinuous transition is observed at low enough temperatures - the ferromagnetic second order phase transition is suppressed, by tuning parameter, until tricritical point (TCP) is reached [3]. At TCP second order transition changes into first order one and is quickly suppressed. Also at TCP metamagnetic transition from paramagnetic state to ferromagnetic appears. With increasing tuning parameter metamagnetic transition is suppressed into quantum critical point. Other UTX compounds exhibiting full or part of discontinuous phase diagram are URhAl [4], UCoGa [5] and UCoAl [6], crystallizing in hexagonal ZrNiAl structure. In order to investigate the low temperature part of the discontinuous phase diagram and e merging phases in the vicinity we prepared single crystals of off-stoichiometric UCoAl and UCoAl doped by subpercent amount of Ru. Both systems have ZrNiAl structure and very low Curie temperatures at ambient pressure being quickly suppressed by application of hydrostatic pressure (pure UCoAl is paramagnet with metamagnetic transition at low fields and at low temperatures [7].). By doping it by only 1% of Ru ferromagnetic ground state is observed and lowering amount of Ru doping acts as a tuning parameter to reach TCP [8]. On the other hand, the small amount of dopant does not change the order of the transition allowing detailed investigation of the phase diagram by varying type of approach to the QPT by pressure and/or substitution. We will present our recent results and compare them with other UTX compounds, especially with respect to the limits of interchangeability between pressure and doping. Magnetization, electric transport and dilatometry data in ambient and hydrostatic pressure will be shown. On the basis of these data the generalized phase diagram will be presented and discussed in the above mentioned context.

U12-08. Suppression of the Anisotropic Phase of $Sr_3Ru_2O_7$ by Hydrostatic Pressure. *L. He*[1], M. Fu[1], D. Sun[5], R. Perry[4], A. Mackenzie[2,3] and S.R. Julian[1] *1. Department of Physics, University of Toronto, Toronto, ON, Canada; 2. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 3. University of St. Andrews, St. Andrews, United Kingdom; 4. University College London, London, United Kingdom; 5. Los Alamos National Laboratory Pulsed Field Facility, Los Alamos, NM, United States*

$Sr_3Ru_2O_7$ has attracted attention because it has a discontinuous metamagnetic transition that can be tuned to a quantum critical end-point (QCEP) by rotating the crystal in the magnetic field[1]. In ultra-pure samples, the QCEP is screened by an anisotropic phase, which was recently shown to be a spin-density-wave (SDW) phase [2]. We have investigated the pressure-dependence of the anisotropic phase by measuring the magnetoresistance anisotropy, with the field applied close to the *c*-axis, under hydrostatic pressure. We find that the anisotropic phase is suppressed by pressure and is completely gone at 7.2 kbar. In contrast, a previous study by our group found that another anisotropic phase, that occurs when the field is applied in the *ab*-plane, is comparatively unaffected by pressure up to 16 kbar [3]. Our results reinforce that the *c*-axis anisotropic phase is connected with quantum criticality, while the physics of the *ab*-plane anisotropic phase may be quite different.

Quantum phase transitions (QPTs) have become an important research area of different fields of modern condensed matter physics. QPTs occur at zero temperature, and can be triggered by varying a non-thermal control parameter as external pressure, chemical composition or magnetic field and driven by a corresponding change of quantum fluctuations between phases. Among these, magnetic QPTs are of special interest as they can have different physical origins and their nature depends on the type of the magnetically ordered state. While quantum critical points and quantum criticality in many itinerant and localized antiferromagnetic systems have been identified and well investigated, for ferromagnetic systems theory predicts a first-order QPTs for sufficiently clean systems rather than critical points [RMP citace 1] but available experimental evidence is rather scarce. U*TX* family of compound is especially suited for in depth investigation of possible scenarios behind the loss of magnetic order due to the large number of isostructural compounds with various ordering temperatures and magnitudes of ordered magnetic moments. We have grown single crystals of UCoGa and URhGa and investigate theirs magnetic and transport properties at ambient pressure and under hydrostatic pressures (acting as tuning parameter). The UCoGa compound undergoes transition to paramagnetic state at 6.5GPa approx., having the power law dependent resistivity with exponent 5/3, similarly to URhAl [2] and pure UCoAl [3]. Contrary to URhAl the studied compound shows significantly higher tricritical temperatur presumably resulting from higher sample quality. On the other hand, the ordering temperature of the URhGa compound increases with applied hydrostatic pressure up to 8.5GPa with moderate (by one third) decrease of ordered moment. Presented results will be discussed in the general framework of uranium magnetism as well as in the context of critical behavior of itinerant ferromagnets.

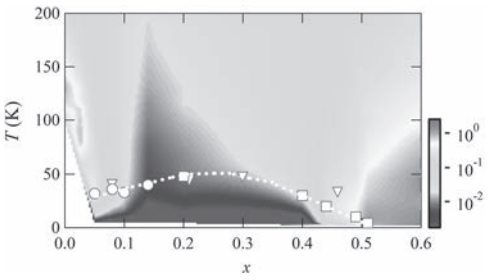
U13-01. Anisotropic pressure effects on superconductivity in S-substituted $Fe_{1+y}Te$. *T. Yamanaka*[1], K. Yamamoto[1], N. Umezawa[1], T. Yamazaki[1,2], D. Ueta[3], H. Yoshizawa[3] and H. Yaguchi[1] *1. Physics, Tokyo University of Science, Noda, Japan; 2. Physics, Waseda University, Shinjuku, Japan; 3. ISSP, The University of Tokyo, Kashiwa, Japan*



Iron-based superconductors have been attracting great research interest. Among them, iron chalcogenides 11-system-iron-based superconductors such as FeSe and $Fe_{1+y}Te_{1-x}S_x$ are suitable to investigate their basic properties owing to the simplest crystal structure. A notable feature is that the superconducting transition temperature (T_c) in FeSe is greatly enhanced by hydrostatic pressure; T_c increases from 8 K to 37 K at 6 GPa [1], concomitant to the vanishing of the antiferromagnetic order [2]. For a wide range of iron-based superconductors, a common relationship between the critical temperature T_c and the anion height (h_{anion}), which is defined as the distance between the anion and the nearest iron layers, has been empirically proposed [3] and the pressure effect in FeSe somewhat obeys the relationship. In this context, the application of pressure is expected to enhance T_c of the iron-based superconductor $Fe_{1+y}Te_{1-x}S_x$. However, hydrostatic pressure on $FeTe_{0.8}S_{0.2}$ reduces its T_c. In the present study, we have investigated uniaxial and hydrostatic pressure effects on superconductivity in $Fe_{1.07}Te_{0.88}S_{0.12}$ using magnetization measurements on single crystals of $Fe_{1.07}Te_{0.88}S_{0.12}$. Uniaxial pressure along the out-of-plane direction is expected to control the anion height more efficiently than hydrostatic pressure. Our magnetic-susceptibility measurements on $Fe_{1.07}Te_{0.88}S_{0.12}$ under pressure show that T_c is enhanced by out-of-plane pressure. In contrast, T_c is reduced by in-plane pressure and hydrostatic pressure [4]. Such anisotropic uniaxial-pressure effects on T_c may be understood according to the mentioned-above relationship between T_c and hanion in a qualitative fashion. In our poster presentation, we will show the details of the experimental apparatuses used for the application of pressure and the results of susceptibility measurements and will discuss the correlation between the pressure directions and the shift of T_c.

U13-02. Pressure-induced Quantum Critical Behavior in $LaFeAsO_{1-x}H_x$ Studied via NMR. *N. Fujiwara*[1], M. Takeuchi[1], T. Kuwayama[1], S. Nakagawa[1], S. Iimura[2], S. Matsuishi[3] and H. Hosono[2,3] *1. Graduate School of Human & Environmental Studies, Kyoto University, Kyoto, Japan; 2. Institute for Innovative Research, Tokyo Institute of Technology, Yokohama, Japan; 3. Material Research Center for Element Strategy, Tokyo Institute of Technology, Yokohama, Japan*

$LaFeAsO_{1-x}H_x$ is a prototypical iron-based superconductor. However, its phase diagram is quite unique unlike the conventional one: the SC phase is sandwiched between two antiferromagnetic (AF) phases appearing in lightly ($x \leqq 0.05$) and heavily ($x \geqq 0.49$) H-doped regimes [1, 2]. The AF phase ($x \geqq 0.49$) is strongly suppressed by applying a pressure of 3.0 GPa. Figure 1 shows the phase diagram at 3.0 GPa and color plot of magnetic fluctuations determined from the relaxation rate of ^{75}As divided by temperature ($1/T_1T$) . A quantum phase transition from the AF to SC phases occurs at around x~0.5. A "bare" AF quantum critical point (QCP) manifests at x~0.55 [3]. The QCP is located away from the optimal doping level (x~0.4) [4]. For x=0.6, we observed a peak and Curie-Weiss behavior in $1/T_1T$, as shown in Fig. 2. The result suggests that the gapped excitation originating from the AF state and the gapless excitation characteristic to the QCP coexist. We applied further pressure for x=0.6 to investigate whether the AF state completely vanishes and a pressure-induced AF QCP manifests. We found that the peak of $1/T_1T$ remains up to 3.7 GPa, and it completely disappears at 4.0 GPa, implying that the pressure-induced QCP is located at around 4.0 GPa. At the conference, we will compare two QCPs appearing by H doping and pressure application in relationship with the superconductivity.

Color plot of $1/T_1T$ and electronic phase diagram under a pressure of 3.0 GPa. The areas colored in dark blue and orange correspond to the SC dome and two AF phases, respectively. The AF QCP is expected at x~0.55. T_c is determined from the resistivity (triangles) and T_1 (squares and circles) measurements.

$1/T_1T$ of ^{75}As measured at x=0.6. Open and closed circles represent the data measured at ambient pressure and 3.0 GPa, respectively. The peaks of $1/T_1T$ correspond to the AF transition temperature (T_N).

U13-03. Hydrostatic Pressure Effects on the Superconductivity of $Ca_{0.9}La_{0.1}FeAs_2$ Single Crystals. *D. Bhoi*[1], B. Min[1], Y. Sur[1], D. Jang[1], C. Kim[1], D. Kim[3], J. Shim[2], K. Murata[1] and K. Kim[1] *1. CENSCMR, Department of Physics and Astronomy, Seoul National University, Seoul, The Republic of Korea; 2. Department of Chemistry & Physics, POSTECH, Pohang, The Republic of Korea; 3. Center for High Pressure Science and Technology Advanced Research (HPSTAR), Shanghai, China*

La-doped $CaFeAs_2$ has been recently found to exhibit a high superconducting transition temperature (T_c ~ 36 K), with a superconducting volume ratio up to 66% [1]. The crystal structure of the La-doped $CaFeAs_2$ is characterized by a conductive intermediate As-As layer located between the FeAs superconducting layers. In this work, we have grown the La-doped $CaFeAs_2$ single crystal with an improved flux method, which exhibits an enhanced T_c ~ 46 K and a large volume fraction ~ 70%. We also investigated the hydrostatic-pressure dependence of resistivity in $Ca_{0.9}La_{0.1}FeAs_2$ up to 8.5 GPa with the combination of a hybrid piston cell and a cubic anvil press. The pressure dependence of T_c reveals a dome shaped behavior with a maximum T_c ~ 51.4 K at 1.7 GPa. At this pressure, *T*-dependence of resistivity shows a linear behavior for $T > T_c$, possibly due to the non-Fermi liquid state in the vicinity of a quantum phase transition or multiband effects. Furthermore, the pressure dependence of slope of the upper critical field, dH_{c2}/dT near T_c, also reveals a sharp peak at 1.7 GPa, suggesting the quasiparticle mass enhancement associated with Fermi surface modification near the optimal pressure.

U13-04. Multigap superconductivity in $RbCa_2Fe_4As_4F_2$ investigated using μSR measurements. *D. Adroja*[1,2], F. Kirschner[3], F. Lang[3], M. Smidman[4], A. Hillier[1], Z. Wang[5], G. Stenning[1] and S. Blundell[3] *1. ISIS Facility, Rutherford Appleton Laboratory, Chilton, United Kingdom; 2. Highly Correlated Matter Research Group, Physics Department, University of Johannesburg, Johannesburg, South Africa; 3. Department of Physics, Clarendon Laboratory, University of Oxford, Oxford, United Kingdom; 4. Center for Correlated Matter and Department of Physics, Zhejiang University, Hangzhou, China; 5. Department of Physics and State Key Lab of Silicon Materials, Zhejiang University, Hangzhou, China*

The superconducting properties of the recently discovered double Fe_2As_2 layered high-T_c superconductor $RbCa_2Fe_4As_4F_2$ with $T_c \approx 30$ K have been investigated using magnetization, heat capacity, transverse-field (TF) and zero-field (ZF) muon-spin rotation/relaxation (μSR) measurements [1-3]. Our low field magnetization measurements and heat capacity (C_p) reveal an onset of bulk superconductivity with T_c ~ 30.0(4) K. Furthermore, the heat capacity exhibits a jump at T_c of $\Delta C_p/T_c$=94.6 (mJ/mole-K^2) and no clear effect of applied magnetic fields was observed on C_p(T) up to 9 T between 2 K and 5 K. Our analysis of the TF-μSR results shows that the temperature dependence of the magnetic penetration depth is better described by a two-gap model, either isotropic *s*+*s*-wave or *s*+*d*-wave than a single gap isotropic *s*-wave or *d*-wave model for the superconducting gap. The presence of two superconducting gaps in $RbCa_2Fe_4As_4F_2$ suggests a multiband nature of the superconductivity, which is consistent with the multigap superconductivity observed in other Fe-based superconductors, including $ACa_2Fe_4As_4F_2$ (A=K and Cs) [4-5]. Furthermore, from our TF-μSR study we have estimated an in-plane penetration depth λ_{ab} (0) =231.5(3) nm, superconducting carrier density n_s= 7.45 × 10^{26} m–^{3}, and carrier's effective-mass *of* 2.45m_e. Our ZF μSR measurements do not reveal a clear sign of time reversal symmetry breaking at T_c, but the temperature dependent relaxation between 150 K and 1.2 K might indicate the presence of spin-fluctuations. The results of our present study have been compared with those reported for other Fe pnictide superconductors.

U13-05. Jahn-Teller distortion in two-band model for iron pnictide superconductors. *B. Pradhan*[1] *1. Physics, BJB College, Bhubaneswar, India*

We have presented a theoretical model for the FeAs based superconductors through a tight binding model with two Fe ions per unit cell and two degenerate orbitals per Fe ion. Based on this, the coexistence of superconductivity and Jahn-Teller effect with s±-wave pairing symmetry of the form coskx × cosky is examined. The analytic expressions for the temperature dependent superconducting and Jahn-Teller order parameters are derived by Zubarev's technique of double time single particle electron Green's function method and solved self-consistently. It is observed that in the interplay region, both the order parameters exhibit very strong dependence of one another. The local density of states (DOS) is also investigated. The DOS feature in the multi band model can be very different than that in the single band model. The DOS shows well-defined coherent peaks with the position determined by the superconducting and Jahn-Teller order parameters. The additional peaks outside the coherent peaks is due to the van Hove singularity, which is a normal-state property. The resultant DOS exhibits a linear behaviour within a very small energy range near the Fermi energy and then reaches a plateau up to a larger energy scale characterised by the amplitude of the s±-wave order parameter. The thermal properties study of the model shows the specific heat jumps at the two transition temperatures, the superconducting transition temperature Tc and the Jahn-Teller transition temperature Td. The other calculations resemble with the experimental findings. Finally, we also have studied the dispersion properties.

U13-06. Phase Separation in $Cs_xFe_{2-y}Se_2$ Superconductor. *M.I. Sturza*[1,2], K. Taddei[2,3], O. Chmaissem[2], S. Rosenkranz[2], S. Wurmehl[1], B. Büchner[4] and M. Kanatzidis[2,5] *1. By simultaneously displaying magnetism and superconductivity in a single phase, the iron-based superconductors provide a model system for the study of magnetism's role in superconductivity. The class of intercalated iron selenide superconductors is unique among these in having the additional property of phase separation and coexistence of two distinct phases—one majority phase with iron vacancy ordering and strong antiferromagnetism, and the other a poorly understood minority microscopic phase with a contested structure. Adding to the intrigue, the majority phase has never been found to show superconductivity on its own while the minority phase has never been successfully synthesized separate from the majority phase. In order to better understand this minority phase, a series of high-quality $Cs_xFe_{2-y}Se_2$ single crystals with were grown and studied. At high temperature, a *122* - type structure with random iron vacancies undergoes a complex iron vacancy ordering scheme below ~500K causing the material to phase separate into $Cs_2Fe_4Se_5$, known as the *245* phase, and a minority *Cs*-site deficient and fully iron stoichiometric $Cs_xFe_2Se_2$ phase (HT*122*). At slightly lower temperatures, the material undergoes another transition with the Fe spins of the main *245* phase ordering into an exotic checkerboard-type magnetic structure with a large magnetic moment. The minority LT*122* phase is reported to either remain nonmagnetic or to become magnetic below ~200K. At temperatures below ~30K, the magnetic material becomes superconducting and the two states appear to coexist. Neutron and x-ray powder diffraction performed on ground crystals show that the average I4/*mmm* structure of the minority

phase is distinctly different from the high-temperature I4/*mmm* parent structure. Moreover, single-crystal diffraction reveals the presence of discrete superlattice reflections that remove the degeneracy of the *Cs* sites in both the majority and minority phases and reduce their structural symmetries from body centered to primitive. Magnetization measurements performed in tandem with neutron single-crystal diffraction provide evidence that the minority phase is the host of superconductivity.

U13-07. Antiferromagnetic order in epitaxial FeSe films on $SrTiO_3$.
D. Wu[1] *1. Nanjing University, Nanjing, China*

Single monolayer (ML) FeSe film grown on Nb-doped $SrTiO_3$(001) substrate shows the highest superconducting transition temperature (T_C ~ 100 K) among the iron-based superconductors (iron-pnictide), while T_C of bulk FeSe is only ~ 8 K. Antiferromagnetic (AFM) spin fluctuations were believed to be crucial in iron-pnictides, which has inspired several proposals to understand the FeSe/$SrTiO_3$ system. Although bulk FeSe does not show the AFM order, calculations suggest that the parent FeSe/$SrTiO_3$ films are AFM. Experimentally, due to lacking of direct probe, the magnetic state of FeSe/$SrTiO_3$ films remains mysterious even though some indirect signature of the AFM order was shown by photoemission experiments. Here, we report the direct evidences of the AFM order in the parent FeSe/$SrTiO_3$ films by the magnetic exchange bias effect measurements. The AFM order disappears by electron doping. Our findings provide crucial information for understanding the superconducting behavior in the FeSe/$SrTiO_3$ films.

U13-08. Interplay of structural properties and magnetic disorder in FeSe: Density-functional theory calculations.
F. Lochner[1,2], I. Eremin[2], J. Neugebauer[1] and T. Hickel[1] *1. Computational Materials Design, Max-Planck-Institut für Eisenforschung, Düsseldorf, Germany; 2. Theoretische Physik III, Ruhr-Universität Bochum, Bochum, Germany*

We calculate the effect of local magnetic moments and particularly their paramagnetic disorder on the normal state of a prototype iron-based superconductor FeSe. For this purpose the spin-space averaging approach [1] for density functional theory (DFT) calculations is applied. Here, we analyze the structural parameters of FeSe, the impact on the electronic properties as well as the interplay of electronic and phononic degrees of freedom in the paramagnetic state. In contrast to original non-magnetic DFT calculations [2], the results in the paramagnetic state agree after relaxation with experimentally observed lattice parameters with an error less than 5%. Based on this achievement a DFT based understanding of the mechanisms underlying the superconducting behavior and driving the nematic transition of FeSe seems now to be feasible.

U13-09. Temperature vs Pressure Phase Diagram of $FeSe_{1-x}S_x$ investigated by μSR.
S. Holenstein[1,2], J. Stahl[3], Z. Shermadini[1], R. Khasanov[1], J. Orain[1], A. Amato[1], E. Morenzoni[1], D. Johrendt[3] and H. Luetkens[1] *1. Laboratory for Muon Spin Spectroscopy, Paul Scherrer Institut, Villigen PSI, Switzerland; 2. Physik-Institut, Universität Zürich, Zürich, Switzerland; 3. Department Chemie, Ludwig-Maximilians-Universität München, München, Germany*

Application of hydrostatic pressure to the iron based superconductor FeSe suppresses the nematic order and leads to the appearance of static magnetic order for pressures above 0.8 GPa [1]. At the same time, the superconducting T_c increases from 8 K at ambient pressure up to 37 K at approx. 7 GPa [2]. A recent study using resistivity measurements at hydrostatic pressures suggests that isovalent S substitution for Se up to 17% leads to a faster suppression of the nematic phase while shifting the magnetic dome to higher pressures. These macroscopic measurements therefore suggest a complete separation of the two phases as a function of pressure [3]. Here, using the local probe technique muon spin rotation (μSR), we show however that static magnetism is already present at much lower pressures than previously thought in our slightly inhomogeneous sample with x ranging between 7% and 12%, although not with a full volume. In fact, the magnetism seems to develop already at slightly lower pressures than for pure FeSe. Our data clearly indicate an increasing moment with increasing pressure, as it has been observed for FeSe, even though the spread of S content in our sample makes a quantitative estimation of the ordered moment size difficult. Finally, the superconducting transition temperature tends to increase with pressure but exhibits a local minimum just above the onset pressure of magnetism. The temperature vs pressure phase diagram as determined by μSR is depicted in Fig. 1.

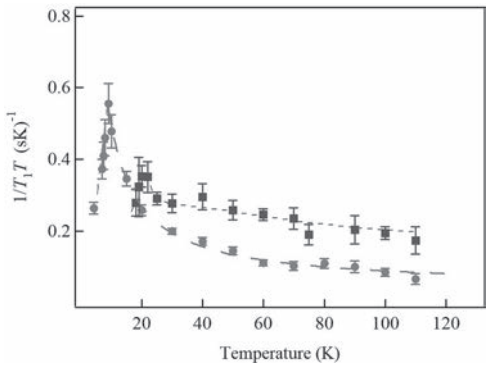
Department of Physics, Kyoto University, Kyoto, Japan; 4. Institute for Solid State Physics, University of Tokyo, Kashiwa, Japan*



Recently, the relationship among superconductivity, nematicity, and magnetism has been paid much attention in iron-based systems. S-doped FeSe offeres an attractive stage in investigating the relationship. FeSe has a unique *T*-*P* phase diagram: following a nematic phase at high temperatures, a superconducting (SC) phase manifests below 9 K without magnetism. The nematic phase disappears under pressures above 2 GPa, and instead an antiferromagnetic (AF) phase manifests [1]. In S-doped FeSe, the nematic phase and the AF phases are separated by the SC phase in the *T*-*P* phase diagram [2], which allows one to investigate the effect of nematicity and magnetism on superconductivity separately. We investigated the relationship between magnetic fluctuations and superconductivity via ^{77}Se NMR for 12%-S doped FeSe, where T_c reaches 26 K at 3.0 GPa. Figure 1 shows the ac susceptivility measured using the tank circuit of a NMR probe. T_c goes up with increasing pressure. The onset of T_c are 9.8 K at 0.1 MPa and goes up to 24.2 K at 3.0 GPa. Figure 2 shows the relaxation rate divided by temperature ($1/T_1T$). At 0.1 MPa, clear Curie-Weiss behavior was observed in $1/T_1T$, and the peak corresponds to T_c. In general, magnetic fluctuations are enhanced near the AF phase boundary, and thus the Curie-Weiss behavior would be enhanced at 3.0 GPa. However, the Curie-Weiss behavior is hardly enhanced despite that T_c is enhanced at 3.0 GPa. A possibility to understand this anomalous result is that the SC state would be different between low and high pressure regimes. To confirm this assumption, the measurements at intermidiate pressures between 0.1 MPa and 3.0 GPa are needed. In the conference, we

will show the data measured at 1.0 and 2.0 GPa, and discuss the relationship between superconductivity and magnetism.

AC susceptibility measured from the tank circuit of a NMR probe.The onset of T_c is 9.8 K at 0.1 MPa and 24.2 K at 3.0 GPa. T_c determined from the crosspoint of two dashed lines is 8.6 K at 0.1 MPa and 22.8 K at 3.0 GPa.

Relaxation rate divided by temperature ($1/T_1T$) measured at ^{77}Se sites under a magnetic field of 60 KOe. The peaks at 9 and 22 K correspond to T_c at 0.1 MPa and 3.0 GPa, respectively.

U13-11. Superconducting gap anisotropy of FeSe single crystal in fully twinned nematic state: upper critical field and conductivity in basal plane. A.V. Sadakov[1], P.D. Grigoriev[1,2], *T.A. Romanova*[1] and D.A. Chareev[3] *1. P.N. Lebedev Physical Institute, Russian Academy of Sciences, Moscow, Russian Federation; 2. L.D. Landau Institute for Theoretical Physics, Russian Academy of Sciences, Chernogolovka, Russian Federation; 3. Institute of Experimental Mineralogy, Russian Academy of Sciences, Chernogolovka, Russian Federation*

Anisotropic nature and symmetry of superconducting (SC) order parameter in highly unconventional multiband superconductor FeSe still remain a debatable issue, despite the immense amount of both experimental and theoretical work in this field. It is known that FeSe undergoes a structural tetragonal-to-orthorhombic nematic transition at a temperature of T_s≈90K, that leads to formation of a multi-domain structure as a result of twinning along the *a* and *b* directions. We report a comprehensive experimental and theoretical study of anisotropic superconducting and electronic properties of fully twinned high quality FeSe single crystals (T_c=9.0K). Anisotropic behavior of upper critical field and electric conductivity in basal plane was studied and described in terms of Ginzburg–Landau theory in the vicinity of T_c. H_{c2} angular dependence experiments were performed by means of *c*-axis resistivity measurements at temperature T=8.8K in magnetic fields up to 4T. In-plane resistivity measurements along crystallographic directions <*hk0*> were carried out on a specifically prepared structure. We observed four-fold symmetry of $H_{c2}(\theta)$ with anisotropy ratio as big as 30% ($H_{c2}(0)/H_{c2}(45)$≈1.3) (Fig.1). In-plane resistivity data below the nematic transition shows that electric conductivity of FeSe along [110], [1-10], [100] and [010] directions differ by 5-10%. According to G.-L. theory for a one-band superconductor in-plane anisotropy of H_{c2} may come from the anisotropy of conductivity (electron velocity) $\sigma = (\sigma_x, \sigma_y)$, from the anisotropy of SC order parameter (ψ(k)), or from the both. In our work we proposed a simplified model that qualitatively describes observed H_{c2} angular behavior (Fig.2). This model was developed for the system of mutually perpendicular orthorhombic domains with two-fold ψ(k) symmetry. We took into account only SC order parameter anisotropy, due to weak σ anisotropy. For quantitative description of the results, however, further investigations including non-resistive experiments on $H_{c2}(\theta)$ and more deep theoretical take are needed. Additional non-resistive H_{c2} experiments will exclude effect of anisotropic pinning of twin boundaries.

We used synchrotron-based high-resolution angle-resolved photoemission spectroscopy (ARPES) to map the three-dimensional momentum dependence of the superconducting gap in FeSe. We found that on both the hole and electron Fermi surfaces, the magnitude of the gap follows the distribution of d_{yz} orbital weight. Furthermore, we theoretically determined the momentum dependence of the superconducting gap by solving the linearized gap equation using a tight binding model that quantitatively describes both the experimental band dispersions and orbital characters. By considering a Fermi surface only including one electron pocket, as observed spectroscopically [1, 2], we obtained excellent agreement with the experimentally deter-

mined gap structure. Our finding of a scaling between the superconducting gap and the d_{yz} orbital weight supports the interpretation of superconductivity mediated by spin-fluctuations in FeSe [3].

The techniques of fabricating epitaxial films have provided us with various fascinating research fields such as surface/interface, low dimensionality, and epitaxial strain effects. Recently, Matsuda *et al*. succeeded in epitaxial growth of Ce-based compound and fabricating the superlattices [1,2]. $CeCoIn_5$/$YbCoIn_5$, one of the heavy-fermion (HF) superlattices, show the characteristic superconducting properties which are different from bulk $CeCoIn_5$: large anisotropy of the upper critical field (H_{c2}) and the strong enhancement of H_{c2}/T_c, where T_c is critical temperature [2]. Although such attractive phenomena have been reported, unfortunately the experimental techniques to study the physical properties of film samples are limited because of the small sample volume and huge contribution of the substrate. Nuclear quadrupole resonance (NQR) and nuclear magnetic resonance (NMR) are suitable techniques for film samples. Indeed, we applied an NMR technique to the HF superlattice superconductor $CeCoIn_5$/$YbCoIn_5$ and revealed that the $YbCoIn_5$ layers remain conventional metal as well as bulk $YbCoIn_5$ and the antiferromagnetic spin fluctuations in $CeCoIn_5$ layers are suppressed [3]. In addition, we applied NQR technique to epitaxial $CeCoIn_5$ film with the 500 nm thickness. In NQR measurements, the signals can be observed without external field and therefore it is a suitable technique for superconducting sample. As a result, we reveal that the magnetic and superconducting properties of the $CeCoIn_5$ thick film are essentially the same as that of the bulk $CeCoIn_5$. However, the NQR spectra of the film sample shifts noticeably and becomes significantly broader than the bulk sample [4]. The origin of the spectrum broadening is partially interpreted by the epitaxial strain effect, but we suggest that the lattice parameters might be optimized in the epitaxial film sample taking into the frequency shifts of the NQR spectra. In our poster presentation, we show the NQR results of the film $CeCoIn_5$ and compare the NQR parameters of the film with that of the bulk $CeCoIn_5$ and calculated ones with WIEN2k. *Present address of the first author: Dept. of Physics, Tokyo Univ. of Science

The Kondo model predicts that both the valence at low temperatures and its temperature dependence scale with the characteristic energy T_K of the Kondo interaction. We studied the evolution of the 4f occupancy, n_f with temperature in a series of Yb Kondo lattices using resonant X-ray emission spectroscopy (RXES). In agreement with simple theoretical models, we observe a scaling between the valence at low T and T_K obtained from thermodynamic measurements. In contrast, the temperature scale, T_v on which the valence increases with temperature is almost the same in all investigated materials while the Kondo temperatures differ by almost four orders of magnitude. This observation is in remarkable contradiction to both naive expectation and precise theoretical predictions of the Kondo model asking for further theoretical work in order to explain our findings. Possible reason of this universal T scale are excitations of crystal electric field states which may also be responsible for the unusual temperature dependence of n_f observed in YbNiSn: Photoemission spectra of heavy Fermion compounds reveal a characteristic 4*f*-derived Fermi level peak, which reflects contributions from the Kondo resonance and its CEF satellites and reveals an unusual temperature dependence in YbNiSn [1]: A steady linear increase of intensity is observed with decreasing temperature which extends over a large interval ranging from 100 K down to 1 K without showing any peculiarities in the region of T_K = 5.6 K. In the light of the single-impurity Anderson model (SIAM) this intensity variation reflects a linear increase of 4*f* occupancy with decreasing temperature, indicating an onset of Kondo screening at temperatures above 100 K, i. e. far above T_K. Within the periodic Anderson model (PAM) this phenomenon could be described by a non-Fermi-liquid-like *T* - linear damping of the self-energy which accounts phenomenologically for the feedback from the closely spaced CEF states.

Uranium compounds have been receiving much attention in their unconventional properties because 5*f* electrons have properties of itinerant and localized features. The ground state in uranium compounds is affected by the hybridization with *p* and *d* electrons. Recently, single crystalline UT_2X_{20} (T = transition metals, X = Al, Zn, Cd) compounds with high quality have been synthesized at a viewpoint of the hybridization effect [1-4]. In UPd_2Cd_{20}, which the hybridization effect is small, temperature variation of U valence has been firstly observed [5], and the variation is strongly corresponding to thermal expansion curve. To discuss a relationship between the hybridization and the U valence states, effect of pressure on the valence state in UPd_2Cd_{20} was investigated by using high-resolution x-ray absorption spectroscopy. High-energy resolution x-ray absorption spectra (PFY) at U L_3-edge in UPd_2Cd_{20} were measured at BL39XU of SPring-8. The PFY-XAS is actualized by using 3*d*-2*p* resonant x-ray emission spectroscopy (RXES) beyond core-hole lifetime-broadening effect in the final states. High pressure is applied by a diamond-anvil-cell, and a Be gasket is used to penetrate incident and emitted X-rays for the RXES measurements. Daphne 7373 is used as pressure media, and pressure is monitored by a ruby fluorescence method. All measurements were performed at room temperature. U valence states are recognized by the chemical shifts between the main peak of PFY for U^{3+} and that for U^{4+} [6]. A split of the main peak of PFY is clearly observed in UPd_2Cd_{20}, and peak energies of two-peak structure corresponds to the energy of U^{3+} and U^{4+} components in comparison with the reference samples (UCd_{11} (U^{3+}) and UPd_3 (U^{4+})). As increasing pressure, U^{3+} (U^{4+}) component is suppressed (enhanced) in the PFY so as to increase U valence. U valence is saturated at about 4 GPa, and the variation of Δv~0.1 in a pressure range of 0–4 GPa is large in comparison with the variation of Δv~0.04 in a temperature range of 3–300 K. Moreover, the PFY at high pressure are similar to that in the other UT_2X_{20} compounds. This result is consistent with the enhancement of hybridization by applying pressure.

U14-04. Micro-structuring the $Ce(Co,Rh,Ir)In_5$ heavy fermion family.
M. Bachmann[1], C. Putzke[1], T. Helm[1], K. Modic[1], K. Shirer[1], M. König[1], A. Mackenzie[1], E. Bauer[3], F. Ronning[3] and P.J. Moll[4] *1. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 3. Los Alamos National Laboratory, Los Alamos, NM, United States; 4. Microstructured Quantum Matter, Max Planck Institute for Chemical Physics of Solids, Dresden, Germany*

Despite its simple crystal structure, the so-called "115" family of heavy fermion metals $Ce(Co,Rh,Ir)In_5$ defies our understanding. We approach this challenge by developing methods that allow the design of micron-sized single crystal structures of highest quality. We use a focused ion beam to micro-machine crystals with sub-micron control over the sample geometry. The high quality of the devices is evidenced by large residual resistivity ratios and pronounced Shubnikov-de Haas oscillations readily observed in the microstructures. Designing crystalline devices has multiple advantages: a) The resistance along arbitrary crystal directions can be directly measured; b) the total device resistance can be increased in devices with extreme geometric factors, such as long and thin meanders. This enables precise measurements of the low resistances common in the heavy fermion state. c) Single domain states can be probed in devices smaller than the coherence length, i.e. of magnetic order. We present recent microstructure investigations of a) a field-induced state with nematic character in $CeRhIn_5$ emerging at magnetic fields above 30T [1]; b) superconductivity with surprisingly unidirectional character in CeIrIn5 between 0.4K and 1.2K; and c) the critical current anisotropy in $CeCoIn_5$.

Ronning et al., Electronic in-plane symmetry breaking at field-tuned quantum criticality in $CeRhIn_5$, Nature, 548, 313–317 (2017)

U14-05. NMR studies on the magnetic fluctuations in the artificial heavy-fermion superlattices of $CeCoIn_5/YbCoIn_5$ and $CeCoIn_5/YbCoIn_5$.
G. Nakamine[1], T. Yamanaka[1], S. Kitagawa[1], K. Ishida[1], M. Naritsuka[1], T. Ishii[1], T. Shibauchi[2], T. Terashima[2], Y. Kasahara[1] and Y. Matsuda[1] *1. Department of Physics, Kyoto University, Kyoto, Japan; 2. Department of Advanced Materials Science, The University of Tokyo, Kashiwa, Japan*

The progress in the epitaxial-growth technique enabled us to synthesize an artificial heavy-fermion (HF) superlattices (SLs) of alternately stacked block layers (BLs) with a few atomic layer thickness. These SLs provide a new platform to study the two-dimensional electronic properties, interaction between different BLs, and magnetic properties at the interfaces [1]. Actually, it was shown from the angle dependence of the superconducting (SC) upper critical field H_{c2} that two dimensional superconductivity is realized in the $CeCoIn_5$ (HF superconductor)/ $YbCoIn_5$ (conventional metal) SL [2], [3]. Another interesting SL is the $CeCoIn_5$ (HF superconductor)/ $CeRhIn_5$ (spin-density-wave metal) SL. The H_{c2} of this SL is enhanced by applying pressure. Since the H_{c2} is determined by the Pauli pair-breaking mechanism, and is proportional to $\Delta/g\mu_B$ in this case, the enhancement of H_{c2} suggests the increase of the SC gap Δ by critical antiferromagnetic (AFM) fluctuations [4]. We performed ^{59}Co-NMR measurements on the $CeCoIn_5/YbCoIn_5$ and $CeCoIn_5/CeRhIn_5$ SL focusing on the $CeCoIn_5$ BL to investigate whether spin fluctuations at the $CeCoIn_5$ BL are different between two SLs or not. We consider that ^{59}Co-NMR is one of the best experimental techniques in the SL samples, since the NMR can derive the magnetic information only from the target BLs. We found that $1/T_1T$ of the $CeCoIn_5$ BL in the $CeCoIn_5/YbCoIn_5$ SL is smaller than that of the $CeCoIn_5$ films as shown in Fig. 1. The suppression of $1/T_1T$ is consistent with the previous ^{115}In-NMR study [5]. On the other hand, $1/T_1T$ of the $CeCoIn_5$ BL in the $CeCoIn_5/CeRhIn_5$ SL does not show such a suppression, but larger component shows up at low temperatures although the same $1/T_1T$ component remains. We show that the AFM fluctuations at the $CeCoIn_5$ BL are clearly different between two SL samples. We suggest that the interface interactions, which depends on the adjacent BLs, are the most important interaction to determine the magnetic properties of the $CeCoIn_5$ BL.

Valence fluctuating compounds $YbAlB_4$ have two polymorphs, namely α-$YbAlB_4$ and β-$YbAlB_4$. β-$YbAlB_4$ is a unique example of the valence fluctuating compounds that shows pronounced non Fermi liquid behaviors and a superconducting transition at 80 mK under ambient pressure and field [1]. On the other hand, α-$YbAlB_4$ at low temperatures is well fit to a Fermi liquid type description [2]. As the origin of quantum criticality in β-$YbAlB_4$, for example, a quantum valence transition and a new type of topological phase transition of the Fermi surface are proposed [3,4]. This Fermi surface topological phase transition is essential to the nodal hybridization which originates from pure $|J = 7/2, J_z = \pm 5/2\rangle$ crystal electric field (CEF) ground state (GS) without admixture of other J_z components. Indeed, the temperature dependence of the magnetic susceptibility is consistent with the CEF GS of $|\pm 5/2\rangle$ [5]. However, the analysis of magnetic susceptibility has uncertainty in determining CEF. To uniquely determine the CEF GS which provides the information of anisotropy in the hybridization, we measured the linear dichroism (LD) of Yb 3*d* core level photoelectron spectrum excited by hard X-rays at BL19LXU of SPring-8. Yb^{3+} 3*d* core level photoelectron spectrum shows multiplet splitting induced by the interaction between Yb 4*f* electrons and the created Yb 3*d* hole. The intensity of the multiplet splitting strongly depends on the orbit of 4*f* electrons, X-ray polarization and the direction of outgoing photoelectron. By controlling the experimental configuration, we can determine a 4*f* electron orbit, namely a CEF GS [6]. We applied this method to α-$YbAlB_4$ and β-$YbAlB_4$, and the results of β-$YbAlB_4$ are shown in the figure. The ion model simulation is qualitatively consistent with $|\pm 5/2\rangle$, but is quantitatively different, which is possibly due to the strong hybridization. On the other hand, no anisotropy in *ab*-plane was found within the experimental error and we can exclude the possibility of admixture of other J_z components. In this presentation, we will discuss LDs and the CEF GSs for both α- and β-$YbAlB_4$.

U14-07. THz conductivity of $YbRh_2Si_2$ thin films grown by molecular beam epitaxy. *S. Paschen*[1,2] *1. Institute of Solid State Physics, Vienna University of Technology, Vienna, Austria; 2. Rice University, Houston, TX, United States*

$YbRh_2Si_2$ is one of the most extensively studied heavy fermion compounds. An interesting and much debated observation is the Fermi surface change across the field-tuned quantum critical point [1,2]. It extrapolates to a sharp jump in the zero temperature limit [1,2] and can thus be rationalized within a Kondo destruction scenario [3,4]: Breaking up the Kondo entanglement localizes the f electrons. Here we report time-domain Terahertz transmission spectroscopy on epitaxial $YbRh_2Si_2$ thin films grown by molecular beam epitaxy. The observed frequency-over-temperature scaling of the charge response explains the non-Fermi liquid behavior of the electrical resistivity and demonstrates that it is the electron localization itself that governs the unconventional quantum criticality in this material [5].

U14-08. Energy Scales of Doped Anderson Lattice Model. *H. Kang*[1], H. Choi[1], J. Kim[1] and J. Shim[1,2] *1. Department of Chemistry, POSTECH, Pohang-si, The Republic of Korea; 2. Department of Physics, POSTECH, Pohang-si, The Republic of Korea*

Kondo effect was firstly discovered in metal with magnetic impurities as a resistivity minimum [1]. Jun Kondo explained the resistivity minimum as a consequence of the anti- ferromagnetic coupling between the spin moment of the magnetic impurity and conduction electron spin moment [2]. The anti-ferromagneitc scattering was revealed to be a relavant coupling in the renormalization group sense, and the Kondo temperature where the resistiv- ity minimum occurs was identified by a unique fundamental energy scale [3–6]. Based on the renormalization group study, Nozi'eres revealed that the ground state with effective infinite coupling strength is described by the Landau Fermi liquid localized at the impurity site [7]. After that, a slave-boson mean-field theory described the Kondo physics as a symmetry-breaking and successfully interpreted the Kondo temperature as a critical temperature for the phase transition [8]. Compared to the single-impurity model, it has not been unveiled yet whether the Kondo lattice model with periodic impurity spin moment has the same energy scale as the single-impurity model case or not. In this study, we studied scaling behavior of doped Anderson lattice model at the Kondo regime using dynamical mean-field theory (DMFT) and continuous-time quantum Monte Carlo (CTQMC) impurity solver. We confirmed that the Kondo temperature of the single-im-

puritty case scales the high-temperature regime of the lattice model regardless of the doping level. At low-temperature regime, a new energy scale is needed to scale the physical observables such as resistivity and local static spin susceptibility. The new energy scale, called coherence temperature, shows additional doping-dependency compared with the Kondo temperature of the single-impurity model. The coherence temperature is found to be consistent with experimental definition of the coherence temperature at which resistivity shows its maximum. We show how other physical observables such as Hall angle, Fermi surface, ARPES spectra, and entropy behave at the local Kondo temperature and the coherence temperature. Effect of the DMFT self-consistency on the scaling will also be discussed.

U14-09. Kondo effects in α-Cerium and SmB_6. *J. Kim*[1], H. Choi[2], K. Kim[3,1] and B. Min[1] *1. Physics, POSTECH, Pohang, The Republic of Korea; 2. Chemistry, POSTECH, Pohang, The Republic of Korea; 3. Physics, Max Planck Institute for Chemical Physics of Solids, Pohang, The Republic of Korea*

The Kondo effect is one of the fascinating correlation phenomena in condensed matter physics, In this research, we have investigated the Kondo phenomena in two different materials. One is the monoatomic compound, cerium(Ce), famous for the α-γ phase transition and the extremely rich phase diagram with at least seven allotropes. The other is sarmarium hexaboride(SmB_6), which is known as a topological insulator recently showing unusual quantum oscillation behaviors. To capture the Kondo physics in both materials, we used the first principles Dynamical Mean-Field Theory(DMFT) approach combined with Density Functional Theory(DFT)[1,2]. Unlike the cases only using DFT, we have observed that the Kondo resonances near E_F are well estabilished in the DFT+DMFT scheme. We theoretically addressed the evolution of Kondo resonances as a function of temperature. Especially for α-Ce, we have explored the temperature-dependent evolution of Fermi surfaces. Additionally, the dimensionality effect of Kondo resonances has been briefly discussed.

U14-10. RKKY interaction revised - spin correlation functions and quantum criticality. *F. Eickhoff*[1], B. Lechtenberg[2] and F. Anders[1] *1. Theoretical Physics, Technical University Dortmund, Dortmund, Germany; 2. Department of Physics, Kyoto University, Kyoto, Japan*

The RKKY interaction describes an effective Heisenberg exchange interaction between two localized moment induced by coupling them to a conduction band. This well known exchange interaction oscillates and decays as function of distance leading to possible ferro- and antiferromagnetic couplings. For arbitrary distance between the moments, we have identified the parts for the conduction band density of states (DOS) that generate either the ferromagnetic or antiferromagnetic (AF) contributions to the RKKY interaction. This is based on a symmetry analysis of parity and distance dependent hybridization function. We investigate the two impurity Anderson model (TIAM) and map the distance dependent fraction of the hybridization function responsible for the AF contribution onto an effective single-particle tunneling term between the impurities. This exchange mechanism predicts a RKKY coupling that is proportional to 1/U in contrary to the two-impurity Kondo model (TIKM) where one would expect a $1/U^2$ dependency. We present a full numerical renormalization group (NRG) calculations [1] to prove the equivalence of the effective and the original two impurity problem and determine the absolute energy scale of the RKKY interaction in the full Hamiltonian. The NRG calculations verify the 1/U dependence in accordance with analytically derived limit $R \rightarrow 0$ [2]. We demonstrate that the RKKY interaction and the resultant spin correlation function decays markedly slower with increasing distance than predicted by the TIKM and even differs in the sign in some regions. The construction of the effective tunneling term can provide new insight to AF contribution to the RKKY interaction. We study the spatial anisotropy of this contribution on a simple cubic lattice and analyze the connecting between the spatial frequency and the band filling. We use our understanding of the different contributions to the RKKY interaction for engineering the recovery of the Varma and Jones quantum critical point [3] in the TIAM for arbitrary distances even for a particle-hole symmetry broken model that generically only shows a continuous change of the conduction electron scattering phase.

U15-01. The exchange bias and giant vertical magnetization shift in $LaMnO_3/SrMnO_3$ superlattice. *X. Xu[1] 1. Chemistry and Material Science, Shanxi Normal University, Linfen, China*

The interface between two correlated electron systems may have properties that are qualitatively different from either of the two constituents, providing a potential route to new physical properties.[1] An example is the interface between the A-type antiferromagnetic (AFM) insulator $LaMnO_3$ (LMO) and the G-type AFM insulator $SrMnO_3$, which experiments on LMO/SMO superlattices are shown to have both ferromagnetism and metallic tendencies.[2] However, LMO typically exhibits ferromagnetic behavior as it is very thin.[3] As we all known, the exchange bias would exist in the interface between ferromagnetic and antiferromagnetic materials.[4] In order to research the exchange bias in these two materials, a series of high quality $[LaMnO_3(n)/SrMnO_3(m)]_{10}$ (L_nS_m) superlattices are grown in an epitaxial way using pulsed-laser deposition. Figure 1a presents the magnetization-magnetic field hysteresis loops for the L_4S_3 superlattice measured at 5 K with the application of ±5 T in-plane magnetic field. After field-cooling from room temperature, a shift of the center of the magnetic loop along the magnetic field axis is observed, revealing the presence of exchange bias in the L_4S_3 superlattice. The exchange bias field can be deduced from the expression $H_{EB}=|H^+ + H^-|/2$. At the same time a vertical magnetization shift (i.e., along the magnetization axis) toward the same sign of the cooling field is observed in this superlattice. This vertical hysteresis shift can be calculated using $M_{shift}=[(+)]/ [(-)]$, where and are the positive and negative saturation values of the hysteresis loop.[5] Therefore, the H_{EB} and M_{shift} in the L_4S_3 superlattice is 784 Oe and 29%, respectively. Figure 1b shows the H_{EB} and M_{shift} dependence of different cooling field. It is obvious the M_{shift} is largest at cooling field as 5 T. Figure1. (a) Magnetization (M) versus magnetic field (H) loops of L_4S_3 superlattice at 5 K after an in-plane field cooling (±5 T), (b) The H_{EB} and M_{shift} dependence of the cooling field of L_4S_3 superlattice.

U15-02. Magnetic,structural and strain properties of FeRh thin films studied using polarised neutron reflectivity and X-Ray characterisation. C. Bull[1], C.W. Barton[1], W. Griggs[1], A. Caruana[2], C. Kinane[2], P.W. Nutter[1] and *T. Thomson[1] 1. School of Computer Science, University of Manchester, Manchester, United Kingdom; 2. Rutherford Appleton Laboratory, STFC, Didcot, United Kingdom*

Equiatomic FeRh in thin-film form has attracted increasing research interest over the last few years, owing to the fact that it undergoes a first-order phase transition from an antiferromagnetic (AF) to a ferromagnetic (FM) ordering at ~350K [1]. Such magnetic switchability at modestly elevated temperature underpins its candidacy as a material for several novel applications, such as heat assisted magnetic recording [2] and antiferromagnetic memory resistors [3]. The change in magnetic order at the FeRh phase transition is accompanied by a ~1% increase in the unit cell volume and previous work has shown that the onset and width of the transition are highly dependent on lattice strain [4-5]. Thus, control of stress fields in FeRh provides a means by which the transition may be tuned. In order for viable implementations of strain-induced switching of FeRh thin films to be realised, a comprehensive understanding of the various mechanisms through which strain may be induced is essential [6]. One such mechanism is epitaxial strain from the substrate. Here we report polarised neutron reflectivity (PNR) measurements performed on FeRh films of varying thicknesses (5nm, 20nm, 50nm). These data, which are complimented by X-ray reflectivity (XRR) measurements, have allowed us to develop a model that identifies the role of island formation, an important means by which strain may be mediated, on the magnetism in FeRh with depth-resolution. In fitting scattering-length-density (SLD) profiles to the PNR datasets (shown Figures 1(a) and 1(b)), comparisons may be drawn between the magnetic properties of each sample and lattice strain (see Figure 1(c)). Strain values were obtained from X-ray diffraction (XRD) measurements. The experimental findings are discussed in the context of each sample's surface topography, which was measured via atomic force microscopy (AFM).

U15-03. Structural and magnetic properties of Cobalt Iron diSulfide ($CoxFe_{1-x}S_2$) nanocrystals. *H.J. Gabold[1], Z. Luan[2], M. Law[2] and A. Paul[1] 1. E21, Technical University of Munich, Munich, Germany; 2. Department of Chemical Engineering & Material Science, University of California, Irvine, Irvine, CA, United States*

We report on synthesis and investigation of nanocrystalline Cobalt-Iron-Pyrites with an emphasis on nanocrystal structure, morphology and magnetic behavior. The nanocrystals (NCs) were 5– 25 nm in diameter as characterized using scanning electron microscopy (SEM) and transmission electron microscopy (TEM). With an increase in Fe fraction, X-ray diffraction and small-angle-X- ray scattering (SAXS) showed a systematic decrease in lattice constant, primary grain/NC size (15 to 7 nm), and nanoparticle (NP) size (70 to 20 nm), respectively. The temperature dependence of the DC

magnetization and AC susceptibility versus frequency revealed a number of magnetic phases in $Co_xFe_{1-x}S_2$. Samples with x = 1 and x = 0.875–0.625 showed evidence of superspin glass (SSG) behavior with embedded ferromagnetic (FM) clusters of NPs. For x = 0.5, samples retained their mixed phases, but showed superparamagnetic (SPM) behavior with antiferromagnetic clusters suppressing magnetic dipolar interactions. Below x = 0.5, the pyrites show increasing paramagnetic character. The phase diagram can be understood in terms of competition between the various dipolar, exchange, inter- and intracluster interactions. Our results suggest that NC size and shape can be tuned to engineer spin-polarized ferromagnetism of n-doped iron Pyrite.

U15-04. Temperature controlled Fe/Au/FeRh spin valves. *P. Drozdz*[1], M. Slezak[1], K. Matlak[1], J. Korecki[1,2] and T. Slezak[1] *1. Faculty of Physics and Applied Computer Science, AGH University of Science and Technology, Krakow, Poland; 2. Jerzy Haber Institute of Catalysis and Surface Chemistry PAS, Krakow, Poland*

The magnetic and structural properties of Fe/Au/FeRh system were investigated. First, the equiatomic FeRh layer with a thickness of 200 Å was grown on a MgO(001) substrate via co-deposition at room temperature followed by annealing at 1300 K for 30 minutes. Next, epitaxial Au wedge-shaped film with thickness varying from 0 to 40 Å was deposited by MBE. Finally, the Fe layer with a thickness of 50 Å was evaporated on the Au surface. Magnetic properties were studied by the longitudinal magneto-optical Kerr effect (LMOKE). The FeRh alloy film has revealed a temperature induced first-order magnetic transition from an antiferromagnetic (AFM) to ferromagnetic (FM) state at a transition temperature (T_T). The LMOKE loops were measured with external magnetic field applied along [100] MgO direction. The loops measured for the selected Au spacer thickness 20 Å and 25 Å at temperatures lower (blue loop) and higher (red loop) than AFM-FM transition temperature are shown in Fig.1. The LMOKE loops acquired for the AFM state of FeRh alloy were always rectangular for all the Au spacer thickness (see blue loops in Fig.1). However, for the temperature corresponding to the FM state of the FeRh alloy the interlayer coupling between Fe and FeRh layers changes non-monotonically between bilinear and biquadratic with increasing Au spacer thickness (see red loops in Fig.1). The maximum of biquadratic coupling corresponds to Au spacer thickness close to 25 Å according to the shape of LMOKE loops characterized by lowered remanence and higher saturation magnetic field value (red loop in Fig.1b). The temperature driven evolution of spin structure in FeRh/Au/Fe system is shown schematically in Fig.2. The dotted line ellipse indicates area of biquadratic interlayer coupling. Our results provide a new scheme of the spin valves architecture that spin structure can be controlled by temperature. This work was supported by the National Science Center Poland (NCN) under Project No. 2015/19/B/ST3/00543.

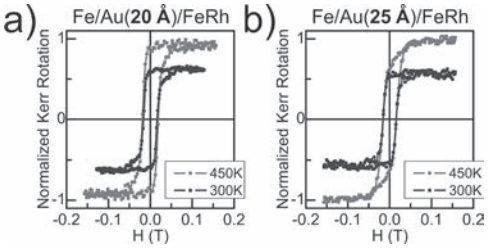

FIG.1 The exemplary LMOKE magnetic hysteresis loops collected for Fe/Au(20 Å and 25 Å)/FeRh. The red and blue curves correspond to FM and AFM state of the FeRh alloy, respectively.

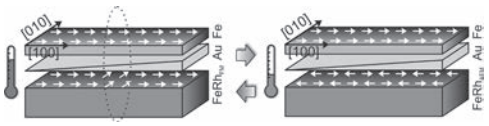

FIG 2. The temperature driven evolution of spin structure in Fe/Au/FeRh.

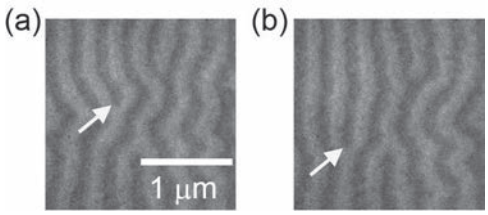
U15-05. Study of magnetic phase transition in $LaCoO_3$ and $La_{0.7}Sr_{0.3}CoO_3$ thin films grown by pulsed laser deposition. *T. Joshi*[1], D. Belanger[1] and D. Lederman[1] *1. Department of Physics, University of California, Santa Cruz, Santa Cruz, CA, United States*



The rare-earth Cobaltite, $LaCoO_3$ has attracted researchers' interest because of its intriguing electronic and magnetic properties. In bulk $LaCoO_3$, Co^{3+} ions have the low spin configuration (S = 0) at low temperatures. Thin films of $LaCoO_3$, however, exhibit a ferromagnetic ground state below ~85 K. There are several efforts to explain underlying physics in terms of multiple spin-state transitions, Jahn-Teller distortions, the Co-O-Co bond angle or the rotation of the CoO_6 octrahedra, Oxygen vacancies, and strain induced by doping with Sr or the substrate-film lattice mismatch. A complete understanding of the mechanism, however, has not been achieved. In this presentation, we discuss the phase transition mechanism of $LaCoO_3$ and $La_{0.7}Sr_{0.3}CoO_3$ thin films less than 30 nm thick grown by pulsed laser deposition under compressive and tensile strain using $SrTiO_3$ and $LaAlO_3$ substrates. We demonstrate that strain plays an important role in the transition and discuss mechanisms related to substrate-induced strain and the formation of structural domains. We will also discuss the roles of effective dimensionality in the thinnest films and anisotropic exchange interactions.

U15-06. Fluctuation of stripe domains mediated by topological magnetic defects. *S. Je*[1,2], M. Jung[2], S. Montoya[3], E.E. Fullerton[4], K. Lee[5], J. Hong[2] and M. Im[1] *1. CXRO, Lawrence Berkeley National Laboratory, Berkeley, CA, United States; 2. Emerging Materials Science, Daegu Gyeongbuk Institute of Science and Technology, Daegu, The Republic of Korea; 3. Space and Naval Warfare Systems Center Pacific, San Diego, CA, United States; 4. UC San Diego, La Jolla, CA, United States; 5. School of Mechanical & Advanced Material Engineering, Ulsan National Institute of Science Technology, Ulsan, The Republic of Korea*

The magnetic stripe domains observed in the vicinity of the spin reorientation transition is a great platform for the study of dynamical behaviors of various topological magnetic states as the domain wall structures include defect spin structures such as magnetic skyrmions [1] and magnetic dislocations [2,3] and those rich variations of topological magnetic defects are strongly associated with the domain motions. In analogy to the edge dislocations in the crystal lattice [4], the presence of the magnetic dislocations plays a crucial role to facilitate the deformation in the overall structure of the stripe domains when they are densely crowded and topologically separated. Although studying the magnetic defects and their roles in the stripe domain phase is highly demanded from both scientific and technological perspectives, only few experimental works have been reported so far. In the present work, we directly observed the fluctuations of stripe domains

as well as the severance and reconnection of the stripe domains mediated by the motion of the topological defects. Using the full-field transmission soft X-ray microscope (XM-1) [5], a few hundred nm-sized magnetic defects created in ferrimagnetic systems are identified as shown in Fig. 1. To align the direction of the stripe axis, in-plane magnetic field was applied and the external perturbations driven by magnetic fields combined with current pulses are given to trigger the movement of the magnetic dislocations. It is found that the magnetic dislocations not only propagate along the direction of the stripe domains but also move perpendicular to the stripe domain by transferring its topology. The motions of dislocations result in a collective drift of stripe domain pattern over the mesoscopic length scales. Additionally, pair annihilation of magnetic dislocations and the motions of bubble skyrmions mediated by magnetic dislocations are also clearly observed.

The structural, thermal, magnetic, and magnetocaloric properties of $Ni_{48}Co_2Mn_{35}In_{15}$ melt-spun ribbons have been investigated using room-temperature X-ray diffraction (XRD), differential scanning calorimetry (DSC), and magnetization measurements. Magnetic and structural transitions were found to coincide in temperature leading to magnetocaloric effects associated with the first-order magnetostructural phase transition. A drastic shift in the martensitic transformation temperature (T_M) of 75 K to higher temperature was observed for melt spun ribbons relative to that of the bulk (T_M = 250 K). A comparison of structural, magnetic properties, and magnetocaloric effects in $Ni_{48}Co_2Mn_{35}In_{15}$ as-spun ribbons and bulk have been shown in details. The roles of the magnetic and structural changes on the transition temperatures of the ribbons are discussed. U15-08. The microstructure and giant magnetocaloric effect of $Ni_{36.0}Co_{14.0}Mn_{35.7}Ti_{14.3}$ alloy ribbons. K. Liu[1], *S. Ma*[1], Q. Ge[1], S. Yang[1], X. Han[1], K. Yu[1] and Z. Zhong[1] *1. Jiangxi Key Laboratory for Rare Earth Magnetic Materials and Devices (IREMMD), Jiangxi University of Science and Technology, Ganzhou, China*

Recently, NiMn-based Heusler alloys have attracted considerable and continuous attention due to its multifunctional properties around the martensitic transformation (MT) temperature. Generally speaking, Heusler alloys are composed of main-group(*p*-group) elements and transition (*d*-group) elements which can provide the excellent *p*-*d* orbital hybridization [1], however, attention on the Heusler alloys completely composed of *d*-group atoms is very less [2, 3]. Here, we prepared the $Ni_{36.0}Co_{14.0}Mn_{35.7}Ti_{14.3}$ alloy ribbons by melt-spinning technique to contrastively study the microstructure and large magnetocaloric effect of this type of all-*d*-metal [2]. The wheel speed was selected to be 15 m/s and some of ribbons were annealed at 850 °C for 10 min as the annealed ribbons. The X-ray diffraction results show that both melt-spun and annealed ribbons consist of 5M martensite and B2 austenite at ambient temperature, which can be confirmed by the surface image of melt-spun ribbons in which the lath-shaped martensite and equiaxed austenite coexist, as shown in Fig. 1(a). In contrast to the melt-spun, the grain size becomes larger and the boundary clearer after annealing, as can be seen in the partial enlarged detail [Fig. 1(c) and 1(d)]. The cross sections show that columnar grains grow perpendicularly with the surfaces for both melt-spun [Fig. 1(e)] and annealed ribbons [Fig. 1(f)]. Under 0-5 T magnetic field variation, what's more, both melt-spun and annealed ribbons show less critical field of phase transition and large magnetic entropy change (ΔS) of 24.19 $Jkg^{-1}K^{-1}$ and 28.12 $Jkg^{-1}K^{-1}$, respectively (Fig. 2), which are superior to the values in similar bulk ones [2]. And large effective refrigeration capacity of 74.2Jkg^{-1} and 82.6 Jkg^{-1} are also observed, indicating giant magnetocaloric effect can be similarly obtained without heat treatment in $Ni_{36.0}Co_{14.0}Mn_{35.7}Ti_{14.3}$ alloy ribbons.

U16-01. Frequency modulation spin waves generator via oscillating vortex core in NiFe disk array. *L. Chang*[1], M. Kao[1], L. Tsai[1], J. Liang[3] and S. Lee[1] *1. Institute of Physics, Academia Sinica, Taipei, Taiwan; 3. Department of Physics, Fu Jen Catholic University, New Taipei City, Taiwan*

We experimentally realize a spin-wave generator, capable of frequency modulation, in a magnonic waveguide. The emission of spin waves was produced by the reversal or oscillation of nanoscale magnetic vortex cores in a NiFe disk array. The vortex cores in the disk array were excited by an out of plane radio frequency (rf) magnetic field. The dynamic behaviors of the magnetization of NiFe were studied using a micro-focused Brillouin light scattering spectroscopy (BLS) setup. In addition to the discrete ferromagnetic resonance (FMR) signals above external dc saturation magnetic field, we observed clear signals at zero magnetic field where vortex cores are present. The schematic of our experiment is show in Fig. 1a. The sample consists of a 20nm-thick and 4wide NiFe magnonic waveguide. The waveguide is at the gap of the GS circuit. Magnetic disk array with thickness 50 nm and diameter 500 nm was fabricated on the surface of the magnonic waveguide as sources of propagating spin waves in this device. Fig. 1(b) shows BLS spectra of the vortex state at different frequency of the external rf magnetic field. The strength and attenuation length of the excitation SW at zero dc field, as a function of disk diameter will be discussed. We have found an ultra-agile mechanism for consistent excitation of propagating spin waves. The frequencies of the spin waves excited in this system are coherently tunable by the frequency of the driving rf signal f from 5 GHz up to 15 GHz. The experimental dispersion relation with different transverse magnetic field is plotted in Fig. 2. The short wavelength down to 80 nm for 13.5 GHz was observed.

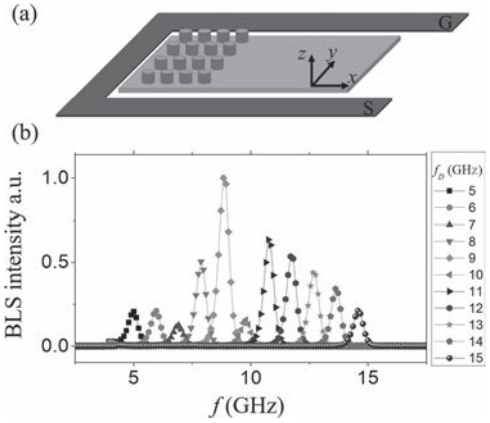

Figure 1. (a) Optical image of the experimental setup. (b) BLS spectra of the out-of-plane radio frequency magnetic field-induced vortex core oscillations at different driving frequencies *f*, as labelled. These data were recorded at zero dc bias field.

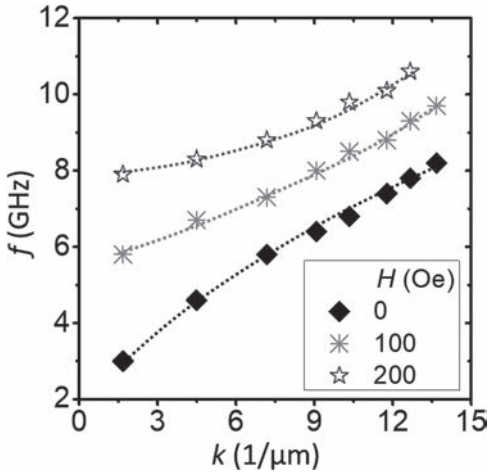

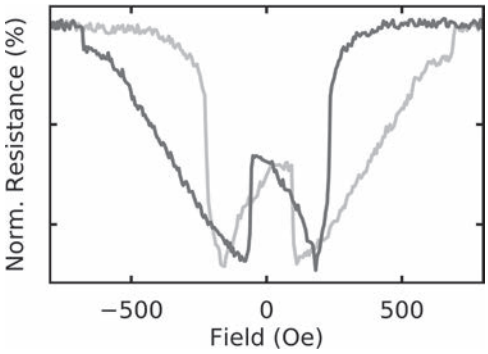

Figure 2. Dispersion relation of spin waves propagating in a NiFe magnonic waveguide with different transverse magnetic field.

U16-02. Effects of pinning in the magnetic configuration of a single disk at low temperatures. *S. Lendinez*[1], J. Ding[1], T. Polakovic[1], J.E. Pearson[1], A. Hoffmann[1] and V. Novosad[1] *1. Materials Science Division, Argonne National Laboratory, Lemont, IL, United States*

A magnetic vortex is the ground state in soft ferromagnetic disks of micrometer size and below. The response of the magnetic vortex under an external magnetic field has been investigated and is well understood. However, there are less studies of the response of the vortex at low temperatures, which would be useful for integration with superconducting circuitry. A previous study suggests that the vortex can be pinned out of the center [1]. Another study shows that the energy barriers at low and high temperatures have different origin [2]. In this work, we investigated the process of nucleation and annihilation of a single magnetic disk at different temperatures. By measuring the anisotropic magnetoresistance (AMR) signal of the disk and comparing it to micromagnetic simulations, we determined the configuration of the magnetization in the disks. As the temperature reached 100 K, we observed a change in the nucleation process of the magnetic vortex. Moreover, we show that pinning of the magnetization below 100 K prevents the formation of a magnetic vortex as a ground state, and an intermediate state is stable at remanence. The magnetic vortex state can be recovered by cycling the external magnetic field. Additionally, we establish that AMR measurements are more sensitive than magnetization measurements to the appearance of an intermediate state. Our results show that pinning and the stability of an intermediate state have to be taken into account for low-temperature operation of magnetic vortices in disks. Supported by the U. S. Resistance measurements of a single disk at 40 K for decreasing (dark blue) and increasing (light blue) field sweeps, from saturation. At remanence, the magnetization is in an intermediate state. The magnetic vortex is created by further sweep of the external field.

U16-03. The Role of Thermal Activation for Magnetic Vortex States. *H. Brueckl*[1], K. Pruegl[2], T. Wurft[2], S. Luber[2], W. Raberg[2], J. Zimmer[2], A. Satz[3] and D. Suess[4] *1. Department for Integrated Sensor Systems, Danube University Krems, Wiener Neustadt, Austria; 2. Infineon Technologies AG, Regensburg, Munich, Germany; 3. Infineon Technologies Austria AG, Villach, Austria; 4. Physics of Functional Materials, University Vienna, Vienna, Austria*

Thermal fluctuations of the magnetization essentially have two effects on the properties of a giant magnetoresistance (GMR) vortex sensor. They cause an intrinsic magnetic noise, increasing with temperature. A clear signature of magnetic noise is detected in the pure vortex state which is as large as the electronic noise. The experiments will be discussed within the framework of the semi-analytical rigid-vortex-model (RVM) [1] which has been extended by thermal excitations. In addition to magnetic noise, thermal fluctuations influence the vortex nucleation and annihilation field. The evaluation of the experimental data in dependence on temperature and free layer thickness is again discussed in the RVM frame. This allows the separation of two contributions, i.e. from saturation magnetization Ms(T) and thermally activated transitions. In the first order RVM, the nucleation field H_n and the annihilation field Han are directly proportional to Ms(T). Hence, an increasing T leads to a decreasing H_n and H_{an} (fig. 1). In contrast, thermal activation causes an increase of Hn and a decrease of H_{an} with temperature. The RVM model reproduces the experimental value of the relative change of the critical fields of -0.03 and -0.07 %/K at room temperature. The change of the critical field is dominated by the Ms(T) dependence in the range of 10 .. 450 K under typical sensor conditions. Thermal activation is a function of time within a probability equation. This is made visible by the statistics of vortex nucleation in a GMR disk ensemble in bridge configuration (fig. 2). The investigation of discrete vortex nucleation in a disk array allows for the determination of time constants and the estimation of energy barriers which determine the stability of the vortex state near critical fields. The typical barrier height to overcome is in the range of 1 J/m^3.

U16-04. Ultrafast Toggle Switching of Magnetic Skyrmions. M. Stifano[1], M. Barbeau[1], T. Rasing[1] and *J. Mentink*[1] *1. Institute for Molecules and Materials, Radboud University, Nijmegen, Netherlands*

Magnetic skyrmions are vortex like spin structures that appear as stable or meta-stable states in magnetic materials due to the interplay between the symmetric and antisymmetric exchange interactions, applied magnetic field and/or uniaxial anisotropy. Their small size and internal stability make them prospective objects for data storage. However, for applications, controllable writing and erasure of skyrmions at high speeds is essential. So far, controllable writing and erasure of single magnetic skyrmions has been demonstrated using scanning tunneling microscopy [1] and more recently by the application of spin-orbit torques to ferrimagnet GdFeCo films [2]. However, electrical control of skyrmion inherently limits device operation speeds to the GHz regime. Here, on the basis of atomistic spin dynamics simulations, we present an alternative scenario for controllable writing and erasure of single skyrmions in magnetic thin films. This scenario is based on the excitation of the medium with ultrashort perturbations of the intrinsic symmetric and antisymmetric exchange interactions with laser-generated acoustic pulses. Interestingly, focusing on a square sample, we find that for optimized pulse parameters the same excitation pulse can both generate and erase a single skyrmion, as shown in Figure 1. For realistic model parameters, this leads to toggle switching of skyrmions at 10-100 GHz rates, considerably higher than feasible with electrical currents. We further demonstrate that the nucleation mechanism is based on bringing the system in the vicinity of an instability of the uniform ferromagnetic phase and support our scenario with calculations of the perturbations of exchange interactions by acoustic pulses.

U16-05. Switching of Skyrmion chirality by local heating. *Y. Nakatani*[1], K. Yamada[2] and A. Hirohata[3] *1. University of Electro-communications, Tokyo, Japan; 2. Gifu University, Gifu, Japan; 3. University of York, York, United Kingdom*

A magnetic Skyrmion is a chiral structure appearing in a magnetic thin film with Dzyaloshinskii-Moriya interaction (DMI) [1-4]. Because of its small size and the small threshold current for motion, it is expected to be used as an information carrier for a magnetic storage system [5-7]. The methods to manipulate the Skyrmion, nucleation, annihilation, switching of the core direction, motion, by external field, spin-polarized current and the others have been proposed. In this paper, we propose a method to switch the chirality of the Skyrmion by a pulse heat spot, and study it by micro-magnetic simulation. Two types of Skyrmions with clock wise (CW) and counter clock wise (CCW) chirality were used as the initial states. In the simulation, a pulse heat spot with Gaussian shape was applied. The σ of the head spot (σ_h) was varied from 25 to 50 nm. The room temperature and the maximum temperature of the heat spot were set to be 300 and 550 K. The material parameters M_s, K_u, A, and D of each prisms were decreased as temperature was increased. Figure 1 shows the simulated time-resolved chirality switching by a heat spot. The CCW Skyrmion (fig. 1(a)) expands by the heat spot keeping the magnetization direction (fig. 1(b)). The Skyrmion shrinks after to cut the pulse, the magnetization rotates to the crock wise direction, and the CW Skyrmion appears (fig. 1(c)). The CW Skyrmion (fig. 1(d)) expands slightly by the heat spot, however the magnetization rotates to the counter clock wise direction (fig. 1(e)). The magnetization keeps to rotate to the same direction after to cut the pulse, and the CCW Skyrmion appears (fig. 1(f)). Figure 2 show the diagram plotting the switching, not switching and annihilating of the Skyrmion structure on σ_h and t_p for CCW (fig. 2(a)) and CW (fig. 2(b)) Skyrmions. They show that there are conditions to switch both Skyrmions and there are also conditions to switch only one type of Skyrmions.

Competing interactions in nanostructured magnets, primarily the Heisenberg exchange and Dzyaloshinskii-Moriya interactions (DMI), which promote spin collinearity and canting respectively, lead to the formation of complex spin textures such as helical and conical structures. Particle-like objects with non-trivial spin configurations, i.e., skyrmions and skyrmion lattices, can also be created upon rotational-symmetry breaking. The individual spins in a skyrmion, if mapped onto a sphere, could wrap it completely one time. This bestows topological protection on the magnetic state, which cannot be continuously unwound to a topologically-trivial ferromagnetic state, and thus a phase transition is necessary. By means of numerical simulations, we have systematically compared systems with isotropic ("bulk") DMI and anisotropic ("interfacial") DMI, and found that in perfect systems skyrmion lattices can be inverted in a field-induced first-order phase transition involving an intermediate creation and annihilation of antiskyrmions. The presence of even a single defect, however, radically changes the system's behavior, where the inversion is replaced by a second-order phase transition of defect-induced lattice melting, in which topological winding of skyrmions is gradually lost. This shows that a defect analysis is necessary for all realistic systems in order to analyze experimental data correctly. Our results provide fundamental insight into the processes that drive magnetic phase transitions and lead the way to an experimental realization of these topological spin phenomena in technologically relevant magnetic systems.

U16-07. Dynamics of isolated skyrmions driven by electromagnon excitations. *A. Takeuchi*[1] and M. Mochizuki[1,2] *1. Department of Physics and Mathematics, Aoyama Gakuin University, Sagamihara, Japan; 2. Department of Applied Physics, Waseda University, Shinjuku-ku, Japan*

Skyrmions are nontrivial swirling magnetic textures, which emerge as a consequence of competition between the Dzyaloshinskii-Moriya interaction (DMI) and the exchange interaction in the presence of an external magnetic field, which are recently attracting active research interest from the viewpoints of both fundamental physics and spintronic applications. Magnetization configuration of skyrmion depends on a way of the breaking of spatial inversion symmetry. For instance, the Bloch-type skyrmions emerge in the B20-type chiral magnets, whereas the Neel-type skyrmions emerge at interfaces between two different magnets. In the later system, strength of the DMI can be controlled by application of an external electric voltage [1]; therefore, manipulation of the interfacial DMI enables the electric control of noncollinear magnetisms. In this study, we numerically demonstrate that an oscillatory motion of an isolated Neel-type skyrmion can be activated by application of the external alternate-current (AC) electric voltage through generating the temporally oscillating DMI. The observed motion can be regarded as oscillatory expansion and shrinkage of skyrmion, which is similar to the breathing mode observed under the out-of-plane AC magnetic field [2,3]. Importantly, this electric technique can selectively activate the eigenmode of the isolated skyrmion in a ferromagnetic background without exciting the ferromagnetic resonance. Therefore, it enables us to control precisely the isolated skyrmion, which can never be achieved by conventional methods using microwave magnetic fields. For a demonstration, we examine the microwave-activated motion of a skyrmion in a nanotrack under a static magnetic field inclined from the perpendicular direction of the nanotrack plane. A previous theoretical study predicted that irradiation of a microwave with out-of-plane polarization can induce a translational motion of the skyrmion through activating the breathing mode [4]. Our simulation demonstrates that similar translational motions are indeed induced by the present electric technique.

U16-08. Fixed Skyrmion Based Resonate and Fire Neuron. *M. Azam*[1], D. Bhattacharya[1], D. Querlioz[2] and J. Atulasimha[1] *1. Virginia Commonwealth University, Richmond, VA, United States; 2. C2N, Université Paris-Sud, Orsay, France*

Biological neurons having subthreshold oscillations of membrane potential can act as resonate and fire neurons [1]. Due to a fixed eigen frequency of the oscillations, such neurons are sensitive to input stimulus of a certain frequency and play an important role in synchronous routing of neural signal in biological systems [2] and artificial neural networks [3]. In this work, we demonstrate a resonate and fire neuron by utilizing the magnetization dynamics of a fixed magnetic skyrmion in the free layer of a magnetic tunnel junction (MTJ). The free layer is a magnetostrictive nanodot deposited on top of a thin heavy metal layer that is deposited on a PZT layer (Fig 1). Input voltage stimulus applied to the PZT layer produces strain which is transferred to the magnetostrictive layer and alters the perpendicular magnetic anisotropy (PMA) of this layer [4]. Owing to this modification of PMA, an excitation triggers expansion and contraction of the skyrmion core known as breathing, which is of decaying amplitude. Consequently, the magnetoresistance of the MTJ stack undergoes an oscillation. Repetitive excitation in-phase with the breathing oscillation can lead the core size of the skyrmion to cross a threshold. The higher resistance achieved at this larger core size can be used in a voltage divider circuit to drive a CMOS buffer and produce a firing output. We show that, the breathing frequency (i.e. the eigen frequency of the neuron) can be altered significantly by manipulation of geometry, PMA, exchange coupling and Dzyaloshinskii-Moriya Interaction (DMI) value of the free layer in the MTJ. Exploiting frequency sensitivity of our proposed neurons would enable several applications of such neurons in artificial neural networks [3]. Micromagnetic and circuit simulation of the proposed device will be used to verify reliable application of this type of neurons in frequency division multiplexing and detection of phase synchronization in STNO oscillators. We acknowledge NSF CAREER grant CCF 1253370, VCU Quest Commercialization grant and Virginia Microelectronics Seed grant.

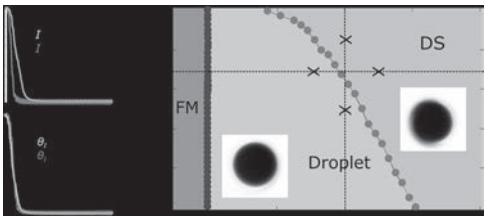
U16-09. Resonance Beyond Frequency-Matching: Multidimensional Resonance. *R. Wang*[1] *1. Xiamen University, Xiamen, China*

Resonance, conventionally defined as the oscillation of a system when the temporal frequency of an external stimulus matches a natural frequency of the system, is important in both fundamental physics and applied disciplines. However, the spatial character of oscillation is not considered in this definition. We reveal the creation of spatial resonance when the stimulus matches the space pattern of a normal mode in an oscillating system. The complete resonance, which we call multidimensional resonance, should be a combination of both the temporal and the spatial resonance. We further elucidate that the spin wave produced by multidimensional resonance drives considerably faster reversal of the vortex core in a magnetic nanodisc. Multidimensional resonance provides insight into the nature of wave dynamics and opens the door to novel applications.

U16-10. Creation of Skyrmions in arrays of coupled oscillators. *H. Vigo Cotrina*[1] and A.P. Guimaraes[2] *1. Centro Brasileiro de Pesquisas Fisicas (CBPF), Río de Janeiro, Brazil; 2. CBPF, Rio de Janeiro, Brazil*



Due to the smaller size and the topological protection, skyrmions in magnetic nanostructures (e.g., Nanodisks, nanostrips, etc) have many potential applications in spintronics [1,2]. Skyrmions can be stabilized tuning parameters as the perpendicular uniaxial anisotropy, the interface Dzialoshinskii-Moriya interaction (DMI) and aspect radio (β = L/R) of the nanostructures. Additionally, the creation and stabilization can be obtained using external parameters, such as magnetic fields and spin polarized currents [1-4]. For applications, the nanostructures are normally organized in arrays. This leads to the question of magnetic interactions between them. There are in the literature several works about the creation and stabilization of skyrmions in isolated nanostructures [3,4], but work is still lacking on the role of magnetic interaction in the process of creation of a skyrmion. The goal of the present work is to study the influence of the magnetic interaction on the creation of a skyrmion in coupled spin-torque oscillators using pulses of polarized current. We used a triangular and a square array of oscillators, and we obtained a phase diagram of polarized current intensity vs. time of application of the current pulse, for different values of parameters such as uniaxial anisotropy, DMI, and distance between the oscillators. Our results show that, depending on the separation distance between the oscillators, it is possible to create or avoid the creation of a skyrmion in a given oscillator; also, the current intensities required to create a skyrmion in an isolated oscillator change due to the magnetic interaction. This is relevant, since the external parameters (e.g., currents and fields, etc) often used to stabilize skyrmions in isolated nanostructures [1-4], would have to be modified in an array of coupled oscillators.

U16-11. Micromagnetic study of spin transfer torque induced dynamical skyrmions and dissipative droplet solitons. *N. Statuto*[1,2], J. Hernàndez Ferràs[1], A. Kent[3] and F. Macià[2] *1. Condensed Matter Physics Department, University of Barcelona, Barcelona, Spain; 2. Institute of Materials Science of Barcelona (ICMAB), Bellaterra, Spain; 3. Department of Physics, Center for Quantum Phenomena, New York University, New York, NY, United States*

Collective magnetic excitations, such as spin waves are attracting a growing interest for their potential in technological applications. The spin-transfer-torque (STT) effect is an important discovery because it provides a new means of manipulating magnetization states without magnetic fields. In particular, in materials with uniaxial magnetic anisotropy, dissipative droplet solitons (DD) have been observed (a self-localized excitation consisting of partially reversed magnetization that precesses coherently in the nanocontact region. It is also possible to generate topological droplet solitons, known as dynamical skyrmions (DS) [1]. Here, we show that DS and DD solitons can be created in a ferromagnetic thin film with PMA and with no DMI. We show that both solitons can be created with a same applied current value by only changing the initial magnetization angle (α_M). Fig.1a) and b) show the time evolution of the magnetization inside a NC for a DS and a DD. In panel a) they are excited at fixed current with different initial angles α_M and in panel b) they are exited at fixed angle α_M and at different current values. Two processes are involved in the creation: i) the STT favors the precession and reversal of magnetization beneath the NC; ii) the Oersted fields from the electric current create a curling in the magnetization. Both processes compete and the final state depends on the initial conditions. Panel c) shows the α_M-current phase diagram for the DS and DD creation. We also studied the stability of both solitonic modes; the DS is more stable than the DD and this feature may be used to distinguish the two modes experimentally.

U16-12. Decay of Skyrmions and Droplets in Uniaxial Ferromagnets. *M. Ruth*[1], E. Iacocca[1] and M. Hoefer[1] *1. Applied Mathematics, University of Colorado, Boulder, Boulder, CO, United States*

Localized magnetic textures have attracted interest both from a fundamental physics perspective and for potential applications in spintronics. In uniaxial ferromagnets, two such localized textures are topologically trivial droplets and non-trivial skyrmions. Droplets and skyrmions can originate from instabilities of elongated stripe domains [1]. Additionally, droplets can be sustained by spin transfer torque [2] while skyrmions can be stabilized by the Dzyaloshinskii-Moriya interaction [3]. In the absence of external forcing, both structures can only exist in uniaxial ferromagnets for a finite time before collapsing from magnetic damping. Here, we use a differential geometry method [4] to parameterize the perimeter dynamics and diameter decay of droplets and skyrmions. For textures with a large-diameter relative to the exchange length, the perimeter can be approximated by a circular

domain whose number of in-plane magnetization phase rotations determines the topology of the texture. Remarkably, the diameter decay and perimeter dynamics exhibit the same features independent of topology in the large-diameter regime. The diameter shrinks algebraically at a rate proportional to damping and the perimeter modulation decay depends on both damping and the quantized mode number, in agreement with a recent report of micromagnetic simulations and experiments [5]. Numerical calculations of the diameter decay using the exact magnetodynamical equations are in quantitative agreement with the analytical prediction in the large-diameter regime (see Fig. 1). For the small-diameter regime, numerical calculations reveal qualitative differences in the decay of droplets and skyrmions: droplets relax to the uniform magnetization state whereas the skyrmions decay to a point singularity is slower, a dynamical manifestation of non-trivial topology. These results provide insights into the temporal evolution of droplets and skyrmions towards annihilation and, consequently, the relevant conditions that hinder their room-temperature stability.

V1-01. Perpendicular Anistropy in $Co_2FeAl_{0.5}Si_{0.5}$ for CPP-GMR devices. W.J. Frost[1], M. Samiepour[2] and *A. Hirohata[2] 1. Department of Electronics, University of York, York, United Kingdom; 2. University of York, York, United Kingdom*

Previous work has shown that perpendicular anisotropy can be induced in Heusler alloys using a tungsten seed layer deposited at 400 °C [1]. In this work modest substrate temperatures TS < 75°C have been used prior to deposition. Samples with the structure Si/W(10nm)/ $Co_2FeAl_{0.5}Si_{0.5}$ (12.5nm)/ W (1.2nm)/ $Co_2FeAl_{0.5}Si_{0.5}$ (2.5nm)/Ru (3nm) were used as a basic spin valve structure. As shown in fig. 1(a) even the modest values of T_S > 45 °C lead to a partially crystallised tungsten seed layer, with a weakly crystallised $Co_2FeAl_{0.5}Si_{0.5}$ layer. These samples had a significant coercivity out-of-plane up to 500 Oe. The crystallisation was enhanced by T_S of 60 °C. With increasing crystallisation the tungsten reflection also relaxes towards the bulk position. The increasing crystallisation is matched by an increase in the coercivity up to 1 kOe caused by the increase in the grain size of the films from 3.5nm to 8 nm. In order to improve the spin valve properties of the film a silver barrier layer was used with a 5nm $Co_2FeAl_{0.5}Si_{0.5}$ layer giving the structure Si/ W(10nm)/ Cov (12.5nm)/ Ag (3nm)/ $Co_2FeAl_{0.5}Si_{0.5}$ (5nm)/ Ru (3nm) deposited at 70 °C. Figure 1(b) shows an example of a CPP-GMR measurement of a pillar with dimensions (150 x 100) nm. The observed ΔRA is low at 0.03% but is sharp and distinct. The GMR ratio will be improved by further optimising layer thickness and deposition temperatures. In this work we have shown that perpendicular anisotropy can be induced in $Co_2FeAl_{0.5}Si_{0.5}$ with modest substrate temperatures. Furthermore we have shown that the anisotropy is strongly dependent upon the crystallisation of a tungsten seed layer and the grain size. Finally, these Heusler alloys layers can be incorporated into CPP-GMR devices operated out of plane, with a small but distinct GMR. The authors would like to acknowledge Kevin O'Grady, University of York for fruitful discussion and Seagate Technology, Derry for their support.

V1-02. $L1_0$-phase FePd fully perpendicular magnetic tunnel junctions for STT-MRAM application. *D. Zhang*[1], C. Sun[3], R. Wu[2], Y. Lv[1], K. Schliep[2], Z. Zhao[1], J. Chen[1], A. Mkhoyan[2], P. Voyles[3] and J. Wang[1] *1. Department of Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States; 2. Department of Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, MN, United States; 3. Department of Materials Science and Engineering, University of Wisconsin-Madison, Madison, WI, United States*

Magnetic materials that exhibit bulk perpendicular magnetic anisotropy (PMA) are promising candidates for the development of ultrahigh density spin memory and logic devices, due to their high thermal stability, scalability, and ultra-low energy[1-2]. $L1_0$-phase bulk PMA FePd is a promising candidate for realizing these devices considering its low damping constant (α~0.007) and large magnetocrystalline anisotropy (K_u~20 Merg/cm^3), which could support node sizes down to 6 nm with a reasonable thickness. Here, we will present our recent experimental results about the development of the PMA FePd thin films and FePd perpendicular synthetic antiferromagnetic (p-SAF) structures, which were developed by high-vacuum magnetron sputtering system. After characterizing the magnetic property, it is found that the K_u~11.5 Merg/cc for PMA FePd thin films and 10.5 Merg/cc for FePd p-SAF structures were obtained. Meanwhile, the larger interlayer exchange coupling J_{IEC}~2.6 erg/cm^2 has been observed in FePd p-SAF structure. Then we used these PMA FePd films to develop the fully perpendicular magnetic tunnel junction (p-MTJ) stacks, which were patterned into micro-size MTJ devices by photolithography and ion milling etching method. The spin transport property was studied by four-probe technique. The experimental results show that the ~8.0% room temperature (RT) and ~34.8% 10K MR ratios were obtained in FePd p-MTJs after post-annealing at 350 °C. In addition, exciting results were obtained in FePd p-MTJs devices using FePd p-SAF layer after 350 °C post-annealing. Specifically, these devices obtained ~25.0% (~60.0%) MR ratios at RT (5K), as shown in Fig. 1. Even ~13% MR ratio was obtained in FePd SAF p-MTJs after 400 °C post-annealing.

These p-MTJs will provide a unique way to realize high-density non-volatile memory, spin logic devices, and spin-torque domain wall devices with high thermal stability and ultralow energy.

V1-03. CPP-GMR of Heusler alloy based junctions: Spacer materials and interface effects. *T. Kubota*[1,2], Z. Wen[1,2] and K. Takanashi[1,2]
1. Institute for Materials Research, Tohoku University, Sendai, Japan; 2. Center for Spintronics Research Network, Tohoku University, Sendai, Japan

Half-metallic Heusler alloy based current perpendicular-to-plane giant magnetoresistance (CPP-GMR) junctions are promising for realizing high GMR ratio[1]. One of interesting features is large temperature dependence of MR for the Heusler based junctions: MR ratios at low temperature are more than three times larger than those at room temperature[2--4], which is an important issue to be improved for enhancing the room temperature CPP-GMR. In this study, we investigated the temperature dependence of CPP-GMR for the interface tailored junctions which show relatively large output voltage at large bias current[5]. The temperature dependence is expected to be changed drastically, because the spacer/Heusler alloy interfaces are crucial points for the CPP-GMR. Epitaxially grown layered films were prepared onto MgO single crystal substrates. The core structure for the CPP-GMR is $Co_2Fe_{0.4}Mn_{0.6}Si$ (CFMS) (20)|Fe or Mg ($t_{Fe\ or\ Mg}$)|Ag_3Mg (5)|Fe or Mg ($t_{Fe\ or\ Mg}$)|CFMS (7), (nm). The Fe or Mg layers are the interface tailoring layers. The thicknesses of the inserts, $t_{Fe\ or\ Mg}$, were changed from 0 to 0.6 nm in 0.15 nm increments. Post-annealing was done after the deposition of the upper CFMS layer at 550°C. CPP-GMR was measured at the temperature in the range of 10-300 K. Fig. 1 shows the temperature dependence of MR ratio. MR ratio increases with decreasing temperature for no-insert and Mg-insert (t_{Mg}: 0.3 nm) junctions. The ratios of the MR ratios at 10 K to 300 K are 3.4 and 2.9 for the no-insert and the Mg-insert junctions, respectively. On the other hand, for the Fe-insert (t_{Fe}: 0.3 nm), MR ratio shows maximum around 250 K and decreases with decreasing temperature. The Mg-inserts improved the temperature dependence probably because of the change of interface electronic structure. The degrade of low-temperature MR for Fe-inserts is possibly because of alloying between the Fe and CFMS around the interface: e.g. Fe-Mn alloy with low Curie temperature was formed locally. Systematic results including other inserts thicknesses will be shown at the presentation. Acknowledgments: JSPS KAKENHI (S) (25220910) and ASRC Japan.

V1-04. Oblique-incidence deposition for custom-designed GMR- and TMR sensor functionalities. *S. Willing*[1,2], K. Schlage[1], T. Gurieva[1], L. Bocklage[1,3], G. Meier[3,4] and R. Roehlsberger[1,3] *1. Photon Science, Deutsches Elektronen-Synchrotron (DESY), Hamburg, Germany; 2. Physics, Hamburg University, Hamburg, Germany; 3. The Hamburg Centre for Ultrafast Imaging, Hamburg, Germany; 4. Max-Planck Institute for the Structure and Dynamics of Matter, Hamburg, Germany*

Magnetic field sensors are extensively used in today's information technology, automotive control, and industrial process management because of their ability to provide accurate data without physical contact. A variety of sensor types exists, however, magnetoresistance sensors have the benefit of being small, low-cost, and easy to produce. By using oblique-incidence deposition (OID) [1], we overcome one of the major challenges in these sensors: the control of the easy axis and the coercive field of one or both magnetic layers without the limitations of interlayer exchange or exchange-biased pinning. The OID method uses the polar and azimuthal deposition angle to induce an additional and definable shape-anisotropy term into the system that tailors the magnetic properties of single layers. In a magnetoresistive sensor system, tunable switching fields and arbitrarily crossed easy axes now allow for a versatile and individual tailoring of the single layers' properties to adapt the functionality to the needs of an application (Fig. 1). Building on our initial findings that OID enables the realization of new and custom-made GMR sensors, we have now extensively explored the actual applicability for industrial use (Fig. 2). In this contribution, the results of investigations regarding temperature stability, signal strength, the influence of

microstructuring, realization of OID on an industrial scale and a transfer from GMR to TMR systems will be presented. We will show, that oblique-incidence deposition is an alternative or complementary way to tailor the properties of magnetoresistive sensors that is not only scientifically interesting but can be used in industrial applications. It is valuable for all magnetoresistive systems, especially GMR and TMR sensors, and beyond that to create more complex multilayers.

V1-06. Scavenging Properties of Metal Spacer in Perpendicular Magnetic Tunnel Junction and its Impact on Switching Characteristics of Spin Transfer Torque Random Access Memory. *H. Dixit*[1], D. Datta[1], S. Agarwal[1] and F. Benistant[1] *1. TCAD, GLOBALFOUNDRIES, Singapore*

Spin-transfer torque (STT) based Magnetoresistive Random Access Memory (MRAM) is potentially a universal memory technology due to its outstanding features such as non-volatility, endurance, low operating voltages and ultrafast switching [1]. However, several key challenges related to materials processing remain and critically affect the performance of CoFeB/MgO-based perpendicular Magnetic Tunnel Junction (p-MTJ) devices in STT-MRAM [2]. One significant issue is the low thermal stability of p-MTJ devices, due to a rapid degradation of the perpendicular magnetic anisotropy (PMA) in MgO/CoFeB/MgO free layer. It is observed that the thermal budget associated with annealing conditions, are responsible for Boron and Oxygen diffusion within the MgO/CoFeB/MgO stack causing detrimental effect on the PMA. To solve this problem, a composite free layer design is proposed [3], as illustrated in Figure 1. Here, using the first-principles simulations, we evaluate the critical role of metal spacer layer in preventing the inter-diffusion of Boron and Oxygen within the composite free layer in p-MTJ stack. We perform a systematic study of the defect concentrations and diffusion lengths for Molybdenum (Mo), Tantalum (Ta) and Tungsten (W) spacer, using the first-principles density functional theory. The calculated formation energies and diffusion barriers prove the effectiveness of Mo spacer in preventing intermixing of atomic species compared to Ta and W, indicating that Mo is the best choice as metal spacer. Our study provides fundamental insights into scavenging properties of the metal spacer and further enables the improvisation of the composite free layer design of the p-MTJ stack. We also evaluate the switching characteristics of p-MTJ device using our proposed quantitative model [4] for switching diagrams. The results shown in Figure 2, suggest that the switching asymmetry is significantly reduced for Mo spacer.

V2-01. Probing Multiferroic Metal Organic Frameworks with Neutrons. *H. Walker*[1], Z. Yang[2], D. Le[1], R. Smith[1], D. Voneshen[1], A. Phillips[2] and D. Keen[1] *1. ISIS neutron and muon source, Rutherford Appleton Laboratory, Didcot, United Kingdom; 2. Centre for Condensed Matter and Materials Physics, Queen Mary University of London, London, United Kingdom*

The unflagging desire to create new functional technologies has pushed materials design and discovery towards Metal Organic Frameworks (MOFs), since they present a versatile platform for the realization of complex magnets, as a result of their high tailorability and tunability derived from their molecular building block nature. While there is clear enthusiasm for the extra functionality magnetic MOFs can offer, most reports rarely go beyond bulk magnetometry, leaving the nature of the magnetism poorly understood. If magnetic MOFs are to be developed for future multifunctional applications, allowing this tunability to be exploited to design materials with targeted functionalities, it is vital that this situation be rectified. The dimethylammonium transition metal formates (DMA*M*F) are a family of magnetic MOFs [1] with a three dimensional perovskite structure; the dimethylammonium cations sit in the pores formed by the formate linked oxygen octahedra coordinating the transition metal ions. Like their inorganic analogues, these materials may exhibit both electric and magnetic ordering, and their properties can be tuned by preparing solid solutions with substitution of either the metal or the organic cation. Starting with the first reported multiferroic MOF - DMAMnF [2], we have thoroughly probed the antiferroelectric and antiferromagnetic ordering using neutron scattering. The ferroelectricity is driven by hydrogen bonds forming between the $(CH_3)_2NH_2^+$ protons and formate group oxygens at 183 K as they undergo a structural transition from *R-3c* to *Cc* [3], when the $(CH_3)_2NH_2^+$ cation orders into one of three sites [4]. The magnetic moments on the Mn^{2+} ions order below 8.5 K into a *G*-type antiferromagnetic structure with moments along the *b*-axis [5]. Inelastic neutron scattering has identified that the interactions form a three-dimensional network with non-equal antiferromagnetic nearest-neighbour interactions. These results will be compared with those obtained for DMACoF, and the effects of substituting the organic pore cation on the multiferroic properties investigated.

V2-02. Theory of Orbital Magnetic Quadrupole Moment and Magnetoelectric Susceptibility. *A. Shitade*[1], H. Watanabe[2] and Y. Yanase[2] *1. Center for Emergent Matter Science, RIKEN, Wako, Japan; 2. Department of Physics, Kyoto University, Kyoto, Japan*

In classical electromagnetism, multipole moments characterize anisotropy of the charge and charge current densities. The lowest order, dipole, has been deeply investigated in the contexts of ferroelectricity and ferromagnetism. Higher orders play important roles in strongly correlated electron systems and recently in localy noncentrosymmetric systems and higher-order topological insulators. Multipole moments are now more ubiquitous than in the nineteenth century when classical electromagnetism was established. Among multipole moments, the magnetic quadrupole moment (MQM) has been believed to be an important ingredient for the magnetoelectric (ME) effect. Starting from Cr_2O_3, many ME materials have been found so far. In particular, locally noncentrosymmetric systems, in which the inversion symmetry as well as the time-reversal symmetry may be broken by the conventional antiferromagnetic (AFM) order, have attracted much attention for their antisymmetric spin-orbit interactions and resulting intriguing phenomena. In these systems, the orbital contribution to the MQM may not be negligible. However, it is difficult to calculate multipole moments quantum-mechanically in periodic systems since the position operator is unbound. The charge polarization can be formulated by calculating the charge current density induced by an adiabatic deformation and expressed by the Berry connection [1]. The orbital magnetization is defined thermodynamically and expressed by the Berry curvature and magnetic moment [2]. Here we derive a quantum-mechanical formula of the orbital MQM in periodic systems [3]. First, we define the MQM and prove a direct relation to the ME susceptibility based on thermodynamics. This relation indicates that the MQM is a microscopic origin of the ME effect. Next, we calculate the orbital MQM using the Gauge-covariant gradient expansion. Finally, we apply the formula to locally noncentrosymmetric AFM semiconductors $BaMn_2As_2$ and $CeMn_2Ge_2$. The itinerant contribution that has been neglected in the previous local analysis of multipole moments is found to be comparable with the local contributions. The orbital contribution to the ME susceptibility is comparable with or even dominant over the spin contribution [4].

Institut Laue Langevin, Grenoble, France; 7. Institute of Physics of Complex Matter, Ecole Polytechnique Federal de Lausanne, Lausanne, Switzerland*

$Cu_3Bi(SeO_3)O_2Cl$, or francisite, is a buckled kagome compound made from two unique Cu spin ½ sites (Cu1 and Cu2) that displays unusual magnetic frustration mechanisms within an antiferroelectrically ordered dielectric phase [1]. The magnetism is defined by strong competition between nearest-neighbor ferromagnetic and next-nearest-neighbor antiferromagnetic interactions. With only isotropic exchange interactions, and despite dominant ferromagnetic couplings, this would lead to a classical degenerate

ground state that should survive quantum fluctuations. However, experimentation reveals a canted magnetic structure below 25 K with highly anisotropic magnetic behavior. A theoretical work has predicted that the essential ingredient stabilizing this magnetic order is a small Dzyaloshinskii-Moriya interaction [2]. We report on single-crystal neutron diffraction and inelastic neutron scattering studies of francisite, complemented by dielectric and electric polarization measurements that clarify a number of open issues concerning this complex material. In particular, we determine the nature of the structural transition inducing the antiferroelectric phase at 115 K, the magnetic structure below 25 K resolved in the antiferroelectric space group, and the microscopic ingredients at the origin of the frustrated magnetic arrangement. This was achieved by an analysis of the measured gapped spin waves, which signifies the need for an unexpected and significant anisotropic exchange beyond the proposed Dzyaloshinskii-Moriya interactions. We also address the multiferroic properties of this material with respect to the space group symmetries.

V2-04. Magnetoelectric Effect in a Newly Synthesized Helical Magnet $Ni_2In_{1-x}A_xSbO_6$ (A_x = $Cr_{0.1}$, $Fe_{0.05}$). *T. Sato*[1], Y. Araki[1], A. Miyake[2], M. Tokunaga[2], T. Honda[3], S. Kimura[4], H. Sagayama[2], N. Abe[1], Y. Tokunaga[1] and T. Arima[1] *1. Department of Advanced Materials Science, The University of Tokyo, Kashiwa, Japan; 2. ISSP, The University of Tokyo, Kashiwa, Japan; 3. IMSS, KEK, Tsukuba, Japan; 4. IMR, Tohoku University, Sendai, Japan*

In materials lacking the inversion symmetry, noncollinear magnetic structures may arise from the competition between Dzyaloshinskii-Moriya interaction and Heisenberg exchange interaction. It is well known that the modulation of electric polarization by a magnetic field, a kind of magnetoelectric effect, can be observed in such noncentrosymmetric magnets. A long-period incommensurate helical magnet Ni_2InSbO_6(NISO), which belongs to noncentrosymmetric chiral and polar space group *R*3, was first synthesized in 2013 [1,2]. NISO has two crystallographically nonequivlent Ni^{2+} sites in the unit cell which are bonded antiferromagnetically. The helical modulation runs perpendicular to the c-axis. We expect that the ferrimagnetic-like helical spin configuration should be realized by the substitution of magnetic ions for non magnetic In^{3+} because the doped magnetic ions would be more strongly bonded to one of two non equivalent Ni^{2+} ions. In this study, we have succeeded in single-crystal growth of $Ni_2In_{1-x}A_xSbO_6$ (A_x = $Cr_{0.1,}$ $Fe_{0.05}$) by means of chemical vapor transport method (Fig.1). A neutron powder diffraction measurement confirmed an incommensurate magnetic modulation in zero field. Magnetization measurement revealed a magnetic phase transition in a magnetic field of 2 ~ 4 T along the *c* axis, which is not seen in undoped NISO. Judging from the extrapolated value of magnetization, the helical magnetic phase should change into a ferrimagnetic phase (Fig.2). We have also found that this magnetic phase transition is accompanied by a change in electric polarization (Fig.2). As a result, the magnetoelectric response in low fields is enhanced by magnetic ion doping on NISO. In our presentation, we will also propose magnetic phase diagram based on the magnetization, electric polarization and dielectric constant measurements in high magnetic field.

V2-05. Magnetoelectric Effect in Buckled Honeycomb Antiferromagnet $Co_4Ta_2O_9$. *N. Abe*[1], T. Sato[1], A. Miyake[2], S. Kimura[3], K.D. Nguyen[4], T. Omi[1], T. Moyoshi[5], A. Nakao[5], M. Tokunaga[2], Y. Tokunaga[1] and T. Arima[1,4] *1. Department of Advanced Materials Science, The University of Tokyo, Kashiwa, Japan; 2. The Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan; 3. Institute for Materials Research, Tohoku University, Sendai, Japan; 4. Center for Emergent Matter Science, RIKEN, Wako, Japan; 5. Neutron Science and Technology Center, CROSS, Tokai, Japan*

Magnetic and magnetoelectric properties of honeycomb antiferromagnet $Co_4Ta_2O_9$ are investigated. This compound belongs to the corundum-related structure, where Co^{2+} layers of buckled honeycomb structure stack along the *c*-axis [1]. Because the Co^{2+} sites lack the local inversion symmetry, these compounds may host odd-parity magnetic multipole ordering giving rise to magnetoelectric effects [2]. It has been reported that polycrystalline sample shows a large linear magnetoelectric effect below Neel temperature T_N = 20 K [3]. Recently, a related compound $Co_4Nb_2O_9$ has been reinvestigated extensively because the material shows the large magnetoelectric coupling [4-6]. In this study, we investigate magnetic and magnetoelectric properties of $Co_4Ta_2O_9$ single crystal. A single crystal neutron diffraction measurement revealed that the magnetic structure of $Co_4Ta_2O_9$ is similar to $Co_4Nb_2O_9$. However, the observed magnetoelectric effect is strongly nonlinear in a sharp contrast to $Co_4Nb_2O_9$. To reveal the origin of the nonlinear magnetoelectric effect, we measured magnetization and magne-

toelectric effect in pulsed high magnetic fields. Magnetization at 4.2 K is saturated at 31 T, where the electric polarization suddenly vanished. This results indicate that magnetoelectric effect in $Co_4Ta_2O_9$ should originate from the spin-dependent *p-d* hybridization.

V2-06. Structural and spectroscopic properties of the new polar antiferromagnet Ni_2MnTeO_6. *S. Skiadopoulou*[1,2], M. Retuerto[3], M. Greenblatt[3], D. Legut[1] and S. Kamba[2] *1. IT4Innovations Center, VSB Technical University Ostrava, Ostrava-Poruba, Czechia; 2. Institute of Physics, Czech Academy of Sciences, Prague, Czechia; 3. Department of Chemistry and Chemical Biology, Rutgers, The State University of New Jersey, Piscataway, NJ, United States*

We present a structural and spectroscopic study of a new compound Ni_2MnTeO_6, closely related to the polar antiferromagnet Ni_3TeO_6 known to show a colossal magnetoelectric effect [1,2] and pronounced elementary magnetoelectric excitations [3]. For the first time, we prepared single crystals and polycrystalline samples of Ni_2MnTeO_6 showing the same polar structure as Ni_3TeO_6, from room temperature down to 4 K, with the *R*3 space group symmetry. Magnetic and dielectric measurements have indicated an antiferromagnetic phase transition at $T_N \approx 70$ K, almost 20 K higher than that of Ni_3TeO_6, as predicted by Mathieu *et al*. [4]. A spin-flop transition is triggered by an external magnetic field above 5 T, i.e. ~3 T lower than that of Ni_3TeO_6 [1]. Since in Ni_3TeO_6 a colossal magnetoelectric effect close to the spin-flop transition is known to exist [1], a strong static magnetoelectric coupling in Ni_2MnTeO_6 might appear at a lower magnetic field, however larger single crystals are needed for such measurements. Extensive infrared, Raman and THz spectroscopy experiments were employed for investigating lattice and spin excitations, revealing all 18 phonon modes predicted by the factor-group analysis for the *R*3 structure ($9E + 9A$, IR- and Raman-active). THz spectra below T_N reveal one new excitation at ~8 cm^{-1} (Figure 1), which is strongly influenced by external magnetic field, thus assigned to a magnon. Based on IR and Raman selection rules, the simultaneous detection of such magnetic excitations by both IR and Raman spectroscopies implies a polar character for the magnon [3], i.e. dynamical magnetoelectric coupling. However, such a low frequency of the magnon does not allow for measuring also its Raman spectra, leaving the question open whether the magnon bears a magnetoelectric character.

STT-MRAM are attracting an increasing interest from microelectronics industry. They are about to enter in volume production with the first goal of replacing embedded Flash memory. To go towards high density STT-MRAM at sub-20nm nodes, two major issues have to be solved. One is the nanopatterning of the magnetic tunnel junctions at 1x feature size (F) and narrow pitch (pitch<2F). The other is to increase the thermal stability of the storage magnetization at sub-20nm nodes. This presentation addresses these two issues and proposes innovative approaches to solve these two difficulties. In our novel approach for the nanopatterning of magnetic tunnel junctions (MTJs), the MTJ stack is directly deposited on pre-patterned conducting pillars consisting of a non-magnetic material for which the patterning process is already well mastered (e.g. Ta pillars prepared by RIE or Cu or W vias prepared by damascene process). Thus, the MTJ stack is naturally patterned while being deposited, not requiring any post-deposition etching. Some magnetic material is also deposited in the spaces between pillars. It can be left there without causing any problem. Dense arrays of MTJs with diameter down to F=30nm and pitch down to 1.5F were thus realized. After electrically contacting these MTJs, TMR and STT switching could be observed in these patterned MTJs. To enhance the thermal stability in sub-20nm MTJs, a novel approach was investigated consisting in dramatically increasing the thickness of the storage layer to values comparable to their diameter. This creates a perpendicular shape anisotropy in the storage layer which adds up to the usual interfacial anisotropy at the MgO/CoFeB interface. As a result, large thermal stability factor above 60 can be maintained down to pillars diameter of 4nm. These memories are called Perpendicular Shape Anisotropy STT-MRAM (PSA-STT-MRAM). The feasibility of such PSA-STT-MRAM and their high thermal stability was experimentally demonstrated for diameter down to 8nm.

Principle of the novel nanopatterning approach consisting in depositing the MTJ stack on prepatterned conducting non-magnetic pillars with undercut. Example of arrays of MTJs with pitch down to 1.5F.

Example of Perpendicular Shape Anisotropy (PSA) STT-MRAM with NiFe and Co based storage layer demonsrating high coercivity and associated high thermal stability at diameter down to 8nm.

V3-02. A 2018 review on STT-MRAM materials. *M. Gottwald*[1]
1. Physical Sciences, IBM T.J. Watson Research Center, Yorktown Heights, NY, United States., New Rochelle, NY, United States

Several materials breakthroughs for STT-MRAM materials have happened over the past 15 years. These materials breakthroughs helped to mitigate some of the technical challenges of building STT-MRAM. First high tunneling magneto resistance (TMR) was demonstrated using CoFeB|MgO based tunnel junctions. Perpendicular anisotropy in such CoFeB|MgO based tunnel junctions allowed using this materials system in the preferred geometry for efficient spin transfer torque switching[Worledge2011]. Using perpendicular tunnel junctions enabled big performance gains in terms of spin torque efficiency for STT-MRAM devices defined as $E_b/I_{c,0}$ [Thomas2013]. Thereby E_b is the energy barrier which is limiting the retention of the bit and $I_{c,0}$ is the write current. Meanwhile first STT-MRAM products are on the market (e.g. [Slaughter2012]). More recently materials improvements for scaled devices lead to short write times while maintaining low write error rates [Nowak2016]. Such fast writing allows considering STT-MRAM for much more advanced applications embedded into high performance logic chips. In this talk we will review the STT-MRAM materials progress over the last years. Since scalability is only given for STT-MRAM based on perpendicular magnetized materials this talk will mainly focus on the development of magnetic materials with perpendicular magnetic anisotropy. We will start with early examples like work with multilayer materials [Mangin2006]. We will then look into CoFeB|MgO based pMTJs [Worledge2011], which have been intensively studied in recent times. We will also discuss how materials science was applied to solve specific technological problems coming with CMOS integration. For example, one topic of high technological impact is the thermal budget magnetic materials have to withstand during CMOS integration [Gottwald2013]. Finally, we will review the materials landscape for potential alternatives for the most commonly used CoFeB|MgO materials system. One example of such potential alternatives might be Heusler materials [Faleev2017]. As a summary we will try to understand the engineering limits of the different materials systems and conclude from there on potential future materials candidates.

V3-03. High Temperature Magnetic Properties of CoFeB Free Layers with Nonmagnetic Impurities for STT-MRAM. *J.M. Iwata-Harms*[1], G. Jan[1], H. Liu[1], S. Serrano Guisan[1], J. Zhu[1], L. Thomas[1], R. Tong[1], V. Sundar[1] and P. Wang[1] *1. TDK-Headway Technologies, Milpitas, CA, United States*

As the production of semiconductor chips integrating spin-transfer-torque magnetic random access memory (STT-MRAM) is expected to debut in major foundries in 2018, there is a growing need to develop predictive models of data retention and the temperature dependence of the magnetic properties. High temperatures are critical to embedded semiconductor memory operation and data retention.[1] To fulfill stringent thermal requirements, a free layer should exhibit a high value of thermal stability factor, Δ, and minimum variation with temperature. However, Δ of a ferromagnetic free layer exhibits strong variation with temperature,[2] and reducing its variation requires measuring and understanding the magnetic properties over a large, elevated temperature range. Typical high Δ STT-MRAM free layers are engineered by inserting nonmagnetic, metallic layers.[3-6] We explored varying amounts of nonmagnetic, metallic impurities within CoFeB (CFB) free layers and examined the influence of temperature on the magnetic properties up to 650 K.[7]. Figure 1 highlights the role of temperature on the saturation magnetization, M_s, and the effects of increased impurity concentration resulting in a smaller M_s, stronger temperature dependence, and lower temperature at which moment vanishes. Based on these results and the expected power law dependence of the interfacial anisotropy energy per unit area, K_i, on M_s,[8] we form predictive models over a wide range of temperatures for a broad set of magnetic parameters. Models of H_k (Fig. 2) and Δ reveal a non-linear dependence on temperature. Furthermore, macrospin and domain wall reversal models of Δ exhibit an identical temperature dependence. In particular, Δ using a domain wall model is in good agreement with Δ obtained from fully integrated devices on complementary metal oxide semiconductor (CMOS) test chip arrays.

V3-04. Quantification of process-induced damage in highly-scaled pMTJ devices for MRAM applications. *S. Rao*[1], M. Perumkunnil[1], S. Kundu[1], L. Souriau[1], J. Swerts[1], S. Couet[1], F. Yasin[1], W. Kim[1], D. Tsvetanova[1], N. Jossart[1], D. Crotti[1], A. Furnemont[1] and G. Kar[1] *1. Imec, Leuven, Belgium*

Spin Transfer Torque (STT)-MRAM is considered a prime technology for high density memory due to its advantages in operating speed, low power consumption and unlimited endurance [1-3]. To meet the density requirements, aggressive scaling processes have been used [4-5] resulting in a strong performance degradation due to process-induced damages (PID). In this work, we present, for the first time, a universal damage model to quantify the radial damage profile in pMTJs down to 40 nm CD in terms of area, RA and TMR degradation. We can reduce PID by 40-50% by optimizing process conditions, and this was confirmed both by modelling and the reduction in measured switching current density (J_{sw}). An initial report [6] assumed the formation of concentric cylindrical regions within a pMTJ due to PID, each region with fixed RA and TMR contributions. This approach, however doesn't quantify the impact of individual process steps on performance loss. Our refined model does not assume the formation of well-defined zones of operation, but allows the RA to vary freely from 0 to ∞ (from the center to the outer edge of the pMTJ pillar) becoming inert at any point within the pillar. Such a change negates the assumption of a damage-free zone within the pillar, as was the case in previous reports. Samples with different process conditions are compared, as defined in Table 1, where the main etch (ME) and over-etch (OE) energy conditions are varied, but with a constant post-etch treatment (PET) process. As shown in Fig. 1, the model suggests that an increase in ME energy (samples S1, S2, S3) reduces the effective CD with little change in the TMR degradation profile. On the other hand, OE energy variation (samples S4, S5) shows a narrowing damage zone width coupled

with a very steep TMR degradation profile, as desired. We also see that there is a ~40% improvement in J_{sw} when comparing our standard process (S1) with the improved process (S5).

V4-01. Spin Engineering in Complex Oxide Heterostructures: From Textures to Spin Ice. *Y. Takamura*[1] *1. Materials Science and Engineering, University of California, Davis, Davis, CA, United States*

Due to the strong interaction between the charge, spin, lattice, and orbital degrees of freedom, complex oxides possess a wide range of technologically relevant properties such as ferromagnetism, ferroelectricity, and superconductivity. Recent advances in modern thin film growth and characterization techniques have revealed that interfacial interactions with structural, chemical, electronic, and magnetic origins can provide additional sources of emergent behavior in complex oxide heterostructures. These emergent properties can enable the engineering of topological spin textures which serve as building blocks for various spin-based memory devices as these complex oxides are patterned down to micron and nanoscale dimensions. In this work, I will describe a unique patterning technique based on e-beam lithography and ion implantation which result in magnetic islands embedded within a non-magnetic matrix. A complex 3D strain state develops within the magnetic islands from the combined effects of the underlying substrate as well as the surrounding amorphous matrix. As a result, distinctive and coupled ferromagnetic (FM) and antiferromagnetic (AFM) spin textures have been observed in x-ray photoemission electron microscopy (X-PEEM) images of heterostructures composed of FM $La_{0.7}Sr_{0.3}MnO_3$ and AFM $La_{0.7}Sr_{0.3}FeO_3$ sublayers, and they demonstrate the intricate interplay that exists between exchange interactions, as well as shape and magnetocrystalline anisotropy energies in these systems.[1,2] In the second half of the talk, I will describe studies performed on arrays of $La_{0.7}Sr_{0.3}MnO_3$ nanomagnets which were patterned into two-dimensional analogs of geometrically frustrated spin ices. These systems enable the investigation of the magnetic behavior of large ensembles of frustrated elements using real-space imaging techniques such as X-PEEM. By varying nanomagnet volume, inter-island distance, and the placement of the islands, a variety of artificial spin ice arrays were fabricated with room-temperature inter-island coupling strengths ranging from $6x10^{-13}$ A^2 m to $3x10^{-12}$ A^2 m, and the effect of the coupling strength on the population of low energy vertex configurations was studied in square, brickwork, shakti, and kagome-based lattices.[3] In the limit of high coupling strength, we found that heating to 350 K is sufficient to drive both square and brickwork lattices into large scale ground state domains, and it is more effective at achieving a high density of low energy vertices when compared to a magnetic field based demagnetization protocol. Together these studies demonstrate that complex oxide heterostructures provide a unique platform for engineering spin textures and for systematic studies of the thermal evolution of frustration in tailored geometries.

V4-02. Competition between magnetic anisotropies in $La_{2/3}Sr_{1/3}MnO_3$ thin film grown on the patterned $SrTiO_3$ substrate. *V.K. Malik*[1,2], R.V. Chopdekar[3], A. Kleibert[3] and C. Bernhard[2] *1. Physics, Indian Institute of Technology Roorkee, Roorkee, India; 2. Physics, University of Fribourg, Fribourg, Switzerland; 3. Paul Scherrer Institut, Villigen, Switzerland*

Manganite materials exhibit variety of correlated magneto-electric properties due to strong entanglement between spin, charge and orbital degrees of freedom. Observation of so-called colossal magneto-resistance(CMR) effect and nearly 100% spin polarization of conduction electrons make these materials attractive candidates for functional spintronic devices.[1,2] Realization of functional devices require fabrication of micro-/nano-structures (MNS) in thin films and understanding of magnetic and electronic properties in such structures. Magnetic properties in MNS of manganites are influenced by shape, size and relative orientation to substrate and determined by strong competition between *magneto-shape*,*-elastic and -crystalline* anisotropies. [3,4] In this work, a different approach has been adopted for fabrication of MNS of manganite materials. $La_{2/3}Sr_{1/3}MnO_3$ (LSMO) thin film has been grown on laterally patterned $SrTiO_3$ (STO) substrate. Line patterns with periods of 1μm and 20 μm length having different orientations with respect to the crystallographic axes of the substrate have been prepared. LSMO film with 16.5 nm has subsequently been grown on the substrate by pulsed laser deposition. Local magnetic properties of the nano-structured thin films have been measured with the technique of X-ray photoemission electron microscopy (X-PEEM) based on X-ray magnetic circular dichroism. X-PEEM measurements have revealed a strong influence of the structural patterning of substrate on the magnetic domain state of the LSMO film. In particular, measurement have shown that a periodic modulation of the magnetization density is induced which is strongly pinned with line patterns of substate due to strong *magneto-elastic* anisotropy. Magnetization reversal in these domains occur approximately at 15 Oe. The easy magnetic axis of these magnetic domains is always parallel to the lines of the structural pattern, irrespective of their orientation. Easy axis of these magnetic domains thus seem to be governed by the *magneto-shape* anisotropy instead of *magneto-crystalline anisotropy.*

The relationship between spin-orbit coupling (SOC), emergent topological states, and spin Hall effects, which are highly relevant for spintronics, has driven the interest in materials with strong SOC in recent years. Likewise, complex oxide heterostructures have garnished much interest due to emergent interfacial phenomena resulting from the competition between charge, spin, and lattice order parameters, and the ability to tune this competition. The question arises as to whether SOC can result in modified interfacial magnetic states. To explore this possibility we have investigated ferromagnetic $La_{0.7}Sr_{0.3}MnO_3$(LSMO)/ paramagnetic $SrIrO_3$(SIO) bilayers deposited on a $SrTiO_3$ substrate with magnetomery, Polarized Neutron Reflectometry (PNR), and X-ray Magnetic Circular Dichroism (XMCD). We find distinct differences of the magnetic properties depending on the growth order and direction of the in-plane applied magnetic field. At low temperatures a significantly larger coercivity is found when LSMO is grown on top of SIO, rather than directly on the substrate. Similar to previous reports [1-3], a net moment on Ir has been recorded with element specific XMCD experiments, as well as a net magnetization within SIO with PNR. Both PNR and XMCD experiments show that this magnetization is aligned antiparallel to the Mn moments within the manganite. Interestingly, we find that the Ir moment does not follow the same temperature dependence as the magnetization of the manganite, but drops off almost linearly with increasing temperature. Likewise, the coercive fields of the Ir and Mn moment hysteresis loops differ. The origins of these results, and comparison to previous work based on manganite/SIO multilayers, will be discussed. V4-04. Phase control in freestanding magnetic oxide membranes via extreme strain engineering. *S. Hong*[1,2], D. Lu[1], A. Vailionis[1], Y. Hikita[2] and H. Hwang[1,2] *1. Stanford University, Palo Alto, CA, United States; 2. SLAC National Accelerator Laboratory, Menlo Park, CA, United States*

Freestanding 2D layers provide a significant degree of freedom to control physical properties. Recent advances in the thin film epitaxy of a water-soluble layer enable the synthesis of many types of complex oxides and heterostructures as a macroscale freestanding membrane [1]. Initial studies on ultrathin membranes found that the 2D limit of the crystalline phase is well described by the Berezinskii–Kosterlitz–Thouless transition [2]. Above a critical thickness scale of ~ 2 nm, we can access crystalline oxide membranes with extreme mechanical flexibility. Here we report an on-chip platform for which strain states can be continuously tuned by design. In the example of a colossal magnetoresistance material ($La_{0.7}Ca_{0.3}MnO_3$), we successfully applied biaxial strain up to 5% and induced a dramatic shift in the metal-to-insulator and magnetic transition, as well as a new phase emerging at high strain states. The systematic control of strain reveals a rich phase diagram of the electromagnetic ground states inaccessible by standard bulk and film techniques. This versatile platform utilized here with low-temperature magnetotransport, X-ray, and optical probes - enables a new avenue to study oxide thin films and heterostructures beyond epitaxial strain.

V4-05. Large Moments in bcc $Fe_xCo_yMn_z$ ternary alloy thin films. *Y.U. Idzerda*[1], R. Snow[1], H. Bhatkar[1], A.T. N'Diaye[2] and E. Arenholz[2] *1. Physics, Montana State University, Bozeman, MT, United States; 2. Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA, United States*

Large magnetic moment materials are essential components in a variety of technologies but are increasingly important, and in many cases the major limiting factor, in information processing and data storage. The magnetic moments for transition metal binary alloys are conventionally displayed in the form of a plot of the saturation magnetization density (M_S) or moment per atom as a function of the number of electrons, known as the Slater-Pauling (SP) curve. The maximum achievable moment is 2.45 m_B /atom at an electron number of 26.3 for a bcc $Fe_{70}Co_{30}$ alloy (often referred to as the Slater-Pauling limit). A potential avenue to larger moments is the addition of Mn to the binary bcc FeCo system, particularly in thin film form where the bcc structure may be stabilized for a larger composition region than in the bulk. The elemental magnetic moments and the average atomic moment of 10-20 nm thick single crystal bcc (bct) $Fe_xCo_yMn_z$ films deposited on MgO(001) have been determined as a function of a broad range of compositions [1]. Thin film epitaxy stabilized the bcc structure for 80% of the available ternary compositional space compared to only a 23% stability region for the bulk. The films that display ferromagnetism represent 60% of the available compositional possibilities compared to 25% for the bulk. A maximum average atomic moment of 3.25 m_B/atom was observed for a bcc $Fe_9Co_{62}Mn_{29}$ film as determined by the summation of the individual moments as measured by X-ray magnetic circular dichroism (well above the limit of the Slater-Pauling binary alloy curve of 2.45 m_B/atom). The $Fe_xCo_yMn_z$ ternary alloys that exhibit high moments can only be synthesized as ultrathin films since the bcc structure is not stable in the bulk for those compositions. V5-01. Growth of FeNiN Films toward Formation of $L1_0$-ordered FeNi Films by Nitrogen Topotactic Extraction. *K. Ito*[1], M. Mizuguchi[1], F. Takata[2], T. Suemasu[2], H. Yanagihara[2] and K. Takanashi[1] *1. Institute for Materials Research, Tohoku University, Sendai, Japan; 2. Institute of Applied Physics, University of Tsukuba, Tsukuba, Japan*

Ferromagnetic materials possessing large uniaxial magnetic anisotropy energy (K_u) and composed of earth abundant elements are required in order to realize the next-generation permanent magnets. We have focused on the $L1_0$-ordered FeNi alloy as a rare-earth free high K_u ferromagnetic material.[1] Recently, the synthesis of $L1_0$-FeNi powder by nitrogen topotactic extraction from FeNiN powder was reported, and a high degree of order (S) was achieved.[2] However, the mechanism of nitrogen extraction and the exact K_u value of $L1_0$-FeNi are still unclear. Thereby, the experiment using the single-crystal FeNiN film is required. In this study, we tried to grow epitaxial FeNiN films by molecular beam epitaxy (MBE). 20 nm-thick FeNiN films were grown on $SrTiO_3$(STO)(001), $MgAl_2O_4$(MAO)(001), and MgO(001) substrates by MBE supplying Fe, Ni, and radio-frequency (RF) N_2 plasma, simultaneously. The lattice mismatches in the c-plane between FeNiN and these substrates are 2.5 (STO), -0.98 (MAO), and -4.9 % (MgO). Supply rates of Fe and Ni were controlled so that Fe/Ni composition was 1. The growth temperature, N_2 gas flow rate, and RF input power were fixed to be 300 °C, 1.0 sccm, and 240 W, respectively. Grown films were characterized by out-of-plane (ω-2θ) and in-plane (ϕ-2θχ) x-ray diffraction (XRD), and vibrating sample magnetometer. Figures 1(a) and 1(b) show the ω-2θ and ϕ-2θχ XRD patterns of the samples, respectively. Only the diffraction peak of FeNiN(200) was observed in Fig. 1(a). In Fig. 1(b), the peaks of FeNiN(020) and FeNiN(002) were obtained. This means the multi-domain epitaxial growth of FeNiN films on (001)-oriented substrates, and epitaxial relationships were FeNiN[001](100)//substrate[100](001) and FeNiN[010](100)//substrate[100](001). Figure 2 shows the magnetization curves of the samples. The magnetization of the FeNiN films on STO(001) and MgO(001) substrates was zero. This indicated that the sufficient nitrogen insertion to the FeNi lattice occurred, and non-magnetic FeNiN films were successfully formed. As a next step, we try to extract nitrogen from the FeNiN films, and form $L1_0$-FeNi films with the high S value.

V5-02. Electronic tunneling through epitaxial cobalt-ferrite (001) films with perpendicular magnetic anisotropy grown on non-magnetic metal layers. *M. Tanaka*[1], K. Naruse[1], K. Nomura[1], T. Taniguchi[2], S. Honda[3], T. Ono[2] and K. Mibu[1] *1. Graduate School of Engineering, Nagoya Institute of Technology, Nagoya, Japan; 2. Institute for Chemical Research, Kyoto University, Uji, Kyoto, Japan; 3. Faculty of Engineering Science, Kansai University, Suita, Japan*

Recently, it has been reported that magnetic insulator $CoFe_2O_4$ (001) films grown epitaxially on MgO (001) substrates have large perpendicular magnetic anisotropy (PMA) [1, 2]. If $CoFe_2O_4$ films with PMA are successfully grown on nonmagnetic metal layers, they can be applied for PMA spintronics devices, e.g. spin filtering devices [3, 4], which have advantage for high magnetic density and fast magnetic switching. In this presentation, we report successfully growth of $Co_xFe_{3-x}O_4$ films with PMA on nonmagnetic metal TiN buffer layers and the electron tunneling characteristics through the $Co_xFe_{3-x}O_4$ films. $Co_xFe_{3-x}O_4$ ($0<x<1$) films of 20 nm were grown on MgO (001) substrates with TiN buffer layers using pulsed laser deposition technique at the substrate temperature of 300°C in background oxygen pressure of 6.0 Pa. Magnetic hysteresis loops were measured using a superconducting quantum interference device magnetometer. To check the cation valency of the $Co_xFe_{3-x}O_4$ layer, ^{57}Fe Mössbauer spectroscopy was performed by means of conversion electron Mössbauer spectroscopy at room temperature. The insulating property of the film was investigated for $Pt/Co_{0.53}Fe_{2.47}O_4/TiN$ tunnel junctions. Figure 1 shows the Co composition dependence of the squareness ratio (remanence magnetization with respect to saturation magnetization) of the out-of-plane hysteresis loops. The high squareness ratio of more than 0.8 was realized for the $Co_xFe_{3-x}O_4$ layers (x = 0.1~0.5). Thus, we successfully fabricated the perpendicularly magnetized $Co_xFe_{3-x}O_4$ films on the TiN (001) layers. Mössbauer spectrum for the $Co_{0.53}Fe_{2.47}O_4$ films on TiN (001) layers indicated that the Co^{2+} ions were replaced by Fe^{3+} ions and vacancies. First principal calculation indicated that the $Co_{0.54}Fe_{2.46}O_4$ film has good insulating property and spin-dependent barrier height. The current–voltage curves of the junctions showed typical tunneling characters. The perpendicularly magnetized $Co_xFe_{3-x}O_4$ films applicable for the magnetic insulator materials for the spintronics devices were thus realized on nonmagnetic metals.

V5-03. Magnetic and transport properties of melt spun ribbons and bulk samples of Mn_2FeGa. *V. Khovaylo*[1], I. Gavrikov[1], M. Seredina[1], Y. Anikin[1], M. Gorshenkov[1], S.V. Taskaev[2] and R. Chatterjee[3] *1. National University of Science and Technology "MIS&S", Moscow, Russian Federation; 2. Physics department, Chelyabinsk State University, Chelyabinsk, Russian Federation; 3. Physics, Indian Institute of Technology Delhi, New-Delhi, India*

Recently, there has been growing interest in the development of novel materials for spintronic applications. Heusler alloys, specifically so-called inverse Heusler alloys [1] and equiatomic quaternary Heusler alloys [2] have been suggested as a potential candidate in this respect. First principles theoretical calculations have suggested [3] that Mn_2FeZ (Z = Al, Ga, Si, Ge, Sb) Heusler alloys can be of interest for experimental studies due to their potential half-metallic properties. Experimental studies of the Heusler alloy with Z = Ga, Mn_2FeGa, have shown that crystal structure and magnetic properties of Mn_2FeGa strongly depend on annealing conditions [4,5]. To further explore physical properties of this alloy, we have prepared Mn_2FeGa in the form of polycrystalline bulk samples by arc-melting method and in the form of melt-spun ribbons by a melt spinning technique and performed a comparative study of the bulk and melt-spun samples by X-ray diffraction (XRD), magnetic and transport measurements. Room-temperature XRD diffraction revealed that the as-spun ribbons have a primitive cubic structure while the bulk samples consist of the main phase and an impurity phase. The main phase crystallizes in a cubic Heusler structure. Magnetic properties of the melt-spun ribbons turned out to resemble properties of antiferromagnetic compounds while ferromagnetism was evident in the bulk samples. Measurement of electrical resistivity revealed that transport properties of melt-spun and bulk samples of Mn_2FeGa are also different in a temperature interval 80 – 360 K. While the melt-spun ribbons demonstrate behaviour of electrical resistivity typical for semiconductors, the bulk samples exhibit metallic behaviour of the resistivity in the measured temperature interval. This work was supported by Russian Science Foundation (grant No. 16-42-02035).

V5-04. Structural, magnetic and dielectric properties of ferrite-ferroelectric ceramic composites. *A. Farheen*[1] and R. Singh[1] *1. School of Physics, Univesity of Hyderabad, Hyderabad, India*

The simultaneous existence of ferroelectricity and magnetic ordering in multiferroic materials are gaining special interest due to their promising applications in various multifunctional devices. In general, combination of both ferroelectric and ferrimagnetic may lead to novel functionalities which are not present in either state alone. The composite multiferroics offer a way to attain magnetic and ferroelectric ordering simultaneously [1]. In the present work, the composites (1-x)BaTiO3+(x)Mn0.5Zn0.5Fe2O4 (x = 0, 0.05, 0.10, 0.20 and 1) were synthesized using the nanoparticles of Mn0.5Zn0.5Fe2O4 (MZF) and BaTiO3 (BTO) by sintering at 1200°C for 6 hours. The nanoparticles of BTO were synthesized by hydrothermal method and the MZF nanoparticles were synthesized by co-precipitation method as described in our earlier work [2,3]. The XRD of composite samples confirm the coexistence of BTO and MZF phases. The microstructure of the composite show that two kinds of grains are present in the samples in which one is related to MZF while the second one is related to BTO grain. The non-uniform distribution of ferrite and BTO grains is due to the different

growth rate of ZMF and BTO in composites. An increase in room temperature magnetization is observed with the increase in ferrite content. All the samples exhibit soft ferrimagnetic hysteresis behaviour with much lower value than pure MZF. This indicates the existence of non-magnetic ferroelectric phase with ferrite phase. Since the ferrite (ZMF) grains are confined in the matrix of ferroelectric material (BTO), therefore ferrite grains will be separated by BTO grains. This separation alters the distribution of magnetic ions and their spin orientation, inflencing the magnetic coupling among the ferrite particles [4]. The significant changes in M(T) plots are observed with the inclusion of ferroelectric phase in the ferromagnetically ordered system. The presence of well-defined magnetic and ferroelectric hysteresis loops at room temperature confirm the ferromagnetic as well as ferroelectric ordering in the composites.

V5-05. Controlling the magnetization and coercivity in quenched FeRh magnetic heterostructures with hydrostatic pressure. *C. Urban*[1], S.P. Bennett[2] and I.K. Schuller[1] *1. Physics, UCSD, San Diego, CA, United States; 2. Materials Science and Technology, U.S. Naval Research Laboratory, Washington, DC, United States*

Control over magnetic materials (e.g. Fe, Ni, Co) in bulk or thin films can be achieved by using compounds which undergo a structural phase transition[1,2]. The transition temperatures of these materials are sensitive to externally applied pressure. We show that this translates well to the magnetization and coercivity of the magnetic materials in close proximity which renders pressure an additional tuning parameter for the magnetism of the material. We recorded magnetization curves and hysteresis loops as a function of temperature and pressure with a standard magnetometer and a pressure cell for magnetic measurements to study systematically the role of pressures up to 1.3 GPa in quenched FeRh/BTO thin films and compare it to unquenched FeRh/BTO thin films. The magnetism aspects at UCSD are funded Office of Basic Energy Science, U.S. Department of Energy, BES-DMS funded by the Department of Energy's Office of Basic Energy Science, DMR under grant DE FG02 87ER-45332. One of us (I.K.S.) acknowledges a US DoD Vannevar Bush Fellowship.

The surface lattice area reflects the structural phase transitions of the BaTiO3 which occur at the same temperature as the saturation magnetization jumps in the 25 nm FeRh/BTO thin film sample.

At the structural phase transition of BTO the coercivity changes aproximately 50%. Applying a hydrostatic pressure of 0.33 GPa shifts the transition to lower temperatures.

V5-06. Study of the Static and Dynamic Magnetic Response of $Ni_{80}Fe_{20}$ Dumbbell Shaped Structures. *P.N. Sherpa*[1,2], S. Khanal[1,2] and L. Spinu[1,2] *1. Physics, University of New Orleans, New Orleans, LA, United States; 2. AMRi/Physics, University of New Orleans, New Orleans, LA, United States*

Over the past few years metamaterials such as magnonic crystals (MC) have been of great interest because of its easily tunable magnetic properties which provides countless new opportunities for exciting technologies. Information transformation, signal processing, spintronic devices, high-density data storage and sensors are a few examples where MC show the promising application. The static and dynamic properties can be easily tuned by simply the changing the shape, size, spacing, and symmetry of the structure. To understand the effects of these changes, extensive studies on various structures such as nanowires, dots, rings, grooves, antidots, modulated wires, etc. have been performed in the past. Periodic modulations on one or both sides of nanowires to study the effect on static and dynamic properties is shown in detail in reference. In this letter, we combined two different structures, wires and dots in a dumbbell configuration, to study the collective static and dynamic properties. Magnetic nanowires where magnetization reversal (MR) generally takes place by nucleation and propagation of domain walls are different from the dot structure where MR takes place depending on the aspect ratio as well as size. Understanding MR on these combined structures and effect on both static and dynamic properties is main drive of this study. Magneto-Optic Kerr Effect (MOKE) and vector network analyzer- ferromagnetic resonance (VNA-FMR) were used to study the static and dynamic properties respectively. Six sets of samples with varying dots diameter were prepared on top of a CPW, three parallel and three perpendicular to the

signal line (since the dot is symmetric, parallel and perpendicular refer to the orientation of the wire axis with respect to the signal line). MOKE was used to study static properties, such as collective magnetization reversal, sweeping the external magnetic field in different directions, for example. VNA-FMR was used to study the dynamic properties at room temperature. The ac magnetic field and dc applied field were always kept perpendicular to each other to satisfy the condition of FMR. To better understand the experimental results, micromagnetic simulations were performed.

V6-01. Spin-orbit induced effective magnetic field in GaMnAs ferromagnetic semiconductor. *S. Lee[1] 1. Physics, Korea University, Seoul, The Republic of Korea*

The effective control of magnetization is an important issue in operating spintronic devices (e.g., Magnetic memory devices). A n intriguing method for the manipulation of magnetization is using a current induced effective magnetic field, called as Spin-Orbit Induced (SOI) field. We have investigated such SOI field in crystalline GaMnAs ferromagnetic semiconductor films by using Hall effect measurements. The presence of SOI field in GaMnAs films was detected in magnetization relaxation process that depends on the current direction. The SOI-field also manifests itself in the form of a hysteresis between planar Hall resistances (PHR) measured with positive and negative currents as an applied magnetic field is rotated in the sample plane at constant field strength. We develop a method for accurate determination of the strength of the SOI field by using a model based on magnetic free energy that includes the effects of magnetic anisotropy. We further investigate the process of selectively manipulating the magnetization alignment in magnetic layers in the Fe/GaAs/GaMnAs structure by current-induced spin-orbit (SO) magnetic field. In the case of the Fe/GaAs/GaMnAs multilayer, hystereses are clearly observed when the magnetization switches direction in the GaMnAs layer, but are negligible when magnetization transitions occur in Fe. This difference in the effect of the SO-field in the two magnetic layers provides an opportunity to control the magnetization in one layer (in the presence case in GaMnAs) by a current, while the magnetization in the other layer (i.e., Fe) remains fixed. Owing to our ability to selectively control the magnetization in the GaMnAs layer, we are able to manipulate the relative spin configurations in our structure between collinear and non-collinear alignments simply by switching the current direction even in the absence of an external magnetic field.

V6-03. Observation of spin-gapless semiconductor-like magnetotransport in CoFeVSi epitaxial films. *S. Yamada[1,2]*, S. Kobayashi[1], K. Arima[1] and K. Hamaya[1,2] *1. Graduate School of Engineering Science, Osaka University, Toyonaka, Japan; 2. Center for Spintronics Research Network, Osaka University, Toyonaka, Japan*

In recent years, spin-gapless semiconductors (SGSs) have attracted considerable attention because of their unique electronic band structures, in which the conduction and valence band edges meet at the Fermi level for one spin channel while there is a finite band gap in another spin channel [1]. Theoretical calculations revealed that some of ternary or quaternary Heusler alloys have SGS-like electronic band structures [2-4]. For bulk Mn_2CoAl (MCA) [2], positive, non-saturating and linear magnetoresistance (MR) curves, one of the unique magnetotransport properties in SGS materials, were observed [2]. However, there is no report on the observation of such behavior in thin-film samples. Here we observe positive, non-saturating, and linear MR curves in CoFeVSi (CFVS) epitaxial films grown by molecular beam epitaxy. Figure 1 shows MR curves at various temperatures for a CFVS film grown at 400 °C. Positive, non-saturating, and linear MR curves can be observed even at around 300 K although small AMR is seen in low-field region. This magnetotransport property is similar to SGS materials even for thin-film samples. Figure 2 displays the field-dependent Hall conductivity for the CFVS film at various temperatures. We also observe small anomalous Hall conductivities less than ~60 S/cm at various temperatures, which is much smaller than those of general ferromagnetic Heusler alloys [5,6]. With decreasing external temperatures, charge carriers can be varied from holes to electrons, meaning that the Fermi level of the CFVS film is located near the center between valence-band edge and conduction-band one as well as SGS materials. Because the room-temperature carrier density at 300 K was ~10^{22} cm^{-3}, much higher than that for bulk-MCA (~10^{17} cm^{-3}) [2], we should further reduce the carrier density induced by the disorder in the CFVS film. This work was partly supported by a Grant-in-Aid for Scientific Research on Innovative Areas “Nano Spin Conversion Science” (Grant No. 26103003) from MEXT and a Grant-in-Aid for Scientific Research (A) (No. 16H02333) from JSPS.

V6-04. InAs quantum dots selectively doped with Mn. *A. Bouravleuv*[1,2] and G. Cirlin[1] *1. St. Petersburg Academic University RAS, St. Petersburg, Russian Federation; 2. Ioffe PhysicaL Technical Institute RAS, St. Petersburg, Russian Federation*

Nanoscale ferromagnetic semiconductor (FS) structures are one of the most promising objects for the control over spin interactions by means of different methods, e.g. electrical or optical, and as a result for the creation of new spintronic devices. Local distribution of spins in such nanostructures seems to be depended not only on their sizes, but also on their shape. This brings up many questions concerning the formation of such nanostructures, including quantum dots (QDs). Usually FS layers grow at relatively low temperatures to avoid phase separations. At the same time, FS nanostructures seem to be form at much higher temperatures, which usually can lead to an increase in the crystalline quality of the synthesized structures. We have elaborated the novel techniques for the molecular-beam epitaxy (MBE) of (In,Mn)As QDs [1-3] at relatively high growth temperatures using Mn selective doping of QD central parts only. Based on these approaches, not only single-layer [1] and multilayer structures with (In,Mn)As QDs [2], but also p-i-n structures where (In,Mn)As QDs were used as active layers, were realized. Here we report on detailed investigation of their structural and optical, including magneto-optical, properties.

V6-05. Engineering Magnetoresistance in Mn_xGe_{1-x} System for Magnetic Sensor Application. *T. Nie*[1] *1. School of Electronic and Information Engineering, Beihang University, Beijing, China*

In 2007, Nobel Prize is awarded to Dr. Albert Fert and Peter Grünberg for their contribution in GMR effect. The magnetic head based on GMR effect has significantly increased the storage density in the hard disk drive, and brought the coming of the digital age. Besides, the rapid development of GMR sensor has opened a wide and promising range of applications, including the aspects in automobile, traffic monitor, biomedicine and space *etc*. As continuously extending the market, it needs GMR sensor with much lower cost, smaller size, higher sensitivity and compatibility with the CMOS technology. In light of that, we give a comprehensive research on the MR effect in Mn_xGe_{1-x} systems, which refer the material growth, magnetic and MR property. In the thin film[1], the MnGe intermetallic compounds are easily formed and a competitive negative and positive MR could be obtained associating with the Mn doping concentration, as shown in Figure 1. Furthermore, a geometric-enhanced MR could be realized through the fabrication of multilayer Ge-MnGe nanostructures, and MR values could be well modulated by tuning the nanostructures. Finally, an electric-field controlled MR[2] was revealed for the first time in Mn_xGe_{1-x} nanomesh, as shown in Figure 2. The fact of well-designed MR effect and high compatibility with Si technology brings a high potential and advantage for fabricating Mn_xGe_{1-x}-based MR sensors, which could be widely used in magnetic head and biomedical sensors among others, with the superiority of much lower manufacturing cost, lower power dissipation, higher integration density and higher sensitivity.

INVITED PAPER

8:30

V7-01. A microscopic perspective at THz spinorbitronics. F. Freimuth[1], J. Hanke[1], S. Blügel[1] and *Y. Mokrousov*[1] *1. IAS-1, Forschungszentrum Julich, Julich, Germany*

In the light of ever growing advances in our ability to manipulate magnetization with laser radiation, the understanding of ultrafast microscopic processes which take place during the interaction of femtosecond electromagnetic pulses with complex materials becomes pivotal. In my talk I will review our recent progress in theoretical material-specific description and understanding of such ultrafast effects as spin-torques on the magnetization, as well as charge and spin currents that are generated by femtosecond laser pulses. In particular I will demonstrate that while the dynamics of the magnetization in response to laser radiation results in charge currents and prominent THz radiation which originates in dynamical exchange splitting, inverse spin-orbit torque effect and superdiffusive spin currents in combination with inverse spin Hall effect in specifically-designed interfacial systems can lead to pronounced optically-ignited charge and spin currents, which are not associated directly with the magnetization dynamics. I will discuss the ways of optimizing the properties of these currents by materials design, and suggest possible applications of associated charge and spin dynamics in spinorbitronics.

V7-02. Efficient Spintronic THz Emitters Based on the Excitation Energy, Crystal Structure and Multilayer Stacking Order. *L. Scheuer*[1,2], S. Keller[1,2], G. Torosyan[3], R. Beigang[1,2] and E. Papaioannou[1,2] *1. Physik, TU Kaiserslautern, Kaiserslautern, Germany; 2. Research Center OPTIMAS, Kaiserslautern, Germany; 3. Photonic Center Kaiserslautern, Kaiserslautern, Germany*

We demonstrated the generation of pulsed broadband terahertz radiation utilizing the inverse spin hall effect in Fe/Pt bilayers on MgO and sapphire substrates. The emitter provided a bandwidth of up to 8 THz which was mainly limited by the low-temperature-grown GaAs (LT-GaAS) photoconductive antenna used as detector and the pulse length of the pump laser. The THz pulse length was as short as 220 fs for a sub 100 fs pulse length of the pump laser. These emitters where optimized with respect to layer thickness, growth parameters, substrates and geometrical arrangement. The experimentally determined optimum layer thicknesses were in qualitative agreement with simulations of the spin current induced in the ferromagnetic layer. Our model takes into account generation of spin polarization, spin diffusion and accumulation in Fe and Pt and electrical as well as optical properties of the bilayer samples [1]. We further explore the efficiency of the THz spintronic emitters. THz pulses for pump powers as low as 1mW and for wavelengths from 400nm to 1500nm were detected. In addition, we show significant differences in the efficiency for samples with epitaxial and polycrystalline grown layers. Besides, we present the influence of the multilayer structure on the emitted radiation. Structures like Ta/Fe/Pt and Fe/Cu/Pt (Ta) are examined with respect to their ability to convert spin current into large amplitude THz pulses. In conclusion, we show that the general performance render the spintronic terahertz emitter compatible with established emitters based on optical rectification in nonlinear crystals.

Max Planck Institute for Microstructure Physics, Halle (Saale), Germany*

The interaction between magnetism and light is receiving considerable interest in recent years, after the groundbreaking experiments that showed that ultrashort (~100 fs) infrared light pulses can be used to demagnetize or even switch the magnetization of thin film ferromagnets [1]. However, to date no clear and commonly accepted understanding of the fundamental physical processes governing the ultrafast magnetization has been reached, partly because accurate modelling of the infrared fs laser-induced highly non-equilibrium state remains a key obstacle. We will present recent experiments where we excited ultrafast spin dynamics in metallic thin film ferromagnets with strong terahertz fields [2], rather than with infrared pulses, and probed it with the time-resolved magneto-optical Kerr effect. In this work, we used the narrow-band THz pulses produced at the High-Field High-Repetition-Rate Terahertz facility at ELBE (TELBE) to drive ultrafast magnetization dynamics in an amorphous CoFeB sample. Our measurements show that demagnetization is strongly dependent on the frequency of the THz pulses. In particular, we observe to a maximum in demagnetization (scaled to the intensity of the THz field) at around 0.5 THz for the material investigated. We propose a simple model to describe our observations at the microscopic level. Our results illustrate the relation between charge- and spin-dependent scattering of conduction electrons, deepening our understanding of ultrafast spin dynamics, and illustrating a possible strategy to optimize the control of the magnetization with ultrashort optical or electrical pulses.

V7-04. Ab-initio Modelling of Ultrafast Spin Dynamics. *P. Elliott*[1], J. Dewhurst[1], S. Sharma[1] and E. Gross[1] *1. Max Planck Institute for Microstructure Physics, Halle, Germany*

Femtosecond spin dynamics induced by a laser pulse is a demanding problem to model due to several possible mechanisms operating on a wide range of timescales. In this work we will use the ab-initio method of time-dependent density functional theory (TDDFT) to study the purely electronic response to the applied laser. From our TDDFT calculations we identified two mechanisms that can cause changes in the local moment: 1) spin-flips mediated by the spin-orbit interaction[1] which contribute to ultrafast demagnetization in simple ferromagnets like Ni,Fe,Co and 2) optically induced inter sublattice spin transfer[2] whereby local magnetic moments can be increased or decreased by the laser. The figure below shows a schematic of the intersublattice spin transfer process for the half-Heusler compound NiMnSb. In our simulations we observed that the moment local to the Ni atom increased while that of the Mn atom decreased. Following further analysis, we determined that this increase on the Ni was due, perhaps counter-intuitively, to minority spins flowing from the Ni to the Mn. Furthermore, this process can be understood from the ground-state DOS, which the figure loosely represents. In this talk I will discuss our recent progress in understanding these two processes in more detail and, in particular, our recent work[3] on magnetic switching.

V7-05. Terahertz Radiation via Inverse Rashba-Edelstein Effect. C. Zhou[2], Y. Liu[1], Z. Wang[3], S. Ma[3], M. Jia[2], R. Wu[4], L. Zhou[3], Y. Wu[3] and *J. Qi*[1] *1. University of Electronic Science and Technology of China, Chengdu, China; 2. Fudan University, Shanghai, China; 3. Physics department, Fudan university, Shanghai, China; 4. Physics and Astronomy, University of California, Irvine, Irvine, CA, United States*

Novel mechanisms for electromagnetic wave emission in the terahertz (THz) frequency regime emerging at the nanometer scale have recently attracted intense attention for the purpose of searching next-generation broadband THz emitters. Nanometerscale magnetic heterostructures via the inverse spin Hall effect (ISHE) are known to emit powerful terahertz (THz) radiation upon excitation of an ultrafast laser pulse[1- 4]. In addition to ISHE, however, the inverse Rashba-Edelstein effect (IREE) occurring at the interfaces [5] can also play a role in the spin-to-charge conversion process. So it would be interesting to find out whether such spin-to-charge conversion at interface can serve as a new THz radiation mechanism. Here, we demonstrate strong THz emission via IREE in Bi/Ag/Fe trilayers, as shown in Figure 1 (a) and (b). The bandwidth shown in Fig. 1(c) dominates between 0.1 to 5 THz for both samples. The dynamical range around 2 THz is well above ~40 dB. This observation is really astonishing because in general the interface effect only stems from a monolayer spatial scale, with a thickness is almost smaller by 7 orders of than that of conventional nonlinear crystals with thickness of millimeter order. Therefore, IREE may provide us a new candidate of mechanism for efficient broadband THz emission.

V8-01. Universal Fluctuations and Quantum Noise Measurement in a Kondo-Correlated Quantum Dot Out-of-Equilibrium. *M. Ferrier*[1,2], R. Delagrange[1], T. Hata[2], T. Arakawa[2], R. Sakano[3], A. Oguri[4], K. Kobayashi[2] and R. Deblock[1] *1. Laboratoire de Physique des Solides, Orsay, France; 2. Osaka University, Osaka, Japan; 3. ISSP, Tokyo University, Tokyo, Japan; 4. Osaka City University, Osaka, Japan*

Most of the time, electronic excitations in mesoscopic conductors are well described, around equilibrium, by non-interacting Landau quasi-particles. This allows a good understanding of the transport properties in the linear regime. However, the role of interaction in the non-equilibrium properties beyond this regime has still to be established. A paradigmatic example is the Kondo many body state, which can be realized in a carbon nanotube (CNT) quantum dot. As CNT possess spin and orbital quantum numbers, it is possible to investigate the usual twofold degenerate SU(2) Kondo effect as well as the four fold degenerate SU(4) state by tuning the degeneracies and filling factor. At very low frequency, combining transport and current noise measurements in such a dot, we have identified the SU(2) and SU(4) Kondo states [1]. Our experiment shows that, a two-particle scattering process due to residual interaction emerges in the non-equilibrium regime. The effective charge e*, which characterizes this peculiar scattering, is determined to be e*/e =1.7 ± 0.1 for SU(2) and e*/e =1.45 ± 0.1 for SU(4), in perfect agreement with theory [2]. This result demonstrates that current noise can detect unambiguously the many-particle scattering induced by the residual interaction and the symmetry of the ground state. In addition, we have measured the high frequency emission noise of another carbon nanotube QD in the Kondo regime. At the lowest measured frequencies the derivative of the noise exhibits an expected Kondo peak. However, this peak is strongly suppressed at higher frequency, pointing towards the existence of a high frequency cut-off of the electronic emission noise at a Kondo resonance. This leads us to postulate that a new timescale, related to the Kondo energy k_BT_K, emerges besides the natural timescale associated to the transport of electrons through the dot, given by the coupling to the reservoirs [3].

V8-02. Fermi-liquid theory for Kondo quantum dots out-of-equilibrium. *C. Mora*[1] *1. Laboratoire Pierre Aigrain, Ecole Normale Superieure, Paris, France*

In contrast with the equilibrium case, exact results are very few in the out-of-equilibrium single-impurity Anderson and Kondo models. We discuss exact transport properties obtained at low energy for these quantum impurity problems. We generalize Nozières' Fermi-liquid theory from the Kondo to the single-impurity Anderson model. To describe the system's low-lying quasiparticle excitations for arbitrary values of the bare Hamiltonian's model parameters, we construct an effective low-energy Fermi liquid Hamiltonian whose parameters are expressed in terms of the local level's spin-dependent ground-state occupations and their derivatives with respect to level energy and local magnetic field. These quantities are calculable with excellent accuracy from the Bethe Ansatz solution of the Anderson model. Our theoretical framework applies throughout the crossover from the strong-coupling Kondo regime via the mixed-valence regime to the empty-orbital regime, and at arbitrary magnetic fields. In order to illustrate our theory, we provide exact results for the coefficients cA, cV and cT, respectively the zero-energy curvature of the spectral function and the curvatures of the conductance as function of voltage and temperature. We also determine the critical magnetic fields for which these three coefficients change sign, indicating a splitting of the Kondo resonant peak.

V8-03. Real-Time Dynamics and Parity Symmetry Protected Spin Entanglement in the Two Impurity Kondo Model. *B. Lechtenberg*[1] and F. Anders[2] *1. Department of Physics, Kyoto University, Kyoto, Japan; 2. Department of Physics, Technical University Dortmund, Dortmund, Germany*

We consider the Two Impurity Kondo Model (TIKM) where two spin ½ impurity spins, separated by a distance R, are coupled via a Heisenberg interaction J to the electron spin densities of a conduction band. The equilibrium properties of the TIKM have been investigated extensively in the literature [1-5] and it has been recently shown [6,7] that for a 1D inversion symmetric dispersion and the specific distances $k_FR=n\pi$, with k_F being the Fermi momentum, conduction electron states with even ($n=1,3,\ldots$) or odd ($n=0,2,\ldots$) parity symmetry decouple from the impurities at low temperatures. For a parity symmetric model this decoupling also enforces a local parity conservation for the impurity spins. In this work, we study the non-equilibrium dynamics of the TIKM employing the time-dependent numerical renormalization-group (TD-NRG) [8] which was developed to treat the real-time dynamics of quantum-impurity systems after a sudden quench. While doing so, we focus our examination on the real-time dynamics of the impurity spin-spin correlation function $\langle S_1S_2 \rangle(R,t)$ for different distances after quenches in the coupling J or magnetic fields H applied to the impurity spins. Starting from initially decoupled impurity spins, the build up of this spatial correlation function is investigated and it is shown that spatial and temporal correlations propagate along a light-cone determined by the Fermi-velocity v_F. We demonstrate that for the specific distances $k_FR=n\pi$ the local parity conservation at low energy scales prevents

the impurity spin-spin correlation function from decaying to its equilibrium value for long times.

DC current can be a powerful tuning parameter of the electronic states of strongly correlated electron systems (SCES) in the vicinity of Mott transition. In this presentation, we show that in a non-equilibrium steady state (NESS) introduced by DC current, a Mott insulator with a small gap is in-situ driven into novel electronic states. We recently demonstrated that flowing DC current strongly suppresses the insulating behavior in the Mott insulator Ca_2RuO_4 and alters its magnetic nature dramatically [1]. Under a few-mA current, the antiferromagnetic ordering at T_N=113 K is completely suppressed and the resistivity $\rho(T)$ exhibits semimetallic nature. Furthermore, we discovered the emergence of "giant diamagnetism" under such current. The observed diamagnetism far exceeds ever known largest diamagnetisms of highly-oriented graphite or Bi. We attribute this diamagnetism to the emergent "Mott semimetal" state, in which the upper and lower Hubbard bands become tiny electron and hole pockets with light quasiparticle mass responsible for large diamagnetism. The electronic states of the layered perovskite Mott insulator Ca_2RuO_4 is particularly sensitive to various external stimuli such as pressure, chemical doping and electric field, due to the strong coupling among spin, orbital and charge. It exhibits insulator-metal transition at room temperature with a tiny electric field (40 V/cm) [2], involving a much larger DC current than in the present study. The small Mott gap (0.5 eV) of Ca_2RuO_4 near room temperature is shown to decrease with current [3]. In this presentation, we present the details of simultaneous magnetization and transport measurements down to 20 K performed under DC current on high-quality Ca_2RuO_4 single crystals [1].

A universal, hourglass-shaped magnetic spectrum as measured by inelastic neutron scattering has been found in a number of hole-hoped copper oxide superconductors. This form of a spectrum emerges naturally from a stripe-ordered ground state which led some theoreticians to believe that stripe fluctuations may be an important mechanism of superconductivity. However, the origin of the hourglass in copper-oxide materials has been widely contested. Instead, we have focused our efforts on an insulating, layered cobalt oxide $La_{2-x}Sr_xCoO_4$. Our findings showed that it also has a characteristic hourglass-like magnetic spectrum [1]. However, direct evidence for a stripe-ordered ground state has been missing and that has led some studies to propose an alternative stripe-free scenario [2]. I will present the results of our polarised neutron diffraction experiments to examine the magnetic order in $La_{2-x}Sr_xCoO_4$ and discuss its implications on the role of stripes in forming an hourglass spectrum [3].

Copenhagen, Copenhagen Ø, Denmark*

We present detailed neutron scattering studies of the static and dynamic stripes in an optimally doped high-temperature superconductor, La_2CuO_{4+y} [1]. We observe that the dynamic stripes do not disperse towards the static stripes in the limit of vanishing energy transfer. Therefore, the dynamic stripes observed in neutron scattering experiments are not the Goldstone modes associated with the broken symmetry of the simultaneously observed static stripes, and the signals originate from different domains in the sample. These observations support real-space electronic phase separation in the crystal, where the static stripes in one phase are pinned versions of the dynamic stripes in the other, having slightly different periods. Our results explain earlier observations of unusual dispersions in underdoped $La_{2-x}Sr_xCuO_4$ (x=0.07) [2]. and $La_{2-x}Ba_xCuO_4$(x=0.095) [3].

Department of Physics and Astronomy, Uppsala University, Uppsala, Sweden*

For the past 30 years, considerable scientific effort has been put into the quest of understanding the mechanism behind high temperature superconductivity. It is believed that clues to the pairing mechanism, can be found in understanding the interplay between spin and charge orders and superconductivity in ceramic cuprates superconductors [1]. Our group is currently investigating the behaviour of spin density waves, so called spin stripes, in highly underdoped $La_{2-x}Sr_xCuO_4$ (LSCO) superconducting single crystals close to the quantum critical point (QCP - representing the zero temperature phase transition between the insulating and superconducting phases at a doping value of x = 0.055). In our most recent neutron scattering experiments we have not observed static stripes signal in a x = 0.08 LSCO single crystal, disputing the general belief that magnetic order is present for all dopings below x = 0.135 [2]. This could be an indication that, in the extremely underdoped region of the LSCO phase diagram, it is not the same ordering phenomena that generates the static and dynamic magnetic stripes. The same argument was also proposed by some of us [3] to explain a discontinuity of the dispersion in the limit of vanishing energy transfer in an oxygen doped La_2CuO_{4+y}. Contrary to all evidence from literature, where a magnetic field is reported to produce an enhancement of low-energy fluctuations in LSCO samples with x = 0.105 [4], x = 0.163 [5] and x = 0.18 [6] or no effect for x = 0.12 [7] (Fig. 1), our x = 0.08 LSCO single crystal showed a low energy (< 1.5 meV) suppression of the dynamic magnetic stripes signal by an applied magnetic field (Fig 2). Going further we plan to make a detailed study of the magnetic stripes on both sides of the QCP.

V9-04. Anomalous lattice dynamics in $La_{2-x}Sr_xCuO_{4+y}$ (LSCO): The role of static or mobile dopants. *T.B. Tejsner*[1,2], M. Boehm[1], A. Piovano[1], K. Lefmann[2], A. Tutueanu[1,2] and L. Udby[2] *1. Institut Laue-Langevin, Grenoble, France; 2. Niels Bohr Institute, University of Copenhagen, Copenhagen, Denmark*

The cuprate $La_{2-x}Sr_xCuO_4$ (LSCO) is an interesting model system for high-temperature superconductivity (HTSC) due to its relatively simple crystal structure and differences in the superconducting transition as function of Sr and Oxygen doping. Hole-doping with Sr^{2+} creates a superconductor where the superconducting transition temperature T_c varies monotonically with doping. Doping with highly mobile, excess O^{2-} by contrast, results in a bulk superconductor separated into two unique phases: 1) An optimally doped, bulk superconducting phase (T_c = 40K)[1] with low pinning[2] and a 2) long-range modulated antiferromagnet with period ≈ 8 similar to the striped cuprates[3]. While both optimally doped LSCO and LSCO+O appear to have similar superconducting properties, the specific role of the dopant ions on a microscopic scale is still unknown. Recently, an anomaly in the Cu-O bond stretching phonon was found to correlate with T_c in Sr-doped LSCO, indicating a coupling to a novel charge mode possibly related to stripes[4,5]. In order to distinguish between a lattice effect driven by the superconducting transition or a lattice anomaly introduced by Sr doping, we concentrated our research on samples that are strongly underdoped in terms of Sr ($x \lesssim 0.06$), but optimally superconducting (T_c = 40K) due to excess Oxygen. First measurements with x = 0.06 clearly shows a phonon anomaly with similar strength to optimally doped LSCO as reported in literature (Fig.1)[6]. Expanding on these results, we will measure the phonon anomaly in LCO+O in spring this year and compare our experimental results with our DFT calculations.

The interplay between superconductivity and spin excitations has an important role in cuprate superconductors. While it is well known that this family of superconductors has a *d-wave* symmetry, the mechanism of Cooper pair formation is yet to be understood. It has been proposed that antiferromagnetic spin excitations may play a role [1]. Studying the evolution of spin excitation for different regimes and doping, is therefore an important issue in order to reveal the optimal conditions for high-temperature cuprate superconductors. Here, we present a systematic Resonant Inelastic X-ray Scattering (RIXS) study of the spin excitations in $La_{1.88}Sr_{0.12}CuO_4$ [2] and the related parent compound La_2CuO_4. Spin excitation spectra are analysed using a dispersion function derived from a Hubbard model [3]. We show that, for $La_{1.88}Sr_{0.12}CuO_4$, the extracted data can be explained only if invoking a two-orbital model in which a second-nearest hopping integral is enhanced as a consequence of the reduction of the crystal field splitting between the d_{x2-y2} and d_{z2} orbitals [4]. The importance of d_{z2} orbital, confirmed by our recent Angle Resolved Photoemission Spectroscopy (ARPES) study [5], is investigated by XAS and RIXS in further detail on the parent compound La_2CuO_4. The obtained results are discussed in the context of superconductivity optimisation.

The narrow-band semiconductor PbTe is an anomalous superconductor with a T_C that is almost an order of magnitude greater than comparable low-density metals, but only when it is doped with valence-skipping elements. There is experimental evidence that upon hole-doping PbTe with Tl superconductivity onsets as the chemical potential is tuned to a point of degeneracy of the Tl 1+ and 3+ valences. At these compositions the Tl dopants can dynamically skip valence by filling and emptying their 6s shell of two electrons simultaneously, naturally raising the question of whether Tl dopants provide the electronic correlations that drive the enhanced superconductivity seen in this compound. In this experimental study of the Fermi surface of $Pb_{1-x}Tl_xTe$ we firmly establish the correlation between the onset of anomalously high temperature superconductivity and the presence of resonant impurity states (associated with the Tl impurities) at the Fermi level. We rule out the scenario where additional valence band maxima play a role in the superconductivity by proving that they remain below the Fermi level at all compositions studied. Through comparison to non-superconducting $Pb_{1-x}Na_xTe$ we conclude that these resonant impurity states are enhancing, or even providing, the pairing interaction for superconductivity. We establish these results from a combination of Shubnikov de Haas oscillations, Hall coefficient, specific heat, and ARPES measurements presented herein.

An illustration of two proposed schemes to describe the fermiology of superconducting $Pb_{1-x}Tl_xTe$. a) The Fermi-level is tuned below a second band maximum at the Sigma point, and b) the Fermi-level is tuned into a resonant impurity state and the second valence band maximum is not relevant for superconductivity. We provide strong support for the latter case.

Data respectively demonstrating the presence of (a) a mismatch between the Luttinger volume and Hall number, (b) a pinning of the Fermi-energy, and (c) excess density of states relative to that found in the measured valence-band at superconducting compositions (x>0.3%). These are all consistent with resonant impurity states. Furthermore, the second valence band maximum is shown by ARPES to remain below E_F.

V10-01. Quasi-one-dimensional Bose-Einstein Condensation in Spin-1/2 Ferromagnetic-leg Ladder Organic Magnets. *Y. Kono*[1], S. Kittaka[1], H. Yamaguchi[2], Y. Hosokoshi[2] and T. Sakakibara[1] *1. The Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan; 2. Department of Physical Science, Osaka Prefecture University, Sakai, Japan*

Recently, several verdazyl radical crystals have been synthesized and found to form ferromagnetic-leg (FM-leg) ladder lattices [1], i.e., leg and rung interactions are ferromagnetic and antiferromagnetic, respectively. They are molecule-based crystals, and each of molecules possesses an $S = 1/2$ quantum spin. Substitution of halogen atoms to various functional groups allows tuning of the intermolecular interactions, and brings about unique magnetic phase diagrams with quantum phase transitions [2-4]. In this presentation, we provide an overview of quantum critical phenomena in the verdazyl-radical-based spin-1/2 FM-leg ladders 3-Br-4-F-V [2], 3-I-V [3], and 3-Cl-4-F-V [4]; the quantum criticality of the three-dimensional (3D) ordering phase boundaries $T_c(H)$ near the quantum critical points (QCPs) is discussed with respect to the universality of Bose-Einstein condensation (BEC) of lattice-gas bosons. 3-Br-4-F-V is strong-rung type ($\gamma = |J_{rung}/J_{leg}| > 1$) and has two QCPs, the lower critical field H_{c1}, at which the spin gap is closed, and the saturation field H_{c2}. We applied the temperature-window fitting technique [5] to extract the critical exponents of $T_c(H)$ near the QCPs in the limit of zero temperature. It yields the universal power-law of 3D BEC, $T_c(H) \sim |H - H_{c1,2}|^{2/3}$ [6]. This is the first observation of the 3D BEC exponent on FM-leg ladder systems. On the other hand, 3-I-V and 3-Cl-4-F-V are strong-leg type ($\gamma < 1$) and have no spin-gapped state due to frustrated interladder interactions. Therefore, they have only one QCP, the saturation field H_c. The phase boundary of 3-I-V shows the linear power law $T_c(H) \sim (H_c - H)$ in the wide temperature range below 1 K [7]. 3-Cl-4-F-V shows successive phase transitions [4], and we have also found the linear phase boundary of lower temperature phase near Hc. These characteristic power laws would be caused by quasi-one-dimensional BEC with the predominant ferromagnetic interactions, which has been predicted theoretically [8]. Thus, the spin-1/2 FM-leg ladders provide unique opportunity for investigating the relationship between one dimensionality and BEC physics in quantum magnets.

Max Planck Institute for Solid State Research, Stuttgart, Germany*

The strongest magnetic interactions in Ba_2CuTeO_6 have been proposed by *ab initio* calculations to be between Cu^{2+} spin-1/2 ions located in two-leg ladders. Isolated ladders are expected to have a singlet ground state protected by a spin gap [1]. Ba_2CuTeO_6 actually orders magnetically, but with a small Néel temperature $T_N = 16$ K relative to the exchange strength $J \approx 86$ K, suggesting that the interladder coupling is relatively small and is only just able to stabilise magnetic order, placing Ba_2CuTeO_6 close in parameter space to the quantum critical point separating the gapped phase and Néel order [2]. To quantify the proximity to the critical point, here we report inelastic neutron scattering measurements of the spin dynamics and compare them with predictions for a coupled ladder system from a quantum Monte Carlo calculation and linear spin wave theory.

V10-03. Spin molecular-orbit coupling and electron correlations in multinuclear organometallic complexes. *J. Merino*[1], A. Jacko[2], A.L. Khosla[2] and B.J. Powell[2] *1. Fisica Teorica de la Materia Condensada, Universidad Autónoma de Madrid, Madrid, Spain; 2. School of Mathematics and Physics, The University of Queensland, Brisbane, QLD, Australia*

Organometallic multinuclear coordination complexes are strongly correlated materials in which spin molecular-orbit coupling is relevant [1] and remain little explored. $Mo_3S_7(dmit)_3$ materials consist of layered honeycomb lattices which are decorated by triangular clusters at each crystal lattice vertex. We have derived an effective spin exchange model for this crystal which consists of pseudospin-one moments arranged in weakly coupled chains with anisotropic magnetic exchange and large trigonal splitting [2,3]. The effective dimensionality is found to be strongly dependent on the Coulomb interactions becoming more one-dimensional with the increase of electronic correlations. Our analysis shows how $Mo_3S_7(dmit)_3$ is in the Haldane phase and maybe tuned to a magnetically ordered phase by applying a sufficiently strong external magnetic field. The effective spin exchange model for isolated layers is an XXZ+120-honeycomb quantum compass model. Exfoliation or growth of $Mo_3S_7(dmit)_3$ monolayers would lead to the realization of decorated hexagonal lattices in which exotic quantum magnetism could be experimentally explored.

V10-04. Double Magnetic Field-induced Phase Transition in the Spin 1/2 Alternating Chain System $AgVOAsO_4$. *F. Weickert*[1], A.A. Aczel[4], R. Movshovich[2], M. Gamza[5], A. Demuer[8], N. Harrison[3], H. Rosner[7] and A.A. Tsirlin[6] *1. NHMFL, Florida State University, Los Alamos, NM, United States; 2. MPA, Los Alamos National Laboratory, Los Alamos, NM, United States; 3. Laboratoire National des Champs Magnetiques Intenses, Grenoble, France*

The investigation of Bose-Einstein condensation (BEC) in quantum magnets stays a vital area of research in experimental and theoretical condensed matter physics [1]. Here, we present a comprehensive study of thermodynamic properties on polycrystalline $AgVOAsO_4$ - an alternating spin 1/2 Heisenberg chain system as established by NMR measurements [2]. The exact spin structure of this compound is unknown, but theoretical modeling points to a rather complicated cross pattern of spin chains with significant frustration [3]. $AgVOAsO_4$ shows a spin gap of 13K in zero magnetic field that closes at about 10T as confirmed in magnetization experiments in pulsed magnetic fields [3]. We find two sharp anomalies in specific heat experiments above 10T, which are characteristic for two separate phase transitions that cannot be explained as onset of simple XY-antiferromagnetic ordering, the simplest realization of field-induced BEC in quantum magnets. This puzzling phase diagram, see Fig.1, promotes $AgVOAsO_4$ as a promising candidate for so-called multi-*Q* BEC [4] with *Q* being the wave vector of the single-particle ground state in boson language. In the case of multi-*Q* BEC, the magnetic field acts not only as external tuning parameter to control the boson density as in single-*Q* BEC [1], but the field also switches between different types of incommensurate antiferromagnetic ordering [4]. Furthermore, we discuss results of inelastic neutron scattering experiments probing minima in the dispersion band - another characteristic difference between single-*Q* and multi-*Q* behavior.

V10-05. Disorder-Induced Bose-Einstein Condensate in a Quantum Magnet at High Magnetic Fields. *M. Horvatic*[1], A. Orlova[1], R. Blinder[1], E. Kermarrec[1], M. Dupont[2], S. Capponi[2], N. Laflorencie[2], H. Mayaffre[1], S. Krämer[1], C. Berthier[1] and A. Paduan-Filho[3] *1. LNCMI-Grenoble / CNRS, Grenoble, France; 2. LPT - Univ. Toulouse/CNRS, Toulouse, France; 3. Instituto de Física, Universidade de São Paulo, São Paulo, Brazil*

The $NiCl_2$-4SC$(NH_2)_2$ compound (DTN) is one of the most studied archetype materials for the magnetic-field-induced 3D-ordered low-temperature phase of the Bose-Einstein condensation (BEC) type. When DTN is disordered by doping with bromine, a localized (incoherent and short-range correlated), compressible gapless Bose-glass (BG) phase is predicted to appear adjacent to the BEC phase [1]. Br-doped DTN is thus proposed as a unique thermodynamic model system for studying BG physics. However, the doping-induced localized degrees of freedom, which create the BG, experience an effective interaction. At sufficiently low temperature, this eventually leads to a *new*, *disorder-induced*, long-range *ordered* (but inhomogeneous) "BEC*" phase, which partially or totally screens the BG regime [2-5]. This phase is a completely new example of "*order as an effect of disorder*", first discussed in [6]. We present here the first experimental evidence, as well as the determination of the phase diagram, for this new quantum phase of matter.

The high-field NMR investigation of 4% doped DTN first provided a clear signature for a level crossing of the energy levels related to the localized, doping-induced impurity states [2]. This suggested a possibility that these impurity states are building elements for a new, inhomogeneous but fully 3D-coherent BEC* phase. A theoretical modelling [3], based on large scale quantum Monte Carlo simulations, confirmed this scenario, and furthermore provided detailed doping-dependence of the *T*-*H* phase diagram [4]. Finally, in a strongly, 13% doped DTN sample, where the BEC* phase is accessible by dilution refrigerator, NMR data confirmed the existence of this phase, and showed that its experimental phase diagram agrees very well with the theoretical predictions [5].

[1] R. Yu *et al.*, Nature 489, 379 (2012). [2] A. Orlova *et al.*, Phys. Rev. Lett. 118, 067203 (2017). [3] M. Dupont, S. Capponi and N. Laflorencie, Phys. Rev. Lett. 118, 067204 (2017). [4] M. Dupont *et al.*, Phys. Rev. B 96, 024442 (2017). [5] A. Orlova *et al.*, preprint, arXiv:1801.01445. [6] J. Villain *et al.*, J. Phys. France 41, 1263 (1980).

A peak in the spin fluctuations measured by the NMR T_1^{-1} relaxation rate in Br-doped DTN directly reflects the level crossing of the impurity states. These localized states provide the building blocks for a new, ordered "BEC*" phase, which is formed despite a strong disorder of their interaction. The theoretically predicted phase diagram for this new phase is now fully confirmed by an NMR experiment.

In $S = 1$ antiferromagnet having an easy-plane single-ion anisotropy a quantum phase transition is caused by the competition between the single-ion anisotropy and spin interaction. In the vicinity of the quantum critical point an enhanced longitudinal mode in addition to transverse mode are predicted [1]. An easy-plane type antiferromagnet $CsFeCl_3$ is an ideal compound for the study; the low-energy excitation of the Fe^{2+} ion is described by a pseudo-spin $s = 1$, and the singlet ground state is realized by the strong easy-plane anisotropy [2]. Furthermore, recent study on the magnetic susceptibility demonstrated that applying pressure induced magnetic long-range order at low temperatures [3]. In order to study the quantum criticality in $CsFeCl_3$, we performed both neutron diffraction and inelastic neutron scattering experiments under pressures. The diffraction experiments evidence that a 120° structure is realized in the ordered phase, and the universality class is $U(1)\times Z_2$. Inelastic neutron scattering spectrum exhibits a softening of the low-lying excitation in the disordered phase by applying pressures. In the ordered phase, a well-defined gapped excitation is observed in addition to a continuum-like gapless excitation. Careful comparison with the calculation based on the bond operator theory reveals that the well-defined excitation corresponds a mixed mode of the transverse and longitudinal fluctuations, and the gapless excitation is a transverse mode.

W1-02. Application of LENS Additive Manufacturing Process for High-throughput Identification of Candidate Permanent Magnet Alloy Compositions. *C.I. Nlebedim*[1], F. Meng[1], R. Chaudhary[1], K. Gandha[1], A. Palasyuk[1], M.J. Kramer[2] and R. Ott[1] *1. Critical Materials Institute, Ames Laboratory, US Department of Energy, Ames, IA, United States; 2. Ames Laboratory, Iowa State University, Ames, IA, United States*

In this talk, we demonstrate the application of an additive manufacturing technique, via the laser engineered net shaping (LENS) high-throughput method, for rapidly identifying candidate alloys for permanent magnets development. For decades, alloys based on Nd-Fe-B and Sm-Co have been the key materials for many high performance permanent magnets applications. Experts agree that any disruptive technology with significant dependence on these materials can trigger supply difficulties and retard technological advancement. Identification of new materials is urgent but conventional methods of alloy synthesis is often time consuming which limits timely discovery of new systems. This talk will focus on our application of the LENS method to binary, tertiary and quaternary materials systems for rapidly identifying compositions with potentials for permanent magnets development. Fig. 1 shows (a) a radar plot of properties including coercivity, remanence and Curie temperature for the LENS additive manufacturing printed samples based on Ce-Cu-Fe-Co (b) magnetic properties of an identified composition (c) improved properties on further development of the composition via casting and heat treatment. Acknowledgement This work was supported by the Critical Materials Institute, an Energy Innovation Hub funded by the U.S. Department of Energy, Office of Energy Efficiency and Renewable Energy, Advanced Manufacturing Office.

W1-03. Magnetic Polymerized Composites for Bonding and 3D-Printing of Alternative Permanent Magnets. *E.M. Palmero*[1], J. Rial[1], D. Casaleiz[1], J. de Vicente[1] and A. Bollero[1] *1. Division of Permanent Magnets and Applications, IMDEA Nanoscience, Madrid, Spain*

Advanced manufacturing using composites of magnetic particles and polymers is nowadays opening new routes for the fabrication of functional structures with complex shapes [1]. For permanent magnets (PMs) applications, 3D-printing of NdFeB-based magnets is attracting much interest. However, due to the increasing need of finding alternatives to rare earth (RE)-based magnets for selected applications, the research must be extended to non-RE elements based materials. MnAl-based alloys and improved ferrites are possible candidates to partially substitute RE-based magnets due to their PMs properties, high availability, reduced costs and environmental impact of extraction and processing of raw materials [2, 3]. This study focuses on the synthesis of hard magnetic polymerized composites by solution casting. The magnetic particles were gas-atomized τ-phase MnAlC particles and ferrites. Moreover, combinations of NdFeB with ferrites were used to reduce RE-elements content and increase the composite filling factor. The particles were homogeneously embedded into polymers forming composites (Fig. 1(a)). By solution casting, it was possible to easily tune the filling factor of the composites, reaching high values above 85% (Fig. 1(b)) [4]. Composites were extruded into magnetic flexible filaments for advanced 3D-printing. Filaments with circular cross section (Fig. 1(c) and 1(d)) and continuous length exceeding 10 m were obtained (Fig. 2(a)). Magnetic measurements of composites and filaments show no deterioration of the magnetic properties of the particles after composite synthesis and filament extrusion (Fig. 2(b)) [4], proving that alternative composites and filaments with PMs properties can be efficiently synthesized for bonding and 3D-printing of a new generation of magnets. Authors acknowledge Höganäs AB for providing the gas-atomized powders.

W1-04. Trajectory of a Non-magnetic Particle transported by a Rotating Magnetic Particle Chain. *W. Lo*[1], C. Lu[1] and C. Chen[1] *1. Mechanical Engineering, National Chiao Tung University, Hsinchu, Taiwan, Taiwan*

Transportation of microscale subject is important in the MEMS application. In this study, movement of a non-magnetic particle induced by a chain consisted by several magnetic particles in a rotational field is experimentally manipulated and observed. It is shown that the non-magnetic particle can be driven to an azimuthal movement by the rotating chain, as shown in figure 1. The results reveal that angular movement is nearly proportional to the length of chain, or the radial distance of the particle away from the center of rotation, for every contact of the non-magnetic particle and rotating chain. The overall trajectory of the moving non-magnetic particle would remain nearly circularly. Nevertheless, interaction with the particle would cause the chain drifting as well, so that the radial distance to the rotational origin varies as well. As a result, the radius of nearly circular movement trajectories varies dependent on the drifting orientation of the chain, as shown in figure 2. Based on the experimental result, a kinetic numerical code is developed, which enable to predict the trajectories associated with different experimental conditions.

Non-magnetic particle (blank) is driven to move azimuthally by interaction with clockwisely rotating chain consisted of 7 magnetic particles (pink). Serial numbers 1 and 7 indicate the particles at two ends.

Trajectories of center of magnetic chain (red) and non-magnetic-particle (black), in which time evolves from lighter to darker color. The center of chain appears apparent drift toward upper-left orientation, which the particle gradually moves toward the center of chain. As a result, the radius of circular trajectory becomes smaller as time evolves.

W1-05. Elastic-ferromagnetic swimmers, pumps, and membranes. *J.K. Hamilton*[1], A.D. Gilbert[2] and F.Y. Ogrin[3] *1. Department of Physics, University of Exeter, Exeter, United Kingdom; 2. Department of Mathematics, University of Exeter, Exeter, United Kingdom; 3. University of Exeter, Exeter, United Kingdom*

In recent years, there have been an interest in incorporating magnetic materials in Lab-on-a-chip technology[1–3]. Such devices hold promise for radically new application in microfluidics and medical diagnostics. In this work, we focus on creating elastic hard ferromagnetic devices, which when actuated by an external magnetic field induce a fluid flow. The external magnetic field creates a magnetic torque on the hard ferromagnetic field. The torque induced in turn creates stretching and torsion modes of the system. The initial experimental investigation indicates how a macroscopic NdFeB particle embedded in a flexible silicone tail (Figure 1a). We investigate the dynamic performance the swimmer on the air-fluid interface as a function of the external field parameters (frequency and amplitude). We show that the speed of the swimmer can be controlled by manipulating the strength and frequency of the external weak magnetic field. By a simple change of reference frame, we create a fluidic pump and investigate the

induced flow. Finally, we show the fabrication of an elastic-ferromagnetic membrane (Figure 1b) and how the device interacts with a surrounding fluid. The magnetic sections of the macroscopic membrane are created with a mixture of micro-scaled NdFeB powder and silicone rubber. The magnetic sections are magnetised out-of-plane, the membrane is actuated using an in-plane uniaxial magnetic field. By manipulating the frequency and amplitude of external magnetic field, the membrane induces a fluid flow. The simple design of these devices are promising for being incorporating into Lab-on-a-chip systems. This investigation paces the way for fabrication of such, swimmers, pump, and membranes on a microscopic scale.

W1-06. Comparative Study of Different Stator Winding Configurations for Variable Flux Permanent Magnet Synchronous Machine.
S. Zhang[1], P. Zheng[1], M. Wang[1] and F. Liu[1] *1. School of Electrical Engineering and Automation, Harbin Institute of Technology, Harbin, China*

Variable flux permanent magnet synchronous machine (VF-PMSM), also known as memory motor, is considered as a promising candidate in adjustable-speed drive applications [1]. The magnetization state of the low coercivity (H_c) magnet equipped in VF-PMSM could be flexibly regulated through the d-axis current pulse energized by the armature winding. Based on the operating condition of the machine, the low-H_c magnet could be demagnetized in the case of light load to extend the operating speed range or be re-magnetized in the case of heavy load to enhance the torque density. The magnetization regulation process needs to be accomplished within dozens of milliseconds and precisely achieves the desired magnetization state of the low-H_c magnet. It is obviously that the stator winding configuration has crucial influences on the magnetization characteristic of the low-H_c magnet in VF-PMSM. In this paper, four VF-PMSM schemes with the same rotor topology and different stator winding configurations, including integral-slot distributed winding, fractional-slot distributed winding and fractional-slot concentrated winding, are studied and compared using the finite-element method (FEM) which could give an insight into the magnetization pattern of the low-H_c magnet. The required fully demagnetization current, fully re-magnetization current and the magnetization uniformity not only within one piece of low-Hc magnet but also among all of low-Hc magnets, are evaluated as important indices. A fair judgment among four winding configurations is made and then considerations on selecting winding configuration for VF-PMSM are given. Magnetization patterns of low-H_c magnets after being demagnetized by different stator winding configurations are illustrated in Fig.1. It reveals that the required demagnetization current in fractional-slot concentrated winding scheme is much smaller than other schemes, however, an uneven demagnetization among different pieces of low-H_c magnets is observed in this scheme. More information and discussion will be included in the full paper.

W1-07. Relationship between anisotropy field and temperature rise caused by AC field applied to Nd-Fe-B permanent magnet.
M. Ishikawa[1], F. Akagi[2] and K. Yoshida[2] *1. Electrical and Electronic Engineering, Kogakuin University, Shinjuku-ku, Japan; 2. Kogakuin University, Shinjuku-ku, Japan*

Motors for highly efficient hybrid and electric vehicles are required to have high-speed rotation. However, the heat generated in the Nd-Fe-B permanent magnet in the motor is a problem. One of the heat sources is eddy currents, which are caused when a high-frequency AC field is applied to the magnet[1)]. In addition, magnetization reversals accelerated by defects in the magnet may cause high eddy currents. In this study, we investigated the relationship between low anisotropy field and temperature rise using a micromagnetic simulator, assuming the defects. The magnetization behaviors of the magnets were calculated using the Landau-Lifshitz-Gilbert equation[1)]. The eddy current field (H_{eddy}) and heat (Q) were calculated by using the following equations. $\nabla\times E_{eddy} = -\partial B/\partial t$, $J = \sigma E_{eddy}$ $\nabla\times H_{eddy}$ (1) $Q = 1/\sigma|J|^2$ (2) E_{eddy} is the electric field, B is the magnetic flux density, J is the current density, and σ is the electric conductivity. The calculation model was assumed to be a magnetic cubic crystal grain with a side length of 60 nm. M_s and σ were 1.61 T and 1.0×10^6 $\Omega^{-1}m^{-1}$, respectively. The anisotropy field (H_k) was changed from 311 to 559 kA/m. The AC field intensity was changed from 160 to -160 kA/m, and the frequency was 1.0×10^7 Hz. Fig. 1 shows the relationship between the normalized coercivity (H_c/H_k) and H_k. From the graph, it can be seen that H_c was considerably lower than H_k when H_k was lower than 546 kA/m. The lower the H_k, the smaller H_c/H_k was. The magnetization did not reverse when H_k was 546 kA/m or more. The threshold of the H_k for magnetization reversal depends on the balance of the effective field. Fig. 2 shows the relationship between H_k and the temperature rise (per sec and m^3). From the graph, it can be seen that the temperature rose when H_k was lower than 546 kA/m. However, the lower the H_k, the lower the temperature rise was because the magnetization reversal speed became lower as H_k became lower.

W1-08. Improved Modeling of Surface Degraded Sintered NdFeB Magnets with Large SA/V Ratios. *K.C. Kurtz*[1,2], M.S. Guthrie[2] and J.F. Naber[1] *1. Electrical and Computer Engineering, University of Louisville, Prospect, KY, United States; 2. Engineering, Quadrant Solutions, inc., Prospect, KY, United States*

The magnetic modeling accuracy degrades for sintered NdFeB magnets with SA/V ratios greater than 1.9/mm. For example, using Infolytica's MagNet[1] and for SA/V values < 1/mm gives modeling errors of less than 5%. However, as the SA/V ratio approaches 1.9/mm, the corresponding error in the model jumps to 10% and almost 25% at a SA/V ratio of 4.0/mm[2]. Figure 1 shows early preliminary data with a SA/V ratio of 4.0/mm after machining and plating. The purpose of this work is to develop more accurate magnetic models for sintered NdFeB magnets with SA/V ratios greater than 1.9/mm. Our approach is to create a Design Of Experiments (DOE) that will look at many of the variables in the manufacturing process to better understand what variables most impact the final magnet and can easily be incorporated into the model. An L16 orthogonal array DOE will be used to reduce a full-factorial of 128 experiments down to only 16. There is a significant amount of time involved in each experiment; a full factorial experiment is not practical. Table 1 shows all the variables and levels for the variables for the L16 array in the DOE. Varying manufacturing processes, including material, cutting, etching, and coating will be studied to identify the property damages caused by comparing pre- and post- production magnetic measurements. Surface damage from manufacturing is suspected in causing large gaps between real world and simulated properties in magnets with a SA/V value, as seen in figure 1. Properties will be measured with a Vibrating Sample Magnetometer (VSM). The degraded properties will be studied with the goal of creating more accurate simulation models and finding the least destructive process included in the experiment. This paper discusses the varying processes of these sintered NdFeB magnets and will present data showing the degraded properties of several samples.

Session W2
ADVANCED SYNTHESIS OF MAGNETIC THIN FILMS AND MULTILAYERS II (Poster Session)

Sophie Ann Morley, Chair
University of California, Santa Cruz, Leeds, United Kingdom

W2-01. Epitaxial growth of magnetostrictive/piezoelectric heterostructures. *K. Dumesnil*[1], V. Polewczyk[1], A. Hillion[2], S. Robert[1], P. Boulet[1] and M. Hehn[1] *1. Institut Jean Lamour, CNRS, Université de Lorraine, Nancy, France; 2. INSA, Université Fédérale Toulouse Midi Pyrénnées, Toulouse, France*

Systems combining coupled magnetic and electric order parameters are interesting to achieve the electrical control of magnetization or to develop sensors. In this context, hybrid magnetic/piezoelectric multiferroic systems should enhance the coupling (via strains), which remains weak in intrinsic multiferroic compounds. Highly magnetostrictive materials, among which Terfenol ($TbFe_2$), are first candidates due to their record room temperature magnetostriction, but the systems synthetized up to now can hardly benefit from such performance because of the amorphous or polycrystalline form of the magnetic compound [1,2,3]. The main goal of this study is to go a step further, towards single crystalline materials that could be strongly coupled to the piezoelectric phase. We present here the recent advances made in the epitaxial growth and characterization of $TbFe_2$ films on $LiNbO_3$ substrates with different orientations (Z-, 41Y-and 128Y-cuts), and using various buffer layers (Ti, Mo, Ti/Mo), required for the crystalline growth on such an oxide buffer relatively unstable at high temperature [4]. The growth on LNO41Y-and 128Y-cuts is particularly interesting due to use of these substrates for SAW applications, but challenging due to unconventional surface planes. On the LNO Z-cut surface with hexagonal symmetry, we show that (0001)Ti planes grow with in-plane directions rotated by 30° respect to the underlying substrate's. (110)Mo growth planes exhibit either three domains (R30 orientation) on LNO or six domains (KS orientation) on Ti. (111)$TbFe_2$ could be epitaxially grown on these different surfaces with surprisingly the same final orientation relationships respect to the underlying LNO (0001) planes. On unconventional LNO41Y-and 128Y-cuts, a detailed analysis of pole figures has revealed that it remains possible to grow crystalline Mo and $TbFe_2$, with 3D orientation relationships similar to those obtained on LNOZ. Specific orientations are however selected among equivalent ones, most likely due to surface energies considerations. The magnetic properties of these$TbFe_2$ films and the magneto acoustic behavior of $TbFe_2$-based Magnetic SAW devices patterned in a resonator geometry are reported.

W2-02. Magnetoelectrodeposition of FePd alloy thin films. *S. Annamalai*[1] and J.R. Mohanty[1] *1. Physics, Indian Institute of Technology, Hyderabad, India*

Superimposition of external constant magnetic field (CMF) during electrodeposition process influence several effects in deposited films. Such helps in improving magnetic, morphological and microstructural properties which is mainly due to magneto hydrodynamic effect (MHD) and Lorentz force (F_L) [1]. The relationship between plating current density (J) and magnetic field (B) direction causing convective force maxima or minima plays an important role in these films [2]. Magnetic properties of FePd alloy thin films are our interest to study in presence of CMF (0.8T) grown samples at reduction potentials of (-1.0V, -1.05V and -1.1V). A clear investigation of magnetic, morphological and microstructural properties of as grown thin films exhibits interesting results. X-ray diffraction measurements of FePd alloys show variation in crystalline structure FCC at (-1.0V and -1.05V) and BCC structure at (-1.1V) confirms the anomalous behavior of FePd alloy system [3]. Formed nanocrystallites (at-1.05V (7.95nm)) are improving in presence of parallel external magnetic field (4.16nm). On the contrary perpendicular magnetic field identified with higher crystallite size (8.42nm). Magnetic hysteresis loop (M-H) measurements show all the deposits are having in-plane magnetization orientation, with increasing saturation magnetization (M_s) as Fe (at%) goes high. However, highest M_s is achieved in parallel magnetic field grown samples. This proves that external magnetic field increases the magnetic anisotropy and quality of films. Atomic force microscopy images reveal high quality deposits with low roughness identified in parallel magnetic field grown case, whereas perpendicular to field leads to higher roughness. Patch-like domain pattern in magnetic force microscopy images (at-1.05V) proves parallel magnetic field causing formation of domains in electrodeposited films. Films grown at higher deposition potential in the presence of parallel magnetic field found to have lesser effect. Counter play between external magnetic field and deposition potentials to achieve high quality films in magnetic field electrodeposition were studied.

W2-03. Magnetic Properties for Synthetic Antiferromagnet with Perpendicular Easy Magnetic Anisotropy. *N. Tezuka*[1], S. Fujikawa[1], M. Matsuura[1] and S. Sugimoto[1] *1. Graduate School of Engineering, Tohoku University, Sendai, Miyagi, Japan*

Magnetic tunnel junctions whose ferromagnetic electrodes possess magnetization perpendicular to the film plane (p-MTJs) have attracted considerable attention due to their high potential in spin transfer torque magnetoresistive random access memory. We have recently found that p-MTJs with a CoFeB/W/CoFeB (synthetic antiferromagnet: SyAF) free layer with interfacial perpendicular magnetic anisotropy and a CoFeB pinned layer in combination with a Co/Pt multilayer to fabricate p-MTJs with high TMR ratio (248%) and low RA products (~10 $\Omega\mu m^2$)[1] at RT. However, the magnetic properties of SyAF with perpendicular anysotropy was not clear. In this

research, we investigated the magnetic properteis of SyAF free layer with perpendicular anysotropy of CoFeB/(W or Ta)/CoFeB and discussed these properties by using LLG micro-magnetic simulatio. The sample of MgO (001) sub. /CoFeB /(W or Ta)/CoFeB /MgO were fabricated by sputtering. The film thickness of CoFeB and (W or Ta) were changed. The magnetic properties of these films were measured by VSM and MOKE. Magnetic hysteresis curves were calculated by LLG Micromagnetics Simulator™. For this simulation, the anisotropy field and the coupling strength (Hex) were varied. Typical two type magnetization curves were found in our samples. One was that the magnetic moment of the top and bottom CoFeB layers were perpendicularly aligned along the same direction even for small magnetic field region. Second was that the magnetic moment of these layers were perpendicularly aligned along the opposite directions for small magnetic region, and the magnetic switching keeping antiparallel configuration was found. Fig.1 shows magnetic hysteresis curves obtained by simulation for SyAFs. From the results of simulation, it was found that the samples with Hex smaller than 0.07 μerg/cm show the magnetization switching without antiparallel configuration, while the samples with Hex larger than 0.07 μerg/cm show the magnetization switching keeping antiparallel configuration. We also found that this boundary shifted to lower coupling strength with increasing saturation magnetization. This work was partly supported by Kakenhi.

W2-04. Structural and magnetic properties of Fe_3O_4 nanoparticles produced by Pulsed Laser Deposition. W.S. Torres[1], R. Huaman[3], R.D. Bini[2], L.F. Cótica[2] and *D.L. Rocco*[1] *1. Physics, Universidade Federal Fluminense, Niterói, Brazil; 2. Physics, Universidade Estadual de Maringá, Maringá, Brazil; 3. Centro Brasileiro de Pesquisas Fisicas, Rio de Janeiro, Brazil*

Magnetite (Fe_3O_4) nanoparticles have been intensely studied due to their semi-metallic nature, high Neel temperature (~850 K) and expected 100% spin polarization at room temperature. These properties make them a suitable candidate for spintronics sensors, as well as conventional biomedical applications[1]. Differently of the magnetic properties of its bulk counterpart, which are well known and studied, the magnetic properties of the nanoparticles (NP) of this material are strongly dependents on the way they are synthesized and the substrate utilized[2]. Thus, our goal in this work was to prepare nanoparticles of Fe_3O_4 using an unconventional route and to study theirs strutural and magnetic properties. Starting from an iron target made by arc melting, we made a deposition, onto silicon substrate, by the Pulsed Laser Deposition (PLD) method using radiation with λ=532 and 1064 nm and beam energy of 300 and 600 mJ, respectively, pressure of 1.3 mbar and argon atmosphere. Transmission electron microscopy technique revealed the formation of spherical nanoparticles with core/shell morphology (Fig. 1) and with diameter of 8 ± 4 nm (λ = 1064 nm) and 16 ± 5 nm (λ = 532 nm). The as deposited NPs were exposed to the air for 5 days, in order to oxidize the nanoparticles, and after that they were thermally treated in 600 °C for 1 hour. After annealing, NPs were analyzed by X-ray diffraction with Rietveld's method, and results show that the they exhibit 58% of Fe_3O_4 and 42% of α-Fe (532 nm) and 85% of Fe_3O_4 and 15% of α-Fe (1064 nm). AC magnetization measurements in different frequencies were carried out for the thermal treated NP. These results were compared to the ones of Fe_3O_4 NP synthesized by chemical route (CR) in which 100% of Fe_3O_4 was obtained[3]. With the curves of the real part of magnetization (M') versus temperature (T) the blocking temperature (T_B) was determined: 257.6, 220.3 and 195.8 K for the ones obtained by CR, deposited with 532 nm and 1064 nm, respectively. As T_B is proportional to the diameter of the NP, magnetic results agree with TEM analyzes.

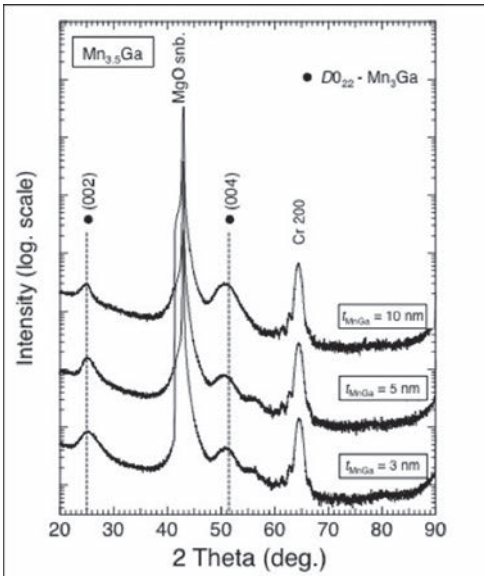
W2-05. Evidence of Martensitic Phase Transitions in Magnetic Thin Films Based on the Mn_2FeSi Inverse Heusler Alloy. H. Samassekou[1], A. Aryal[1], S. Pandey[1], *I. Dubenko*[1], A. Granovsky[2], E. Lähderanta[3], E. Soboleva[3], S. Stadler[4], D. Mazumdar[1] and N. Ali[1] *1. Physics, Southern Illinois University Carbondale, Carbondale, IL, United States; 2. Lomonosov Moscow State University, Moscow, Russian Federation; 3. Lappeenranta University of Technology, Lappeenranta, Finland; 4. Louisiana State University, Baton Rouge, LA, United States*



The magnetic Heusler alloys of the X_2YZ general chemical composition (where X and Y are 3d elements and Z belongs to the s-p-group) show diverse magnetic and structural properties important for the understanding and development of multifunctional smart materials. Electronic band calculations show that, if the valence of the Y elements is the larger than valence of the element in the X sites, the alloys (called inverse Heusler alloys) could exhibit behaviors very different from those of the "common" Heusler alloys. In this report, we present results on the growth and the magnetic and crystal structures of thin films of inverse Heusler alloys of Mn_2FeSi nominal composition. The films were fabricated using simultaneous and sequential magnetron sputtering techniques from pure element (3 N) targets on Si (001) substrate at room temperature followed by an in-situ annealing treatment at different temperatures (T=300-750ºC). Strutural and magnetic properties of the films were studied using high resolution XRD techniques (300 K), AFM and MFM measurements in the temperature interval (300-383 K), and SQUID magnetometer measurements in the temperature interval (5-400 K) in magnetic fields up to 5 kOe. Evidence of temperature structural transitions to the martensitic phase with low magnetization were found for all studied samples in the temperature interval (200-250 K). Influence of the substrate and annealing temperatures on the magnetic and structural properties are discussed. Acknowledgements: This work was supported by the U.S.

W2-06. Thickness dependence on magnetic properties for Mn_xGa ultra-thin films. K. Sato[1], Y. Takahashi[1], S. Katayama[1], T. Shima[1] and *M. Doi*[1] *1. Faculty of Engineering, Tohoku Gakuin University, Tagajo, Japan*

Thin films of tetragonal Mn-Ga alloy with high perpendicular magnetic anisotropy K_u (PMA) [1-3] and small saturation magnetization M_s [1-3] have attracted much attention for spintronic device applications such as spin-transfer-torque and spin-obit-torque magnetic random access memory. Quite recently, we have discovered the Mn-Ga thin films (20 nm) on Cr/Pt buffer layer with low M_s, high K_u, and low surface roughness (R_a) [4]. However, the thickness of the magnetic free layer for the applications are required to be below 5 nm in general [5]. In this study, we investigated magnetic properties of Mn_xGa ultra-thin films on Cr/Pt buffer layers made by ultra-high-vacuum electron beam (UHV-EB) evaporation method. $Mn_{1.0}Ga$ target alloys were prepared by arc melting method in argon atmosphere. Mn_xGa thin films were prepared on MgO(100) single crystal substrates with different buffer layer using an UHV-EB evaporation system with a base pressure below 8.9×10^{-7} Pa. The stacking structure of the samples was as follow: MgO(100)-substrate/ Cr (5 nm)/Pt (5 nm) buffer layer/Mn_xGa layer (20 ~ 3 nm)/Cr protection layer (10 nm). The substrate was heated to T_s = 300°C during deposition and annealed at 300 ~ 500°C. All growths are monitored in real-time using reflection high-energy electron diffraction (RHEED). The crystal and structures surface were investigated by X-ray diffraction (XRD) and atomic force microscope (AFM). Composition of samples was analyzed by Energy Dispersive X-ray spectroscopy (EDX). Magnetic properties were measured by using a superconducting quantum interference device (SQUID). XRD patterns for $Mn_{3.5}Ga$ films prepared on Cr/Pt buffer layer are shown in FIG. 1. From XRD pattern, a fundamental (004) peak, (002) superlattice peak of the $D0_{22}$-Mn_3Ga phase were clearly observed. Therefore, the formation of $D0_{22}$-$Mn_{3.5}Ga$ was confirmed at the MnGa ultra-thin film with Cr/Pt buffer layer. The result shows that MnGa film on Cr/Pt buffer layer has excellent magnetic properties even in the ultra-thin film region. The detail relationship between magnetic properties and film structures will be discussed at the conference.

Co-Ni-Fe multilayers, intercalated with Cu intermediate layers, thin films were grown by the method of DC Sputtering, from multiple (4) metallic targets (99.99% purity, 5.1 cm diameter) under argon atmosphere at base pressure of 4.5 x 10-4 mbar, on substrates of SrTiO3 (100). The thickness of the thin films was obtained with the technique of profilometry on the surface. The parameters for optimal growth were determined for each layer. The structural characterization of the films was performed by X-ray diffraction (XRD), in order to determine the crystal structure, the presence of different phases; lattice parameters were determined from a Rietveld refinement by properly fitting the XRD experimental spectra. The resistance as a function of magnetic field at temperature ranging from 20 to 300 K of several configurations, bilayers, trilayers and multilayers, was investigated. An external magnetic field as large as 1.2 Tesla was applied perpendicular to the plane of the layers. We conclude that the architecture of our samples have real potential applications in nanotechnology and sensors.

Superspin glass (SSG) magnetic order is often observed in granular metallic alloys, where a high degree of disorder in the magnetic particles positions constitutes a key ingredient of the collective behavior. Here we present a study of the structure and magnetic properties of granular Co/Ag multilayers, a system with reduced disorder in comparison to granular solids due to the stacking periodicity. Multilayers were grown by molecular beam epitaxy on MgO(001) substrates. The nominal thickness of the Co layers was 0.5 and 1 monolayers (ML) and that of Ag was 8 ML and 16 ML. Samples were studied by X-ray reflectivity and diffraction, transmission electron microscopy (TEM), magnetometry (VSM and SQUID) and ac-susceptibility. From these results we concluded that: i) a clear superlattice periodicity was built in the samples, see Fig.1; ii) the Co layers were discontinuous, presenting a highly monodisperse Co particle distribution (the mean diameter of the Co nanocrystals embedded in the Ag(001) matrix was 1.6 nm, as derived from TEM images); iii) samples exhibited hysteresis below temperatures in the range 5 - 20 K (depending on sample composition) and magnetization not saturable at fields of up to 6 T; iv) samples evidenced sharp peaks in the zero-field cooling dc- and ac- susceptibility curves at low temperatures (Tp), in the same range as the hysteresis onset; v) the frequency dependence of these peak temperatures in the ac- curves can be explained according to the Vogel-Fulcher law (see Fig. 2) and yielded values of the frequency shift parameter between $\Gamma = 0.040$ and $\Gamma = 0.05$; vi) Henkel plots obtained from the isothermal and demagnetization remanences indicated demagnetizing interactions at the whole field range of the magnetization process. Hence, we conclude that, below the critical temperatures identified from the ac- susceptibility curves, our samples behave as a SSG, originated by the interparticle dipolar interactions. The degree of disorder within the Co layers of these samples seems thus to be sufficient to cause this magnetic collective behavior.

W2-09. Oblique Angle Deposition to Control the Structural, Magnetic, and Transport Properties of Some Metal Thin Films. *Z. Ali*[1], D. Basaula[1], W. Zhou[1], J.A. Brock[1], M.U. Khan[1] and K. Eid[1] *1. Physics, Miami University, Oxford, OH, United States*

We report on the structural, magnetic, and transport properties of three different ferromagnetic metallic films grown using oblique angle deposition (OAD). Increasing the oblique angle above 60° during DC magnetron sputtering causes the films of Ni, Py, and the Heusler alloy Co_2FeAl to show clear nano- columnar structures rather than the usual compact films. The resistivity of all films increased sharply (up to three orders of magnitude) with the increase in deposition angle above 80°, yet Co2FeAl films show the largest increase, possibly due to stronger oxidation promoted by the porous structure and the aluminum content. [1] Furthermore, we observed a significant anisotropy in the resistivity, depending on the current flow direction. This anisotropy is driven by the 'self-shadowing' effect, which creates voids in the film along one direction. Interestingly, the resistivity change with temperature deviates from that expected from phonon scattering. Rather, it changes from metallic-like to insulating-like behavior. The change in resistivity is consistent with either a metal-insulator transition (MIT) or a Kondo effect, where the transition temperature is controlled by (i.e. changed) by changing the oblique angle during deposition.. The magnetization of the films also changed significantly, where the OAD induced a strong uniaxial magnetic anisotropy in the plane of the film and a large enhancement of the coercivity. The easy axis of magnetization went out of the plane of the film for very large oblique angles (e.g. larger than 80°).

W2-10. Magnetic Properties of $La_{0.67}Sr_{0.33}Mn_{1-x}Ni_xO_3$ Synthesized by Sol Gel Method. *B. Kurniawan*[1], U. Widyaiswari[1], G. Yudharma[1], I.N. Rahman[1] and D.R. Munazat[1] *1. Department of Physics, Universitas Indonesia, Depok, Indonesia*

The previous study of $La_{0.67}Sr_{0.33}MnO_3$ compound showed that it has the highest T_C = 370 K. In order to shift T_C of the compound to the near room temperature, Ni doped was given to Mn site of LSMO. In this paper, Mn site of $La_{0.67}Sr_{0.33}Mn_{1-x}Ni_xO_3$ compound was doped by Ni with various value of x = 0; 0.05; 0.10; 0.20; 0.30. LSMNO compound synthesized by sol gel method and sintered at 1200°C for 2 hours. Then the compound was characterized using XRD. Furthermore, the single phase compound was characterized using Vibrating Sample Magnetometer (VSM) to measure the temperature dependence of magnetization and plot it as M(T) curve. The result showed that the curie temperature of LSMO compound was 372.4 K which is near the result of previous study. Moreover, the value of T_C is decreased with the increasing of x value. In the near room temperature, hysteresis curve of compound showed that the increasing of Ni doped decreased value of saturation magnetization while compound with x value 0.20 and 0.30 indicated the paramagnetic behaviour. It is caused by the increasing of antiferromagnetic state with increasing on Mn^{4+}-O-Mn^{4+} and Ni^{2+}-O-Ni^{2+} bonding as a result of Ni doped.

W3-01. Interface Doping Effects in IrMn/CoFe Exchange Bias Systems. *J. Gompertz*[1], R. Carpenter[2], G. Vallejo-Fernandez[3], S.A. Cavill[4,5] and K. O'Grady[3] *1. Department of Physics, University of York, Heslington, UK YO105DD, York, United Kingdom; 2. Imec, Leuven, Belgium; 3. The University of York, York, United Kingdom; 4. Physics, University of York, York, United Kingdom; 5. Diamond Light Source Ltd, Didcot, United Kingdom*

IrMn/CoFe is the system of choice for pinning a ferromagnetic (F) layer in a read head. This derives from its high corrosion resistance and the large anisotropy of the antiferromagnetic (AF) alloy. The anisotropy is obtained by texturing the (111) planes of the fcc structure in the plane of the film. This gives high thermal stability in the orientation of the AF order and control of the grain size distribution enables the production of customised AF materials [1]. It is known that there can be varying interfacial exchange stiffness between the layers. This is due to the competing F and AF exchange interactions at the interface which cause magnetic disorder. This leads to a setting field dependence of the exchange bias (H_{ex}) and spontaneous spin freezing at the interface [2]. We have also reported that interface doping with Mn can lead to an increase in H_{ex}. We now describe the temperature variation of this H_{ex} with different levels of Mn doping. We have recently described that the interface spin structures have a strong temperature dependence down to 2 K. This result is surprising because H_{ex} persists to room temperature. This indicates that the exchange stiffness must be associated with clusters of spins in addiction to single spins that order at low temperatures. Figure 1 shows the variation of H_{ex} with temperature for three samples with different effective thicknesses of Mn (t_{Mn}). The variation of H_{ex} with temperature is very similar but the interface is not completely stiff down to 2 K. In [3] we showed that an interlayer thickness of one atom increases the exchange bias by ~10%, but an interfacial Mn layer of less than one atomic layer also increases H_{ex} significantly. The origin of this effect is unknown and is the subject of modelling that should be available at the conference. This is not the result of a compositional variation in either the F or AF layers since Figure 2 shows that while H_{ex} can be enhanced by ~10% the blocking temperature of the samples is unaltered.

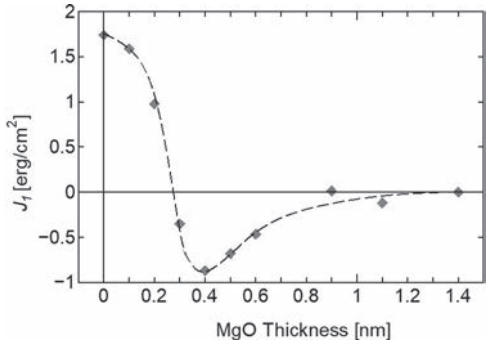
W3-02. Interlayer Exchange Coupling in the Fe/MgO/$(Co,Fe)_3O_4$ Tri-layer System. M. Hagihara[1], S. Sharmin[1] and *H. Yanagihara*[1] *1. Applied Physics, University of Tsukuba, Japan, Tsukuba, Japan*



Interlayer exchange coupling (IEC) is widely found in multilayer films of magnetic and non-magnetic metals[1]/insulators such as Fe/MgO/Fe[2] and Fe/MgO/γ-Fe_2O_3 [3]. In this study, we report the IEC of a tri-layer structure of Fe/MgO/$(Co,Fe)_3O_4$. In this tri-layer system, since the epitaxial films of $(Co,Fe)_3O_4$ grown on MgO(001) substrates exhibit extremely large perpendicular magnetic anisotropy[4], we can examine the IEC between perpendicular and in-plane magnetization layers. The multilayered structure of Ru(2 nm)/Fe(5 nm)/MgO(0-1.5 nm)/$(Co,Fe)_3O_4$ (50 nm) was deposited on a MgO (001) substrate by the RF magnetron sputtering method. The thickness of the MgO interlayer t_{MgO} was sloped by using a continuously moving mask. The sample was fabricated into a Hall bar shape. Since both MgO and $(Co,Fe)_3O_4$ are insulating, the measured Hall effect reflects only the magnetization process of the Fe layer and an ordinary Hall term. From the magnetization process of the Fe layer for different t_{MgO}, we evaluated the

coupling strength J_1 of the IEC as a function of t_{MgO}. Fig. 1 shows the results of typical Hall resistivity measurements for various t_{MgO}. Depending on t_{MgO}, the saturation magnetic field changes clearly. The saturation magnetic field (H_S) is maximum at t_{MgO} of 0.4 nm, indicating the presence of negative J_1. H_S lower than $4\pi M$s of Fe at t_{MgO}~0 nm indicates that the direct exchange interaction with positive sign exists at the interface between $(Co,Fe)_3O_4$ and Fe layers. Fig. 2 plots the coupling strength J_1 dependence on the MgO insertion layer thickness. Here, we assumed that the IEC is negligibly small at the region where the MgO is sufficiently thick. The J_1 reaches a maximum value of -0.87 erg/cm^2 at t_{MgO} of 0.4 nm. This result suggests that indirect magnetic coupling occurs between the Fe layer and the $(Co,Fe)_3O_4$ layer through the MgO insertion layer, similar to the case of the previously reported Fe/MgO/γ-Fe_2O_3[3]. In the region where the MgO film thickness is small, direct coupling occurs between the Fe layer and the $(Co,Fe)_3O_4$ layer because of imperfections in the MgO layer.

W3-03. Large exchange bias and giant vertical shift in $LaFeO_3$-NiO nanocomposite. *P. Sharma*[1], S.K. Srivastav[1] and R. Chatterjee[2]
1. Physics, Indian Institute of Technology, Delhi, Faridabad, India;
2. Physics, Indian Institute of Technology Delhi, New-Delhi, India

We have investigated the exchange bias effect in $LaFeO_3$-NiO core-shell structured nanocomposite synthesized by chemical route. The conventional signatures of exchange bias (H_{eb}) are observed in the form of shift in field-cooled hysteresis loop along with an enhancement in the value of coercivity. The influence of cooling field and temperature on exchange bias are investigated. The magnitude of H_{eb} increases with the cooling magnetic field from 650 Oe to 2050 Oe for cooling field of 10 kOe and 60 kOe, respectively. This shows that the strength of exchange bias effect is tunable by the cooling field. The exchange bias shows strong dependence on temperature too; at 60 kOe cooling field the value of H_{eb} decreases from 2050 Oe at 5 K to 75 Oe at 300 K. The presence of giant vertical shift along magnetization axis is also observed [1].

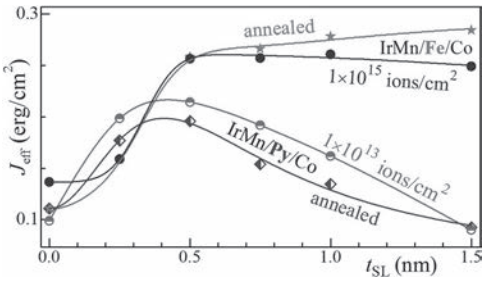
W3-04. Magnetic domain observation of FePt/ Fe nano-composites. K. Ohwada[1], T. Sato[1], M. Doi[1] and *T. Shima*[1] *1. Faculty of Engineering, Tohoku Gakuin University, Tagajo, Japan*



The demand of renewable and sustainable energy drives us to develop high efficient electromagnetic conversion system. In particular, to open up a next generation motorization, the development of high performance motors consisting of rare-earth permanent magnets are strongly needed to fulfill the automotive applications such as hybrid vehicles (HVs), plug-in hybrid vehicles (PHVs) and electric vehicles (EVs). However, due to an environmental and geometrical issues, the reduction of indispensable elements from the Nd-Fe-B sintered magnets and consequently, high performance new permanent magnets are required. In this work, in order to confirm the effect of nano-composite structure and to find the optimum configuration, ring-shaped samples embedded with another magnetic materials have been investigated. $L1_0$ ordered FePt phase and bcc-Fe phase are selected as "hard" and "soft" magnetic phase, respectively. The samples were prepared by using an ultra-high vacuum magnetron sputtering system. A Fe seed layer of 1 nm and epitaxial Au buffer layer of 40 nm were grown on a MgO (100) single crystal substrate at room temperature (R.T.). The FePt layer with the thickness of 10 nm was deposited at a substrate temperature (T_s) of 300 °C. Then, the sample was annealed 200 ~ 500 °C for 1 hour. The ring shaped FePt arrays

with 2 μm in outer diameter was microfabricated by using an electron beam lithography followed by an Ar ion milling. Then, soft magnetic Fe was deposited and embedded into the FePt rings. The magnetic properties were measured by μ-MOKE, magnetic domain structure was observed by MFM in applied fields ± 6 kOe. It is confirmed that well-defined shape of the FePt rings embedded with Fe have been successfully prepared. The coerciveity of the FePt/ Fe samples with inner diameter (D_{id}) of 0.8 to 1.8 μm was increased from 2.4 kOe to 5 kOe. From the magnetic domain structure, a bull's eye-shaped domain was distinctly observed at D_{id} = 1.2 and 1.4 μm and it was more clearly observed by annealing.

W3-05. Mechanisms determining the exchange coupling and coercivity modifications in annealed and ion-irradiated IrMn/Fe/Co and IrMn/NiFe/Co films. J.B. Salazar[1], L. Pereira[1], P. Grande[1], J. Schneider[1], J. Schmidt[1] and *J. Geshev*[1] *1. Instituto de Física, UFRGS, Porto Alegre, Brazil*

The exchange bias (EB) comes from exchange coupling between a ferromagnet (FM) and uncompensated spins (UCSs) at the interface region of, normally, an antiferromagnet (AF) [1]. It manifests itself as a hysteresis-loop field shift (H_{EB}) and is still intensively investigated given the advent of new production technologies. We report on the EB and coercivity (H_C) modifications in either annealed or ion-irradiated IrMn/SL/Co films, where Fe or Py thin spacer layer (SL) with thickness (t_{SL}) of up to 1.5 nm is used. Important insights about the mechanisms responsible for EB and the H_C-enhancement are obtained from the ion-irradiation fluence dependencies of the effective interface coupling $J_{eff} = H_{EB}[M_S(\mathrm{Co})t_{Co} + M_S(\mathrm{SL})t_{SL}]$ and H_C. Differently from $H_{EB}(t_{SL})$ and $H_C(t_{SL})$, J_{eff} versus fluence shows monotonous variations only. Remarkably, the variations with the fluence of J_{eff} and H_C of IrMn/Py/Co are completely opposite to those of IrMn/Fe/Co. We estimated that the mechanisms determining the J_{eff} and H_C variations for SL = Py are interdiffusion and defect creation at the AF/FM interface. A proof that defects' creation at the "bulk" of the AF determines the EB evolution in IrMn/Fe/Co is found in the figure below, where $J_{eff}(t_{SL})$, for the samples which yield the highest EB are plotted. The initial raise of J_{eff} is attributed to a coupling enhancement as the pinned Co atoms are replaced by Fe or Py ones (both $J_{IrMn/Fe}$ and $J_{IrMn/Py}$ are higher than $J_{IrMn/Co}$). Once the Fe atoms have covered practically all pinning UCSs, the number of the latter remains constant no matter what the thickness of the FM layer subsequently deposited is, in agreement with the hypothesis that in polycrystalline films the pinning UCSs are located at grain boundaries on top of the AF layer [2]. None of the treatments of our films with $t_{Fe} \geq 0.5$ nm changed significantly the pinning part of the AF/FM interface. On the other hand, the Mn affinity to interdiffuse with Ni seems much greater than that for Mn-Fe interdiffusion, thus decreasing the IrMn anisotropy at the interface as t_{Py} raises, lowering its pinning capacity and therefore the bias, see the figure.

W3-06. Spontaneous perpendicular exchange bias effect in $L1_0$-MnGa/FeMn bilayers grown by molecular-beam epitaxy. *X. Zhao*[1], D. Wei[1], J. Lu[1] and J. Zhao[1] *1. State Key Laboratory of Superlattices and Microstructures, Institute of Semiconductors, Beijing, China*

Exchange bias effect is a key element in future spintronic devices, such as magnetic sensors, magnetoresistive read heads, and magnetic random access memories (MRAMs). Among the various PMA materials, $L1_0$-MnGa alloy has shown many attractive properties, such as large PMA, small Gilbert damping constant, and high spin polarization [1]. On the other hand, FeMn is a typical noncoplanar antiferromagnet with a high Néel temperature ($T_N \sim 500$ K) [2]. We have observed the spontaneous perpendicular exchange bias effect in as-grown $L1_0$-MnGa/FeMn bilayer system [3]. An FeMn layer with different thickness is introduced as an antiferromagnetic layer to couple with single-crystalline ferromagnetic $L1_0$-MnGa, which is epitaxially grown on GaAs (001) substrate by molecular-beam epitaxy. The perpendicular exchange bias shows a strong dependence on both the thickness of FeMn layer and measurement temperature. A large spontaneous perpendicular exchange bias up to 8.9 kOe is achieved in $L1_0$-MnGa/FeMn bilayer system at 5 K without any external magnetic treatment. The corresponding effective interfacial exchange energy J_{eff} is estimated to be 1.4 mJ/m^2. The spontaneous perpendicular exchange bias effect in the (001) textured $L1_0$-MnGa/FeMn bilayer paves the way of novel spintronic devices based on exchange biased perpendicularly magnetized materials.

W3-07. Superparamagnetism and Exchange Bias effect in an antiferromagnetic nanostructured perovskite $La_2Fe_{0.875}Cr_{0.125}GaO_6$. *R. Dhal*[1], P. Neenu Lekshmi[1] and P. Santhosh[1] *1. Department of Physics, Indian Institute of Technology Madras, Chennai, India*

Research on antiferromagnetic nanoparticles (AF-NPs) had been carried out mostly focused on NiO, MnO, Cr_2O_3 and a-Fe_2O_3. Our work focuses on a B-site (Fe/Cr) disordered antiferromagnetic perovskite oxide. Further, non-magnetic Ga has been introduced to the B-site so as to dilute the antiferromagnetic interactions. Nanostructured $La_2Fe_{0.875}Cr_{0.125}GaO_6$ was prepared through sol-gel method. The average particle size is around 20-30 nm, and the compound crystallizes in disordered orthorhombic structure with

Pbnm (62) space group. Detailed magnetic properties are explored from the DC magnetisation measurement using different protocols. Thermomagnetic analysis even up to 350 K lacks the antiferromagnetic transition (T_N). However, magnetization curve exhibits a superparamagnetic (SPM) blocking temperature (T_B) at around 278 K (at 0.001 T) and is shifted toward lower temperatures at higher fields. Additionally, zero field cooled as well as field cooled magnetisation curves rise sharply below 50 K showing the enhanced surface spin effects at lower temperatures [1, 2]. The most interesting observation is the presence of hysteresis at 120 K with a highest coercivity of 6450 Oe, and either side of this temperature shows decreased coercivity. Magnetic data perfectly cope with Core-Shell model [3]. Detailed analysis regarding Thermoremanent magnetization (TRM) and Isothermoremanent magnetization (IRM) has been carried out to find out the exact magnetic behaviour. TRM and IRM reveals that the sample behaves as SPM at high temperature (above 278 K) and at low temperature (5 K) it behaves as a two dimensional dilute antiferromagnetic in field (2D-DAFF). The Core-Shell features further points to the existence of exchange bias (EB) phenomenon and the uniqueness observed in the present material is the existence of EB above 100 K. Detailed analyses of experimental results will be presented.

W3-08. Topologically stable helices in exchange-coupled rare-earth/rare-earth multilayer. *J. Ye*[1], T. Baldauf[1], M. Opel[2], S. Mattauch[3] and A. Paul[1] *1. Physik-Department E21, Technische Universität München, Garching, Germany; 2. Walther-Meißner-Institute, Garching, Germany; 3. Forschungszentrum Julich, Garching, Germany*

Magnetization process of a two-dimensional random anisotropy system is directly connected with topologically stable helices in the form of 2π-planar domain walls (DWs) and are often reported for rare-earth (RE) / transition metal (TM) systems. In this contribution, we investigate such DWs within a RE/RE system, namely $[Dy/Tb]_{10}$ multilayers with two different anisotropic layers. Super spin glass (SSG) type of behavior is consistent with DC magnetization and AC susceptibility measurements as a function of temperature and frequency. Interestingly, magnetic investigations on these samples revealed an exchange bias field up to –0.88 kOe, which is commonly reported in RE/TM films, but not in RE/RE films. Using polarized neutron reflectometry (PNR), we find evidences of superimposed helical ferromagnetic magnetic configurations with 2π-DWs within both Dy and Tb leading to spin-frustrated interfaces. Off-specular neutron scattering indicate vertically correlated structure and fluctuations of the magnetization around the mean magnetization from vertically uncorrelated domains. Fundamentally, the helical ground states coexistent with spin-glass-like ordering are topologically stable and thus in principle can be manipulated in all-spin-based technology.

W3-09. Variation of magnetic properties of bilayered and trilayered NiFe and IrMn-based thin film structures. *C. Gritsenko*[1], V. Rodionova[1], A. Berg[1], G. Babaytsev[2], I. Dzhun[2], N. Chechenin[2], M. Volochaev[3] and A. Sokolov[3] *1. Laboratory of Novel Magnetic Material, Immanuel Kant Baltic Federal University, Kaliningrad, Russian Federation; 2. Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russian Federation; 3. Kirensky Institute of Physics, Federal Research Center KSC SB RAS, Krasnoyarsk, Russian Federation*

Thin film structures fabricated from ferromagnetic and antiferromagnetic materials are widely used systems for creating spin-valve structures that are indispensable components of magnetic recording and spintronics devices. Firstly, we presented the results of studies of exchange bias phenomenon in bilayered and trilayered thin film structures NiFe/IrMn, IrMn/NiFe and NiFe/IrMn/NiFe on Si substrate with different content of Ni (40% or 75%) in NiFe alloy, prepared by magnetron sputtering in presence of homogeneous magnetic field. We showed how the composition of NiFe influences the crystal structure, morphology of interfaces and, consequently, on magnetic properties of thin films, especially exchange bias. Hysteresis loops, measured by VSM, and TEM images, were used to describe properties of samples. The second part of our work is dedicated to investigation of how the inhomogeneous magnetic field to be applied during thin film deposition can influence the hysteresis loop shape of above-mentioned systems. Thus, we have analyzed and explained a mechanism of dependence of magnetic anisotropy of our samples on magnetic field, which creates this anisotropy. As a result, we showed, that in bilayered structure $Ni_{40}Fe_{60}$(10nm)/$Ir_{50}Mn_{50}$(20nm) we can create such an anisotropy, which leads to a step-like hysteresis loop.

W4-01. Critical properties of a generalized *XY* model with competing nematic-like couplings. *M. Zukovic*[1] and G. Kalagov[1] *1. Institute of Physics, P. J. Šafárik University, Košice, Slovakia*

A standard two-dimensional *XY* model is well known to show a topological Berezinskii-Kosterlitz-Thouless (BKT) phase transition with the quasi-long-range-order ferromagnetic (FM) phase characterized by an algebraically decaying correlation function [1,2]. Recent studies have shown that including higher-order terms can lead to the appearance of new phases with phase transitions belonging to different universality classes [3,4]. In the present work we study critical properties of the generalized *XY* model involving solely nematic-like higher-order terms, $\cos(q\phi)$ with q = 2, 3, and 4, by spin-wave theory and Monte Carlo simulation. We find that, even though neither of the terms alone can induce the FM ordering, their coexistence and competition can lead to a complex phase diagram including the FM phase at low temperatures. In particular, in the model involving the first two terms the FM phase appears wedged between the two nematic-like phases induced by the respective couplings. Thus, except for the muticritical point, at which all the phases meet, for any considered coupling parameters there are two phase transitions: one from the paramagnetic phase to one of the two nematic-like phases followed by another one at lower temperatures to the FM phase. The finite-size scaling analysis indicates that the phase transitions between the FM and nematic-like phases belong to the Ising and three-state Potts universality classes. Inside the FM phase the spin-pair correlation function is found to decay even much more slowly than in the standard *XY* model with purely FM interactions. Such a phase is characterized by an extremely low vortex-antivortex pair density. On the other hand, in the model with the first and last terms there is no competition and topology of the resulting phase diagram is the same as in the well-studied model with q = 1 and 2. Finally, in the model including all the nematic-like terms it is possible to observe up to three different phase transitions: the order-disorder transition belonging to the BKT universality class is followed by two more phase transitions, as the system passes through two nematic-like phases to the FM phase at low temperatures, that belong to the Ising universality class.

W4-02. Magnetic Transitions in the Heusler Compounds $Fe_{3-x}Mn_xSi$. *T. Nonoyama*[1], M. Hiroi[2], I. Shigeta[1], R. Kato[1], H. Manaka[2] and N. Terada[2] *1. Department of Physics and Astronomy, Graduate School of Science and Engineering, Kagoshima University, Kagoshima, Japan; 2. Department of Electrical and Electronics Engineering, Graduate School of Science and Engineering, Kagoshima University, Kagoshima, Japan*

The Heusler compounds $Fe_{3-x}Mn_xSi$ for a wide range of x were predicted to be half-metals by first-principles band structure calculations; in a half-metal there are 100% spin-polarized conduction electrons.[1] However, for $x \geqq 0.75$ they are not half-metals because the ground state is not ferromagnetic. It is known that for $x \geqq 0.75$ the ferromagnetic (F) transition at T_C, and, in addition, an antiferromagnetic (AF) transition at a lower temperature, T_A occur. The phase below T_A will be referred to as the AF phase where F and AF components exist. Though T_C and T_A approach each other around x~1.7, the magnetic properties were not fully clarified.[2] In previous studies on magnetization, $M(B)$, for x=1.7, a meta-magnetic-like transition was observed at low temperatures.[2,3] Our recent study of the temperature dependence of magnetization $M(T)$ for x=1.7 revealed that another AF transition occurs at a temperature lower than T_A. The transition temperature and the phase below are defined as T_{A2} and the AF2 phase, respectively. It was found that T_{A2} depends on B and the transition corresponds to the meta-magnetic-like transition observed in $M(B)$.[4] Because T_{A2} has not been observed for x<1.6 so far, the AF2 phase is considered to appear around x~1.7. In this study the magnetic properties of $Fe_{3-x}Mn_xSi$ around x~1.7 were investigated. The figure shows $M(T)$ of $Fe_{1.2}Mn_{1.8}Si$ for different magnetic fields. It was found to exhibit the AF transition at T_A and another transition at a lower temperature, T_{A2}. In $Fe_{1.2}Mn_{1.8}Si$ the meta-magnetic-like transition in $M(B)$ was also observed. $Fe_{1.25}Mn_{1.75}Si$ also exhibits the similar transitions at T_A and at a lower temperature, T_{A2}. These results shows that the AF2 transition occurs for x=1.75 and 1.8, as well as for x=1.7. Nevertheless, for x=1.8 spontaneous magnetization does not appear for $T>T_A$, judging from the Arrot plots obtained from the $M(B)$ measurements. This implies that the F transition is absent. This demonstrates that for x=1.8 the ferromagnetic transition disappears, although the AF2 phase exists. This is different from the behavior for x=1.7.

W4-04. Novel Quantum and Thermal Phase Transitions of Easy-Axis Triangular Antiferromagnets in a Transverse Field. *D. Yamamoto*[1], G. Marmorini[2], M. Tabata[1] and I. Danshita[3] *1. Department of Physics and Mathematics, Aoyama-Gakuin University, Sagamihara-shi, Kanagawa, Japan; 2. Research and Education Center for Natural Sciences, Keio University, Kanagawa, Japan; 3. Yukawa Institute for Theoretical Physics, Kyoto University, Kyoto, Japan*

We study the quantum and thermal phase transitions in frustrated triangular antiferromagnets with easy-axis anisotropy. The magnetic field effects on this system have been well studied for the field parallel to the easy axis [1,2]. However, the case of transverse field, which explicitly breaks the rotational symmetry around the easy axis, is less understood, in part because of practical difficulties in numerical analyses of frustrated systems without total S^z conservation. Here we use the numerical cluster mean-field method with cluster-size scaling (CMF+S) [2] and Monte Carlo simulations, respectively, to determine the quantum ground state for S=1/2 and to discuss thermal phase transitions for finite temperatures away from the highly-quantum regime [3]. The CMF+S analysis reveals that the ground state phase diagram shows a rich variety of quantum phases via the order-by-disorder mechanism, in sharp contrast to the featureless classical-spin phase diagram. Especially, we find an emergent "spin reorientation" transition induced by the interplay of quantum fluctuations and transverse field. Moreover, it is found that thermal fluctuations give rise to a nontrivial two-step phase transition through an intermediate phase in which the broken symmetry at zero temperature is partially restored.

W4-05. Non-equilibrium phase transitions in magnetic systems. *A. Galda*[1,2] and V. Vinokur[2] *1. James Franck Institute, University of Chicago, Chicago, IL, United States; 2. Materials Science Division, Argonne National Laboratory, Lemont, IL, United States*

We investigate non-equilibrium phase transitions in open dissipative magnetic systems. We introduce a non-Hermitian Hamiltonian formalism, in which the imaginary part of the Hamiltonian describes the effects of Gilbert damping and Slonczewski spin-transfer torque (STT). We reveal spontaneous breaking of parity-time symmetry in a single-spin and Heisenberg spin-chain models under the action of STT. The corresponding STT-driven phase transition occurs between the regimes of precessional and exponentially damped spin dynamics. The connection between dynamic and thermodynamic properties of the Heisenberg spin-chain system is illustrated by studying the distribution of zeros of the system's partition function, the approach first introduced by Yang and Lee for studying equilibrium phase transitions in Ising spin chains. The physical interpretation of imaginary magnetic field as describing the action of non-conservative forces opens the possibility of direct observation of Lee-Yang zeros in out-of-equilibrium physical systems.

W4-06. Magnetic and electrical properties of R_5Ir_3 (R = Tb, Er). *K. Ueda*[1] and T. Tsutaoka[1] *1. Graduate School of Education, Hiroshima University, Higashi-Hiroshima, Japan*

The rare earth compound R_5Ir_3 (R = Tb, Er) crystallizes in the Mn_5Si_3 type hexagonal structure with the space group $P6_3/mcm$ in which R occupies two non-equivalent sites. In the R_5Ir_3 system, it has been reported that for the R_5Ir_3 (R = La to Gd) have tetragonal Pu_5Rh_3 type structure; the R_5Ir_3 (R = Tb to Lu) show the hexagonal Mn_5Si_3 type one [1,2]. As far as we know, there is no report for the magnetic and electrical properties of these compounds, so far. In this study, we have prepared single phase polycrystal samples of Tb_5Ir_3 and Er_5Ir_3 and investigated magnetic and electrical properties. Polycrystalline ingots of R_5Ir_3 were prepared by arc-melting the constituent elements of 3N rare earth and 3N Ir in high purity argon atmosphere. Powder X-ray diffraction (XRD) indicated the all samples were in single phase with the Mn_5Si_3 type hexagonal structure. The magnetic and electrical resistivity measurements were performed using a SQUID magnetometer and conventional four-terminal method. Magnetization curve of Tb_5Ir_3 at 2 K is shown in Fig.1. As shown in the inset, a ferromagnetic like hysteresis curve was observed. However, small magnetization jumps at H_{C1} and H_{C2} were recognized in the initial magnetizing process; relatively large magnetization jump was observed in the hysteresis curve as well. This indicates that Tb_5Ir_3 may show an irreversible antiferromagnetic to ferromagnetic transition which has been reported in several compounds, $DyCo_3$[3] or Nd_5Ge_3 [4]. Meanwhile, Er_5Ir_3 shows ferromagnetic property at 2 K. Magnetic susceptibility χ of Tb_5Ir_3 and Er_5Ir_3 is shown in Fig.2 as a function of temperature T. In Tb_5Ir_3, reentrant magnetic behavior was observed; the Curie temperature T_C and second transition temperature T_t are 49.0 K and 6.5 K, respectively. In Er_5Ir_3, paramagnetic to ferromagnetic transition takes place at T_C = 10.0 K. Paramagnetic susceptibility obey the Curie-Weiss law for both compounds as shown in the inset of Fig.2. Asymptotic Curie temperature θ_p and effective magnetic moment μ_{eff} are 59.0 K and 9.8 μ_B for Tb_5Ir_3 and 11.7 K and 9.6 μ_B for Er_5Ir_3, respectively.

W4-07. Magnetic properties of $Li^{57}Fe_{0.01}Mn_{0.99}PO_4$ investigated by using external field Mössbauer spectroscopy. *H. Choi*[1] and C. Kim[1] *1. Department of Physics, Kookmin University, Seoul, The Republic of Korea*

The $Li^{57}Fe_{0.01}Mn_{0.99}PO_4$ polycrystalline sample has been studied by x-ray diffraction (XRD), vibrating sample magnetometer(VSM), and Mössbauer spectroscopy. The crystal structure is found to be orthorhombic with space group *Pmnb*. The lattice constants are a_0=6.1009, b_0=10.4435, and c_0= 4.7427 Å. The magnetic properties of the sample were measured by using a VSM. The temperature dependences of ZFC and FC magnetizations at an applied field of 100 Oe. They show that magnetic Néel temperature (T_N) and spin-reorientation temperature (T_S) is 34 and 8 K, respectively. Mössbauer spectra of $Li^{57}Fe_{0.01}Mn_{0.99}PO_4$ have been taken at various temperatures ranging from 4.2 to 295 K. Magnetic hyperfine and quadrupole interaction in $Li^{57}Fe_{0.01}Mn_{0.99}PO_4$ at 4.2 K have been studied, yielding the following result; hyperfine field H_{hf} = 320.78 kOe, electric quadrupole splitting ΔE_Q = 2.81 mm/s, θ = 90°, ϕ = 0°, η = 0.75, and R = 1.2. Also, we were performed the Mössbuaer measurements with a high external field of 4.8 T. The value of magnetic hyperfine field (329.97 kOe) with external field of 4.8 T at 4.2 K was larger than that 320.78 kOe with zero magnetic field. While, the electric quadrupole splitting (2.62 mm/s) with external field 4.8 T at 4.2 K was smaller than that 2.81 mm/s with zero applied field. The abrupt increase in H_{hf} and magnetization was caused by orbital angular moment contribution from spin-orbit coupling.

W4-08. Magnetic study on inverse spinel compounds Co_2XO_4 (X = Ti, Sn) with partial substitution of Zn for Co. *H. Ohta*[1], S. Takada[1], G. Ueda[1], K. Yamagishi[1] and H. Aruga Katori[1] *1. Department of Applied Physics, Tokyo University of Agriculture and Technology, Koganei, Japan*

Inverse spinels Co_2XO_4 (X = Ti, Sn) are known as compensated ferrimagnets with their ferrimagnetic transition temperature T_N = 48 K and 41 K for X = Ti and Sn, respectively[1-3]. In their ferrimagnetic state, a spin-glass-like behavior is also observed. Thus, these compounds are categorized as the semi spin glass[3,4]. Although the magnetic structure in the ordered state has been revealed, the reason why the moments show both collinear ordering and spin glass freezing is still unclear. In Co_2XO_4, Co ions occupy both the whole of the A site and a half of the B site, and X ions occupy the rest of the B site. Thus, the B site, also known as the pyrochlore lattice, is just half-filled with magnetic ions. In this situation, spins are distributed onto the pyrochlore lattice at perfectly random, and this may lead to the spin glass. To understand the origin of semi spin glass of Co_2XO_4 and physics of the half-filled pyrochlore lattice, we studied Co_2XO_4 by partially substituting Zn for Co. Here, Zn preferentially replaces the A site rather than the B site. From the analysis results of the powder X-ray diffraction measurements, we confirm that Co atoms on the A site are selectively replaced with Zn atoms in both cases of X. After Zn atoms fully occupy the A site, the Co atoms on the B site are replaced with Zn atoms. The magnetic measurement results show that T_N of both compounds decreases with the increase of the ratio of Zn to Co, and their magnetism changes from ferrimagnetism to spin glass when all the Co atoms on the A site are replaced with Zn atoms. These results indicate that the pyrochlore lattice which is half-filled with Co atoms shows spin glass due to its randomness, and semi spin glass of Co_2XO_4 originates from this nature of the half-filled pyrochlore lattice.

W4-09. Magnetic Property of Polymorphs $(Al_xFe_{2-x})GeO_5$. *H. Aruga Katori*[1] *1. Department of Applied Physics, Tokyo University of Agriculture and Technology, Koganei, Japan*

The polymorph Al_2SiO_5 is known as a geophysically important mineral having three structures of kyanite (space group P , andalusite (*Pnnm*), and sillimanite (*Pnma*). In each structure, the edge-shared AlO_6 octahedra construct chains running parallel to one of the crystallographic axes. But other Al-O polyhedra have shapes and arrangements unique to their structures. Natural minerals generally contain more than one transition element but their content cannot be controlled. We are interested in whether the magnetism of polymorph in which Al is systematically substituted with transition elements is different depending on the structure or not. Magnetic system $(Al_xFe_{2-x})GeO_5$, which is a polymorph similar to Al_2SiO_5, is one of the materials that we are interested. It has been reported that $(Al_xFe_{2-x})GeO_5$ changes its crystal structure from an andalusite to a kyante structure depending on x when synthesized under atmospheric pressure [1]. But details of the x dependence of the crystal structures and the magnetic properties have not been clarified. In order to reveal the relationship between crystal structure and magnetism, we synthesized polycrystalline samples of $(Al_xFe_{2-x})GeO_5$ with $0<x<2$ by solid state reaction method. We determined the crystal structures of synthesized samples by X-ray diffraction experiments and measured their magnetizations. From the result of the crystal analysis, We obtained the synthesis temperature T versus x phase diagram of $(Al_xFe_{2-x})GeO_5$. The kyanite, andalusite, and sillimanite were realized depending on synthesis conditions of temperature and atmosphere. As a result of magnetization measurement for the sample with x=0.3, we found that magnetic behavior of the sample with andalusite structure is like a spin-glass, while magnetic behavior of the sample with kyanite structure is largely different from the behavior of well-known magnets. This indicates that the magnetism depends on both the crystal structure and x.

W4-11. Origin of Magnetocrystalline Anisotropy in Trigonal Magnetics with Zero Orbital Moment. *J. Kliava*[1], K. Seleznyova[2], M. Strugatsky[2], A. Drovosekov[3], S. Yagupov[2] and V. Zubov[4] *1. LOMA, Université de Bordeaux, Talence, France; 2. Physics and Technology Institute, Crimean Federal University, Simferopol, Russian Federation; 3. P.L. Kapitza Institute for Physical Problems, RAS, Moscow, Russian Federation; 4. Lomonosov Moscow State University, Moscow, Russian Federation*

In magnetics with zero orbital moment exchange coupling in a good approximation is isotropic, so that magnetocrystalline anisotropy can include only contributions of dipole-dipole and crystal field interactions [1]. In the present work we focus on trigonal easy-plane magnetic crystals where in addition to volume magnetocrystalline anisotropy, significant surface magnetocrystalline anisotropy also can exist [2]. The best example of such materials is iron borate $FeBO_3$ [3]. The *volume* magnetocrystalline anisotropy in $FeBO_3$ has uniaxial and basal (hexagonal) components. Previously, the *dipole-dipole contribution to the basal anisotropy* was ruled out on the grounds of symmetry. Indeed, the dipole-dipole interaction usually is considered for "point dipoles", in which case it is isotropic in the basal plane. We take into consideration "extended dipoles" in a model of circular current loops [4] and show that this approach can adequately describe the dipole-dipole contribution to the basal anisotropy. A comparison between the experimental (obtained by AFMR) and theoretical results corroborates this approach and incidentally yields realistic estimates of effective dipole sizes associated with Fe^{3+} ion [5]. On the other hand, the *surface* magnetocrystalline anisotropy in $FeBO_3$ previously was described neglecting the *crystal field contribution* [6]. We provide a complete description of this anisotropy by comprehensively considering structure distortions in the near-surface layer. To account for the lowering of symmetry in this layer, the generalized spin Hamiltonian has been used and its parameters have been calculated within the superposition model [7]. The crystal field contribution to the surface anisotropy energy has been calculated in perturbation theory [8]. In summary, the theory of volume and surface magnetocrystalline anisotropy of magnetics with zero orbital moment has been extended by consistently taking into account both the dipole-dipole and crystal field contributions. Multiferroic materials, with simultaneous magnetic and ferroelectric ordering, have attracted much attention due to their potential technological applications as spintronics or memory devices. We here focus on the understanding of the magnetoelectric effect in Ni_3TeO_6. This compound was recently reported as a pyroelectric and collinear antiferromagnet (AFM), in which a magnetoelectric switching occurs in an unusual way without hysteresis[1]. The magnetic ordering temperature is 52K[2,3] and the electric polarization drastically changes at the magnetic transition. The isothermal magnetization of Ni_3TeO_6 along the c axis at different applied magnetic fields shows two linear regimes with a sudden increase between them at a critical magnetic field of approximately 9 T. This have been proposed to be a field-induced spin–flop type magnetic transition[1] where the magnetoelectric coupling is believed to be driven by a symmetric exchange-striction mechanism,[4] though some authors report inconsistencies between the spin-flop and the expected second order phase transition. By measuring a mosaic of 12 crystal and a combined mass of 120 mg using the neutron instrument MultiFLEXX aligned in the (1,0,0)-(0,0,1) plane a map of the low energy excitations has been measured, c.f. figure 1. A systematic switch of low and high intensity between two different symmetry positions is present where at low energy one point is intense and the other weak while at higher energy vice versa. Further, it is seen that the expansion of the spin waves are most pronounced along c. This is in agreement with the believed weaker interactions of the spins along the c-direction. The spin wave behavior at higher energies is believed to contain furhter spin waves and possibly branching of these, base upon inelastic powder data.

The compound $NdCrTiO_5$ has been classified as a type ii multiferroic [1]. $NdCrTiO_5$ exhibits a long range antiferromagnetic (AFM) ordering below ~ 21 K, confirmed by dc magnetic susceptibility and specific heat measurements and another anomaly associated with the broad peak in the magnetic susceptibility around T =11 K [2]. At the onset of AFM ordering (~21 K) spontaneous electrical polarization occurs [3]. For deeper insight on the role of non-magnetic rare earth site in magnetic interactions of $NdCrTiO_5$, we have selected an isostructural compound $EuCrTiO_5$, Nd replaced by non-magnetic Eu^{3+} ($4f^6$). Here, we report structural, magnetic, electronic structure and dielectric properties of $EuCrTiO_5$. Synchrotron x-ray diffraction pattern of $EuCrTiO_5$ and Rietveld refinement cconfirms the orthorhombic structure (s.g. P*bam*) similar to $NdCrTiO_5$. Our magnetization study reveals a predominantly antiferromagnetic type of transition at ~180 K, by Curie Weiss fitting. Another magnetic transition is observed at lower temperature ~11 K, evident as an anomaly in the first derivative of M vs T (Inset Fig 2(a)). Magnetization isotherms at lower temperatures (Inset Fig.2(b)) show small but finite amount of coercivity and non-saturation behaviour up to the magnetic field ~7 T, which might be due to the simultaneous existence of AFM and ferromagnetic domains at those temperatures. The soft x-ray absorption spectroscopy (XAS) have been employed to study the electronic structure of this compound. We confirm the valence state of Eu and Cr as +3 while Ti is in +4 state. Dielectric measurements reveal comparatively larger value of dielectric constant and smaller loss than that of $NdCrTiO_5$.

W5-03. Field-induced antiferromagnetic cone structure in multiferroic $BiFeO_3$. *M. Matsuda*[1], S. Dissanayake[1], Y. Ozaki[2], T. Ito[2], X. Liu[3], M. Bartkowiak[3] and O. Prokhnenko[3] *1. Neutron Scattering Division, Oak Ridge National Laboratory, Oak Ridge, TN, United States; 2. AIST, Tsukuba, Japan; 3. Helmholtz-Zentrum Berlin für Materialien und Energie, Berlin, Germany*

$BiFeO_3$, a rare multiferroic compound that shows antiferromagnetism and ferroelectricity simultaneously above room temperature (T_N~640 K), has been studied intensively. Recently, a new magnetic phase was found between the cycloidal and canted antiferromagnetic phase under magnetic field [1]. This intermediate phase, where a large magnetoelectric effect is observed, is considered to originate from the anisotropic magnetic interactions that are coupled to the ferroelectric property. It is important to clarify the magnetic structure to fully understand the multiferroic behavior of this material. To this end, neutron diffraction measurements were performed in high static magnetic fields up to 19 T on HFM/EXED facility at BER II research reactor in Helmholtz Zentrum Berlin [2]. The magnetic field dependence of the peak profile around the (1/2, 1/2, 1/2) magnetic Bragg peak was measured at several temperatures. The weak incommensurate peaks were successfully observed around 13 T which split along the magnetic field direction [1,1,-2] at the (1/2, 1/2, 1/2) main peak. The magnetic field and the temperature region, where the incommensurate peaks appear, is consistent with that of the phase diagram obtained by the magnetization measurements [1]. The magnetic structure in the intermediate phase is confirmed to be the antiferromagnetic cone structure which was predicted theoretically. The detailed magnetic structure (magnetic wave vector, and cone angle) will be presented and the correlation between the magnetic structure and the magnetoelectric effect will be discussed.

W5-04. Magnetic and magneto-dielectric coupling behavior of Ho_2BaNiO_5, a Haldane spin-chain compound. S.K. Upadhyay[1] and *E. Sampathkumaran*[1] *1. Tata Institute of Fundamental Research, Mumbai, India*

In recent years, we have reported magnetodielectric coupling and multiferroicity (due to magnetism and ferroelectricity) for many members of the Haldane spin-chain family, R_2BaNiO_5, except for R= Ho, and reported many new features [1]. Though the Ho member was reported in the literature [2] to exhibit electric-polarization induced by magnetic field (H) above T_N (55 K), we find the need to perform additional studies to understand this compound better, motivated by new anomalies seen in other members of this family. We have therefore performed magnetization and heat-capacity as a function of temperature (T), H, dielectric constant, magnetodielectric, pyrocurrent and bias pyrocurrent measurements above 2 K. The results reveal new information: (i) *T*here is another magnetic transition near 12 K. (ii) A peak in dielectric constant around 12 K is seen, thereby establishing the existence of magneto-dielectric coupling at such low temperatures; correspondence between isothermal magnetization and magnetodielectric features establishes the existence of a coupling between magnetic and electric dipoles. (iii) The pyrocurrent peak, which is sensitive to H, actually appears even in the absence of a magnetic field itself at T_N and the peak is found to depend on the rate of change of temperature. Therefore, this feature at T_N is due to thermally stimulated depolarization current; in addition, no feature could be seen in the bias pyrocurrent studies in the temperature interval of investigation. Hence this compound is interestingly not a multiferroic, unlike other isostructural heavy rare-earth members (Gd, Tb, Dy, and Er) of this family. It is of interest to address this aspect further.

The magnetic properties of CuO encompass several contemporary themes in condensed matter physics, including quantum magnetism, magnetic frustration, magnetically-induced ferroelectricity and orbital currents. Here I present polarized and unpolarized neutron inelastic scattering measurements which provide a comprehensive map of the cooperative spin dynamics in the low temperature antiferromagnetic (AFM) phase of CuO throughout much of the Brillouin zone. At high energies (E > 100 meV) the spectrum displays continuum features consistent with the des Cloizeax--Pearson dispersion for an ideal S=1/2 Heisenberg AFM chain. At lower energies the spectrum becomes more three-dimensional, and we find that a linear spin-wave model

for a Heisenberg AFM provides a very good description of the data, allowing for an accurate determination of the relevant exchange constants in an effective spin Hamiltonian for CuO. In the high temperature helicoidal phase, there are features in the measured low-energy spectrum that we could not reproduce with a spin-only model. I will discuss how these might be associated with the magnetically-induced multiferroic behavior observed in this phase.

Centro de Nanociencias y Nanotecnología, Universidad Nacional Autónoma de México, Ensenada, Mexico; 6. Physics, Universidad del Cauca, Popayán, Colombia*

Polycrystalline samples of the $KNb_{1-x}Co_xO_3$ system (x = 0, 0.03, 0.05, 0.07 and 0.1) were prepared by standard solid-state reaction using high-purity precursors $K_2CO_3 1.5H_2O$, (98.5 %), Nb_2O_5 (99.995 %), and Co_2O_3 (99.9985 %). The precursors in the appropriate stoichiometry ratio were mixed with polyvinyl alcohol to obtain 1 g of the compound. Homogeneous mixtures with different concentrations were pressed into to 1 cm ϕ and 2 mm thickness at a pressure of 4 Ton. The pellets were preheated at 850 °C for 12 hours, and then sintered at 900 °C for 12 hours in air. The crystal structure of pellets was analyzed by X-ray diffraction (XRD) using CuKα radiation (λ = 1.542 Å) in a standard θ–2θ configuration. XRD patterns demonstrate that all compounds are single-phase with the polycrystalline perovskite structure of the $KNbO_3$ phase. It is observed that the peaks of Co-doped samples are shifted to higher angles as compared to the pattern of the undoped compound. Scanning electron microscopy evidences that crystallite size increases with the Co content. Measurements of polarization as a function of the applied electric field on undoped and doped samples evidence a hysteretic feature characteristic of the ferroelectric materials. Figure 1 shows curves for the undoped and 10% doped samples with remnant polarization of 0.70 x 10^{-2} μC/cm^2 and 1.47 x 10^{-2} μC/cm^2, respectively. The magnetic response of the pellets was detected by measurements of the magnetization as a function of the magnetic field using a VSM and are shown in Figure 2. Undoped samples are paramagnetic, however, doped samples exhibit weak ferromagnetism. Interactions between bound magnetic polarons are considered as a possible scenario to explain the appearance of the ferromagnetic signal in the Co-doped samples.

Ferroelectric hysteresis loops of $KNb_{1-x}Co_xO_3$ samples with x = 0 and 0.1 at room temperature.

Renewed research interest has peaked for multiferroic and magnetoelectric materials which is seen through increased efforts in research to find new routes for memory as well as developing new magnetoelectric sensors. As theoretical and experimental results have shown multiferroic materials that possess frustrated magnetic states are of interest as it is well understood that they are sensitive to small perturbations that can be introduced through chemical substitution, magnetic and electric fields, or external pressure [1]. These perturbations can result in new states with different magnetic order(s) as well as ferroelectric properties, which can result in complex and rich phase diagrams. One such system is Co doped $MnWO_4$, which to date has one of the most complex multiferroic phase diagrams [2]. As chemical doping has been well studied up to 30 % Co, to further explore this system we have applied external pressure on well orientated single crystals. To gain information on the ferroelectric as well as the other known magnetic phases, dielectric as well as pyroelectric measurements were completed across the phase diagram with pressures up to 18 kbars. To date it is well understood that for higher dopings of Co that pressure has a dramatic effect which is driven by the spin-flop of the polarization where the a-c spiral is stabilized

into the conical spin structure. This results in an observed increased in the polarization as well as dramatic changes in the neutron high pressure data reported by Wang *et. al.* [3] and is surprisingly similar to Co doping effects. However, lower doping high pressure neutron measurements found that pressure has little effect on the magnetic structures. This talk will focus on the pressure effects on the lower Co doping observed in dielectric, loss, as well as polarization measurements.

W5-10. Nature of spiral state, electric polarisation and magnetic transitions in Sr-doped $YBaCuFeO_5$ from first-principles study. D. Dey[2], S. Nandy[2], *T. Maitra*[1], C.S. Yadav[3] and A. Taraphder[2] *1. Physics Department, Indian Institute of Technology, Roorkee, Roorkee, India; 2. Physics, Indian Institute of Technology Kharagpur, Kharagpur, India; 3. School of Basic Sciences, Indian Institute of Technology Mandi, Mandi, India*

The nature of the spiral magnetic state in type II multiferroic $YBaCuFeO_5$ has recently been a matter of debate[1,2]. Using first-principles density functional theory (DFT) calculations within LSDA+U+SO approximation, we reveal the nature of spiral state and corresponding ferroelectric response in the incommensurate magnetic phase of $YBaCuFeO_5$. A helical spiral state with spins living in the ab-plane is found to be more stable. Owing to negligibly small Dzyaloshinskii-Moriya interaction and the absence of any spin current mechanism in the helical spiral state, electric polarization is predicted to be zero. These results are in good agreement with the recent single-crystal data[2]. We further investigated $YBa_{1-x}Sr_xCuFeO_5$) in the entire range of doping x. A quantum Monte Carlo (QMC) calculation on an effective spin Hamiltonian with exchange interactions estimated from DFT calculations shows that the paramagnetic to commensurate phase transition temperature increases with doping till x=0.5 and decreases beyond consistent with experimental findings[3].

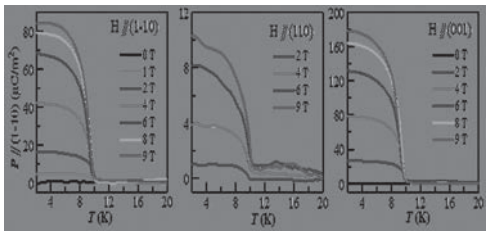
W5-11. Magnetic order in rare-earth ferroborate $CeFe_3(BO_3)_4$. *S. Hayashida*[1], S. Asai[1], D. Kato[1], S. Hasegawa[1], M. Avdeev[2,3], H. Cao[4] and T. Masuda[1] *1. University of Tokyo, Kashiwa, Japan; 2. Australian Nuclear Science and Technology Organization, Menai, NSW, Australia; 3. School of Chemistry, The University of Sydney, Sydney, NSW, Australia; 4. Oak Ridge National Laboratory, Oak Ridge, TN, United States*



The rare-earth ferroborates $RFe_3(BO_3)_4$ (R = rare-earth metal or Y) are a series of multiferroic compounds containing R^{3+} and Fe^{3+} ($3d^5$ S = 5/2) as magnetic ions. Variety of the magnetic anisotropy of the R^{3+} moments and the interaction between the Fe^{3+} and R^{3+} moments, *f-d* coupling, induce diverse magnetoelectric effects depending on the species of the R^{3+} ions [1]. Among the rare-earth ferroborates, $CeFe_3(BO_3)_4$ has been less studied; a brief report on a magnetic long-range order on the polycrystalline sample by means of the heat capacity and magnetic susceptibility measurements is the only publication [2]. We carried out thermodynamic and neutron diffraction measurements on both polycrystalline and single-crystal samples of $CeFe_3(BO_3)_4$. The occurrence of an antiferromagnetic order at 29 K is found from the heat capacity and magnetic susceptibility. In the powder neutron diffraction, the magnetic Bragg peaks indexed by the commensurate propagation vector k_{CM} = (0,0,3/2) and the incommensurate vector k_{ICM} = (0,0,3/2+δ) are observed. It is found from magnetic structure analysis that the magnetic moments aligning in the *ab* plane form the collinear antiferromagnetic structure having k_{CM} and helical structure having k_{ICM}. Detailed measurements of the magnetic susceptibility exhibit additional anomaly at 27 K. In addition, the temperature evolution of the neutron diffraction profile on the single crystal shows that incommensurate structure appears at 29 K and commensurate structure does at 27 K. These results suggest a phase separation state between the collinear and helical structures. The multiferroicity of $CeFe_3(BO_3)_4$ is discussed on the basis of the determined magnetic structure.

W5-12. Magnetoelectric effect in frustrated spinel $CoAl_2O_4$ single crystal. *C. De*[1] *1. CPMU, Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore, India*

Magnetically (electrically) induced ferroelectric polarization (magnetization), so called magnetoelectric (ME) effect has drawn enormous attention in the past decade due to its potential application in technology[1]. Here, we have successfully grown $CoAl_2O_4$ single crystal using optical floating zone furnace with less anti-site disorder of Co and Al ions in the tetrahedral and octahedral sites and observed ME effect. In $CoAl_2O_4$, Co^{2+} ions makes diamond type lattice where two FCC lattice are bipartite[2]. The ground state of this material has been a long time controversial issue due to fact that the ratio of nearest neighbor interaction (J_1) among the inter FCC lattices and next nearest neighbor interaction in the intra FCC lattice (J_2) inhabits to the close boundary between spiral spin-liquid ground state and the long-range antiferromagnetic ordering[2-4]. Here, we demonstrate the observation of magnetoelectric effect which suggests the long range antiferromagnetic ordering of Co^{2+} ions. From the experimetnal value of polarization ratio ($P_{1\text{-}10}$) measured while magnetic field applied along [1-10] and [001] and from the symmetry allowed theoritical calculated polarization, we confirm the magnetic easy axis to be along [100] which is shown in figure 1 and 2. Further a spin flop induced polarization flop is observed along [110]. These results are compared with other ME spinel oxides Co_3O_4 and MnB_2O_4 (B = Al, Ga)[5,6] and suggested that the single ion contribution of the magnetic ions located at the non-centrosymmetric environment is responsible for the ME effect.

W6-01. Anomalous Pressure Effect on the Nèel Temperature and Volume of DyB_6. *G. Oomi*[1], T. Eto[1], T. Sakai[2], Y. Uwatoko[3] and S. Kunii[3] *1. Kurume Institute of Technology, Fukuoka, Japan; 2. National Institute of Technology, Omuta, Japan; 3. Department of Physics, Sendai, Japan*

RB_6 compounds (R: rare earth element) with cubic CaB_6 structure have been well known to show a wide variety of interesting electronic and magnetic properties depending on R. Among them, DyB_6 is a novel Dy compound because of the existence of ferroquadrupolar (FQP) ordered phase and antiferromagnetic (AFM) ordering. It shows a structural phase transition at T^*=30 K from CaB_6 to rhombohedral structure and AFM transition at T_N=25 K [1]. In the present work we measured electrical resistance under high pressure. The pressure dependence of lattice constants is also measured to clarify the relation between elastic properties and magnetic ordering temperature. The main results are summarized as follows. (1) Nèel Temperature T_N at high pressure T_N is plotted as a function of pressure in Figure 1. It is found that T_N increases rapidly with pressure below about 1.5 GPa with $\partial T_N/\partial P$ =2.6 K/GPa and above it T_N increases very slowly. (2) Pressure dependence of volume (lattice constants) The lattice constants a (Å) at high pressure were are shown in Figure 2. The bulk modulus was estimated using Murnaghan's equation of state. From the close look of the compression curve in Figure 2, we can recognize that the compression below 2 GPa is larger than that above 3 GPa. So the compression curve seems to be difficult to fit to Murnaghan's equation in the whole range between 0 and 14 GPa. Here we tried to fit the data in the range 0-2 GPa and in the range 2-14GPa, separately. We obtained the bulk moduli as B_0=132 GPa for the range of 0-2 GPa and 215 GPa for the range of 2-14 GPa. The pressure dependence of T_N is usually described as [2] $\partial T_N / \partial P = 10 T_N / 3B_0$ (1) This equation shows that the small B_0 corresponds to a large pressure dependence and vice versa. From this consideration, the pressure change of T_N below 2 GPa is larger than that of high pressure range because the B_0 in the high pressure range is larger than that in the low pressure range. This result is qualitatively consistent with the present result in Figure 1.

W6-02. Kondo Destruction in Multipolar Order: Implications for Heavy-Fermion Quantum criticality. *H. Lai*[1] *1. Physics and Astronomy, Rice University, Houston, TX, United States*

Motivated by the quantum-critical heavy-fermion systems [1, 2] that exhibit multipolar orders, we theoretically study an effective field theory of a Kondo lattice model involving both spin and quadrupole degrees of freedom. The field theory contains a quantum non-linear sigma model of the antiferroquadrupolar (AFQ) phase in spin-1 systems, with Kondo couplings to conduction electrons. In the absence of the Kondo coupling, we demonstrate the stability of the AFQ phase numerically using density matrix renormalization group analysis, which treats the quantum fluctuations fully, in the underlying spin model. We proceed to analyze the effect of the Kondo couplings, using a mixed fermion-boson renormalization group procedure [3]. We show that the Kondo couplings are exactly marginal implying a Kondo destruction in the multipolar phase. Our results provide theoretical basis for the recently advanced notion of sequential Kondo-destruction [1].

W6-03. Transport properties of multipolar ordering compounds $Ce(Pd,Pt)_3S_4$. *S. Michimura*[1,2], U. Nishikawa[2], R. Iizuka[2], R. Numakura[2] and M. Kosaka[2] *1. Research and Development Bureau, Saitama University, Saitama-city, Japan; 2. Graduate School of Science & Engineering, Saitama University, Saitama-city, Japan*

$CePd_3S_4$ displays a simultaneous ordering of an antiferroquadrupolar (AFQ) ordering and a ferromagnetic (FM) ordering at T_C= 6.3 K [1-4]. Interestingly, T_C is higher than that of $GdPd_3S_4$ (T_N = 5.8 K). We confirmed the $\langle O_2^0 \rangle$ type AFQ ordering using resonant X-ray diffraction experiments[4]. T_C of $CePd_3S_4$ is well scaled by the squared Stevens factor, implying that the interactions between quadrupole moments are dominant in this system. Therefore, we speculate that the quadrupolar interaction gives rise to the evolution

of magnetic ordering temperature T_C. However, the FM and AFQ orderings are not allowed to realize simultaneously in accordance with the group theoretical analysis in ref.[5]. To reveal the relation between the magnetic and quadrupolar interactions, recently, we synthesized the $Ce(Pd_{1-x}Pt_x)_3S_4$ samples and performed magnetization measurements[6]. We intended to change in the strength of the magnetic and quadrupolar interactions by substituting Pt for Pd. The transition temperature $T_C(x)$ of $Ce(Pd_{1-x}Pt_x)_3S_4$ decreases down to about 1.9 K with increasing Pt concentration x. The only one phase transition is observed at $T_C(x)$ up to x = 0.23. Therefore, since the magnetization behaviors show no sign of separation between the FM and AFQ ordering below x = 0.23, we consider that the quadrupolar interaction is weakened with increasing x. On the other hand, we found another antiferromagnetic(AFM) transition in addition to the AFQ/FM ordering although it is not known how the magnetic correlation depends on Pt substitution. This AFM transition appears abruptly at around 7 K above x = 0.29. In this study, we performed specific heat and electric resistivity measurements to investigate the magnetic correlation in $Ce(Pd_{1-x}Pt_x)_3S_4$. Fig.1 shows the temperature dependence of ρ for $Ce(Pd_{1-x}Pt_x)_3S_4$. The $-\ln T$ dependence ofρis observed for x=0. The slope below 100 K becomes larger up to around x = 0.23 and then reduces above x = 0.29. Generally, the $-\ln T$ dependence ofρis caused by a Kondo scattering. Kondo effect may be enhanced in the range $0<x\leqq0.23$ in which the quadrupolar interaction becomes weak with increasing x. In the range $x\geqq0.29$ where the AFM ordering occurs, it is considered that the Kondo effect is weakened.

W6-05. Sequential Localization and Strange-metal Behavior in a Multipolar Kondo System. *A. Cai*[1], E. Nica[2], C. Liu[1], R. Yu[3], S. Paschen[4] and Q. Si[1] *1. Rice University, Houston, TX, United States; 2. University of British Columbia, Vancouver, BC, Canada; 3. Renmin University of China, Beijing, China; 4. Institute of Solid State Physics, Vienna University of Technology, Vienna, Austria*

Quantum criticality and the beyond-Landau physics of Kondo destruction [1,2] in heavy fermion systems with multipolar degrees of freedom is attracting considerable interest. Recent experiment on the heavy fermion compound $Ce_3Pd_{20}Si_6$ shows evidence of two consecutive Fermi surface collapsing quantum critical points (QCP) as a function of magnetic field [3], where antiferromagnetic (AFM) and antiferroquadrupolar (AFQ) order develops successively. At both QCPs, other features of Kondo destruction criticality appear such as linear in temperature resistivity and a logarithmic divergence of specific heat coefficient. We are able to understand it by advancing a theory of sequential destruction of an SU(4) spin-orbital-coupled Kondo entanglement. Under cubic crystal field environment, the lowest energy Γ_8 quartet provide a fundamental representation of SU(4) group. We thus consider an SU(4) Bose-Fermi Kondo model with both spin and orbital degrees of freedom coupled to different bosonic baths, which represents an effective model for a multipolar Kondo lattice system with Kugel–Khomskii type interaction. As a function of coupling strength to the bosonic baths, we find that a generic trajectory in the parameter space contains two QPTs, each being associated with the Kondo destruction of spin or orbital degrees of freedom. For the corresponding Kondo lattice problem, this corresponds to two stages of Fermi surface jump, thus providing a natural understanding of the experimental findings. Broader implications of our results will be discussed.

Orbital-related physics attracts growing interest in condensed matter research, but direct access to the orbital degree of freedom is challenging. Here we report the visualization of a surface-assisted orbital ordered structure on a cobalt-terminated surface of the heavy fermion compound $CeCoIn_5$. With extremely small tip-sample distance in our scanning tunneling microscopy, cobalt atoms are found to be dumbbell-shaped alternatingly in the [100] and [010] directions. A domain boundary of this ordered structure, which is localized within an atomic terrace, denotes two-dimensionality of the ordered structure. First-principles calculations reveal that this structure is a consequence of the staggered d_{xz} and d_{yz} orbital order assisted by enhanced on-site Coulomb interaction at the surface [1]. Our finding suggests that the surface-assisted orbital ordering could be ubiquitous in transition metal oxides, heavy fermion superconductors, and other materials but has been overlooked.

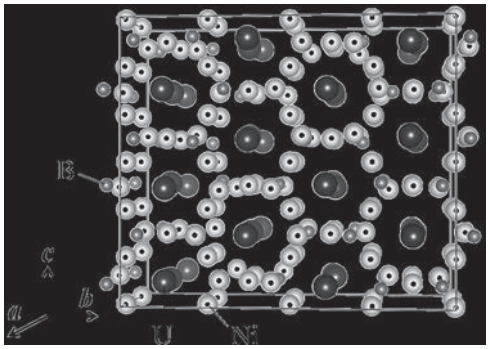
Tip-sample-distance dependent STM topographies of cobalt terminated surfaces of $CeCoIn_5$ (left panels, top: sample bias voltage V_S=10 mV, tunneling current I_T=1 nA, bottom: V_S=10 mV, I_T=30 nA) and integrated density of states in the plain of 0.25 nm (top) and 0.10 nm (bottom) above the top-most Co layer calculated based on density functional theory (right panels). The shape of a cobalt atom changes depending on the tunneling current with fixed bias voltage: the tip-sample distance. When the tip is far, an atom appears to be circular while it has a dumbbell-like shape when the tip is close.

W6-07. Field Direction Dependence of Specific Heat in Dilute Quadrupolar System $Pr_{0.05}La_{0.95}Pb_3$. *T. Kawae*[1], M. Koga[2], Y. Sato[1], Y. Inagaki[1], T. Kitai[3] and H.S. Suzuki[4] *1. Applied Quantum Physics, Kyushu University, Fukuoka, Japan; 2. Faculty of Education, Shizuoka University, Shizuoka, Japan; 3. Faculty of Engineering, Kyushu Institute of Technology, Kitakyushu, Japan; 4. National Institute for Material Science, Tsukuba, Japan*



We have studied the low temperature properties of $Pr_xLa_{1-x}Pb_3$ with a G_3 doublet in the CEF ground state. A non-Fermi liquid (NFL) behavior has been found for a very dilute Pr concentration below $x = 0.05$ [1,2]. The electronic specific heat C_{el}/T increases monotonically below $T \sim 2$ K, which can be scaled with a characteristic temperature T^* defined at each concentration x. Moreover, the temperature dependence of the non-linear susceptibility c_3, which reflects the fluctuation of the quadrupolar moments, at $x = 0.05$ show $-\ln T$–dependence in the [100] and [110] directions below $T \sim 2.5$ K [3]. These features are consistent with the prediction by quadrupolar Kondo effect [3]. In this presentation, we report the field dependence of the specific heat at $x = 0.05$ in the three field directions H//[100], [110] and [111]. NFL behavior of C_{el}/T shows a significant field direction dependence. In H//[100] the slope of C_{el}/T at $H = 4$ T decreases above $T \sim 0.7$ K, implying the beginning of suppression of NFL behavior. As the magnetic field is increased above $H = 6$ T, the NFL behavior collapses and C_{el}/T becomes almost constant at low temperatures. On the other hand, in H//[110] NFL behavior with increasing C_{el}/T seems to persist up to $H = 8$ T. These features can be explained by the crossover of the NFL to the Fermi liquid with increasing magnetic field [4].

W6-08. X-ray Crystal Structure Analysis of Toroidally-Ordered Metal UNi_4B. *C. Tabata*[1], H. Sagayama[1], H. Saito[2], H. Nakao[1] and H. Amitsuka[3] *1. Institute of Materials Structure Science, High Energy Accelerator Research Organization, Tsukuba, Japan; 2. Institute of Materials Structure Science, High Energy Accelerator Research Organization, Tokai, Japan; 3. Graduate School of Science, Hokkaido University, Sapporo, Japan*

The phenomena that magnetism couples with ferroelectricity, which is called the magnetoelectric (ME) effect, has been studied intensively since the discovery of multiferroic materials. Although the ME effect had been considered as a property that only insulating materials can exhibit, a recent theoretical study proposes that the ME effect can arise also in metals in which the magnetic moments order in vortex-like arrangements, referred to as toroidal order [1]. UNi_4B is the first example of toroidal ordering metal that is confirmed experimentally to exhibit magnetization induced by electric current [2]. The experiment and the theory are, however, partly inconsistent with each other. One of the problems that hinder understanding of this phenomena is that we have two controversial reports of the crystal structure of this compound: the hexagonal (*P*6/*mmm*) [3] and orthorhombic (*Cmcm*) [4] ones. We performed crystal structure analysis using high-energy synchrotron X-ray, in order to determine the crystal structure of UNi_4B. The diffraction of high-energy synchrotron X-ray was measured at the beamline PF-AR NE1A in Photon Factory, using a single-crystalline sample of UNi_4B. The obtained diffraction patterns strongly suggest the orthorhombic unit cell, whose lattice constants are: $a = 6.922(4)$ Å, $b = 14.773$ (2) Å, $c = 17.04$ (1) Å, which is the same as one of the previously reported structures [4]. The observed reflection conditions indicate possible space groups as follows: *Cmcm* (D_{2h}^{17}, no. 63), *Cmc*2_1 (C_{2v}^{12}, no. 36), and *C*2*cm* (C_{2v}^{16}, no. 40). The direct method and the least-squares refinement give very similar structures for each of these space groups, which have distorted triangular lattices formed by U atoms, without local inversion symmetry at each U site (see Fig. 1). The differences of *R*-values of the refinements among these space groups are no more than 0.5 %. In order to choose the correct space group out of these three candidates, we need a careful check from other experimental methods that are sensitive to the symmetry of the system, such as NMR, and so on.

W7-01. Observation of the valence fluctuation by time-resolved reflectance on Yttrium doped Samarium mono-sulfide. *H. Watanabe*[1], R. Ikeda[1], K. Imura[2], H.S. Suzuki[3,4], N.K. Sato[2] and S. Kimura[1]
1. Osaka University, Osaka, Japan; 2. Nagoya University, Nagoya, Japan; 3. National Institute for Materials Science (NIMS), Tsukuba, Japan; 4. Institute for Solid State Physics, The University of Tokyo, Chiba, Japan

Samarium monosulfide shows the valence transition from Sm^{2+} of a black-insulating phase to Sm^{3+} of a golden-metallic phase by applying pressure [1]. The valence transition also occurs by the chemical pressure by the substitution of Sm for yttrium (Y) ions, Sm1-xYxS, and the valence transition occurs at x ~ 0.17 [2]. At the golden-metallic phase, valence fluctuation (VF) is expected. To obtain the information of the change of the electronic structure in the VF time scale, we performed an ultra-fast pump-probe reflectance spectroscopy of black $Sm_{0.83}Y_{0.17}S$ (x = 0.17) and golden $Sm_{0.67}Y_{0.33}S$ (x = 0.33) at room temperature using an pulsed-laser (1 kHz, 1.55 eV, 70 fs). Figure 1 shows the temporal development of reflectance change ($\Delta R/R$) after laser irradiation. In both materials, $\Delta R/R$ increased just after the photo-irradiation (< 1ps) and fast relaxations (1-10 ps) to photo-induced (PI) states with a long life time (>10 ps) are commonly observed. However, the signs of $\Delta R/R$ of the PI state are opposite, i.e., positive in x = 0.17 and negative in x = 0.33. Since the energy of 1.55 eV is above (below) the plasma edge in x = 0.17 (x = 0.33), $\Delta R/R$ corresponds to the change of carrier density in conduction bands (CB). These relaxation time and the sign correspond to the time scale and the direction of the charge transfer between localized 4f levels and CB after the photo excitation. In x = 0.17 (x = 0.33), the nearest 4f state is located below (above) the Fermi level (E_F) because the configuration of Sm^{2+} $4f^6$ (Sm^{3+} $4f^5$) is dominant. Therefore, the positive (negative) decay curve of x = 0.17 (x = 0.33) originates from the charge transfer from CB to Sm^{2+} $4f^6$ (from Sm^{3+} $4f^5$ to CB), which is considered to be related to the time of VF. Figure 1. The time dependence of reflectance with 1.55 eV pump and 1.55eV probe on $Sm_{1-x}Y_xS$ (x = 0.17, 0.33) at 300K. The inset shows the schematic electronic structure of Sm 4f states and conduction bands near the Fermi level (E_F).

W7-02. Quasiparticle Dynamics in $CeCoIn_5$ Studied by Ultrafast Optical Spectroscopy. Y. Liu[1,2], H. Lee[3], Y. Yang[4], H. Yuan[3] and *J. Qi*[1]
1. University of Electronic Science and Technology of China, Chengdu, China; 2. Fudan University, Shanghai, China; 3. Zhejiang University, Hangzhou, China; 4. Institute of Physics, Chinese Academy of Sciences, Beijing, China

In heavy fermion materials, a wide range of phenomena are believed to arise from a competition between the single impurity physics (Kondo effect), correlations between local moments (lattice effects), electronic structure etc.. Here, we present studies of quasiparticle dynamics in the typical heavy Fermion $CeCoIn_5$ using ultrafast optical pump-probe spectroscopy. Properties of the electronic excitations are detected by studying transient changes in reflectivity as a function of time. These properties have been observed to experience clear changes across T*~50 K (see Figure 1), which is exactly the same as the coherence temperature (T_{coh}) assumed to be close the Kondo temperature (T_K) as reported by previous experiments. Our results show that below ~50 K, there appear a hybridization gap opening and a strong coupling between Kondo effect and lattice vibrations.

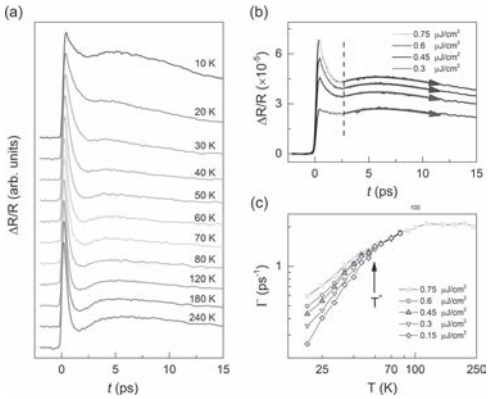

Figure 1 Temperature-dependent ΔR(t)/R in $CeCoIn_5$. (a) Typical ΔR(t)/R as a function of temperature. Very similar shape was observed for the signals at high temperatures. (b) ΔR(t)/R at 5 K as a function of pump fluence. Relaxation below ~2.5 ps shows strong fluence dependence. The relaxation can be fitted well by a single exponential decay: Aexp(-Γt)+Const., where Γ is the decay rate. The fitting results are indicated by different colors. In contrast, dynamics above ~2.5 ps is fluence indpendent, as indicated by the same wine arrow. (c) The decay rate Γ as a function of temperature measured at different pump fluences. Clear fluence-dependent behavior appears below T*~50 K. The fluence-dependence decay indicates a bimolecular recombination process emerges below ~50 K involving a gap opening near the Fermi level. In $CeCoIn_5$, such gap can arise from the hybridization between conduction electrons and localized f electrons.

W7-03. Time crystals realized by spatial translation and its symmetry breaking. *K. Mizuta*[1], K. Takasan[1], M. Nakagawa[2] and K. Norio[1]
1. Department of Physics, Kyoto University, Kyoto, Japan; 2. RIKEN, Wako, Japan

The system whose Hamiltonian is periodic in time is called a Floquet system. In Floquet systems, not only phases characterized by symmetry breaking or topology can be controlled, but also there are various phases which cannot exist in equilibrium. Thus, Floquet systems have attracted much interest. One of the most notable phases in Floquet systems is a time crystal phase because it cannot exist in thermal equilibrium [1] and several time crystals have already been observed in experiments [2,3]. A time crystal is a phase where time translation symmetry is spontaneously broken. In the case of Floquet systems, observables have an integer multiple period of periodic driving, and the period of the oscillation is robust to some perturbations. This phase is called a discrete time crystal (DTC). In many of conventional time crystals, symmetry operation and its symmetry breaking are utilized [4,5], but only on-site symmetries are focused on. Therefore, we propose a new kind of DTCs named "spatial-translation-induced DTC"(STI-DTC), which is realized by spatial translation and its symmetry breaking. STI-DTCs have notable properties which do not exist in conventional time crystals due to the characteristics of spatial translation and its symmetry. First, spatial translation symmetry breaking can induce many kinds of orders such as various crystal structures and charge density wave (CDW) orders. By utilizing these characteristics, various time crystal orders can be realized and controlled without changing the protocol. Second, spatial translation operation can induce local transport of charge or spin, thus local current of charge or spin emerges and shows nontrivial oscillation, which is the sign of time crystal orders. This property has merits in detection or application of time crystal phases. In our presentation, we discuss how to realize the new time crystal phase, and show a concrete model composed of spinless fermions, where CDW orders are utilized as spatial translation symmetry breaking. We also provide promising experimental resources for our new DTCs and especially refer quantum circuits as new setups for the DTCs with discussing required unitary gates.

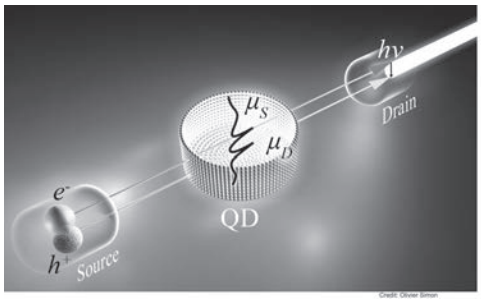
W7-04. Electric Field driven Mott Metal-Insulator Transition Using NCA in Non-Equilibrium Steady State DMFT. *B. Goh*[1] and J. Shim[1,3]
1. Chemistry, POSTECH, Pohang, The Republic of Korea; 3. Physics, POSTECH, Pohang, The Republic of Korea



We develop the non-equilibrium steady state dynamical mean field theory (NESS-DMFT) with non-crossing approximation (NCA) as the impurity solver to study strongly correlated electronic system on a dissipative lattice under static uniform electric field. In this framework, the Coulomb interaction and the external field which is described in Coulomb gauge are treated nonperturbatively via DMFT. The steady state is achieved by considering fictitious Fermion reservoir where the energy given by the electric field is dissipated. For the one band Hubbard model in dissipative cubic lattice with half filling, the electric current per spin and the local energy distribution function are calculated beyond the linear response regime, and the phase diagram of the metal-insulator transition driven by the field, temperature, and the Coulomb interaction strength will be discussed. These are compared with NESS DMFT with iterated perturbation theory (IPT)[1]. The results could be applicable to NiO[2] and $Cr_xV_{2-x}O_3$[3]. The NCA solver is multiorbital-extended, and can readily be used to study multi-band models which could be applied to account VO_2 case or be incorporated to cluster extension of the NESS-DMFT.

W7-05. Emission Noise in an Interacting Quantum Dot: Role of Inelastic Scattering and Asymmetric Coupling to the Reservoirs. A. Crépieux[2], S. Sahoo[1,3], T. Duong[2], R. Zamoum[4] and *M. Lavagna*[1]
1. Univ. Grenoble Alpes, CEA INAC-PHELIQS, Grenoble, France; 2. Aix Marseille Univ., Université de Toulon, CNRS CPT UMR 7332, Marseille, France; 3. Physics Department and Research Center OPTIMAS, University of Kaiserslautern, Kaiserslautern, Germany; 4. Faculté des sciences et des sciences appliquées Université de Bouira, Bouira, Algeria

The fluctuations of electrical current provide information on the dynamics of electrons in quantum devices. Understanding the nature of these fluctuations in a quantum dot is thus a crucial step insofar as this system is the elementary brick of quantum circuits. In this context, we develop a theory for calculating the noise at finite-frequency in a quantum dot connected to two reservoirs in the presence of interactions and for any symmetry of the couplings to the reservoirs [1,2]. This theory is developed in the non-equilibrium Keldysh Green function technique. We establish an analytical expression for the noise in terms of the various transmission amplitudes between the reservoirs and of some effective transmission coefficient which we define. The obtained expression can be seen as the analog of the Meir-Wingreen formula [3] for the current in the sense that it includes inelastic scattering contributions. Moreover we give a physical interpretation of the result on the basis of the transmission of an electron-hole pair to the concerned reservoir where it emits an energy after recombination. The interactions are then treated by solving the self-consistent equations of motion for the Green functions. We find that the noise derivative is zero until the voltage reaches a threshold value set by the measuring frequency, beyond which a Kondo peak appears when the system is in the Kondo regime. Our findings are in good agreement with recent measurements in carbon nanotube quantum dots [4,5]. Figure caption : Illustration of one of the physical processes contributing to the noise in the drain with the transmission of an electron-hole pair from the source to the drain where it emits an energy after recombination.

W7-06. Differential conductances and charge susceptibility of a double quantum dot. *M. Lavagna*[1], V. Talbo[1], T. Duong[2] and A. Crépieux[2]
1. Univ. Grenoble Alpes, CEA, INAC-PHELIQS, Grenoble, France; 2. Aix Marseille Univ., Université de Toulon, CNRS, CPT UMR 7332, Marseille, France

We calculate the electrical and thermal differential conductances as well as the charge susceptibility [1] of a double quantum dot coupled to two metallic reservoirs both in equilibrium and nonequilibrium situations when a bias voltage is applied between the two reservoirs. This work is motivated by

recent experiments carried out in Silicon-based double quantum dot probed by reflectometry techniques [2]. The calculations are performed by using the nonequilibrium Keldysh Green function (NEGF) method. In the non-interacting case, the conductance and the charge susceptibility are shown to exhibit peaks as a function of the gate voltages V_{G1} and V_{G2} applied to each dot, leading to a characteristic phase diagram for the system. We show how the method can be extended to the case of an interacting quantum dot.

College of Physics Science and Technology, Yangzhou University, Yangzhou, China; 5. Department of Physics, Fudan University, Shanghai, China*

The Kondo effect describes the screening of the magnetic moment of the impurity by the surrounding bath electrons through the exchange interaction [1]. There is a characteristic temperature called Kondo temperature (T_K) and it is associated with the density of states (DOS) at Fermi level $\rho(E_F)$ and the exchange constant J. When a surface state crosses the Fermi level, it is anticipated to influence $\rho(E_F)$ and thus T_K. However, the fundamental questions on whether and how the surface state influences the Kondo temperature remain as an ongoing debate. By using atomic manipulation with LT-STM, we performed systematic studies of the Kondo resonance for Co monomers on Ag(111) and found compelling evidence that the surface state does influence the Kondo temperature. The width of the Kondo resonance oscillates with the same period of half Fermi wavelength of the surface state. But the amplitude increases for the three cases studied of a Co adatom: (i) placed next to another Co adatom, (ii) at the vicinity of a step edge, and (iii) quantum confined within nano-corrals (see Fig. 1). A larger than 3-times enhancement of the resonance width can be achieved when the lateral quantum confinement is introduced (see Fig. 2). The oscillations of the Kondo temperature are compared with the corresponding *dI/dV* spectra at E_F obtained by moving the originally probed Co adatom apart and similar oscillations were found. The experiments can be understood by an analytical model where the contributions of the bulk and surface states are weighted by their exchange values with the magnetic impurity (J_b and J_s). Within the model, J_b and J_s are derived consistently for all three cases. Our experiments show that the Kondo resonance width can be continuously and significantly tuned by quantum confinement of the surface state, which pave a new pathway to tailor the Kondo effect. In addition, we developed a Green's function based method to calculate the Kondo resonance width, which reproduced the results of Kondo resonance width oscillation as a function of the corral diameter well (see Fig. 2).

The multi-functionality of hybrid molecular spintronics has the potential to revolutionise current device architectures. Key to this are the magnetic interface effects that emerge between molecules and other materials.[1] The possibility of modifying these effects by electrical or optical gating is an exciting prospect for tuneable structures.[2] We have developed such a system based on a MnO_2/C_{60} interface. This hybrid heterojunction demonstrates photovoltaic, memristive and spin filtering properties. We have measured striking changes in the Near Edge X-ray Absorption Fine Structure (NEXAFS) electronic structure at the carbon K-edge of a C_{60} magnetic tunnel junction after a small electric current being applied (Figure 1). The post-current state is spin polarised, hours after the voltage was applied. Upon grounding the sample, the signal returns to the typical initial state. We have also characterised these systems by Low Energy Muon Spin Rotation (LE-μSR). Changes to the muon depolarisation rate, probing local magnetic field distributions, were observed at the $MnOx/C_{60}$ interface before and after bias (Figure 2). DFT calculations show that hybridisation with the molecule leads to a half metallic state induced in the manganese oxide. Simultaneously, bonding between the C_{60} and O ions form a polar layer, leading to an interfacial energy well that traps charge.[3] With a discharge time that is spin dependent, this device would be the molecular spin equivalent to a capacitor in conventional electronics. Combining the magnetic phenomena observable at molecular interfaces with conventional semiconducting heterostructures, in this way, opens new possibilities for spin selective opto-electronic devices.

Institute of Physics, Johannes Gutenberg-Universität, 55128 Mainz, Mainz, Germany; 4. Department of Chemistry, Imperial College, London, United Kingdom*

Despite the fact that organic semiconductors (OSCs) have enabled many applications such as organic light emitting diodes, transistors and solar cells, they are unexploited in their potential for use in solid state devices for spintronics and spin-based information processing [1], [2]. OSCs have attracted much interests in the domain of spintronics due to their exceptionally long spin lifetimes arising from weak spin orbit coupling due to their composition of primarily light elements [3]. Even though two-terminal vertical organic spin valve has become a routine measurement of spin transport in organic materials, the formation of pin-holes and other defects necessitate an artefact-free technique for probing spin transport in organic materials [4]. Standard four terminal non-local spin valve is the most widely accepted technique for studying spin dynamics in inorganic metals and semiconductors. Here, we present a comprehensive study of non-local spin valve devices that used high mobility conjugated polymer with high structural order as the spin transport material. We show the evolution from conventional four terminal lateral spin valve to novel non-local spin transport architectures is the key to probe spin transport in these organic semiconductors. In addition, we have also studied spin current transmission in a range of organic semiconductors using tri-layer spin pumping technique [5]. We demonstrate the spin diffusion lengths of conjugated organic semiconductors can approach half a micron by tuning the molecular structure and charge transport property of the polymers.

W8-03. Spin transport in poly-acene films and the derivative films by using the spin-pumping. *Y. Tanaka*[1], T. Kono[1], Y. Teki[3] and E. Shikoh[2] *1. Graduate School of Engineering, Osaka City University, Osaka, Japan; 2. Engineering, Osaka City University, Osaka, Japan; 3. Science, Osaka City University, Osaka, Japan*

Organic semiconductors(OSs) have unique properties, and are often used in recent spintronics. We achieved spin transport in thermally evaporated pentacene films[1]. In this study, we investigate spin transport properties of OS films using tetracene as a poly-acene and 6,13-bis (triisopropylsilylethynyl) pentacene (TIPS-pentacene) having a structure in which part of pentacene is substituted. Spin transport is observed in Pd(10 nm in thick) / OS(50~200 nm) / $Ni_{80}Fe_{20}$(25 nm) trilayer samples. All films were formed by vacuum evaporation, under a vacuum pressure of < 10-6 Pa. The ferromagnetic resonance(FMR) is excited in the $Ni_{80}Fe_{20}$ using an ESR system, and a pure spin current is injected into the OS by the spin-pumping, which is independent of the conductance mismatch problem at the interface. The pure spin current transported through the OS is detected with a nanovoltmeter as an electromotive force(EMF) caused by the inverse spin Hall effect(ISHE) in Pd. All measurements were implemented at room temperature. In the TIPS-pentacene sample, an EMF was detected in the Pd layer, under the FMR of the $Ni_{80}Fe_{20}$. When the direction of the static magnetic field for exciting the FMR was reversed, the detected EMF was also inverted. In a control experiment in which Pd was changed to Cu, the EMF detected in the Cu was become about 1/10 of that in Pd. We think that the ISHE in pure Cu is very weak, but the ISHE in oxidized Cu causes relatively large EMF and the latter was detected in this experiment. Thus, we concluded that the spin transport in TIPS-pentacene films was achieved. We also conducted a similar experiment using tetracene films. When a magnetic field was applied by the ESR system, any FMR signal was not observed. At measuring the magnetization curve of $Ni_{80}Fe_{20}$ on a tetracene sample, the residual magnetization was small. By using AFM, it was found that the surface of the $Ni_{80}Fe_{20}$ film on a tetracene was very rough. So, the $Ni_{80}Fe_{20}$ film was not uniform on a tetracene film, compared with that on a regular pentacene film.

W8-05. Defect-mediated ferromagnetism in doped and undoped Cu_2O thin films. *M.A. Tumelero*[1], I.S. Brandt[2] and A.A. Pasa[2] *1. Physics Department, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 2. Departamento de Fisica, Universidade Federal de Santa Catarina, Florianopolis, Brazil*

The magnetic characterization of Co doped and undoped Cu_2O thin films grown by electrochemical deposition was performed. The doped films showed ferromagnetic behavior, with impressive Curie temperature above room temperature. Undoped samples also presented magnetic moments, but much reduced when compared to doped ones. The observed magnetism in undoped and doped samples was taken as an indicative of a defect-mediated ferromagnetism. Moreover, the sample magnetization was reduced as a consequence of a decreasing in defect density due to thermal annealing. X-Ray Circular dichroims measurements demonstrated that oxygen derived orbitals are the source of the observed magnetic moment. Structural, optical and electrical characterization confirms the doping of of Co atoms in the Cu_2O lattice at substitutional sites, without the formation of secondary segregated Co phases. In addition, Electron Paramagnetic Resonance and Glow Discharge Optical Emission Spectroscopy measurements reject the existence of impurities in the samples, dismissing them as the source for the observed magnetism. Computational calculations have shown that Co doping shall locally increases the amount of defects, such as interstitial O, leading to highly oxidized regions from where the unpaired spin could arises. This situation generates a picture similar to the magnetic polaron theory, but with the dopants pinning the defects [1].

W8-06. Electrical and Optical Characterization of Fe/*n*-GaAs Non-Local Spin Valve. *J. Kim*[1], M. Samiepour[1], J. Ryu[2], D. Iizasa[2], T. Saito[2], M. Kohda[2], J. Nitta[2], H. Beere[3], D. Ritchie[3], E. Jackson[1] and A. Hirohata[1] *1. University of York, York, United Kingdom; 2. Materials Science, Tohoku University, Sendai, Japan; 3. Physics, University of Cambridge, Cambridge, United Kingdom*

Spin field-effect transistor (FET) [1] is a critical vehicle to study injection, manipulation and detection of spin-polarised electrons in a semiconductor. In particular, Fe/*n*-GaAs system has been intensely investigated due to its desirable lattice matching where successful spin injection and detection have been previously reported [2]. However, manipulation of injected spins via electric or optical gates is still required to create a working spin FET. In this study, we fabricated Fe/*n*-GaAs non-local spin valves and investigated spin transport using electrical and optical methods. The *n*-GaAs structure consisted of 2 μm of Si-doped *n*-GaAs ($n = 2 \times 10^{16}$ cm^{-3}), 15 nm of $n^- \rightarrow n^+$ transition layer, and 15 nm of highly-doped n^+ layer ($n = 5 \times 10^{18}$ cm^{-3}) deposited on a semi-insulating GaAs(001) substrate. The spin valve structures were fabricated using electron-beam lithography, Ar-ion milling and wet-etching. Three- and four-terminal Hanle measurements were performed as seen in Fig. 1(a). Lorentzian peaks were obtained with half-width at half-maximum field values of around 440 mT. According to the formula used in Nam *et al.* [3], the spin dephasing time was calculated to be around 60 ps for the both 3- and 4-terminal measurements. The large (~1 T) saturation field indicated that the injected spins are dephasing in the n^+ layer between the injector and the detector contacts. The spin dephasing time of the channel *n*-GaAs layer was confirmed by pump-probe time-resolved Kerr rotation measurements. As seen in Fig. 1(b), the strongest Kerr modulation was observed when the excitation wavelength was 821 nm (1.51 eV). Employing a fit function accounting the exponential decay and the Larmor precession of spins, a spin dephasing time of 2.9 ns and an electron *g*-factor of -0.43 were estimated. Further optimisation of the Fe/*n*-GaAs interface has been achieved using non-destructive junction imaging [4]. This work has been partially supported by UK-EPSRC (EP/M02458X/1).

W8-07. Measurement of the Overhauser field in a two-dimensional electron system. X. Qian[1] and *Y. Ji*[1] *1. Institute of Semiconductors, Chinese Academy of Science, Beijing, China*

The nuclear-spin system in semiconductors has attracted interest for potential applications in classical and quantum spin-based computation schemes[1-2]. Its isolation from the surrounding environment yields exceptionally long coherence times, which can be as much as nine orders of magnitude longer than electron spin coherence time. Optical-induced electron spin polarization is shown to produce nuclear hyperpolarization through dynamic nuclear polarization (DNP). Through DNP, the nuclear-spin system could be manipulated indirectly through control of the electron spin system[2-4]. However, the strength of the nuclear field in such system is still not very clear. Here, we report optically induced DNP measurements in GaAs/AlGaAs two-dimensional electron system, with the nuclear Overhauser field being determined via an improved pump-probe measurement scheme based on time-resolved Kerr rotation system[5]. We demonstrate the measurement of the nuclear magnetic fields in the case of left- and right- circularly polarized pump light, respectively. We also show the dependence of the Overhauser field on the intensity and/or the polarization of the pump light. This experimental method could be easily extended to other materials with long spin dephasing time of electrons, thus being useful for a wide range of nuclear magnetic resonance and magnetic resonance imaging experiments.

W8-09. Influence of in-situ x-ray exposure on the magnetotransport properties of NPB and MADN based blue OLED structures. *J. Bobo*[1], R. Monflier[2], L. Salvagnac[2], E. Bedel Pereira[2] and I. Séguy[2] *1. CEMES CNRS, Toulouse, France; 2. LAAS CNRS, Toulouse, France*

Magnetic Field Effects (MFE) on Organic Semiconductors (OSC) have a large fundamental and technological interest presently due to the development of organic electronics devices like OLED (organic light emitting diodes) or OPV (organic photovoltaic). Up to now, the largest observed MFE[1] have been reported for OLED-type devices. They are related to the interaction between excited states (singlet, triplet) and charge carriers, either free or trapped.[2] The origin of the magneto-conductance (MC) is still controversial and depends on the device structure. In particular, the materials choice plays an important role, as well as film thickness, fabrication process, temperature. X-ray exposure during the deposition of metal layers with an electron gun may modify optoelectronic properties of OSC and MC.[3, 4] It is assumed to cause punctual trap defects in OSC films. We compare two HTL organic materials, NPB and MADN, with nearly the same HOMO and LUMO but large differences in published values for hole mobility which are respectively 10^{-4} and 3.10^{-7} $cm^2/V.s$ for NPB and MADN.[5, 6] We have prepared devices with an OSC single-layer, ITO anode and Al cathode. For photoluminescence (PL) experiments, similar OSC single layers were deposited on bare silicon substrates. All organic layers of one sample set were grown during the same evaporation run, then individually x-ray treated at various acceleration voltages of the e-gun. In the case of NPB, we report a dramatic dependence of current onsets that increase with the e-gun voltage (typically from 4 to 8 V for 100 nm NPB respectively pristine and 5 kV exposed). X-ray exposure is less significant for MADN-based devices with a shift from 4 to 5 V. However, they gave the optimal MFE with up to +6.3 % at 300 mT applied magnetic field for 4 kV exposure. We also report a neat dependence of MFE on the voltage conditioning of the samples, *i.e.* applying direct polarization to the device. Our results strongly support the fact that MFE is governed by a combination of extrinsic x-rays-induced local defects in OSC layers. We will analyze the observed effects in terms of trap formation, occupancy and polaron-triplet exciton coupling according to present models and the obtained PL spectra.

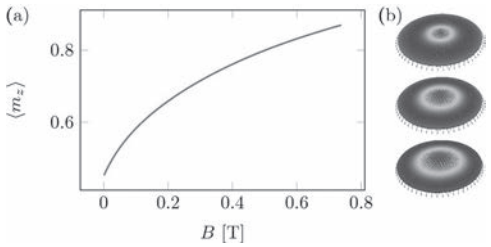
W9-01. Magnetostatic Interaction Between Two Bubble Skyrmions. *M. Castro*[1], D. Mancilla-Almonacid[1], A. Valdivia[2] and S. Allende[1]
1. Universidad de Santiago de Chile, Santiago, Chile; 2. Departamento de Física, Facultad de Ciencias, Universidad de Chile, Santiago, Chile



During the last decade, a great deal of attention has been focused on the study of the magnetic skyrmion in magnetic structures because they have potential applications in magnetic storage and spintronic devices[1-3]. In nanostructures such as nanodisks it is possible to find different type of skyrmions, like Néel, Bloch, or bubble configurations. In particular, the magnetic profiles of the Bloch and the bubble skyrmions are identical in a magnetic disk, where the only difference is that the Bloch skyrmion is stabilized by the Dzyaloshinskii–Moriya interaction, while the bubble skyrmion is stabilized by a perpendicular magnetic anisotropy[4,5]. Recently, arrays of bubble skyrmions in nanodisks have been proposed for the implementation of spintronic devices[6]. In these systems, the interaction between the skyrmions through the magnetostatic field can be strongly dependent on their locations. This magnetostatic interaction could even influence their movements and may also affect their magnetic structures[7,8] affecting the operation of the device. Therefore it becomes necessary to study in detail the interaction between two bubble skyrmions. In our work, a detailed analytic and numerical analysis of the interaction between two bubble skyrmions has been carried out. Results from micromagnetic calculations show a strong dependence of the magnetic parameters of the skyrmion magnetic profile as a function of the magnetostatic interaction. The magnetic core and end-width sizes of the skyrmion increase or decrease depending on the relative position between the skyrmions and the uniaxial perpendicular anisotropy. This behaviour can be explained by the magnetic interactions between the magnetostatic fields created by the magnetizations of the cores and the end-widths of the skyrmions. Thus, the results can be used for the control of the magnetic parameters of the skyrmions in magnetic spintronic devices that need to use this configuration. W9-02. Hysteresis-free out-of-plane magnetic field sensor based on skyrmions. *C. Abert*[1], F. Bruckner[1], C. Vogler[1] and D. Suess[1] *1. Faculty of Physics, University of Vienna, Vienna, Austria*

Recently, the use of magnetic vortex structures for in-plane field sensing was proposed [1]. The position of the vortex core is shifted depending on the field strength, leading to a change of the average in-plane magnetization in the thin-film structure. This shift is sensed by exploiting the change of the electric resistivity either by the giant magnetoresistive effect (GMR) or the tunnel magnetoresistive effect (TMR). A great advantage of this technology is the lack of magnetic hysteresis which leads to superior noise properties in sensing applications. We propose a thin-film magnetic field sensor based on magnetic skyrmions. The idea is to carry the concept of topologically protected magnetic structures to out-of-plane applications in order to obtain a hysteresis free transfer curve. The skyrmion is generated due to an antisymmetric exchange induced in the magnetic thin film by an adjacent heavy-metal layer. Its core is magnetized out-of-plane and thus sensitive to perpendicular external fields. We investigate the transfer curve by means of finite-element micromagnetic simulations [2], see Fig. 1. The sensor shows a clear magnetic response over a large field range. In order to eliminate magnetic hysteresis, the sensor has to be designed such that the magnetic skyrmion reliably nucleates in the magnetic layer even if it is destroyed e.g. by large external fields. We propose an asymmetric fried-egg structure, see Fig. 2 (a), in order to enable a reliable skyrmion nucleation. While the inner circular region is subject to antisymmetric exchange that enables the nucleation of skyrmions, the outer region is only subject to perpendicular anisotropy. Due to the asymmetry of the outer region, any domain wall arising in this area will move towards its thinnest spot, finally giving rise to the creation of a skyrmion in the inner circle, see Fig. 2 (b)-(c).

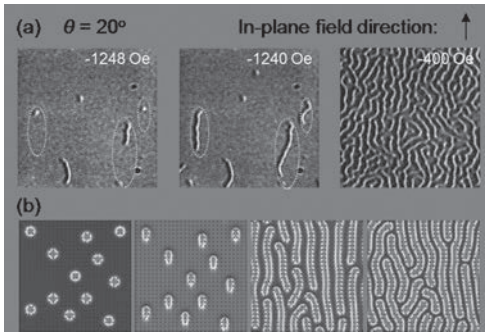
W9-03. Twisted skyrmions through dipolar interactions. *S. Castillo-Sepulveda*[1,2], R.M. Corona[4,2], A. Nuñez[5,2] and D. Altbir[3,2] *1. Universidad Autónoma de Chile, Santiago, Chile; 2. Center for the Development of Nanoscience and Nanotechnology, Santiago, Chile; 3. Physics, Universidad de Santiago de Chile, Santiago, Chile; 4. Departamento de Física, Universidad de Santiago de Chile, Region Metropolitana, Chile; 5. Universidad de Chile, Santiago, Chile*

The manifestations of the dipolar interaction in magnetic nano-devices can take subtle forms. In this work, we address the effects of dipolar interactions on skyrmions textures. The so-called twisted skyrmion is a natural state between the Bloch skyrmion, that arises from the bulk-like Dzyalonshinskii-Moriya (DM) interaction, and the Nel-skyrmion, that results from the interfacial form of the DM interaction. Often neglected, or approximated by local interactions, we show how, when explicitly included, dipolar interactions generate gaps in the phase diagram for certain helicities and give stability to twisted skyrmions. Besides, this interaction allows the existence of Bloch skyrmions with two chiralities, which are unstable when the dipolar interaction is approximated by a shape anisotropy. In this work we have shown that a proper consideration of dipolar interaction leads to skyrmions with a significantly modified internal structure as those obtained with a shape anisotropy contribution. Dipolar interaction favors the generation of twisted skyrmions and, when DM interaction in the bulk is absence (Db is null), allows the existence of skyrmions with two chiralities, a very important fact that, otherwise, cannot be observed. The dipolar interaction generates gaps in the phase space, restricting the helicities that can be found in spiral skyrmions. In addition, when the DM interaction in the bulk is included; our results show the existence of a critical Di (DM constant in the interfase) value that allows considering the dipolar interaction as local anisotropy. The figure illustrate the behavior of the chirality for diferents Di and Db values.



Stable skyrmion structures as a function of Db for difference values of Di for a dot with L = 4t when considering (a) full dipolar energy and (b) shape anisotropy. Square dot corresponds to the stable state with Di = 5 mJ/m^2, the circular dot represents results for Di = 0 and the triangular dot corresponds the full ferromagnetic state obtained for Di = Db = 0.

W9-04. Determination of Néel-type skyrmion chirality using Lorentz-TEM under a tilted magnetic field. *S. Zhang*[1], J. Zhang[1], Q. Zhang[1] and X. Zhang[1] *1. Physical Science and Engineering Division (PSE), King Abdullah University of Science and Technology (KAUST), Jeddah, Saudi Arabia*

Magnetic skyrmion, a topologically protected spin texture, hold great promise for next generation non-volatile storage [1], spin transfer nano-oscillator [2] and logic devices [3], due to its very small size and an ultralow current density required for current-driven motion [4]. Chirality is a very important property for skyrmions. However, the Néel-type skyrmion chirality cannot be observed from the Lorentz transmission electron microscopy (L-TEM) images [5]. In this work, we report the determination of the chirality of Néel-type skyrmions from the magnetization reversal behaviors in $[Pt/Co/Ta]_n$ multilayers by considering the in-plane field. Figure 1a shows the *in-situ* L-TEM observation of the magnetization reversal behaviors. The sample was first saturated to down direction and then the images were taken at a tilt angle of 20° during decreasing the field magnitude. The in-plane component field direction is marked by black arrow. It was found that some isolated skyrmions emerged first and then extended to snake-like structures. The snake-like structures became longer and longer and finally the density of snake-like structures achieved maximum over the entire film, forming an almost aligned arrangement. We compare the two images obtained at -1248 Oe and -1240 Oe and marked the structure differences with green dashed ellipses. Interestingly, we found that the snake-like structures mainly extended toward the direction that opposite with the in-plane field direction. Micromagnetic simulations reveal that this phenomenon is governed by the skyrmion chirality which is determined by the sign of DMI constant *D*. By comparing the relationship between the preferred extension direction and the in-plane field direction obtained from the simulation (Fig. 1b) with our experimental observation, we identify that the sign of *D* (skyrmion chirality) is positive for our $[Pt/Co/Ta]_n$ multilayers.

Recent studies on magnetic skyrmions have been focused on heavy metal/ferromagnetic multilayer systems with strong interfacial Dzyloshinskii-Moriya interaction (DMI)[1-4]. Compared to non-centrosymmetric single crystals, such multilayer systems not only can be more easily incorporated into spintronics technology, but also exhibit skyrmions stabilized at room temperature. For widespread application of skyrmion based memory devices, it would be desirable if such skyrmions exist at higher temperatures. In this study, we report our discovery of a skyrmion lattice phase stabilized at high temperatures, up to T = 730 K. The temperature and magnetic field dependent magnetic domains in Pt/Co/Ru multilayers were observed using Lorentz transmission electron microscopy (Lorentz TEM). When the magnetic domains of this multilayer structure is measured as the temperature is increased, we find that the stripe domain phase present at lower temperature (T < 650 K) transforms into a skyrmion lattice phase with ~180nm period at high temperature (T ~ 730 K) in the presence of a static out-of-plane magnetic field of H ~ 600 Oe (Fig. 1). When the temperature is decreased from T ~ 730 K to room temperature, the skyrmion lattice disappears as the skyrmion density decreases and only a few isolated skyrmions are left at room temperature; the stripe domain phase does not appear during this cool down process. The change of the domain phase with temperature is likely due to the large change in the magnetization and magnetic anisotropy, which we observed by measuring the temperature dependent magnetic hysteresis loops, and the subsequent change in magnitudes of the competing energy terms that determine the domain structure. When the magnetic field is changed at a fixed temperature (T ~ 700 K), we find that the domain phase changes reversibly between a skyrmion lattice phase stabilized at an out-of-plane field of H ~ 600 Oe, and a stripe domain phase stabilized at zero field H = 0 Oe.

W9-06. Twisted domain walls in perpendicularly magnetized multilayers.
I. Lemesh[1], F. Buettner[1] and G. Beach[1] *1. Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, MA, United States*

Multilayer films with perpendicular magnetic anisotropy (PMA) are highly active media in modern magnetic technologies and research. Domain walls in such materials are usually treated either similarly to homogeneous magnetic layers [1] (via the so-called effective medium model), or as in multilayers, but with a trivial assumption of a fixed domain wall width Δ and angle ψ across the layers [2], as depicted in Fig. 1. However, recently it has been argued that the actual equilibrium configuration of the domain walls in multilayers is rather different [3, 4]. Both Δ and ψ, as revealed from the explicit multilayer simulations in these studies, vary from layer-to-layer, with the Néel-like caps of opposite chirality developing at the bottom and the top layers (see Fig. 2). In this work, we rigorously prove that such a twist is indeed a ground state in PMA multilayers and find that it persists even for films with high Dzyaloshinsky-Moriya Interaction (DMI). By solving the exact magnetostatic integrals, we evaluate the total micromagnetic energy density of the domain walls in multilayers analytically and derive the equilibrium Δ and ψ (in every magnetic layer). We provide the relations that enable extracting the value of the threshold DMI, at which all the layers become Néel. We analyze the exact influence of this twist on the size of the domains and skyrmions, and also on the dynamics of skyrmions in multilayers. We find that the extraction of DMI from the domain width measurement is highly inaccurate in the region of small and intermediate values of DMI, where the wall twist usually persists. Finally, we show that the skyrmion size, velocity and skyrmion hall angle derived from the exact multilayer theory can vary significantly compared with the predictions of the effective medium approach. We confirm our findings with micromagnetic simulations.

W9-07. Search for Small Skyrmion in Amorphous Ferrimagnets. *C.T. Ma*[1], Y. Xie[2], J. Ma[2], Y. Tan[2], H. Vakilitaleghani[2], A. Ghosh[2] and J. Poon[1] *1. Department of Physics, University of Virginia, Charlottesville, VA, United States; 2. Department of Electrical and Computer Engineering, University of Virginia, Charlottesville, VA, United States*

Magnetic skyrmions are topologically protected, stable spin textures. Small skyrmions with a diameter of several nanometers have the potential to improve bit density and energy efficiency in memory and logic devices. In magnetic materials, skyrmions are stabilized through Dzyaloshinskii-Moriya interaction (DMI). DMI is an antisymmetric magnetic interaction arising from broken inversion symmetry that exists, for example, in non-centrosymmetric B20 phase, or at the interface of ferromagnetic layer and adjacent heavy metal layer. The skyrmions observed so far are either large or at low temperature. To further reduce the size of skyrmions at room temperature, we need to explore other materials. Amorphous rare-earth transition-metal ferrimagnets are promising materials for observing small skyrmion at room temperature. Gd-based alloys exhibit robust perpendicular magnetic anisotropy at 300K without the need for epitaxial growth, as shown in Figure 1 (Ding 2013). This intrinsic anisotropy provides an important recipe for stabilizing skyrmion at room temperature. The magnetic properties particularly the compensation temperature of these amorphous ferrimagnets can be tuned by varying the composition. These enabling properties suggest that amorphous ferrimagnets are promising materials for skyrmion-based devices. For guiding experiment, we employ atomistic simulation to search the parameter space of amorphous ferrimagnets. Using a rapidly quenched amorphous structure generated by molecular dynamics, we vary various parameters, such as DMI and thickness, to identify ideal conditions for ultrasmall skyrmion at room temperature. Preliminary results demonstrate stable, smaller than 10-nm skyrmion in GdFe at 300K. Further simulations are underway to gain a deeper understanding of the interplay of DMI, exchange coupling, and magnetic anisotropy. Results from these simulations will provide guidance for realizing stable, ultrasmall skyrmions in experiments. This work is funded by DARPA.

W9-08. Computational search for ultrasmall and fast skyrmions in the Heusler family. *Y. Xie*[1], J. Ma[1], Y. Tan[1], C.T. Ma[2], H. Vakilitaleghani[2], J. Poon[2] and A. Ghosh[1] *1. Department of Electrical and Computer Engineering, University of Virginia, Charlottesville, VA, United States; 2. Department of Physics, University of Virginia, Charlottesville, VA, United States*

Magnetic skyrmion is a topologically protected state with a size that can be scaled down potentially to just a few nanometers, making it favorable for next-generation high density, fast memory/logic applications. The state of art experimental observations of skyrmions mainly come from two material classes: B20 helical materials with intrinsic Dzyaloshinskii-Moriya (DMI) interaction and conventional magnetic memory materials like CoFe, with interfacial DMI interaction arising from an adjacent heavy metal layer. However, those skyrmions are either too large (about 100 nm) or only exist at low temperatures. Aggressively tailoring material properties to downscale skyrmion size (<10 nm) can be challenging. Skyrmion size and energetics are determined for a given thickness by the overall magnetization, DMI, anisotropy, exchange and external magnetic field H. To facilitate the efforts in creating ultrasmall and fast skyrmions, we identified the optimal multi-parameter space for stable ultrasmall skyrmions at room temperature based on micromagnetic simulations and analytical equations. High Curie temperature for stability, as well as low saturation magnetization (Ferrimagnet or Antiferromagnet) and low magnetic damping, are the key targets for fast stable

skyrmions. We identified multiple ferrimagnetic inverse Heusler compounds from a database consisting of hundreds of inverse Heuslers extracted from our first principle studies[1]. Based on the intrinsic magnetic properties, we further determined the external conditions under which ultrasmall (<10 nm) skyrmions with the maximum velocity can be found (assuming the skyrmion is driven by current induced spin-orbit torque from the bottom heavy metal layer). Fig. 1 shows the micromagnetics simulations of skyrmion radius for different D and H for Mn_2FeAl as an example. This work is funded by the DARPA Texitronics program.

W10-01. Magnetic properties of FeNiMo compacted powder.

D. Oleksakova[1], P. Kollar[2], M. Jakubcin[2], P. Slovensky[2] and J. Fuzer[2]
1. Faculty of Manufacturing Technologies with seat in Presov, Technical University in Košice, Presov, Slovakia; 2. Institute of Physics, Faculty of Science, P.J. Šafárik University, Kosice, Slovakia

Most remarkable permalloys are the alloys with composition close to $Fe_{20}Ni_{80}$, where both anisotropy and magnetostriction fall to zero at almost the same composition. A tendency towards unfavourable Ni_3Fe-type L12 atomic ordering can be suppressed by Mo addition (supermalloy FeNiMo). We have focused our interest on frequency dependence of losses and coercieve field of $Fe_{16}Ni_{79}Mo_5$ (wt. %) powder compacts prepared by the compaction of the powder obtained by a mechanical way to obtain near-to-spherical form of powder elements. The small pieces of $Fe_{16}Ni_{79}Mo_5$ alloys prepared by grinding from sheets by a lathe were milled using a Retsch Planetary Ball Mill PM 100 with hardened steel vials and balls for 6 hours. The powder was sieved to separate the powder with particle size from 100 to 300 μm. The prepared powder fraction was mechanically treated to obtain near-to-spherical shape of powder elements. This powder was consequently compacted at a pressure of 700 MPa at the temperature of 410 °C stabilized for 5 min. in the form of ring (outer diameter 24 mm, inner diameter 18 mm, height 2.5 mm). The core losses and the coercieve field were measured by a MATS-2010SA hysteresisgraph at maximum induction of 0.05 T, 0.1 T and 0.2 T in the frequency range from 50 Hz to 10 kHz, Fig. 1. As presented in our earlier work [1], the FeNiMo samples, prepared by the compaction of powder (without mechanical rounding of powder particles) at the same conditions and consequently heated at 1100 °C, exhibit only a bit better values of core losses (1.4 W/kg) and coercivity (12 A/m) than the sample prepared by the compaction of powder particles with near-to-spherical form of particle with diameter from 100 to 300 μm without heated treatment after compaction. After suitable heat treatment of this sample, we are expecting that this sample will be a suitable precursor for the soft magnetic composite preparation. This work was supported by the Slovak Research and Development Agency under contract No. APVV-15-0115 and by the Scientific Grant Agency of the Ministry of Education of the Slovak Republic and the Slovak Academy of Sciences, VEGA 1/0330/15 and VEGA 1/0377/16.

W10-02. Effects of static and exchange fields on magnetization reversal time with different damping constants in soft magnetic material.

H. Ohta[1], F. Akagi[2] and K. Yoshida[2] *1. Electrical and Electronics Engineering, Kogakuin University, Shinjuku-ku, Japan; 2. Kogakuin University, Shinjuku-ku, Japan*

Magneto-impedance (MI) sensors using amorphous wires with soft magnetic properties are needed to improve detection sensitivity of magnetic fields for use in biological and medical fields [1]. For that purpose, the magnetization reversal time should be as short as possible. We investigated the effects of static and exchange fields on magnetization reversal time with different damping constants by using a micromagnetic simulator in soft magnetic materials. Dynamic magnetization behaviors of amorphous wires were calculated using the Landau-Lifshitz-Gilbert equation as shown below.

$$dM/dt = -\gamma(M\times H_{eff})+\alpha(M\times(dM/dt))/M_s \quad (1)$$

Where M is the magnetization vector, γ is the gyro magnetic constant, α is the damping constant, M_s is the saturation magnetization, and H_{eff} is the effective field (sum of external, static, anisotropic, and exchange fields) vector. The calculation model for a soft magnetic film was a cube with a side length of 16 nm, including cube-cells with a side length of 2 nm. Table 1 shows the magnetic characteristics. In addition, the soft magnetic film was assumed to have a uniaxial anisotropy. External fields with strength equal to the anisotropy fields (H_k) of the soft magnetic film were applied in an easy axis direction. We defined the magnetization reversal time as the time interval when the magnetization changed from 0.5 to -0.5 times of the saturation magnetization. Figure 1 shows the damping constant dependence of the magnetization reversal time. We compared the dependencies with and without static and exchange fields. From the figure, the magnetization reversal time was faster when the damping constant increased regardless of presence or absence of the static and exchange fields. However, the magnetization reversal time with the two fields was 1.6 times longer than that without them.

W10-03. Magneto-optical Terbium Iron Garnet and Ce-substituted TbIG thin films for integrated photonics. *T. Fakhrul*[1], Y. Zhang[1], L. Beran[2], E.R. Rosenberg[3], M. Veis[4] and C. Ross[1] *1. Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, MA, United States; 2. Institute of Physics, Charles University, Prague 2, Czechia; 3. Massachusetts Institute of Technology, Cambridge, MA, United States; 4. Institute of Physics, Charles University, Prague, Czechia*

Cerium and Bismuth doped yttrium iron garnet (YIG) films have excellent magneto-optical (MO) figure of merit in the near-IR and have been incorporated into on-chip optical isolators. Recently, rare earth garnets have also been developed for MO applications that have the advantage of not requiring garnet seed-layers to crystallize on Si. Here we examine the growth on Si substrates and the optical and magnetic properties of polycrystalline thin films of terbium iron garnet ($Tb_3Fe_5O_{12}$, TbIG) substituted with Ce and Bi using pulsed laser deposition (PLD). The growth conditions that produced polycrystalline single-phase TbIG films were at temperatures of 720-750^{o}C and at oxygen pressures of 2-10 mTorr, with a rapid thermal anneal at 900^{o}C/3 min. The film of Fig. 1(a) had in-plane coercivity of 47.7 kA/m and out-of-plane saturation field of 360 kA/m. The magnetic moment was 40 kA/m, lower than that of YIG due to the proximity to the compensation temperature of TbIG. Structural characterization revealed the growth of single phase polycrystalline TbIG films on Si without any secondary phases. Faraday rotation of TbIG/Si films measured at a wavelength of 1550 nm was ~600^{o}cm^{-1} (Fig.1 b) and the spectral dependence of the Faraday rotation, optical absorption and refractive index (Fig. 2) was characterized. The Faraday rotation can be increased significantly by Ce or Bi substitutions in the garnet. The step coverage of TbIG films on SOI waveguides was investigated, and the performance of TbIG in lithographically patterned TE and TM mode on-chip optical isolators based on ring resonators and Mach-Zehnder interferometers will be described.

W10-05. Synthesis of γ'-Fe_4N Soft Magnetic Material by High Pressure Nitriding Approach. *Y. Jiang*[1] *1. Jiangnan University, Wuxi, China*

Ferromagnetic γ'-Fe_4N has many attractive properties, such as high saturation magnetization and electrical resistivity, making it an ideal candidate to replace current magnetic materials[1]. It is composed of earth-abundant and nontoxic elements, possesses an anti-perovskite structure and a Curie temperature (Tc =767 K) that is well above room temperature. However, synthesis of γ'-Fe_4N is challenging. Up to now, most of the synthesis works are based on thin film preparation[2,3]. Several efforts on bulk material preparation have been reported. But products often contain multiple phases of iron nitride or undesirable morphology and particle size. For its practical application in power electronics, nanoscale γ'-Fe_4N with high volume phase ratio is required to exhibit high permeability and low loss at high frequency, ultimately enabling smaller devices, such as transformers and inductors operated in high frequency semiconductor switches. A novel synthesis approach is developed to prepare nanoscale γ'-Fe_4N in this paper. Starting from iron powder, high power ball milling process at room temperature is used to create nanocrystalline Fe powder. There are many vacancies, grain boundaries and dislocations generated in the milling process. The milled powder is nitridized in high pressure environment. The grain boundaries and the defects can serve as specific pathways for nitrogen atoms from ammonia gas. A post-annealing step is followed to anneal the sample, activate the nitrogen atoms, and crystallize the sample. Finally, the prepared sample is characterized by XRD, VSM and TEM to show its excellent crystalline and magnetic properties. Figure 1 shows its XRD spectrum, showing obvious γ'-Fe_4N phase. Figure 2 shows the TEM images of the prepared nanoscale samples. The proposed approach can have potential application in large volume production of γ'-Fe_4N soft magnetic material.

W10-06. Single Superparamagnet Dynamics. A.M. Abdelgawad[1], *B. Parks*[2] and S. Majetich[2] *1. Materials Science and Engineering, Carnegie Mellon University, Pittsburgh, PA, United States; 2. Physics, Carnegie Mellon University, Pittsburgh, PA, United States*

We have previously demonstrated the ability to observe superparamagnetism in single 18 nm Fe_3O_4 nanoparticles by making them part of a magnetic tunnel junction (MTJ) and measuring resistance fluctuations with a conductive atomic force microscopy (C-AFM) probe [1]. The preference for a given magnetization state could be tuned with an external magnetic field, and the average lifetime before switching was on the order of milliseconds. Here we extend this technique and show that it can be used to directly measure dynamics on the tens to hundreds of nanoseconds time scale. Here the superparamagnetic "particles" are 2.5 nm thick circular nanodots of CoFeB ranging from 20 to 80 nm in diameter, Pt-capped and on top of a 1 nm MgO tunnel barrier. The reference layer is a PtMn-pinned synthetic antiferromagnet of CoFe, which was unpatterned. Compared with the particles in the previous measurements, these particles are crystallographically aligned and uniaxial. Tunnel magnetoresistance (TMR) as a function of magnetic field showed a size-independent coercivity of ~7 Oe, which indicates that reversal occurs through nucleation and domain wall motion rather than by coherent rotation. The nucleation volume is estimated to be a 17 nm diameter region of the disk. Figure 1 shows the distribution of apparent switching times obtained from analysis of the TMR fluctuations as a function of time. For a random process an exponential distribution is expected, and this trend is seen at long times. Below the RC time constant of the electronics events are too fast to detect, and slightly above this threshold a larger than expected values are seen because multiple events overlap. Using a fast preamplifier in order to reduce the effective RC time constant of the circuit, telegraphing can be observed on a much shorter time scale, as shown in Figure 2. On very short time scales apparent partial switching events are observed. These data are analyzed as a function of particle diameter and magnetic field.

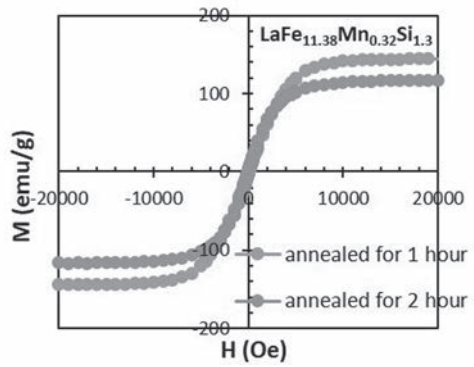
W10-07. Constraining the Decline of the Moon's Magnetic Field Using Apollo 12 Basalts. *B. Strauss*[1,2], S. Tikoo[2], J. Gross[2], J. Setera[2] and B. Turrin[2] *1. Material Measurement Lab, National Institute of Standards and Technology, Gaithersburg, MD, United States; 2. Department of Earth and Planetary Sciences, Rutgers University, Piscataway, NJ, United States*



Natural rocks hold a wealth of information about the planetary magnetic fields in which they form. The magnitudes of these fields can vary over time due to changing conditions in planetary interiors. By studying dynamo fields like that of the Earth's Moon, we can learn about the deep interiors and histories of other planets. Magnetic studies of lunar samples from the Apollo missions indicate that the Moon generated a core dynamo field between at least 4.25 and 2.5 billion years ago (giga-annum, Ga)[1–5]. A high field period (surface field intensities ≈40-110 μT) occurred 3.85-3.56 Ga[6], followed by a decline in surface field intensity to < ≈4 μT by 3.19 Ga[7] that left the dynamo in a weakened state at ≈2.5-1 Ga[5] until its demise. The change from a high field state to a low field state suggests a change in the mechanism of field generation between 3.56 and ≈3.2 Ga. However, the poor magnetic properties of most lunar rocks have hindered prior attempts to retrieve information from those magnetized in weak fields < 3.56 Ga. Vitrophyric basalts are volcanic rocks containing large crystals in a glassy matrix. These rocks cooled below their magnetic blocking temperatures at faster rates than more crystalline basalts and thus may contain smaller (i.e., pseudo-single domain sized) ferromagnetic grains capable of recording weaker fields. We studied the magnetic properties of three vitrophyre basalt samples (12008, 12009, and 12015) that were collected during the Apollo 12 mission to constrain the behavior of the Moon's dynamo field between 3.3 and 3.1 Ga, near the end of its initial decline. Our paleomagnetic experiments show that all three samples have excellent magnetic recording capabilities for lunar basalts and can record fields as small as ≈4-7 μT. However, the lack of stable magnetization indicates that these rocks formed in fields with intensities lower than ≈4-7 μT, confirming that the lunar field declined sharply between 3.56-3.19 Ga. These results replicate the low-field recording capabilities found in other glassy lunar materials[7,8]. We explore the relationship between magnetic recording and grain size through magnetic characterization and electron microprobe analyses of metallic grains.

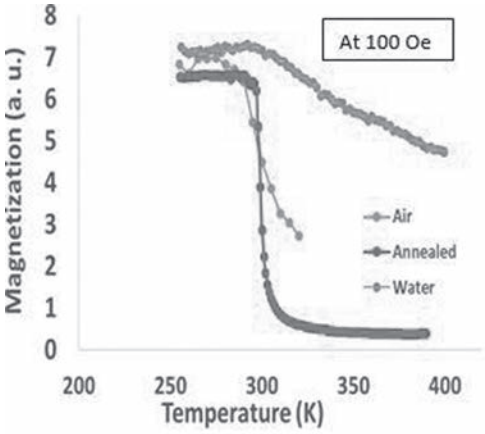
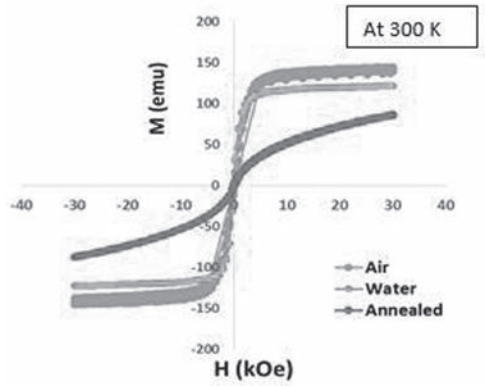
W10-09. Effects of rapid solidification and annealing on magnetic properties of $LaFe_{11.38}Mn_{0.32}Si_{1.3}$ compound. B. Macan[1], K. Sarlar[1], *E. Civan*[2] and I. Kucuk[1] *1. Uludag University, Bursa, Turkey; 2. National Defence University, Izmir, Turkey*

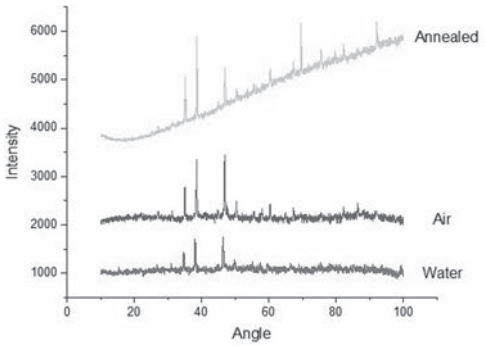
In this study, the effect of annealing on the magnetic properties of $LaFe_{11.38}Mn_{0.32}Si_{1.3}$ compound rapid solidified by suction casting method was investigated. Master alloy with nominal compositions of $LaFe_{11.38}Mn_{0.32}Si_{1.3}$ alloy was prepared by arc-melting the mixtures of pure elements in high-purity (>%99.9) argon atmosphere. To ensure low oxygen content in the alloy zirconium was used. In order to get homogeneity, the procedures were repeated at least four times and then the alloy was suction-cast in Edmund Buhler MAM-1 arc melting system into a cylindrical copper mold with a length of 30 mm and a diameter of 2 mm. The samples were then annealed for 1 and 2 hour at 1273 K under an argon atmosphere. The structures of as-quenched sample and annealed samples were identified by X-ray diffraction (XRD) with CuKα radiation. The magnetic properties measurements were conducted with a Microsense EZ9 vibrating sample magnetometer (VSM). The temperature dependence of magnetisation (*M–T*) curves were measured under a field of 0.01 T and the isothermal initial magnetisation curves (*M–H*) were measured under a field of 0–2 T. The alloys show good soft magnetic properties in the room temperature as illustrated in Fig. 1. The saturation magnetisation (M_s) and coercivity (H_c) at room temperature annealed alloys for 1 and 2 hour at 1273 K were found to be 144 and 117 emu/g, 21 and 27 Oe, respectively.





Hysteresis loops of $LaFe_{11.38}Mn_{0.32}Si_{1.3}$

W10-10. Stability Of Fine Powders Of Magnetocaloric $La(Fe_XCo_YSi_{1-x-y})_{13}$ In Water And Air. *K. Javed*[1], N. Palapati[1], S.M. Harstad[2], V. Pecharsky[3], S. Gupta[3] and R.L. Hadimani[2] *1. Mechanical Engineering, Virginia Commonwealth University, Richmond, VA, United States; 2. Mechanical and Nuclear engineering, Virginia Commonwealth University, Richmond, VA, United States; 3. Division of Materials Science and Engineering, Ames Laboratory, US Dept. of Energy, Ames, IA, United States*



Co-doped Lanthanum-iron-silicide, $La(Fe_xCo_ySi_{1-x-y})_{13}$ is a room temperature magnetocaloric material that has potential for applications in magnetocaloric refrigeration and air-conditioning [1]–[3]. It exhibits different magnetic properties when stored in water or air when compared to the same stored in inert environment. $La(Fe_{0.842}Co_{0.073}Si_{0.084})_{13}$ was synthesized by arc melting of elements under argon atmosphere. A total of 20 g of elements taken in stoichiometric proportions were melted together and as-cast ingot was broken into smaller pieces, wrapped in a tantalum foil and sealed inside a fused-silica tube under helium. Annealing was done at 1050°C then crushed in an agate mortar inside an argon-filled glove box. The powder was then dry ball-milled using a SPEX8000 mill under argon atmosphere and was used for characterization. Fig. 1 compares magnetization vs temp. for three samples. Transition at 300K for the sample stored in vacuum is between ferromagnetic and paramagnetic states of the $La(Fe_xCo_ySi_{1-x-y})_{13}$ phase. The sample stored in deionized water for 14 days shows no obvious magnetic transition(s), and retains large magnetization beyond 400 K. This is indicative of relatively fast hydrolysis and removal of some or all La as hydroxide from fine powders, leaving behind La-poor or, potentially, La-free Fe-Co-Si containing ferromagnetic residue with much higher Curie temp. The sample stored in air for 14 days shows a broadened transition, still at 300K, and it retains large magnetization beyond 300K. Like water, air with 30-50% humidity, removes La from the fine powders in the form of mixed lanthanum oxides and hydroxides at a slower rate compared to water. Both show high saturation magnetization and permeability, (Fig. 1). XRD analysis (Fig. 2) reveals similar Bragg scattering by all three samples, where the concentration of the La-free, Fe-Co-Si solid solution phase is clearly enhanced in samples stored in air and water compared with the sample stored in inert atmosphere. Complete interpretation of the powder diffraction patterns and measurements of magnetocaloric effect (that is expected to be lower for the samples stored in water and air) are ongoing and will be presented.

W10-11. Magnetostriction in Bulk Rare Earth Doped Galfenol.

M.C. Grijalva Castillo[1], M.O. Adelani[2], J.S. Uribe Chavira[2], M. Botello-Zubiate[2], R. Sáenz-Hernandez[2], C. Santillan-Rodriguez[2] and J. Matutes-Aquino[2] *1. CONACYT - Centro de Investigación en Materiales Avanzados, S.C., Chihuahua, Mexico; 2. Centro de Investigación en Materiales Avanzados, S.C., Chihuahua, Mexico*

The importance of magnetostrictive materials, such as Fe-Ga alloys (galfenol), in modern industry ranges from active vibration control, control surface deployment and energy harvesting, to stress and torque sensing. Galfenol has been reported to have moderate magnetostriction (~350 x 10^{-6} in single crystal) under low magnetic fields, is relatively inexpensive, shows low hysteresis and high Curie temperature, high tensile strength and limited variation in magneto-mechanical properties [1]. Also, is machinable, ductile, can be welded and is corrosion resistant [2]. Recently has been reported a drastically improvement in the magnetostriction coefficient of polycrystalline Galfenol melt spun ribbons doped with rare earths such as Tb [3-5] and Dy [6]. The practical application of melt-spun ribbons could be limited by their brittle nature, their small size and the increase of the costs in fabrication. In this work, bulk samples of $Fe_{80}Ga_{20}Tb_x$ and $Fe_{80}Ga_{20}Dy_y$ were fabricated by arc melting under argon atmosphere. The composition of the samples was verified by energy dispersive X-Ray spectroscopy microanalysis. The crystalline structure was observed by X-ray diffraction using Cu Kα radiation and Rietveld refinement. Magnetostriction was measured using a Quantum Design Dilatometer for a Physical Properties Measurement System (PPMS) with an applied magnetic field up to 1 Tesla at room temperature. X-Ray diffraction results are shown in Figure 1 and the transversal magnetostrictive coefficients are plotted in Figure 2. For $Fe_{80}Ga_{20}$ samples, all peaks were indexed to a single A2 bcc structure. The addition of Tb induced the formation of a secondary DO3 phase which is known to decrease the magnetostrictive coefficient [7]. However, the application of heath treatment under vacuum at 1000 °C for 2 hours and subsequent quenching improved the magnetostriction coefficient three times while decreasing the magnetic field needed for saturation. Meanwhile, Dy doped samples showed a change in sign of the transversal magnetostrictive coefficient.

W11-01. Electronic and magnetic properties of single-layer MPX_3 metal phosphorous trichalcogenides. *B. Chittari*[1], Y. Park[1], D. Lee[1,4], M. Han[1], A. MacDonald[2], E. Hwang[3] and J. Jung[1] *1. University of Seoul, Seoul, The Republic of Korea; 2. University of Texas at Austin, Austin, TX, United States; 3. Sungkyunkwan University, Suwon, The Republic of Korea; 4. Gwangju Institute of Science and Technology, Gwangju, The Republic of Korea*

We survey the electronic structure and magnetic properties of two dimensional (2D) MPX_3 (M= V, Cr, Mn, Fe, Co, Ni, Cu, Zn, and X = S, Se, Te) transition metal chalcogenophosphates to shed light on their potential role as single-layer van der Waals materials that possess magnetic order. Our *ab initio* calculations predict that most of these single-layer materials are antiferromagnetic semiconductors. The band gaps of the antiferromagnetic states decrease as the atomic number of the chalcogen atom increases (from S to Se to Te), leading in some cases to half-metallic ferromagnetic states or to non-magnetic metallic states. We find that the competition between antiferromagnetic and ferromagnetic states can be substantially influenced by gating and by strain engineering. The sensitive interdependence we find between magnetic, structural, and electronic properties establishes the potential of this 2D materials class for applications in spintronics.

W11-02. Magnetic moments and correlation effects in Co-doped Nb and V clusters. A. Diaz Bachs[1], L. Peters[1], V. Chernyy[1], R. Logemann[1], J. Bakker[2], M. Katsnelson[1] and *A. Kirilyuk*[2] *1. Institute for Molecules and Materials, Radboud University Nijmegen, Nijmegen, Netherlands; 2. FELIX Laboratory, Radboud University, Nijmegen, Netherlands*

Small magnetic clusters are attracting significant interest due to their unique behavior, such that every added atom significantly affects the properties [1]. All energy levels in the clusters are discrete and tunable by varying their size, leading to the unique possibility to tune the microscopic correlations and thus macroscopic properties, to our needs. In this work we present a comprehensive study of the mechanisms governing the formation of magnetic moments in small Nb and V clusters doped with single Co impurity. Our magnetic deflection experiments demonstrate a strong size dependence of magnetic properties, with large magnetic moments in some clusters, and fully non-magnetic behavior of others. This striking absence of magnetism of Co can be accounted for in two different ways. Either there is no local Co magnetic moment or it is screened by the delocalized electrons, i.e. the Kondo effect. The first experimental challenge is to obtain exact geometries of the clusters, as very few techniques are available. We solve this by measuring their vibrational spectra at the FELIX free electron laser, and then fit them with those obtained from DFT calculations. From the theoretical perspective, the difficulty in explaining the observed magnetic behavior is in the treatment of the electronic correlations. One could expect correlations to be stronger in small clusters than in the bulk due to a stronger localization of the wave-functions. On the other hand, for the clusters less screening channels are present, leading to an almost constant Coulomb interaction [2] and thus rendering correlations effects to be unimportant. Thus, in order to obtain a physical understanding of the experimentally observed magnetic behavior, we perform an analysis based on the Anderson impurity model [3,4]. From this analysis it is observed that the absence of a magnetic moment in the doped clusters is due to an absence of the Co moment and not the Kondo effect [5]. Moreover, the magnetic behavior of the Co impurity can be understood from an inspection of the electronic structure. Magnetism is favored when the effective hybridization around the chemical potential is small, while the large hybridization quenches the magnetic moment entirely.

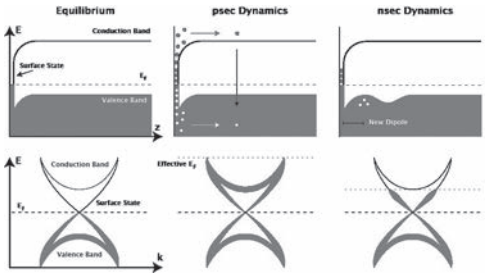
W11-03. Magnetic ordering on a boron-doped Si(111)-$\sqrt{3} \times \sqrt{3}$ surface. *C. Moon*[1], D. Eom[1] and J. Koo[1] *1. Quantum Technology Institute, Korea Reserach Institute of Standards and Science, Daejeon, The Republic of Korea*

We perform first-principles calculation to investigate the possible magnetism on the Si(111)-$\sqrt{3} \times \sqrt{3}$ surface, which is stabilized for highly boron-doped samples. When the silicon adatom on top of a boron atom is removed to form a defect structure, three silicon dangling bonds are exposed, generating half-filled doubly degenerate energy levels in the band gap, which stabilizes a local magnetic moment of 2 μ_B. When many such defect structures are adjacent to one another, they are found to align antiferromagnetically. However, we demonstrate that the ferromagnetism can be stabilized by adjusting the number of electrons in the defects, suggesting a possibility towards spintronic applications for this unique silicon surface structure.

W11-04. Angle resolved photoemission spectroscopy study of Ce-doped Bi_2Se_3 3D topological insulator. *E. Lee*[1], S. Seong[1], J. Kim[2], M. Jung[2], B. Park[3] and J. Kang[1] *1. Physics, The Catholic University of Korea, Bucheon, The Republic of Korea; 2. Department of Physics, Sogang University, Seoul, The Republic of Korea; 3. Pohang Accelerator Laboratory, Pohang, The Republic of Korea*



Three-dimensional (3D) topological insulators (TIs), which have the metallic surface states inside the insulating bulk energy gap, were identified for Sb_2Te_3, Bi_2Te_3, and Bi_2Se_3. Among them, Bi_2Se_3 has been studied extensively due to its characteristic of a very large bulk bandgap and a simple Dirac cone-shaped surface-state band. According to the previous studies, the Dirac point of Be_2Se_3 is near ~0.3 eV and there is no energy gap between the bulk valence band and the surface-state band near the Dirac point. It has been reported that, when divalent Fe^{2+} magnetic impurities are substituted for Bi^{3+} sites, an energy gap occurs near the Dirac point.[1] But, in this case, when divalent (2+) magnetic impurities are substituted for trivalent ions (3+), charge carriers are doped concomitantly, which makes it difficult to observe the purely magnetic impurity effect. This problem might be solved if trivalent (3+) rare earth ions, such as Ce^{3+} and Gd^{3+}, are substituted for Bi^{3+}.[2] In this study, we have investigated the electronic structure of Ce-substituted $(Bi_{2-x}Ce_x)Se_3$ ($0 \le x \le 0.12$) by employing angle resolved photoemission spectroscopy (ARPES). The circular-shape Fermi surface (FS) was observed for x=0, consistent with the previous studies. Magnetic force microscopy (MFM) and Ce 4f resonant ARPES measurements showed that doped Ce ions were substituted well in $(Bi_{2-x}Ce_x)Se_3$. In contrast, no appreciable changes were observed in the measured FS and the dispersive ARPES images for $0 \le x \le 0.12$, suggesting that $(Bi_{2-x}Ce_x)Se_3$ are antiferromagnetic TIs. The origin of this finding is under study by employing high-resolution ARPES.

The realization of intrinsic topological materials provides new mechanisms for the development of novel electronic and optical devices. In this study, we utilize Time-Resolved Angle-Resolved Photo-Emission Spectroscopy (TrARPES) to observe a surface photovoltage in p-doped Bi_2Se_3 with a lifetime on the order of 2 nanoseconds. The topologically protected spin-locked surface states of this topological insulator create an ideal situation for a surface photovoltage akin to surface localized gap states in conventional semiconductors and produces a chemical potential shift around 150 mV. Moreover, we discuss the importance of the the Fermi-level with respect to the bulk gap and the spin-momentum locking of the surface state on the nature of this strong and long lived excitation.

Fast dynamics that take place within 10 picoseconds of pump pulse correspond to high energy excitations that move freely into the bulk bands. Long nanosecond dynamics are due to the migration of the holes from the photo-excited electron-hole pairs into the bulk leaving subgap energy electrons to remain at the surface above E_f.

W11-06. Formation of antiferromagnetic NiO spiral domain and its effect on the magnetic anisotropy in Py/NiO/$Co_{0.5}$ $Ni_{0.5}$O/vicinal Ag(001). *M. Yang*[1], Q. Li[1], N. Gao[1], A.T. N'Diaye[2], Q. Dong[1], C. Klewe[2], P. Shafer[2], E. Arenholz[2], C. Hwang[3], J. Li[4] and Z. Qiu[1] *1. Physics, University of California, Berkeley, Berkeley, CA, United States; 2. It has been a fundamental issue on how the Mauri's model describes the effect of an antiferromagnetic (AFM) layer on a ferromagnetic (FM) layer. Although recent result shows that Mauri's model not necessarily gives raise an exchange bias, it is unclear on how the planar spiral domain in the AFM layer induces a magnetic anisotropy in the FM layer in a FM/AFM system. Here we report an experimental study of Py/NiO/$Co_{0.5}Ni_{0.5}$O/vicinal Ag(001) system using x-ray linear dichroism (XMLD) and rotating magnetic field magneto-optic Kerr effect (ROTMOKE). The $Co_{0.5}Ni_{0.5}$O frozen AFM spins are aligned by the vicinal surface atomic steps and pin the NiO spins at the NiO/$Co_{0.5}Ni_{0.5}$O interface. In this way, as the top Py layer magnetization is rotated by an external magnetic field, the Py/NiO interfacial coupling rotates the NiO spins at the Py/NiO interface to twist the NiO spins into a planar spiral domain. As a function of the NiO thickness, we measured the NiO spiral spin structure using XMLD and the Py magnetic anisotropy using ROTMOKE. We find that the NiO AFM spins are almost frozen below ~3nm thickness, gradually develop into a planar spiral domain wall in the range of 3-16nm, and complete the domain wall formation thicker than ~16nm. Correspondingly, the frozen, incomplete spiral, and complete spiral NiO domain walls are well revealed in the magnetic anisotropy of the Py layer.

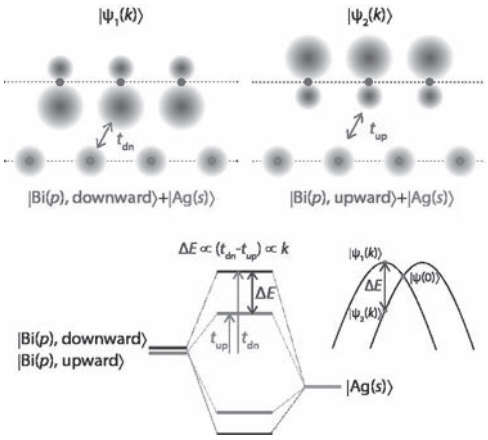
W11-07. First-principles study of magneto-optical Kerr effect in antiferromagnets. *T. Koretsune*[1], M. Suzuki[2] and R. Arita[2] *1. Physics, Tohoku University, Sendai, Japan; 2. RIKEN, Saitama, Japan*



Magneto-optical Kerr effect (MOKE) has been known as a powerful tool to investigate magnetic properties of materials. Usually, the MOKE has been observed in ferromagnets or ferrimagnets and the net magnetic moment has been considered to be crucial for the Kerr rotation angle. In the recent experiment, however, a large Kerr rotation angle is detected in the antiferromagnet, Mn_3Sn[1]. Such behavior is also expected theoretically in Mn_3Ir[2] and explained by the cluster multipole theory[3]; Namely, not only a cluster dipole moment (ferromagnetic moment) but also a cluster octupole moment can induce the MOKE. In this study, we show that the MOKE in weak ferromagnets, where the Dzyaloshinskii-Moriya interaction induces canted ferromagnetic moment, is also explained by the cluster octupole moment. Furthermore, we find that the Kerr rotation angle in such antiferromagnets or weak ferromagnets rapidly oscillates with the wavelength of the incident light, which is in sharp contrast to the case of ferromagnets. We discuss that this difference comes from the energy distribution of the angular momentum in the electronic structures.

W11-09. Giant Rashba-type spin splitting through spin-dependent interatomic-hopping. *J. Hong*[1], J. Rhim[2], I. Song[2], C. Kim[2], S. Park[3] and J. Shim[1] *1. POSTECH, Pohang, The Republic of Korea; 2. Seoul National University, Seoul, The Republic of Korea; 3. Incheon National University, Incheon, The Republic of Korea*

Rashba-type spin splitting (RSS) has recently drawn added attention due to its central role in the field of spintronics. In that regards, designing materials with giant RSS is highly desirable for practical spintronic applications, and thus disclosing the origin of the giant RSS could pave the way for it. Here, we theoretically demonstrate that the giant RSS emerges from the spin-dependent interatomic-hopping, not from a uniform electric field. Our density functional theory calculation and tight-binding analysis show that the interatomic-hopping strength between the surface and subsurface are spin-dependent as a result of the spin-dependent asymmetric charge distribution around the surface. This new interpretation on the RSS successfully explains the giant RSS in Bi/Ag(111) surface states and has implication for the RSS mechanism in general.

Rare earth iron garnet thin films with perpendicular magnetic anisotropy (PMA) have recently attracted a great deal of attention for spintronic applications. The first of these materials to be successfully grown and characterized was thulium iron garnet (TmIG). The spintronic properties and spin-orbit torque switching of TmIG has been reported in the literature[1–3]. However, TmIG is not the only rare-earth iron garnet that can be grown with PMA. We report the growth, magnetic and spintronic properties of epitaxial terbium iron garnet (TbIG) and europium iron garnet (EuIG) thin films with PMA. Reciprocal space maps show that the films are lattice matched to the substrate without strain relaxation, even for films up to 70 nm thick. The lattice strain produces PMA in certain cases due to magnetostriction. TbIG grows on (111) GGG with PMA due to the in-plane compressive strain, whereas TbIG on (111) SGGG is in tension and has an in-plane easy axis. EuIG grows with PMA on (100), (110), and (111) GGG substrates, which facilitates the investigation of orientation-dependent spintronic properties. Both garnets have excess rare earth which is believed to occupy Fe octahedral sites and in the case of TbIG leads to an increase in the compensation temperature to 330K, higher than the bulk value. EuIG films have magnetization of ~70 kA/m and coercivities in the range of 10-100 Oe whereas the room temperature magnetization of TbIG is ~20 kA/m due to the proximity to the compensation temperature. Anomalous Hall effect (AHE) measurements of Pt/TbIG Hall crosses showed a sign change at the compensation point, analogous to findings in all-metallic compensated ferrimagnets, and indicating that the effect originates from one sublattice rather than the net magnetic moment. AHE measurements of Pt/EuIG Hall crosses show that the spin mixing conductance of Pt/EuIG is orientation-dependent, with G_i values for (111) EuIG being an order of magnitude larger than those of (001) EuIG. Finally, FMR data gives a Gilbert damping constant of 0.025 for 26nm thick EuIG (111).

W12-03. Observation of complementary transistor operation using the Rashba channel. *Y. Park*[1], J. Choi[1], H. Kim[1], J. Chang[1] and H. Koo[1,2] *1. Spin Convergence Research Center, Korea Institute of Science and Technology, Seoul, The Republic of Korea; 2. KU-KIST Graduate School of Converging Science and Technology, Korea University, Seoul, The Republic of Korea*

The spin-field effect transistor (Spin-FET), proposed by Datta and Das[1] and proved experimentally by H. C. Koo, *et al*[2], is one of the candidates for the next generation device due to low power consumption, high speed, and nonvolatility. The spin-FET consists of ferromagnetic electrodes (FMs) on an InAs-based Rashba channel. The manipulation of spin-procession angle by a gate electrode is main mechanism of Spin-FET. The Rashba field arises along the *y*-axis in a semiconductor quantum well, so the magnetization direction of source and drain should be along the *x*- or *z*-axis perpendicular to the Rashba field to induce spin precession. Previous reports used the *x*-axis source and drain so external magnetic field had to be applied for saturating FMs[2]. To be utilized for the spin logic gate, we should operate spin transistor without an external magnetic field and therefore in this research we suggest parallel- and antiparallel types of spin-FET (P-ST and AP-ST) which can

replace conventional *n*- and *p*-MOSs[3] as shown in Fig 1. In this experiment, we choose the FMs with magnetization along the *x*-axis. The lateral sizes of FMs are 0.5 μm × 15 μm and are 0.8 μm × 15 μm, respectively. Since the shape anisotropy leads to a FM magnetization along the *y*-axis, we employ an exchange bias field along the *x*-axis using $Co_{84}Fe_{16}/Ir_{22}Mn_{78}$ bilayers. During the sputtering of $Co_{84}Fe_{16}$ and $Ir_{22}Mn_{78}$, we applied magnetic fields of +20 mT and −20 mT along the *x*-axis, respectively. Due to interfacial exchange interactions between the $Co_{84}Fe_{16}$ and $Ir_{22}Mn_{78}$, the first interfacial layer of $Ir_{22}Mn_{78}$ has the same magnetization direction as the $Co_{84}Fe_{16}$ layer. The antiferromagnetic order of $Ir_{22}Mn_{78}$ causes subsequent layers to have alternating magnetizations. The antiferromagnetic order is very stable, so that the ferromagnetic $Co_{84}Fe_{16}$ layer retains its magnetization direction even without a magnetic field. The ferromagnet/anti-ferromagnet bilayers have +35.5 mT and −36.3 mT of exchange bias. We experimentally realized the complementary spin transistor operation using those parallel and antiparallel types spin-FET[3] as shown in Fig. 1.

W12-04. Monotonicity of the spin signal by controlling the growth of silver in Py/Ag/Py lateral spin valves. *G. Stefanou*[1], K.A. Moran[1], M. Ali[1], M. Rosamond[3], G. Burnell[1] and B. Hickey[1] *1. Physics and Astronomy, University of Leeds, Leeds, United Kingdom; 3. Electronic and Electrical Engineering, University of Leeds, Leeds, United Kingdom*

The downturn of the spin signal (ΔRs) at low temperatures (T) split the scientific community. A side supports that it is due to scattering that occurs in the oxidised outer sides of the normal metal channel (NM)[i] and another one that derives from scattering from magnetic impurities (MI) either in the edges of the NM[ii] or in the bulk of it[iii]·[iv]. According to the latter, the cleaner the structure the more the spin signal follows an Elliot-Yafet type of scattering mechanism. In silver (Ag) based lateral spin valves (LSVs) this downturn is apparent as well[v]. Our devices were fabricated using a combination of electron beam and thermal evaporation through a shadow mask defined by electron beam lithography in a PMMA/MMA resist and conventional optical lithography and lift-off techniques. The use of a 3-axes sample rotation stage coupled with a base pressure of 10^{-10} mbar permitted a flexible device design whilst retaining very clean interfaces between the Ag and Permalloy (Py) electrodes. We grew two sets of devices keeping the same 0.10 ± 0.02 Å/s deposition rate for Py and changing the deposition rate of Ag from 0.20 ± 0.02 Å/s in the first set, to 0.40 ± 0.03 Å/s in the second. By growing faster the NM channel, we managed to improve its micro-structure, increase the grain size and in extension decrease the resistivity and increase the ΔRs (figure 1a) and spin diffusion length (λ_{NM}). The spin transport measurements revealed that the infamous downturn in the ΔRs was only apparent in the devices where the transport channel was grown with a low deposition rate (figure 1a) and that the λ_{NM} of the fast grown NM follows a trend similar to the mean free path of electrons (figure 1b).

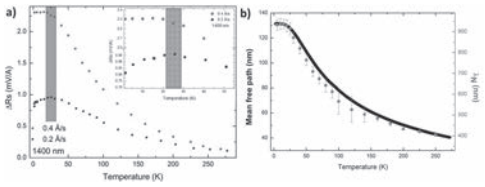

Figure 1: In red (r) are the devices grown with 0.4 Å/s and in black (bl) for the 0.2 Å/s. In (a) is a comparison of the ΔRs as a function of temperature for two devices with same L_{FM} of 1400 nm. The (r) presents a ΔRs that is higher than the (bl) and the downturn is apparent only in the (bl) as shown in the inset. In b) is comparison of the spin diffusion length of the devices where a high deposition rate was used, against the mean free path of the electrons calculated using the Drude model.

W12-05. Structural and Spin Transport Properties of Co_2FeSi/MgO/GaAs(001) Heterostructures. G. Hoffmann[1], M. Ramsteiner[1], B. Jenichen[1] and *J. Herfort*[1] *1. Paul-Drude-Institute, Berlin, Germany*

Lateral spin valve (SV) structures allow the investigation of spin generation in semiconductors (SC) as well as spin transport and detection within one device. Regarding the spin-polarized contacts, ferromagnetic Heusler alloys, such as Co_2FeSi (CFS), are of particular interest because of their halfmetallic behavior. However, the properties of CFS/SC hybrid structures are often deteriorated by the diffusion of Fe and Co into the SC. MgO interlayers at the CFS/SC interface have the potential to prevent the Fe and Co diffusion and to act as spin-filtering barriers. We studied CFS/MgO/GaAs(001) hybrid structures with different MgO layer thicknesses (0 to 2.1 nm) grown completely by molecular beam epitaxy (MBE) without breaking the vacuum during the different growth steps. X-ray reflectivity (XRR) measurements together with XRR simulations and high resolution transmission electron microscopy images confirm the successful growth of a polycrystalline MgO film on GaAs substrate. Furthermore, no precipitates of Fe and Co in GaAs are found for MgO interlayer thickness of 1.6 nm indicating MgO works successfully as diffusion barrier. Magnetic measurements reveal a rotation of the easy axis of magnetization for all samples with MgO by 90° with respect to samples without MgO. For the evaluation of the spin generation and transport, SV devices were processed and investigated by utilizing a nonlocal SV arrangement. The current-voltage characteristics of the Co_2FeSi/MgO/GaAs contacts approves MgO interlayers effectively working as tunnel barrier. Regarding the spin injection, both the non-local spin valve and non-local Hanle arrangement provide clear signatures of spin polarized electrons. For samples with MgO interlayers, qualitatively changed spin transport properties due to the defect structure at the different interfaces were observed. The spin generation efficiency increases for samples with MgO layer thicknesses between 0.8 and 1.3 nm compared to samples without MgO as shown in Fig. 1. Our results demonstrate the potential benefit of MgO interlayers in Co_2FeSi/MgO/GaAs hybrid systems for future device applications.

W12-06. Inverse spin-Hall effect in Pd/$Ni_{80}Fe_{20}$ bilayer films under a mechanical strain. *K. Yasuda*[1], Y. Teki[2], H. Tsujimoto[3] and E. Shikoh[3]
1. Graduate School of Engineering, Osaka City University, Osaka, Japan; 2. Science, Osaka City University, Osaka, Japan; 3. Engineering, Osaka City University, Osaka, Japan

The magnetic anisotropy of a ferromagnetic film deposited on a flexible substrate is changed by deformation of the films[1]. It is also expected for increasing magnetic anisotropy to affect output voltage properties due to inverse spin-Hall effect (ISHE) induced by the spin-pumping. This is because the spin-pumping is caused by the ferromagnetic resonance (FMR). In this study, a $Ni_{80}Fe_{20}$/Pd bilayer sample, which has quite small magnetocrystalline anisotropy, was formed on a PET substrate and the FMR and ISHE voltage properties of the films were investigated under a mechanical strain. A $Ni_{80}Fe_{20}$ (25)/Pd (10 nm in thick) bilayer samples were prepared on a PET substrate by using an electron-beam deposition under the vacuum of 10^{-6} Pa. After the depositions, the samples were bent along pedestals having curvature radius is 7.5, 10.0, or 12.5 mm. By this operation, different strains were applied to the samples. The FMR was excited by an electron spin resonance system. When the FMR of the $Ni_{80}Fe_{20}$ of samples was excited, a spin current was generated in the Pd layer by the spin-pumping. Then, the spin current was converted to a charge current due to the ISHE in the Pd layer, and detected as an electromotive force. All measurements were performed at room temperature. The FMR field was shifted to the higher magnetic field side as the strain increased. And the output voltage due to the ISHE of samples placed along the 7.5 mm pedestal was 5.83 μV, while that of the non-strained sample was 6.71 μV. Thus, the output voltage became 0.87 times by applying the strain compared to without any applying strain. The output voltages depended on the magnitude of the strain. These results indicated that the output voltage due to the ISHE was decreased by increasing the magnetic anisotropy due to deformation of the films.

W12-07. Vertical spin transport in Cu with $Ni_{80}Fe_{20}$/Cu/Pd trilayer films using the spin-pumping. *T. Kitamura*[1], Y. Teki[3] and E. Shikoh[2]
1. Graduate School of Engineering, Osaka City University, Osaka, Japan; 2. Engineering, Osaka City University, Osaka, Japan; 3. Science, Osaka City University, Osaka, Japan

Cu is a promising material for spintronics because it is industrial friendly and has long spin diffusion length. Previously, spin transport in Cu was achieved by an electrical spin injection method from $Ni_{80}Fe_{20}$(Py), which had very small anisotropy, to Cu directly [1]. In that method, thin wire structure samples had to be prepared for matching the interface resistances between materials, which was not easy to form and needed lithography systems. Meanwhile using the spin-pumping method induced by ferromagnetic resonance(FMR), we don't need making the wire samples. Using this method and $Y_3Fe_5O_{12}$(YIG), spin transport in Cu was achieved [2]. However, YIG was needed a district condition to induce a pure spin current, and it was difficult to find the condition, especially on industries. In this study, we demonstrate successful vertical spin transport in the Cu layer of Py/Cu/Pd trilayer films by using the spin-pumping at room temperature. A Py (10)/Cu (10-50)/Pd (10 nm in thick) trilayer sample was prepared on a Si/SiO_2 substrate by using electron beam deposition under the vacuum of 10^{-6} Pa. The Cu layer was easily oxidized, so Cu and Py layers were sequentially formed without breaking the vacuum after the Pd deposition. The pure spin current is generated in the Cu layer by the spin-pumping with the FMR of the Py film. The generated spin current is absorbed into the Pd layer. Then the spin current is converted into a charge current by the inverse spin-Hall effect(ISHE) in the Pd layer, and detected as an electromotive force. An electromotive force was observed from the samples under the FMR of the Py film, and the sign of the electromotive force was inverted at the magnetization reversal of the Py film, which is a typical behavior of the ISHE. That is, we successfully demonstrated the vertical spin transport in the Cu layer by the spin-pumping. The electromotive force exponentially decayed as the thickness of the Cu layer in samples became thick. Concerning this, the spin diffusion length of the Cu was estimated to be 34.5nm which was short comparing to the preceding study [1].

W12-08. Determining the Spin Diffusion Length in a Cobalt Iron alloy through Spin Absorption. *K.A. Moran*[1], G. Stefanou[2], M. Rosamond[5], M. Ali[2], G. Burnell[2], O. Kazakova[3] and B. Hickey[2] *1. Condensed Matter, University of Leeds, Leeds, United Kingdom; 2. Physics and Astronomy, University of Leeds, Leeds, United Kingdom; 3. National Physical Laboratory, Teddington, United Kingdom; 5. Electrical Engineering, University of Leeds, Leeds, United Kingdom*

The high polarization of Cobalt Iron (CoFe) makes it an ideal electrode material for spin current generation and detection in lateral spin valves (LSV). Here, the spin signal,ΔR_S, is the difference in resistance between parallel and antiparallel electrode states. The temperature dependence of elucidates the underlying physics and from it we can extract key material parameters such as material spin diffusion lengths, λ, and ferromagnet polarization, α. Contrary to expectations, was observed by a number of groups to reduce at low temperatures. This behaviour was explained as a manifestation of the Kondo effect arising from the magnetic impurities present in the bulk of the normal metal and at the interfaces with the electrodes due to inter-diffusion. For the latter, this effect was thought to reveal itself in the low temperature reduction of the extracted. However, this interpretation relies on the assumption that the other interdependent and unknown parameter, the ferromagnet spin diffusion length, $\lambda_{FM,}$ follows the empirical relationship $\lambda_{FM}(T) \propto 1/\rho_{FM}(T)$. It is imperative to attempt to independently determine this parameter in order to clarify if a Kondo effect is truly at the heart of the observed behaviour. We therefore employ the spin absorption technique to uniquely determine the temperature dependence of the spin diffusion length of CoFe and thus confirm α(T).

W12-09. Evidence for anisotropic Berry phase effect in epitaxial MnAs films. *J. Ma*[1], H. Wang[1], X. Wang[1] and J. Zhao[1] *1. State Key Laboratory of Superlattices and Microstructures, Institute of Semiconductors, Chinese Academy of Sciences, Beijing, China*

Berry phase effect on electronic properties has been recognized in many branches of physics, and it is continuously found to be responsible for many novel physical phenomena. In this work, utilizing the epitaxial capability of hexagonal MnAs films on cubic GaAs substrates with various orientations, the anisotropic Berry phase effect in MnAs films has been systematically investigated. Specifically, the Berry phase effect is characterized by the intrinsic anomalous Hall conductivity γ, which is extracted via treating various scattering sources independently. More than 50% change of γ is observed when changing the electric current direction from MnAs [2-1-10] to [0001], while γ varies moderately for the cases of applying the current along two orthogonal directions in the close-packed crystal plane. The above

phenomena can be explained under the framework of anisotropic spin-orbit interaction, which is revealed by the giant anisotropic magnetoresistance. Our results provide solid experimental data for the theory of the anisotropic Berry phase effect and its contribution to the anomalous Hall effect.

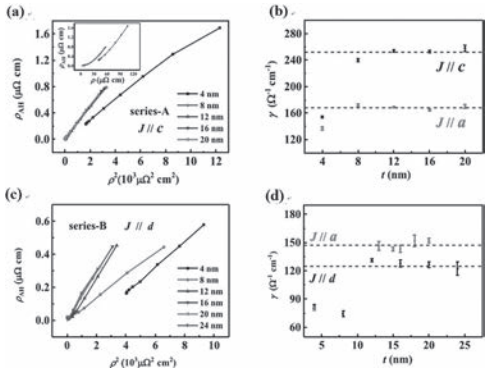

Fig. 1. Anomalous Hall resistivity, ρ_{AH} as a function of the square of longitudinal resistivity, ρ^2 in MnAs (a) (01-10) and (c) (0001) films with different thicknesses. Intrinsic anomalous Hall conductivity, γ as a function of the thickness in MnAs (b) (01-10) and (d) (0001) films, and the electric current is applied along two orthogonal directions in both series of MnAs films.

W12-10. Two types of sign change of anomalous Hall effect in heavy metal/ferrimagnetic insulator heterostructures. *Q. Shao*[1], A.J. Grutter[2], C. Tang[3], G. Yu[1], Y. Liu[3], C. Yang[1], D.A. Many nonmagnetic functional materials exhibit novel quantum transport properties upon the introduction of magnetic order. This can be achieved directly by introducing magnetic dopants, but this method may be accompanied by unwanted degradation of crystallinity of the functional materials. Exchange coupling between functional materials and magnetic insulators allows time-reversal symmetry breaking without introducing disorder. When ferrimagnetic insulator is used to introduce exchange coupling, the sublattice effect must be examined carefully. Here, we report the observation of two types of sign change of exchange coupling-induced anomalous Hall effect (AHE) in a bilayer consisting of a tungsten (W) thin film and a ferrimagnetic insulator thulium iron garnet ($Tm_3Fe_5O_{12}$ or TmIG) thin film. We first study the exchange coupling effect using polarized neutron reflectometry and X-ray magnetic circular dichroism. These spectroscopic results suggest that the magnetic proximity effect (MPE) [1] turns on at low temperature and induces a net magnetic moment in the W that is antiferromagnetically coupled to the Fe sublattice. Through magnetotransport measurements, we show that the spin current effect [2-3] dominates at elevated temperatures. The competition of spin current effect and MPE leads to the first type of sign change of AHE. Temperature-dependent AHE's in W/TmIG with different TmIG thickness (t_{TmIG}) reveal that the onset temperature of MPE increases with the t_{TmIG}, which is consistent with the enhanced magnetism of TmIG with the t_{TmIG} [4]. The second type of sign change of AHE occurs at the magnetization compensation temperature; this shows that the Fe sublattice dominates the interfacial exchange coupling and sign of AHE follows the direction of the Fe sublattice. Our results could serve as a standard reference for future exchange coupling-based studies and spintronic, magnonic, and spin caloritronic applications. The work done at UCLA was supported by the DOE-EFRC-SHINES and SRC-FAME.

W12-11. Extraordinary Hall effect in Pd/[Co-SiO_2] multilayer thin films with perpendicular magnetic anisotropy. *S. Michea*[1], S. Oyarzún[2] and J.C. Denardin[2] *1. Institute of Applied Chemical Sciences, CEDENNA, Universidad Autónoma de Chile, Santiago, Chile; 2. Physics Department, CEDENNA, Universidad de Santiago de Chile, Santiago, Chile*

In this work, it is reported the change in the extraordinary hall resistivity in Pd/Co multilayer thin films fabricated by sputtering due the inclusion of an insulating SiO_2 material. The first system studied is constituted by a Pd/Co-SiO_2 multilayer thin films, where the insulating layer was introduced by different methods to obtain the maximum increment in the hall resistivity, this means by alternate sequential sputtering and co-sputtered deposition where the relative concentration between the ferromagnetic and the insulating materials was kept over the metal-insulator transition. It is observed that the highest hall resistivity was achieved when the sputtered Co film was embedded in the SiO_2 insulator matrix while the perpendicular magnetic anisotropy still remains. With the prior consideration, a second system was analysed varying the relative concentration between the ferromagnetic and the insulating materials from metallic behaviour to the metal-insulator transition in order to tailoring the effect over both, the magnetic anisotropy and the hall resistance where the best result appears on this last condition.

W13-01. Superconductivity in new Oxyanion Superconductors: $TlSr_4Cu_2O_z(SO_4)_{1-x}(CrO_4)_x$. *H. Lee[1] 1. Physics, Kangwon National University, Chuncheon, The Republic of Korea*

$TlSr_4Cu_2O_z(SO_4)_{1-x}(CrO_4)_x$ (x = 0 – 1.0) polycrystalline samples were synthesized by using a solid state reaction technique to investigate the effect of Cr substitution for S on the structure and the superconducting properties of the recently discovered superconducting compound $TlSr_4Cu_2O_z(SO_4)$. Samples were characterized by means of powder X-ray diffraction (XRD), transport, and magnetization measurements. XRD measurements revealed that the almost single-phase samples with tetragonal structure could be obtained in a range of $0 \le x \le 1.0$. The *a* lattice parameter tended to increase slightly as the chromate content x increased. All the samples showed a superconducting transition behavior and the magnetic onset transition temperatures of the samples were 74 K, 70 K, 73K, 75K, and 75 K for the x = 0, 0.25, 0.5, 0.75 and 1.0 samples, respectively and the observed superconductivity was of bulk nature.

Ionic control of materials offers an opportunity to develop novel functionalities through which the physical properties can be tuned by modifying ion distributions. For example, recent works have demonstrated control over the Cu-site valence and doping level in cuprate thin films using ionic liquid gating approaches, enabling electrical control over the superconducting transition [1,2]. Here we report a scalable solid-state approach towards doping level control in 100 nm thick films of optimally doped $YBa_2Cu_3O_{7-\delta}$ (YBCO). In our approach, a thin (3-20 nm thick) Gd capping layer is deposited onto epitaxial YBCO films. Due to its high oxygen affinity [3], the Gd initiates a solid state redox reaction at the metal/oxide interface by removing oxygen from the YBCO. X-ray diffraction and polarized neutron reflectometry measurements show an expansion of the lattice consistent with the removal of oxygen from deep within the YBCO film, not just at the interface, due to the high ionic conductivity of YBCO [4]. X-ray absorption spectra (Fig. 1) show a reduction in the Cu valence state, indicating a shift towards lower hole doping level. A drastic reduction of the critical temperature (T_c) is observed in the Gd-capped films (Fig. 2), correlated with the Gd capping layer thickness. For the film with the thickest Gd cap, the superconducting transition is completely suppressed. This work demonstrates an effective means to tune the superconducting properties of the cuprates and extends the viability of ionic control over the hole-doping level to the quasi-bulk regime. *Work supported by NSF (DMR-1610060 and ECCS-1611424). L_3-edge Resonant Inelastic X-rays Scattering (RIXS) can probe orbital, charge and spin excitations and the possibility to measure the polarization of scattered photons can greatly help the assignment of spectral features. Here, we present a study of orbital and magnetic excitations in cuprates, made at the ID32 beamline of the ESRF with full polarization selectivity and 80 meV instrumental band width. The device installed on the high resolution ERIXS spectrometer is based on a polarization-selective optical element and allows the measurement of the degrees of linear polarization of the scattered radiation. We measured Cu L_3 RIXS spectra of undoped, underdoped and optimally doped $NdBa_2Cu_3O_{7-\delta}$ (NBCO) at two different in-plane momentum transfer ($q_{//}$=0.2 r.l.u. and $q_{//}$=0.4 r.l.u. in the 10 direction), with both σ and π incident polarization. We compare experimental results to single ion model calculations for the cross sections and observe that the agreement is very satisfactory also in the polarization resolved data. To gain further insight, we looked at the "crossed" dichroism, defined as the difference between the two different crossed channels (πσ' and σπ'); these dichroic spectra highlight the progressive shift of the $3d_{xy}$ peak to lower energy loss with increasing doping. In the low energy scale (Mid-IR) we have confirmed that the main peak with π polarization has crossed character, i.e. it is almost purely spin-flip at all doping levels, not only in the antiferromagnetic parent compound.

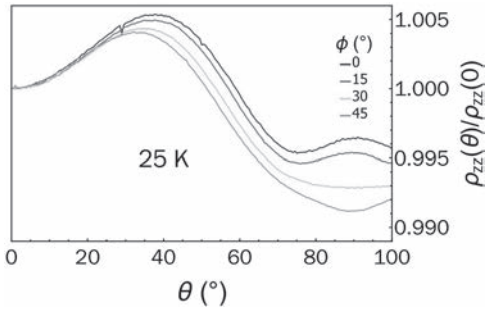
Comparison between polarization-resolved RIXS spectrum in the *dd* spectral range (left) and simulated spectrum (right) of undoped $NdBa_2Cu_3O_{7-\delta}$. Experimental data have been measured with horizontal (π) incident polarization at the scattering angle 2θ = 150° and in plane momentum transfer $q_{//}$ = 0.2 r.l.u. along the 10 direction.

W13-04. Pressure enhanced superconducting phase of the metallic double chain compound $Pr_2Ba_4Cu_7O_{15-x}$.
H. Taniguchi[2], R. Kumagai[1], M. Matsukawa[1] and T. Sasaki[3] *1. Department of Physical Science and Materials Engineering, Iwate University, Morioka, Japan; 2. Department of Physical Science and Materials Engineering, Iwate University, Morioka, Japan; 3. IMR, Tohoku University, Sendai, Japan*



The copper-oxide compound $Pr_2Ba_4Cu_7O_{15-x}$ (Pr247) is an intermediate between $PrBa_2Cu_3O_7$ (Pr123) and $PrBa_2Cu_4O_8$ (Pr124). In this compound, CuO single-chain and double-chain blocks are alternately stacked along the c-axis. In oxygen removed polycrystalline Pr247, the superconductivity appears at an onset temperature of $T_{c,on}$ =15 K. In our previous study, we examined the effect of external pressure on the magneto-transport properties in superconducting and non-superconducting polycrystalline samples. The application of pressure to the superconducting sample suppresses the superconducting transition temperature $T_{c,on}$ from 27 K at 0 GPa down to 18 K at 1.6 GPa. The negative pressure dependence of the superconducting phase is qualitatively consistent with a theoretical prediction on the basis of the Tomonaga-Luttinger liquid theory. In this presentation, we demonstrate the superconducting and normal phases of the metallic double chain compound Pr247 under a hydrostatic pressure of 2 GPa. The superconducting Pr247 shows a monotonous decrease in T_c until the applied pressure reaches 1.6 GPa. However, the applied pressure of 2 GPa causes a rapid rise in $T_{c,on}$ up to 30 K. The magnetoresistance effect according to the downward convey behaviors at low fields is observed in the normal–state temperature region above 30 K. Our findings are discussed on the basis of the model of slightly warped Fermi surfaces.

W13-05. The Fermi Surface of Nd-LSCO Inside the Pseudogap State.
B. Ramshaw[1], L. Taillefer[2], P. Goddard[3] and A. Legros[2] *1. Physics, Cornell University, Ithaca, NY, United States; 2. University of Sherbrooke, Sherbrooke, QC, Canada; 3. University of Warwick, Coventry, United Kingdom*

The relationship between the pseudogap and the Fermi surface in high-Tc superconductors remains an outstanding problem. While small electron pockets have been observed in multiple underdoped cuprates [1], these appear to be tied to the presence of charge-density wave order. There are, however, regions of the underdoped phase diagram near optimal doping that do not have charge order but still have a pseudogap [2]. The Fermi surface in this region is inaccessible at low temperature in $YBa_2Cu_3O_{6+X}$ and $HgBa_2CuO_{4+\delta}$ due to the presence of superconductivity and an extremely high upper critical field [3], leaving the "intrinsic" ground-state Fermi surface of the pseudogap a mystery. The $La_{2-x}Sr_xCuO4$ family of cuprates have highly suppressed T_cs and upper critical fields, but are too disordered to observe the low-temperature high-field Fermi surface using quantum oscillations. We have instead measured the angle-dependent magnetoresistance (AMR) - which is also sensitive to Fermi surface geometry - of $La_{1.6-x}Nd_{0.4}Sr_xCuO_4$ (Nd-LSCO) at 45 tesla. For x = 0.25, where there is no pseudogap, I will show how the AMR reveals the large unreconstructed Fermi surface as expected, with increased quasiparticle scattering near the antinodes. I will then discuss our measurements at lower doping where AMR is able to provide the first determination of the pseudogap-Fermi surface in the absence of both charge order and superconductivity. I will discuss how this impacts our interpretation of the pseudogap and how it relates to Fermi surface reconstruction in the cuprates.

The angle-dependent magnetoresistance of Nd-LSCO at 45 tesla and 25 kelvin. Theta = 0 degrees represents the field along the c-axis. The field is then rotated into the plane at an angle phi from the a-axis. The structure in the data as a function of angle provides direct Fermi-surface geometry information.

W13-06. Dual fermion approach to the Fermi arc formation in the two-dimensional square-lattice Hubbard model. *A. Tanaka*[1] *1. Department of Quantum Matters, ADSM, Hiroshima University, Higashi-hiroshima, Japan*

The filling dependence of the spectral function in the two-dimensional square-lattice Hubbard model is investigated with the ladder dual fermion approach (LDFA) [1] to discuss the formation mechanism of the Fermi arcs observed in the high-Tc cuprate superconductors. Although a numerous works has been published on this subject using the dynamical mean field theory (DMFT) and its extension to the clusters, these techniques are only capable for short-range spatial correlation. However, the importance of the long-range antiferromagnetic (AFM) fluctuation in the two-dimensional Hubbard model at the half-filling has been discussed [2]. The purpose of this study is to investigate the effects of the long-range AFM fluctuation on the spectral functions away from the half filling with LDFA, which is a perturbative extension of DMFT and can incorporate the effects of long-range correlation. Although the continuous-time quantum Mote Carlo method is used to solve the effective Anderson impurity problem in the majority of previous LDFA studies, the Lanczos exact-diagonalization technique is applied in this study. This technique is advantageous to access low temperatures and obtain accurate spectral functions on the real axis. It is found that even with a small amount of hole doping, new states are created inside the Mott gap with U/t>~6. The Fermi level is shifted to the valence band top and the pseudo-gap due to the AFM fluctuation is formed. At low doping concentrations, the pseudo-gap cases the formation of the Fermi arc. As the doping concentration increases, the formation of the pseudo-gap is limited in the vicinity of the X point and finally lost accompanied by a transition of the Fermi surface topology from electron-like to hole-like (the Lifshitz transition). These results are consistent with those of cluster DMFT [3] and dynamical cluster approximation [4] studies.

W13-07. Transport Signatures of Charge Density Wave Order and the Pseudogap Critical Point in Cuprate Superconductors. *S. Badoux*[1,2], W. Tabis[3], F. Laliberté[2], G. Grissonnanche[2], B. Vignolle[3], D. Vignolles[3], J. Béard[3], D.A. Bonn[4,5], W.N. Hardy[4,5], R. Liang[4,5], N. Doiron-Leyraud[2], L. Taillefer[2,5] and C. Proust[3,5] *1. University of Bristol, Bristol, United Kingdom; 2. Université de Sherbrooke, Sherbrooke, QC, Canada; 3. LNCMI, Toulouse, France; 4. University of British Columbia, Vancouver, BC, Canada; 5. CIFAR, Toronto, ON, Canada*

Since the observation of quantum oscillations combined with the negative Hall and Seebeck coefficients measured in high fields at low temperature revealed that the Fermi surface of cuprates undergoes a reconstruction in the underdoped side of the phase diagram, transport measurements in high magnetic fields has led to major discoveries. A few years later, the mechanism for this reconstruction was shown to be charge-density-wave (CDW) order by NMR and x-ray measurements. Understanding the mechanism of superconductivity in cuprates requires that we understand the role of the different phases present in these materials. One of the biggest mysteries remains the nature of the pseudogap phase its links and interplays with other phases. Also the pseudogap and the CDW phases both ends close to the maximum of T_c and the fluctuations associated to these phases could therefore be responsible to the high T_c. In order to study these phases at low temperature, high magnetic fields are required to suppress superconductivity in order to recover the normal state. After a brief introduction to the cuprates, I will present recent transport measurements on three cuprate materials, YBCO [1], LSCO [2,3] and Nd-LSCO [4], performed in magnetic fields large enough to suppress superconductivity at low temperature. These measurements yielded two main findings. First, the pseudogap critical doping p* and the onset of the charge-density-wave order occur at different doping values. So the two phenomena are separated. Secondly, the carrier density n is observed to drop sharply at p*, going from n = 1+p above p* to n = p below p*. This signature imposes strong constraints on the possible nature of the pseudogap phase. I will also present new pressure measurements showing that the pseudogap cannot open on an electron-like Fermi surface, and can only exist below the doping p_{FS} at which the large Fermi surface goes from hole-like to electron-like, so that $p^* \leq p_{FS}$ [5].

W13-08. Hybridization Effects on the Pseudogap of Hole and Electron Regimes of a Hubbard d-p Model. *E.J. Calegari*[1], D.d. Lalis[1], S.G. Magalhaes[2], C.M. Chaves[3] and A. Troper[3] *1. Physics, Universidade Federal de Santa Maria, Santa Maria, Brazil; 2. Physics, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 3. EXP, Centro Brasileiro de Pesquisas Fisicas, Rio de Janeiro, Brazil*

In this work, we studied the effects of a k-dependent hybridization on the normal and superconducting properties of a Hubbard d-p model. The model is treated by the Green's function technique together with a two-pole approximation [1,2] which allows the presence of a pseudogap [3] as that one observed in the normal state of cuprates superconductors. Superconductivity with singlet $d_{x^2-y^2}$-wave pairing is considered, following the factorization procedure proposed by Beenen and Edwards [2]. The model is investigated in both situations with hole and electron doping. The following different symmetries have been considered for the hybridization, the $d_{x^2-y^2}$-wave, the extended *s*-wave, and a *d-p*-wave symmetry. The main focus is to investigate how the different symmetries considered for the hybridization affect the pseudogap and the superconducting critical temperature in both hole and electron doping regimes. The results show that all the symmetries decrease the superconducting critical temperature T_c. However, while T_c is deeply affected by the hybridization with extended *s*-wave symmetry, the hybridization with $d_{x^2-y^2}$-wave symmetry is the one that least affects T_c. On the other hand, the analysis of the density of states of the normal state, shows that the hybridization with $d_{x^2-y^2}$-wave symmetry favors the pseudogap appearing while the other symmetries act in the sense of suppressing the pseudogap. The topology of the Fermi surface in the hole- and electron-doped regimes has been also investigated and the results are in agreement with recent experimental ARPES data for $La_{2-x}Sr_xCuO_4$ (hole doping) and $Nd_{2-x}Ce_xCuO_4$ (electron doping). In the hole-doped case, the pseudogap emerges at the saddle points $(0,\pm\pi)$ and $(\pm\pi,0)$ where the effects of the hybridization is stronger. On the other hand, for the electron doping regime, the pseudogap emerges at the nodal points $(\pm\pi/2,\pm\pi/2)$.

W13-10. Al-impurity-induced magnetic excitations in heavily overdoped $La_{0.7}Sr_{0.3}Cu_{0.95}Al_{0.05}O_4$. *K. Ikeuchi*[1], S. Kawamura[2], K. Nakajima[2], R. Kajimoto[2], S. Wakimoto[3], K. Suzuki[4] and M. Fujita[4] *1. Neutron Science and Technology Center, CROSS, Tokai, Japan; 2. J-PARC Center, Tokai, Japan; 3. JAEA, Tokai, Japan; 4. IMR, Tohoku University, Sendai, Japan*

The characteristic behavior of the magnetic excitations in the layered parovskite cuprates is one of primary aspects to understand various ground states realizing in the system including high-T_c superconductivity. Recently, we found that, on magnetic excitations of the cuprate superconductor $La_{2-x}Sr_xCuO_4$ (LSCO) $x = 0.25$, in which the dynamical magnetic correlation has been regarded as 4-fold incommensurate (IC) structure at around the magnetic G point $Q = (0.5, 0.5)$, new type structure evolves owing to increase temperature: the magnetic excitation with ring-like shape appears at around $Q = (0.5, 0.5)$ [1]. Furthermore, doping Fe^{3+} magnetic impurity

into LSCO $x = 0.30$, in which the magnetic correlations in low energy region disappear owing to heavily overdoping of holes, induces the ring-like excitation in addition to the IC excitations, quite similar to the magnetic excitations in the impurity-free LSCO $x = 0.25$ [2]. The fact shows an intimate relationship between the temperature-change and impurity-substitution on the magnetic correlations in the cuprate superconductor and can be a key to understand how the strong spin correlations give the system an inter-electron coupling behind the high-T_c superconductivity. In order to study a role of impurity in the upgrowth of the spin correlation, we performed inelastic neutron scattering experiments to observe magnetic excitations of $La_{1.7}Sr_{0.3}Cu_{0.95}Al_{0.05}O_4$, substituted by Al^{3+} non-magnetic impurity. The experiments were carried out with the chopper spectrometer BL14 AMR installed at J-PARC. We observed the IC spin-fluctuation induced by the Al-substitution. In addition to the IC spin-fluctuation, we also observed the magnetic excitation with a ring-like shape, same in the case of the Fe^{3+} substitution. In this presentation, we will discuss the Al-induced spin correlation and its temperature dependence from a dynamical point of view.

W13-11. Model-mapped RPA to determine a model Hamiltonian from first-principles. *H. Sakakibara*[5], S. Jang[2], H. Kino[3], M. Han[2], K. Kuroki[4] and T. Kotani[1] *1. Department of Applied Mathematics and Physics, Tottori University, Tottori, Japan; 2. Department of Physics, Korea Advanced Institute of Science and Technology (KAIST), Daejeon, The Republic of Korea; 3. National Institute for Materials Science (NIMS), Tukuba, Japan; 4. Department of Physics, Osaka University, Toyonaka, Japan; 5. Applied Mathematics and Physics, Tottori University, Tottori, Japan*

Physical phenomenon such as superconductivity or magnetism can be understood through low-energy models. An appropriate method to estimate the model parameters might enable us to predict novel materials. The model parameters should be determined so as to reproduce the electronic structure obtained from first-principles calculations. Then the calculation may be based on the local density approximation (LDA) or quasi-particle self-consistent *GW* approximation (QSGW) [1]. Usual low-energy models for correlated materials are given as Hubbard type models, which consist of the hopping integrals and the onsite-interactions U. The hopping integrals can be evaluated based on the Maximally Localized Wannier Function semi-automatically [2]. For the evaluations of the interaction terms, the constrained random phase approximation (cRPA) is often adopted [3,4,5]. However, as reported previously, cRPA contains several theoretical problems [6]. For example, range truncation is not considered. To overcome such problems, we have introduced a method named model-mapped RPA (mRPA) [6]. The method mRPA imposes the constraint that $W_{FP} = W_M$ on U, where W_M and W_{FP} are calculated in the discrete lattice model and first-principles, respectively. The constraint $W_{FP} = W_M$ makes U include the non-local screening effect, which is not considered in cRPA, in its value. Therefore, mRPA is expected to bring better evaluations than cRPA. In the previous SCES2016 meeting, we have presented the result of a single orbital case. In the forthcoming meeting, we will present the value of U given by two-orbital model considering the d_{z2} orbital on top of the d_{x2-y2} orbital. The former orbital probably works against the d-wave superconducting paring [7]. We also perform the fluctuation exchange approximation (FLEX) to compare the superconducting critical temperature of the two materials, La_2CuO_4 (T_c=40K) and $HgBa_2CuO_4$ (T_c=100K).

W13-12. Quantized Massive Gauge Fields, Anomalous Angle-resolved Photoemission Spectra, and Other Anomalous Properties in High-Tc Cuprates. *I. Kanazawa*[1] *1. Physics, Tokyo Gakugei University, Tokyo, Japan*

Quantized massive gauge fields, which might mediate Cooper pair formation, have been presented as collective modes, which contain effects of spin fluctuation, charge fluctuation, and phonon, around doped holes from the viewpoint of adjacent interactions, Taling into account the restoration of spontaneous symmetry breaking, we have discussed the anomalous properties in the strange metal phase and the criticality in high-Tc cuprates [1,2]. Also we have discussed the anomalous spectra of angle-resolved photoemission of high-Tc cuprates, using quantized massive collective-gauge fields, from the field-theoretical point of view [3]. The relation between the bospnic function of electric origin and the quantized massive collective-gauge fields has been discussed. The present theoretical-formula satisfies both renormalization and unitalization conditions.

W14-01. Absence of superconductivity in $Eu(Fe_{1-x}Cu_x)_2As_2$. *A. Laha*[1] and Z. Hossain[1] *1. Department of Physics, Indian Institute of Technology, Kanpur 208016, Uttar Pradesh, Kanpur, India*

The discovery of high-Tc superconductivity and the interplay between superconductivity and magnetism in iron pnictide family has been one of the most attracting research topic in condensed matter physics for several years. Conventional superconductors exhibit traditionally antagonistic behavior with magnetism while unconventional superconductivity is closely related to magnetism in heavy fermion compounds, cuprate superconductor and iron-based pnictide family. Cu substitution at Fe site in $BaFe_2As_2$ incduce superconductivity at T_c = 2.1 K by suppressing the SDW/structural transition due to Fe moments [1]. $EuFe_2As_2$ is quite interesting in iron pnictide family due to the antiferromagnetic ordering of Eu^{2+} moments and SDW type ordering of Fe moments. Magnetism related superconductivity was observed in $Eu(Fe_{1-x}Co_x)_2As_2$ [2] and Reentrant superconductivity was found in $Eu(Fe_{1-x}Ir_x)_2As_2$ [3]. We investigate the physical properties of $Eu(Fe_{1-x}Cu_x)_2As_2$ ($0 \le x \le 0.20$) by measuring electrical resistivity, magnetic susceptibility, magnetization and magnetoresistance. Powder x-ray diffraction data represent that all the members of this series crystallize in $ThCr_2Si_2$ type body centered tetragonal structure with space group *I4/mmm*. $EuFe_2As_2$ consists a spin density wave (SDW) / structural transition related with Fe moments at 195 K which is completely suppressed at $x = 0.20$ and no superconductivity is observed down to 2.5 K as shown in the figure 1. A large hump which is found at around 100 K for $x = 0.05$ was also seen in many iron pnictides at lower doping concentration [4]. The antiferromagnetic (AFM) ordering of Eu^{2+} moments at $T_N = 20$ K for $x = 0$ is decreased to $T_N = 15$ K for $x = 0.05$ which is sustained with increasing x up to $x = 0.20$ as shown in the figure 2 and it is equal to the AFM ordering temperature of $EuCu_2As_2$. Magnetization and magnetoresistance data reveal that $EuFe_2As_2$ exhibits metamagnetic transition at $T = 3$ K which is not observed for $x \ge 0.05$.

W14-02. Scaling Analysis of Magnetotransport and Linear Magnetoresistance in the High-Temperature Paramagnetic Phase of $Ba(Fe_{1-x}Co_x)_2As_2$ Series. *R. Kumar*[1], S. Singh[1,2] and S. Nair[1,2] *1. Department of Physics, Indian Institute of Science Education and Research, Pune, India; 2. Center for Energy Science, Indian Institute of Science Education and Research, Pune, India*

Comprehensive magnetotransport measurements in $Ba(Fe_{1-x}Co_x)_2As_2$ single crystalline samples are carried out [1]. Three representative compositions are studied: $BaFe_2As_2$(x = 0), x = 0.038(underdoped) and x = 0.074(optimally doped). The scaling analysis in these systems shows that both Kohler and modified Kohler's rule are violated in entire phase space of all three compositions. Interestingly, however, as an exception, modified Kohlers' rule is obeyed exceptionally well in the magnetically ordered phase of underdoped composition(3.8%Co) of this series. Additionally, Hall angle(Θ_H) shows a sudden increase at high temperatures which coincides with the broad crossover seen in interplane resistivity(ρ_c) which is interpreted as the presence of a pseudogap like phase by Tanatar et al. [2]. Remarkably, we see that magnetoresistance is linear in paramagnetic phase of all three compositions. We also see that a scaling [3] that relates linear magnetoresistance to the ratio of magnetic field and temperature(B/T) also works in the paramagnetic phase of all the compositions of this series. Possible explanations of these results are discussed.

W14-03. Possible Magnetic Pinning Effects in Substituted (Ba, Sr) Fe_2As_2 Single Crystals. *M.M. Piva*[1], T.M. Garitezi[1], P. Rosa[2], C. Adriano[1], R.R. Urbano[1] and P. Pagliuso[1] *1. DEQ, Instituto de Física Gleb Wataghin - Unicamp, Campinas, Brazil; 2. Condensed Matter and Magnet Science, Los Alamos National Laboratory, Los Alamos, NM, United States*

The discovery of the Fe based superconductors in 2008, has given the scientific community a new class of compounds with high transition temperature (T_c) superconducting states, which can be induced by the suppression of an antiferromagnetic ordering (spin density wave) as other unconventional superconductors like the heavy fermions and cuprates. All these superconductors share similar layered crystalline structures. Also, the addition of localized magnetic moments (pinning centers) in the antiferromagnetic layers leads to an enhancement of the critical current (J_c), as previously reported for some cuprates. In this regard, one could expect a similar behavior in the Fe-based superconductors. Therefore, to directly explore the effects of

pressure in the Fe 3*d* partially-localized moments and its relation with J_c we have performed critical current measurements in Cu, Co/Eu, Co/Mn and P substituted $BaFe_2As_2$ and Co substituted $SrFe_2As_2$ single crystals as a function of temperature and pressure (up to 27 kbar) with magnetic fields up to 9 T. Usually, J_c followed the behavior of T_c, but, at low pressures, a detailed analysis of the T_c and J_c evolution as a function of pressure and/or magnetic field indirectly revealed an evidence for an enhancement of the pinning effect associated with the Cu^{2+} localized and Fe^{2+} partially-localized moments. There was no evolution of the localized character of Mn^{2+} and Eu^{2+} ions, indicating an absence of hybridization with the conduction electrons in the studied pressure range, which contrasts with the Cu substituted ones. Furthermore, we have found no evidence for pinning enhancement as function of pressure/field associated with the Mn^{2+} and Eu^{2+} local moments. Moreover, we attribute the enhancement of J_c in P substituted ($BaFe_2As_2$) and Co substituted ($SrFe_2As_2$) samples to an increase in the superconducting volume as a function of pressure. Finally, we discuss our results considering the effects of applied pressure and chemical substitution in the spin density wave phase to shed new light in the evolution of J_c in these systems.

W14-04. External Pressure Studies in $Sr(Fe_{1-x}Co_x)_2As_2$ Single Crystals Grown by In-flux. M.M. Piva[1], C.B. Jesus[2], *C. Adriano*[1], R.R. Urbano[1] and P. Pagliuso[1] *1. DEQ, Instituto de Física Gleb Wataghin - Unicamp, Campinas, Brazil; 2. Departamento de Física, Universidade Federal de Sergipe, Brazil, Itabaiana, Brazil*

The iron-based superconductors were discovered in 2008. Since then a lot of attention has been given to these materials by the scientific community, driven by their high superconducting transition temperatures (T_c), their structural and antiferromagnetic transitions (T_S and T_{SDW}) and, more recently, by the nematic transition. These materials become superconducting with the suppression of an antiferromagnetic order by chemical substitution and/or application of external pressure. A lot of effort was employed to understand the parent compounds AFe_2As_2 (A = Ba, Ca, Sr, Eu), but there are only a few reports about a combined study of chemical substitution and applied external pressure in $SrFe_2As_2$ [1]. Therefore, we report electrical resistivity experiments under pressure in $Sr(Fe_{1-x}Co_x)_2As_2$ (x = 0, 0.05, 0.1 and 0.3) single crystals, grown by the In-flux technique. For the pure compound (x = 0) we have observed the spin density wave antiferromagnetic transition closely connected to the tetragonal-to-orthorhombic structural transition at 203 K at ambient pressure. Increasing pressure suppresses both transitions, but we could not see a full superconducting state, only the onset of T_c around 30 K at 22 kbar. Increasing the Co content to 0.05 decreases T_S to 182 K and T_{SDW} to 178 K and induces a superconducting state with a broad transition around 18 K. Applying pressure favors the superconductivity, which achieves a T_c of 34 K at 21 kbar, remarkably high for these compounds. For x = 0.1, at ambient pressure, T_S = 151 K, T_{SDW} = 147 K and T_c = 21 K. As a function of pressure, T_c achieved a maximum of 31 K at 24 kbar, while T_S and T_{SDW} were suppressed. With further addition of Co, x = 0.3, at ambient pressure T_S and T_{SDW} were almost completely suppressed and T_c were around 21 K. T_c increased only to 24 K at 21 kbar, indicating that the disorder in this system is high enough to disturb the superconducting state. We discuss the results, based on the temperature-pressure-composition phase diagram of our In-flux single crystals of $Sr(Fe_{1-x}Co_x)_2As_2$, considering the effects of crystal quality, pressure and chemical substitution in the evolution of the magnetic and electronic properties of these compounds.

W14-05. Investigation of the Band Structure and the Fermi Surface of $BaFe_2As_2$ and $EuFe_2As_2$ Compounds by means of Polarization Dependent ARPES. *K.R. Pakuszewski*[1], M.M. Piva[1], W.S. Silva[2], P. Rosa[3], P. Pagliuso[1] and C. Adriano[1] *1. DEQ, Instituto de Física Gleb Wataghin - UNICAMP, Campinas, Brazil; 2. Laboratório Nacional da Luz Síncrotron, Campinas, Brazil; 3. Condensed Matter and Magnet Science, Los Alamos National Laboratory, Los Alamos, NM, United States*

Since the discovery of superconductive in iron-arsenide compounds, many studies have been reported about their physical proprieties. As a common factor, all these compounds present a FeAs layer in their crystal structure, with the band structure near the Fermi level been dominated by conduction electrons from the Fe 3*d* orbitals [1]. However, their physical proprieties can present many dissimilarities, which include effective masses, size of superconducting gap and T_C itself. By this reason, studying the band structure and the Fermi surface of these compounds is very important to understand their physical behavior in low temperature, including the mechanism behind the formation of the superconducting state and the relationship with the magnetic order. In this work we present polarization-dependent angle resolved photoemission spectroscopy (ARPES) measurements for the Indium-flux grown $BaFe_2As_2$ and $EuFe_2As_2$ single crystals below and above the magnetic transition temperature (T_{SDW}) using the facilities of the Advanced Light Source at HERS 10.0.1 beamline. Our preliminary results show that the existence of five Fe 3*d* Fermi surface sheets in the paramagnetic regime for both compounds, with two electron-like bands around X-point and three hole-like bands around Γ-point of the Brillouin zone. These results agree with DFT calculations [2], which show the existence of five Fermi surface sheets with the predominance of t_{2g} orbitals (d_{xy}, d_{xz}, d_{yz}) near the Fermi level. Actually, our results suggest the contribution of bidimentional/planar orbitals (d_{xy}, $d_{x^2-y^2}$) is larger in $BaFe_2As_2$ compound than in $EuFe_2As_2$, which agree with another results of our group [3,4,5] that indicate that the predominance of bidimentional/planar orbitals favors the arise of superconductive in FeAs compounds.

Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany*

Over the last years a lot of theoretical and experimental efforts have been made to identify states with broken time reversal symmetry (BTRS) in multiband superconductors below the superconducting transition temperature (T_c). In particular, it was theoretically proposed that in the $Ba_{1-x}K_xFe_2As_2$ system either an s + is or an s + id BTRS state may exist at high doping levels in a narrow region of the phase diagram [1,2]. These complex order parameters may arise from a frustrated competition of superconducting order parameters with different symmetry [3] close to a Lifshitz transition. Here we report the observation of an enhanced zero field muon spin relaxation rate below T_c in high quality single crystalline samples in the doping range $0.8 < x < 0.7$. We found that the BTRS onset temperature T* is strongly doping dependent. At a critical doping of x=0.73, T^* is equal to T_c whereas at lower and higher doping T* is several degrees below T_C [4]. The BTRS state is also documented by anomalies in the specific heat. Our results are consistent with the multi-band s + is superconducting state in $Ba_{1-x}K_xFe_2As_2$ in this doping range [5].

AFe$_2$As$_2$ (A: Ba, Sr and Eu) with a tetragonal *I4/mmm* structure exhibits a single-Q commensurate stripe-type antiferromagnetic (sAFM) order at T_o^{Fe} with a structural change to an orthorhombic *Fmmm* structure [1-2]. This T_o^{Fe} value is suppressed by applied pressure or substitution and then bulk superconductivity emerges at low temperature [3-6]. Recently, there has been considerable interest in a new double-Q spin density wave (SDW) order because the double-Q SDW order has been found with the reentrant tetragonal structure and superconducting state in contrast to the orthorhombic sAFM state [7,8]. Two different magnetic orders in the double-Q SDW state were predicted by using a weak-coupling itinerant electron model; one is the charge-spin density wave (CSDW) with a nonuniform magnetization and the other is the spin-vortex crystal (SVC) with a noncollinear magnetization [9]. These two magnetic orders are degenerate in the regime without impurity scattering and disorders in the substituted system lift its degeneracy [9]. The magnetic structures in the coexistence phases of substituted AFe$_2$As$_2$ compounds were confirmed as the CSDW by neutron diffraction and conventional Mössbauer spectroscopy [7,8]. These results raise an intriguing question for a magnetic state in the coexistence phase with no impurity scattering. Here, we have found the new coexistence between an antiferromagnetic order in the Fe sublattice and bulk superconductivity of EuFe$_2$As$_2$ and SrFe$_2$As$_2$ under pressure by ^{57}Fe nuclear forward scattering using a single crystal sample. The magnetic state in the Fe sublattice changes to a new antiferromagnetic one with superconductivity from a sAFM state observed in normal conducting state with decrease in the magnetic hyperfine field at the Fe nuclei. The emergence of the new antiferromagnetic order with superconductivity provides crucial knowledge for discussing a pairing glue of superconductivity in AFe$_2$As$_2$ under pressure.

Superconductivity in iron-based compounds emerges when long-range antiferromagnetic order is suppressed by doping, pressure or atomic disorder. This, and the similarity with other unconventional superconductors, such as the high-Tc cuprates, indicates an important role of magnetic fluctuations in the pairing mechanism. Elucidating the nature of the magnetic ground state of iron-based superconductors is therefore of paramount importance in unveiling the mechanism behind their high-temperature superconductivity. Originally, it was thought that superconductivity emerges only from an orthorhombic, antiferromagnetic stripe phase with two competing scenarios for its origin; one a more localized picture in which orbital ordering drives both the structural and magnetic transitions, and a second, itinerant scenario in which stripe-SDW magnetism is the primary instability. However, we recently observed that tetragonal symmetry is restored inside the magnetically ordered state of hole-doped compounds [1], revealing the existence of a new magnetic phase that strongly competes with superconductivity. By combining neutron diffraction and Mössbauer spectroscopy [2], we were able to establish unambiguously that this novel magnetic ground state is a rare double-Q magnetic structure in which two orthogonal spin density waves combine to produce a a non-uniform magnetization with tetragonal symmetry. In this state, half of the iron sites are non-magnetic, whereas the other half has nearly double the magnetic moment as in the orthorhombic stripe-SDW phase. Such a ground state is incompatible with localized spins, but is naturally explained in a double-Q magnetic structure as the result of destructive and constructive interference between two commensurate spin-density waves. These results provide clear evidence for the electronic itinerancy of the system and that the structural and magnetic transitions are driven by magnetic fluctuations, while more generally also providing a conclusive demonstration of the wave-like properties of metallic magnetism.

W14-09. Resonant Ultrasound Spectroscopy of the Nematic Transition in an Iron-Based Superconductor. *S.K. Lewin*[1,2], V. Nagarajan[1,2], E. Lachman[1,2] and J. Analytis[1,2] *1. Physics, University of California, Berkeley, Berkeley, CA, United States; 2. Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, United States*

A nematic order that breaks fourfold rotational symmetry is a common feature of the iron-based superconductors. In some compounds, this order precedes a stripe-type magnetism; in others, the breaking of fourfold symmetry occurs at the same temperature as the onset of magnetism [1]. The origin of the nematic phase, as well as its influence on superconductivity, are still being studied. Yet an even more fundamental question may still be unanswered: at what temperature does the nematic phase actually onset? One commonly studied iron-based superconductor is barium iron arsenide (Ba122), which can be doped with holes or electrons, or can have phosphorous isovalently substituted for arsenic. In such phosphorous-substituted compounds, measurements of thermal expansion, torque, and birefringence all seem to indicate different temperatures at which the nematic order onsets for a given level of substitution [2-4]. These differing results necessitate further study. In this work, we demonstrate how Resonant Ultrasound Spectroscopy—the study of a material's resonant frequencies—can be used to detect minute changes in the structure and symmetry of Ba122 as a function of temperature, helping to resolve this outstanding question.

W14-10. Nematic fluctuations in iron arsenide superconducting system probed by ^{75}As NMR. Y. Kobayashi[1], M. Toyoda[1] and *M. Itoh*[1] *1. Department of Physics, Nagoya University, Nagoya, Japan*

We have conducted ^{75}As NMR measurements on iron pnictide superconductors, Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$ (Ba122) with x = 0, 0.02, 0.05, and 0.08, NaFeAs,

and LiFeAs to investigate their nematic state. We found that the anisotropic amplitude (η) of As-site electric field gradient (EFG) with symmetrical axes parallel to Fe-Fe directions within Fe-plane obeys to Curie-Weiss like behavior ($C_1/(T-T_\eta)+C_2$) in the tetragonal phase (The C_1 and C_2 are constant), and that the x dependence of T_η of Ba122 is quite similar to that of Weiss temperatures (T_{Raman}) of the charge nematic susceptibility deduced from the Raman spectra [1]. While T_η-values for the Ba122 with x = 0, 0.02, and 0.05 and NaFeAs being with structural and antiferromagnetic transitions are positive and smaller than their structural transition temperature T_S-values, the Ba122 with x = 0.08 and LiFeAs with only superconducting transition indicate negative. Thus, the in-plane anisotropies of the As-site EFG could monitor the charge nematic susceptibility as well as Raman response. Moreover, We discuss the relationship between nematic susceptibility and emergence of superconductivity by comparing with the anisotropies of As-site EFG for other iron pnictides/chalcogenides showing superconductivity without atomic substitutions.

W14-11. Superconducting gap structure and its temperature dependence of layered iron-free pnictide superconductor $BaPd_2As_2$.
A.S. Usoltsev[1], *T.A. Romanova*[1] and M. Abdel-Hafiez[2] *1. P.N. Lebedev Physical Institute, Russian Academy of Sciences, Moscow, Russian Federation; 2. Institute of Physics, Goethe University Frankfurt, Frankfurt, Germany*

We present experimental research of recently discovered palladium based analog of 122 iron arsenide [1]. Single crystal of $BaPd_2As_2$ with sharp superconductor transition at T_c=3.7K were studied by means of break-junction technique on clean cryogenic cleavage. Intrinsic multiple Andreev reflections effect (IMARE) spectroscopy were used to obtain superconductive gap (SG) structure. Our data shows single energy gap with a value Δ=0.85mEv. Studying Andreev spectra temperature behavior from 1.5K up to T_c (Fig.1) we plotted SG temperature dependence Δ*(T)* (Fig.2) that demonstrates BCS-like behavior. Meanwhile characteristic BCS ratio is found to be 5.3 that is much larger than for conventional superconductors. That value is close to iron based Ba-122 and revealing strong electron-boson interaction [2,3].

$A Fe_2As_2$ (*A*: Ba, Sr and Eu) with a tetragonal *I4/mmm* structure exhibits a single-Q commensurate stripe-type antiferromagnetic (sAFM) order at T_o^{Fe} with a structural change to an orthorhombic*Fmmm* structure [1-2]. This T_o^{Fe} value is suppressed by applied pressure or substitution and then bulk superconductivity emerges at low temperature [3-6]. Recently, there has been considerable interest in a new double-Q spin density wave (SDW) order because the double-Q SDW order has been found with the reentrant tetragonal structure and superconducting state in contrast to the orthorhombic sAFM state [7,8]. Two different magnetic orders in the double-Q SDW state were predicted by using a weak-coupling itinerant electron model; one is the charge-spin density wave (CSDW) with a nonuniform magnetization and the other is the spin-vortex crystal (SVC) with a noncollinear magnetization [9]. These two magnetic orders are degenerate in the regime without impurity scattering and disorders in the substituted system lift its degeneracy [9]. The magnetic structures in the coexistence phases of substituted $A Fe_2As_2$ compounds were confirmed as the CSDW by neutron diffraction and conventional Mössbauer spectroscopy [7,8]. These results raise an intriguing question for a magnetic state in the coexistence phase with no impurity scattering. Here, we have found the new coexistence between an antiferromagnetic order in the Fe and Eu sublattice and bulk superconductivity of $EuFe_2As_2$ under pressure by ^{57}Fe and ^{151}Eu nuclear forward scattering using a single crystal sample. The magnetic state in the Fe sublattice changes to a new antiferromagnetic one with superconductivity from a sAFM state observed in normal conducting state with decrease in the magnetic hyperfine field at the Fe nuclei. The emergence of the new antiferromagnetic order with superconductivity provides crucial knowledge for discussing a pairing glue of superconductivity in $A Fe_2As_2$ under pressure.

W14-13. Low temperature heat capacity in the iron-based superconductor YFe_2Ge_2. *K.J. Murphy*[1], J. Chen[1], J. Banda[2], J. Baglo[1], M. Brando[2], M. Sutherland[1] and M. Grosche[1] *1. Cavendish Laboratory, University of Cambridge, Cambridge, United Kingdom; 2. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany*

Unconventional superconductivity is rare in transition metal compounds outside the layered iron pnictide/chalcogenide and cuprate material families. These systems typically have highly anisotropic electronic properties and nearly 2D Fermi surface geometries. The iron-based unconventional superconductor YFe_2Ge_2, by contrast, displays a comparatively isotropic, 3D electronic structure. Its Sommerfeld ratio C/T, is enhanced by an order of magnitude above the band structure value to $\gamma \sim 100$ mJ/(mol K^2) at low temperature, and it displays an anomalous form for the temperature dependence of the resistivity, $\rho(T) = \rho 0 + AT^{3/2}$. Theoretical proposals for the pairing mechanism in YFe_2Ge_2 include both triplet [1] and singlet, $s^{\pm}$ order parameter wave functions [2], prompting a renewed effort to examine the heat capacity well below the transition temperature in newly available bulk superconducting single crystals. We present recent heat capacity data on YFe_2Ge_2 at temperatures down to 30 mK and in fields up to 5 Tesla, which suggests that the upper critical field H_{c2} may be greater than 3 Tesla.

1. D. J. Singh, Phys. Rev. B 89, 024505 (2014). 2. A. Subedi, Phys. Rev. B 89, 024504 (2014).

Heat capacity C/T vs T of YFe_2Ge_2 in the field range from $0 \leq B \leq 5$ Tesla. The superconducting anomaly is seen in the zero field data at ~ 1 K and is still present at 3 T (onset at around 500 mK). There is a large contribution to the heat capacity below 90 mK (zero field data) due to a Schottky type anomaly arising from the nuclear quadrupole moment of the Ge ions, which varies as a function of magnetic field.

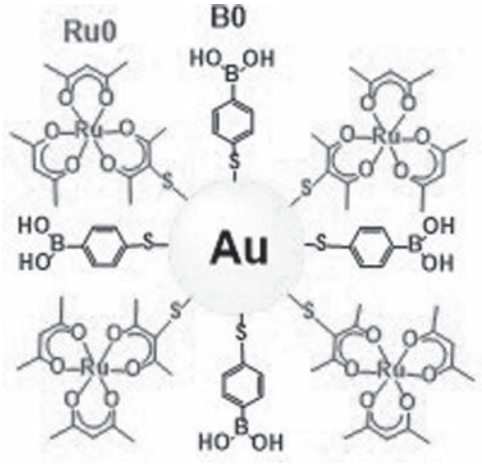
W15-01. Thermoelectric Power in Magnetic Field for Contaning Co Nanoparticles Films. *A.I. Dmitriev[1] 1. I.M. Frantsevych Institute for Problems of Material Science, National Academy of Sciences of Ukraine, Kyiv, Ukraine*



The effect of the magnetic field H on thermo-power (TP) in films of magnetic nanocomposites (NC) with nanoparticles (NP) Co in Al2O3 and SiO2 matrices was studied. The result was estimated as the coefficient of magneto-TP - $\delta\alpha = [(\alpha_H-\alpha_0)/\alpha_0]\%$ at the temperature of 90 K, where α_H is the magneto-TP at H = 5 kOe, α_0 is the value of the TP at H = 0 Oe. For NC Co / Al2O3, the value $\delta\alpha > 0$ exceeds the value of ≈70% [1]. For Co / SiO2, $\delta\alpha$ is negative and reaches ≈ -90% [2]. The concentration of Co did not exceed the percolation threshold values. Such sharp difference of magnetic characteristics of the NC can be explained by the features of the composition and magnetic properties of the NP. Hopping conductivity in NC occurs due to vacancies of oxygen in the matrix and NP. In the Al2O3 matrix, the magnetic moments of the FM NP and free electron spins in the external field H are collinear [1]. This leads to their mutual "repulsion" in the process a transport and substantially reduces the number of scattering NP's. The consequence of this is an increase in the conductivity of the films and their α_H, which reaches a giant value of ~ 0.01 V / K [1]. The ferromagnetic (FM) NP consisting of Co in an oxygen-containing matrix is covered with an CoO [3]. In the SiO2 matrix, $\delta\alpha < 0$ is a consequence of the interaction of electron spins and positively charged magnetic oxygen vacancies (OV) with the Co-CoO [4] interface, stimulated by the magnetic field. Spins and magnetic moments of OV are antiparallel in an external magnetic field, which leads not only to the Coulomb, but also to the magnetic attraction of electrons and OV. As a result, the electron "sticks" to the OV, a state arises that excludes electrons from transport processes due to the small mobility of the OV. Such a state can be called a quasi-exciton dielectric (QED). The QED lifetime is probably not large, but this leads to an increase in the resistance of the NC and a significant negative value of $\delta\alpha$. In Co / Al2O3 QED does not arise due to a large dielectric constant ((Al2O3 - ε = 10; SiO2 - ε = 3.9). The degradation of the magneto-TP over time indicates the significant role of the OV.

W15-02. Low temperature magnetism of gold nano particles contained in electrochemical sugar recognition system. *T. Goto[1]*, Y. Kitamoto[2], K. Matsui[1], H. Kuroe[1], A. Endo[2], T. Hashimoto[2], T. Hayashita[2], S. Iguchi[3] and T. Sasaki[3] *1. Physics Division, Sophia University, Chiyodaku, Japan; 2. Department of Materials and Life Science, Sophia University, Tokyo, Japan; 3. Institute for Materials Research, Tohoku University, Sendai, Japan*

The recently reported electrochemical sugar recognition system consisting of a gold nano particle (GNP), a ruthenium complex (Ru0) and a pheylboronic acids (B0), attracts much interest because of its high sensitivity for various sugars such as D-glucose or D-fructose[1]. From a viewpoint physics, this system can be considered as an S=1/2 spin cluster (Ru0's) assembled on a nano-sized metal particle (GNP) with the averaged diameter of 13 nm. The purpose of this study is to elucidate its magnetic properties; the result will be of help for understanding this nano-sized magnet [2,3] as well as for its sugar-sensing mechanism. We have measured the uniform susceptibility and ^{1}H-NMR spectra at temperatures down to 1.8 K. The former showed the temperature dependence described by a summation of Curie-Weiss term with Θ = 0.6 K and a small positive constant term. There was no indication of magnetic order down to 1.8 K. From the Curie-Weiss amplitude, the average number of Ru0 complexes on a GNP was estimated to be 118, which is 23 % of the closed-packed limit [1]. Although the finite positive constant term suggests the Pauli paramagnetism of gold, it has long been considered that bulk metal gold is diamagnetic, and was explained in terms of the effects of ionic core and band structure. One needs further careful investigation to judge. Next, proton NMR spectra at room temperature showed two narrow motional-narrowed peaks, separated with 5 Oe. As lowering temperature, this sharp structure disappears below 100 K, and changes into a broad peak. This means that the wavering motion of Ru0 complexes on GNP is frozen below 100 K. The temperature dependence of shift and width are scaled with the uniform susceptibility, and from the scaling factors, the isotropic and anisotropic part of hyperfine coupling constant was obtained to be A_{iso}=–100 Oe/μ_B and A_{an}= 200 Oe/μ_B, respectively. These values indicate that the proton NMR probes well the magnetization of the trivalent Ru ion. Possible effects of GNP's magnetism onto the NMR spectrum will also be discussed.

W15-03. Observation of Dzyaloshiskii-Moriya Interaction Effect in Co/Pt Multilayers with variation of repeat number. *L. Huang*[1], J. Jung[2], C. You[2] and D. Kim[1] *1. Department of Physics, Chungbuk National University, Cheongju, The Republic of Korea; 2. Department of Emerging Materials Science, Daegu Gyeongbuk Institute of Science & Technology (DGIST), Daegu, The Republic of Korea*

Recently it has been known that Dzyaloshinskii-Moriya interaction (DMI) plays an important role in magnetic domain wall motion in field- or current-driven magnetic domain wall (DW) motions [1]. It has been reported that the DMI takes part in forming a Néel-type DW in thin magnetic multilayers [2], where a magnetic field causes the transformation of the Bloch wall into the Néel wall due to the broken inversion symmetry at the interface. This effective field arises from the DMI as a result of high spin-orbit coupling linking the broken inversion symmetry at the interface to the spin structure [3, 4]. In this work, we report our observation of DMI in $[Co/Pt]_n$ (n = 1, 2, 3, and 4) multilayers with interfaces adjusted to stabilize either left-handed or right-handed Néel wall by modifying the multilayer repeat number. Field-induced DW images were investigated by a polar magneto-optical Kerr effect (MOKE) microscopy. Asymmetric DW extension was immediately observable as in Fig.1. Since the antisymmetric exchange energy from the DMI lets the magnetic film favors a Néel-type wall rather than a Bloch-type wall. The asymmetric DW velocities with different multilayer repeat number as a function of the in-plane field strength was measured as seen in Fig.2. The DW velocity under out-of-plane fields can be described by the creep law [5]: $v = v_0 \exp[-\zeta(\mu_0 H_z)^{-1/4}]$. And the effective DMI constant D is extracted by using $D=\mu_0 H_{DMI} M_S \Delta$ for multilayers with different repeat number. It has been observed that the magnetization within DWs is no longer pointed from black domains to white domains under longitudinal magnetic field, implying a transformation from a left-hand to a right-handed Néel wall. It is considered that the interface between the Ta and the Co/Pt multilayer play a key role in determining the DMI strength and the chirality of the DWs. It has been supported by [Grant No 2015R1D1A3A01020686] and by Max Planck POSTECH/KOREA Research Initiative Program [Grant No 2016K1A4A4A01922028].

W15-04. Interlayer Effects on Magnetic Reversal and Critical Current Transparency of Fe Thin Films with Applications for a Cryogenic Memory. *M. Loving*[1], T. Ambrose[1], I. Dayton[1], H. Ermer[1], E.C. Gingrich[1], S. Keebaugh[1], D. Miller[1], N. Rizzo[1], N. Siwak[1] and O. Naaman[1] *1. Advanced Concepts & Technologies, Northrop Grumman Corporation, Linthicum, MD, United States*

Josephson magnetic random access memory (JMRAM) is being pursued as a cryogenic memory component for a superconducting computer. Such a memory component combines superconducting electrodes with a ferromagnetic (FM) multilayer structure in a magnetic Josephson junction. Optimization of a JMRAM device requires that magnetic layers behave as single domain elements with an abrupt magnetization reversal and low switching fields, at cryogenic temperatures. JMRAM requirements are further complicated as FM and normal metal (NM) materials selection and thicknesses must carry a sufficient critical current (I_c), consistent with low error rate operation at 4K. To this end, it is necessary that both magnetic and electrical properties be optimized to achieve a working memory device. Here, we compare Nb/Cu/Fe/NM/Nb structures (NM = normal metal interlayer) to Nb/Cu/Fe/Nb. We describe structural, magnetic and transport results which highlight the ability to use interface modifications to improve the magnetic reversal of Fe bits, while a maintaining consistent electrical performance. Ultra-thin Fe films (~7-20Å) were deposited onto a 1.5kÅ Nb/50Å Cu starting surface; the precise film thicknesses were determined using x-ray reflectivity measurements. Grazing-incidence x-ray diffraction suggests that Fe films, deposited on (111)-Cu, conform to a face centered cubic structure. The Fe magnetization was assessed in both continuous films and patterned arrays, at 10K. Fe films capped with a NM interlayer, which promotes a positive lattice misfit, showed substantial improvements in the Fe magnetic hysteresis (Fig 1) and positive magnetostriction, as compared to Fe/NM films with a negative lattice misfit. Fabricated electrical bits, of all samples, demonstrated the ability to transmit supercurrent, with a similar magnitude and decay. Finally, Fraunhofer effects (i.e. field dependence of I_c) were observed in all sample structures (Fig 2). Ultimately, these results serve as a pathway to optimize magnetic switching in FM materials while maintaining I_c value which are relevant to emerging JMRAM technologies.

T = 10K hysteresis of 1x2μm elliptical arrays of Nb/Cu/Fe/NM/Nb

Representative I_c vs H curve of 1.5kÅ Nb/50Å Cu/Fe/Nb fabricated device

W15-05. Magnetic properties of Fe/Pd(001) bilayer affected by quantum-well states formed in Pd layer. *K. Mochihara*[1], S. Nakahara[1], S. Sakuragi[2], M. Sawada[3] and T. Sato[1] *1. Department of Applied Physics and Physico-Informatics, Keio University, Yokohama-shi, Japan; 2. ISSP, The University of Tokyo, Kashiwa-shi, Japan; 3. Hiroshima Synchrotron Radiation Center, Hiroshima University, Higashihiroshima-shi, Japan*

Interface between 3d transition metal and (Pd, Pt) is known to exhibit a strong magnetic anisotropy. Moreover, quantum-well states (QWs), formed in Pd (100) thin films, changes depending on the film thickness[1]. In this study, we investigated the magnetic properties of Fe/Pd bilayer which is affected by the QWs formed in Pd layer in order to elucidate the relation between the magnetic anisotropy and electronic structures of magnetic multilayer systems. We prepared epitaxial Au(20 nm)/Fe(3 monolayers (MLs))/Pd(3-10 nm)/$SrTiO_3$. Reflection high-energy electron diffraction (RHEED) was used for evaluation of film quality. The in-plane and out-of-plane magnetization measurements were performed in order to determine the magnetic anisotropy energy (MAE) using a SQUID magnetometer. We also measured x-ray magnetic circular dichroism (XMCD) spectra of epitaxial Fe(1.2 ML)/Pd(5 - 20 ML)/Cu(001) at HiSOR-BL14. Figure 1 shows the MAE of Fe/Pd as a function of Pd layer thickness in comparison with the saturation magnetization of the Pd thin film reported in the previous study[1]. MAE of Fe/Pd changed in oscillatory manner with the same period as the appearance of ferromagnetism in Pd caused by the QWs[1]. This indicates that QWs, formed in the Pd layer, modulates MAE of Fe/Pd. Figure 2 shows the Pd M_3 x-ray absorption spectroscopy (XAS) and XMCD of Fe as a function of Pd layer thickness. XAS of Pd shows the local dips (shown by gray hatch) in addition to monotonic increase depending on the volume. The interval of local dips is 5-6 ML which is same as the period originating from QWs. Considering that XAS intensity corresponds to the hole number, the local dips should be caused by the unoccupied states of Pd depending on QWs band. The change with the same interval is also observed in XMCD of Fe. This shows that Pd QWs modulate magnetism of Fe. Therefor the change in MAE observed in magnetic measurement originates from Fe. The oscillatory change in MAE is attributed to the coupling between bands of Fe and QWs band which changes depending on Pd film thickness.

W15-06. Differential Conductance Anomalies in Superconducting Vanadium and Niobium with Hydrogen and Deuterium Impurities. *S. Wen*[1], M.S. Islam[1], H. Takata[1], M. Shiga[1], Y. Inagaki[1], K. Hashizume[2] and T. Kawae[1] *1. Applied Quantum Physics, Kyushu University, Fukuoka, Japan; 2. Advanced Energy Engineering Science, Kyushu University, Fukuoka, Japan*

To study the impurity effect on the superconducting-normal metal interface, we measured the differential conductance (dI/dV) spectra of Josephson junction, which were made by niobium (Nb) and vanadium (V) with a few percent of hydrogen(H) and deuterium(D) impurities. H atoms are generally absorbed to be almost neutral condition in metals, and therefore act as a composite boson. On the other hand, a D atom as an isotope of H has a half-integer spin like a composite fermion due to its constituent particle of neutron. In the experiments, the nanocontacts are created by a mechanical breaking junction method. For the VH0.05 and VD0.05 in Fig.1, below the superconducting transition temperature Tc, the spectra of dI/dV exhibit a series of conductance anomalies outside the superconducting energy gap, referred as an over-the-gap structure indicated by the black arrows, along with the superconducting gap [1]. The dashed line in the figure indicates the 2Δ gap of V. The similar features are observed in the spectra of dI/dV for $NbH_{0.03}$ and $NbD_{0.03}$ nanocontacts. Below the transition temperature, a series of differential conductance anomalies appear not only inside the superconducting gap 2Δ, but also outside the gap as in the case of V hydride. In the presentation, we discuss the origin of these anomalies.

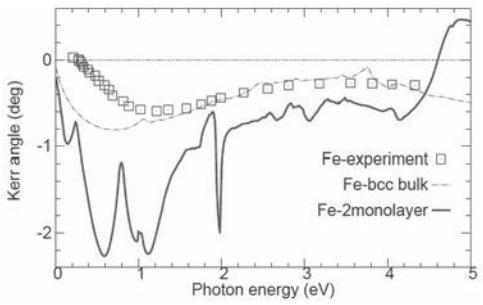
W15-07. Low temperature divergence in the AHE and AMR of ultra-thin Pt/Co/Pt trilayers. *E. Zion*[1] *1. Physics, Bar Ilan University, Tel Aviv, Israel*

We study the anomalous Hall effect (AHE) and anisotropic magnetoresistance (AMR) in a series of ultra-thin Pt/Co(x)/Pt trilayers (0.1 nm <x< 0.5 nm).

We find that the AHE exhibits a significant increase at low temperatures (T). This increase cannot be attributed to a trivial increase in magnetization or resistivity. A similar T dependence is observed in the AMR measurements. Interestingly, these effects show almost no dependence on cobalt thickness. Our measurements indicate that the deviation from common behavior is related to an additional scattering mechanism that we attribute to an interface induced magnetic proximity effect in the Pt layers, which increases at low T.



(a) ρ_{xy} as function of T. Co thicknesses are marked. (b) ρ_{xy} in the low T regime for sample 0.3, dotted line is the expected extrapolation. Inset: schematic illustration of sample structure and measurement geometry. (c) Curie temperature as function of the Co thickness. W15-08. Enhanced magneto-optical Kerr effect and Faraday effect at Fe/insulator interfaces. *B. Gu[1,2] 1. Kavli Institute for Theoretical Sciences, University of Chinese Academy of Sciences, Beijing, China; 2. Advanced Science Research Center, Japan Atomic Energy Agency, Tokai, Japan*

The magneto-optical Kerr effect (MOKE) is the phenomenon in which the light reflected from a magnetized material has a rotated plane of polarization, and the Faraday effect is the similar phenomenon in which the light transmitted through a magnetized material has a rotated plane of polarization. The MOKE and Faraday effect originate from spin-orbit coupling in materials and have been extensively studied. For applications to magneto-optical devices, large MOKE and Faraday effect are hihgly required. By density functional theory calculations, we have found an enhanced MOKE and Faraday effect in Fe/insulator interfaces. Our study indicates that interfacial Fe atoms in the Fe films have a low-dimensional nature, which causes the following two effects: (i) The diagonal component σ_{xx} of the optical conductivity decreases dramatically because the hopping integral for electrons between Fe atoms is suppressed by the low dimensionality. (ii) The off-diagonal component σ_{xy} of the optical conductivity does not change at low photon energies, but it is enhanced at photon energies around 2 eV, where we obtain enhanced orbital magnetic moments and spin-orbit correlations for the interfacial Fe atoms. Enhanced Kerr angle and Faraday angle develop in proportion to the ratio σ_{xy}/σ_{xx}. Our findings indicate an efficient way to enhance the effect of spin-orbit coupling at metal/insulator interfaces without using heavy elements.

PLENARY IV: HIDDEN MAGNETIC ORDER IN MULTIFERROICS AND SUPERCONDUCTORS

Mark D. Stiles, Chair
National Institute of Standards and Technology, Gaithersburg, MD, United States

INVITED PAPER

11:30

X1-01. Hidden Magnetic Order in Multiferroics and Superconductors.
N.A. Spaldin[1] 1. ETH Zürich, Zürich, Switzerland

Most magnetic materials, phenomena and devices are well described in terms of magnetic dipoles of either spin or orbital origin. There is mounting evidence, however, that higher-than-dipolar order multipoles both exist (often in hiding) and lead to intriguing magnetic behaviors. In this talk I will discuss the relevance of the so-called magnetoelectric multipoles, which form the next-order term, after the magnetic dipole, in the multipolar expansion of the magnetization density with the magnetic field. First I will describe how magnetoelectric multipoles underlie multiferroic behavior and in particular how they determine the magnetic response to applied electric fields. Then I will discuss signatures of hidden magnetoelectric multipolar order, how it can be unearthed using density functional theory calculations and possibilities for its direct measurement. Finally, I will demonstrate that such magnetoelectric hidden order occurs in the high-Tc cuprate materials, where it might be relevant for the superconducting behavior, providing a link between multiferroism and exotic superconductivity.

Y1-01. Evidence for Topological Order in a Magnetic van-der-Waals Material. *K. Burch*[1] *1. Physics, Boston College, Chestnut Hill, MA, United States*

There is considerable excitement for realizing non-Abelian Anyons, particles whose phase upon exchange depends on the path taken. Their observation signals the emergence of new topological phases and offers a route to quantum computation. I will outline the reasons to expect such particles in a particular quantum spin-liquid, where there is long-range entanglement but no magnetic order. I will then describe a particularly promising van-der-Walls material for realizing such particles, $RuCl_3$. Via Raman spectroscopy, we have uncovered the Fermi statistics emerging from the Majorana particles in this insulating system. Time permitting, I will discuss the possibility of creating novel heterostructures in our new cleanroom in a glovebox with $RuCl_3$

Y1-02. Antiferromagnetic Ordering in 2-dimensional Layered Materials. K. Kim[1], S. Lim[1], J. Lee[1], S. Lee[2], T. Kim[2], K. Park[2], G. Jeon[3], C. Park[2], J. Park[2] and *H. Cheong*[1] *1. Department of Physics, Sogang University, Seoul, The Republic of Korea; 2. Department of Physics and Astronomy, Seoul National University, Seoul, The Republic of Korea; 3. Department of Physics, Ewha Womans University, Seoul, The Republic of Korea*

Magnetism in low dimensional systems is attracting much attention not only for the fundamental scientific interest but also for possible applications in sensors and data storage. Recent discovery of ferromagnetism in atomically thin materials [1,2] ignited much interest in magnetism in 2 dimension in general. Antiferromagnetic ordering, on the other hand, is much more difficult to study as the net magnetism is zero. Conventional techniques such as neutron scattering, which is a powerful tool to detect antiferromagnetic order in bulk materials, cannot be used for atomically thin samples due to a small sample volume. Magneto-optical Kerr effect, which has proven to be an effective tool to detect ferromagnetic ordering in 2-dimensional materials cannot be applied to antiferromagnetic materials due to lack of net magnetization. Raman spectroscopy, on the other hand, has proven to be a powerful tool to detect magnetic ordering in atomically thin materials by monitoring the zone-folding due to the antiferromagnetic order [3,4] or the signal from two magnon scattering. We report on the observation of antiferromagnetic ordering in the two-dimensional limit. We demonstrate that Ising-type antiferromagnet $FePS_3$ exhibits antiferromagnetic ordering down to the monolayer limit, in good agreement with the Onsager solution for two-dimensional order-disorder transition. The transition temperature remains almost independent of the thickness from bulk to the monolayer limit with T_N ~118 K, indicating that the weak interlayer interaction has little effect on the antiferromagnetic ordering. [4] For an XXZ-type antiferromagnet $NiPS_3$, two-magnon scattering, quasi-elastic scattering due to spin fluctuations, Fano resonance of a phonon mode with two-magnon exciation, and magnetic-ordering-induced splitting of a phonon mode are monitored to study antiferromagnetic ordering as a function of the thickness. It has been found that antiferromagnetic ordering is quite robust down to 2-layers but is strongly suppressed in the monolayer limit.

Y1-03. Symmetry controlled optical and magnetic properties in 2D antiferromagnets. *D. Xiao*[1] *1. Carnegie Mellon University, Pittsburgh, PA, United States*

Layered magnets have emerged as a new focal point in current 2D material research due to the possibility of hosting magnetism in their thin-film limit. In this talk, I will discuss some symmetry controlled properties of 2D antiferromagnets. I will first show that magneto-optic effects can be generated and manipulated by controlling crystal symmetries through a gate voltage in layered collinear antiferromagnets. I will then show that the intrinsic symmetry of honeycomb antiferromagnets also allows a magnon spin Nernst effect. These properties would be useful for novel spintronic devices.

Y2-01. Tensor Network Study on Kitaev Materials. *T. Okubo*[1]
1. Department of Physics, The University of Tokyo, Tokyo, Japan

Novel quantum phenomena induced by strong spin-orbit interaction have recently attracted much interest in condensed matter physics. Iridium oxides offer a typical example that shows rich phenomena. Among them, A_2IrO_3 (A=Na or Li) and alpha-$RuCl_3$ have intensively been investigated since the theoretical proposal that the Kitaev spin liquid would be realized. In this talk, we discuss the ground state properties of Na_2IrO_3 based on the ab initio Hamiltonian [2,3] and the Kitaev-Gamma model as a simple model for alpha-$RuCl_3$ [4]. In order to investigate the ground states, we employed tensor network methods where a wave function was efficiently represented by a product of small tensors. The advantage of the tensor network states is that they can represent a wave function of infinite systems directly. In this study, we used one of the infinite tensor network states called infinite Tensor Product State (iTPS) or infinite Projected Entangled Pair State (iPEPS) [5,6]. By means of the iTPS (iPEPS) together with the two-dimensional density matrix renormalization group and the exact diagonalization, we show that the ground state of Na_2IrO_3 is a magnetically ordered state with zigzag configuration in agreement with experimental observations [3]. We also discuss the phase diagram in the parameter space away from the ab initio value of Na_2IrO_3 controlled by the trigonal distortion. It turns out that the phase diagram contains several magnetically ordered phases near the zigzag phase. It suggests that potentially rich magnetic structures may appear in A_2IrO_3 compounds for A other than Na. We also discuss the ground state phase diagram of Kitaev-Gamma model [4] where an off-diagonal interaction "Gamma term" exists in addition to the Kitaev Kitaev coupling as a simple model for alpha-$RuCl_3$.

Y2-02. A Clear Understanding of the Skyrmionic A-phase Stability in MnSi. V. Laliena[1], *J. Campo*[1] and G. Albalate[1] *1. Aragon Materials Science Institute (CSIC-UZ), Zaragoza, Spain*

The phase diagram of the cubic helimagnet in the vicinity of the critical temperature has been analyzed by Mühlbauer *et al*. [1] by means of an appropriate Landau-Ginzburg model, minimizing the free energy in Fourier space and including fluctuations perturbatively to one-loop level. However, within such scheme, it is unclear the relation between the solution identified with the A-phase and the Skyrmion lattice (SKL) made up of nonlinear solitonic Skyrmion configurations. In this contribution we solve a similar problem but in the configuration space, with fluctuations computed around the fully non-linear SKL configuration by using the saddle point approach. In figure 1 the free energy for the SKL and the conical state is computed with and without the effect of Gaussian fluctuations. These results show that the SKL is stabilized by the fluctuations in a region of the phase diagram, as also happens at low temperature [2]. The phase diagram in the temperature and magnetic field plane is described and a comparison with the results of [1] is discussed.

Y2-03. The Bosonic RKKY Effect: Magnetic Order in a Dissipative Spin Chain. *M. Butcher*[1], J. Pixley[2] and A. Nevidomskyy[1] *1. Physics and Astronomy, Rice University, Houston, TX, United States; 2. Rutgers University, Highland Park, NJ, United States*

Boson-mediated interactions are well known to give interesting long-range orders, such as Cooper pairs in conventional superconductivity. However, magnetic systems under the influence of environmental bosons remain poorly understood. To investigate boson-mediated magnetic ordering, we consider a quantum Ising spin chain in a dissipative bath. Such a system can be directly realized, for example, by ultra-cold atomic gases in an optical lattice or an array of Josephson junctions. The bosonic bath can be shown to induce long-range, frustrated interactions between sites in the spin chain. To study the effects of these interactions using Monte Carlo simulations, we employ a quantum-to-classical mapping [1] to derive the action of the corresponding classical Ising model in two dimensions. Due to the frustration and long-range nature of the interactions, this effective model is highly nontrivial. We investigate the different phases of this frustrated model by using a combination of Monte Carlo methods such as cluster updates, histogram resampling, and parallel tempering. Previous studies of non-frustrated approximations of this model have observed BKT transitions associated with the localization of individual spins [2], but the critical behavior associated with the magnetic ordering has remained out of reach until now.

[1] S. Sachdev, Quantum Phase Transitions (Cambridge University Press, Cambridge, England, 1999). [2] A. Winter, H. Rieger, Phys. Rev. B, 90, 22 (2014).

The effective bath-induced interactions for the dissipative chain in the fully classical limit, in which each quantum spin is treated as a block spin with no fluctuations in imaginary time. In the plot, S_c is the contribution to the classical action, where $S_c > 0$ is ferromagnetic, which takes the functional form $S_c \propto \sin(R_{ij})/R_{ij}$. R_{ij} is a scaled lattice spacing which depends on a high-frequency cutoff within the bosonic bath and the velocity of the bath modes. Even in this limit, we can see that the long-range and oscillating nature of the interactions can induce frustration. In the full quantum treatment, oscillations in imaginary time direction further complicate the interactions.

2:30

Y2-04. Specific heat and non-linear susceptibility in the spin glass state with random fields. M.V. Romitti[1], F. Zimmer[1], C.A. Morais[2] and *S.G. Magalhaes[3] 1. Physics, Universidade Federal de Santa Maria, Santa Maria, Brazil; 2. Physics, Universidade Federal de Pelotas, Pelotas, Brazil; 3. Physics, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil*

We study the magnetic specific heat $_{Cm}$ and the non-linear susceptibility X3 following the suggestion that a random field (RF) can be induced even by a weak transverse field Ht. This mechanism was proposed to explain how the characteristic sharp peak in the X3 marking a Spin Glass (SG) second order phase transition at the freezing temperature Tf in the compound LiHoxY1-xF4 is replaced by a rounded maximum when a Ht is applied. We analyse this problem by adopting a cluster version for the Sherrington-Kirkpatrick model in the presence of RFs [1,2]. The clusters are used to improve previous mean-field treatment [3,4] allowing to include long-range disordered interactions among clusters, and short-range interactions within the clusters, besides a local RF for each spin. The RF follows a Gaussian distribution with standard deviation D. We adopted the replica formalism within one-step replica symmetry breaking (RSB) to get an exactly solvable single cluster problem. We analyse the behavior of Cm, X3 and phase diagrams for different disorder configurations. In the absence of RF, the X3 exhibits a divergence at Tf, identifying the SG phase transition that occurs with RSB. The Cm curve shows a broad maximum at a temperature T**, which is 30% above Tf, as expected for conventional SG systems. In the presence of RF, this scenario is completely changed. Cm still shows the broad maximum at T** that is weakly dependent on D. However, the Tf decreases as D increases, enhancing the ration T**/Tf. In addition, the divergence in X3 is replaced by a rounded maximum at a temperature T* which becomes increasingly higher than Tf as D enhances. As a consequence, the paramagnetic PM phase is unfolded in three regions: (i) a conventional paramagnetism (T>T**); (ii) a region with formation of short range order with frozen spins (T*<T<T**); (iii) a region with slow growth of free-energy barriers slowing down the spin dynamics before the SG transition (Tf<T<T*). This process can enforce the proposal of an intermediate Griffiths phase between the PM and SG [4]. Our results reproduce qualitatively some findings of LiHoxY1-xF4 as the X3 behavior trigger by RF and the deviation of the conventional relationship between the Tf and T** [4].

Y2-05. Boosting the Modeling of Heusler Alloy Using Game Tree Search. *R. Sawada*[1], Y. Iwasaki[1,2] and M. Ishida[1] *1. IoT Device Laboratory, NEC Corp, Tsukuba, Japan; 2. JST-PRESTO, Tokyo, Japan*

Composition optimization of material is common and costly problem. To avoid redundant measurements, it is effective to expect unknown result by considering previous results. The basic strategy is to give the priority of measurement according to mathematically expected value and uncertainty using e.g. expected improvement (EI) algorithm [1] and the upper confidence bound (UCB) strategy [2]. However, such expectation frequently misleads measurement due to unexpected characteristics inside real materials and it causes local optimum trap. This study presents game tree search can escape from local optimum by managing whole history and spatial resolution of search with the tree structure and will open a way to boosting material development with AI algorithms and/or machine learning. Fig.1 shows a virtual experiment on optimizing spin polarization of Fe_xPt_{1-x} alloy using the game tree search. After each experiment (e.g. $Fe_{0.5}Pt_{0.5}$), candidates for next measurement will be given in the vicinity of the measured point with a fixed distance $d_0/2^{depth}$. Then we can estimate the priority of measurement with a certain criteria [1,2] and select next measurement point. If the estimated priority becomes lower than a certain value, we can exclude this point from the set of candidates (error pruning). Fig.2 shows the result of optimization of spin polarization in Heusler alloy $Co_2Cr_xMn_yFe_{1-x-y}Al_aSi_bGe_{1-a-b}$ using EI algorithm, UCB strategy and the game tree search. The spin polarization is obtained by coherent potential approximation simulation, and Gaussian regression is used to expect the value and error. The wrong prediction happened in all of the algorithms. However the game tree search could escape from local maximums quickly. This is because the spatial resolution of search is controlled appropriately with the tree depth and pruning mechanism. Once higher peak was found, the leaves around local maximums were pruned leading to escape from local maximums. This work was supported by JST-ERATO (JPMJER1402) and JST-PRESTO (JPMJPR17N4).

Fisica Aplicada, Universidad Autónoma de Madrid, Madrid, Spain

Future advances in nanotechnology rely in part on our ability to accurately engineer high quality oxide-based epitaxial nanostructures with customizable functionalities.[1] However, control of properties at the nanoscale remains a challenge due to the critical influence of structural defects that proliferate at the ultrathin level, such as surface roughness or antiphase boundaries. Our work[2,3]demonstrates a route for fabricating highly perfect spinel magnetic nanostructures: ultrathin islands of up to 100 μm^2 with atomically flat surfaces and free from antiphase boundaries (APB), which is achieved by reactive molecular beam epitaxial growth on a Ru(0001) surface. Indeed, the spinel islands ($CoFe_2O_4$ and Fe_3O_4) grow from single crystallographic nuclei and are thus APB-free. The extremely low defect concentration leads to a robust magnetic order -even for thicknesses below 1 nm- and exceptionally large magnetic domains (4 orders of magnitude larger than previously reported). We perform 3D x-ray magnetic circular dichroism inside a photoemission electron microscope (XMCD-PEEM) to obtain the three-dimensional distribution of magnetization in the nanostructures. The 3D magnetization maps have been used as the initial magnetization configuration for micromagnetic simulations of islands with the same lateral and vertical dimensions as the experimental ones. Using XMCD-PEEM in combination with micromagnetic simulations and atomic/magnetic force microscopy allows determining the relevant material parameters underlying the magnetic behavior as well as the influence of specific structural defects. It can be extrapolated to other complex oxide-based heterostructures, opening fascinating opportunities from basic and applied standpoints. Y4-02. Real-space imaging of topological spin textures and their dynamics. *X. Yu*[1] and Y. Tokura[2] *1. RIKEN, Saitama, Japan; 2. RIKEN Center for Emergent Matter Science (CEMS), Saitama, Japan*

Topological spin texture (magnetic skyrmion shown in Fig. 1(a)) and its manipulation are of current great interest toward the development of next-generation magnetic devices and understanding of topological matters[1-2]. Recently, with the magnetic field excitations, we have realized skyrmion crystal with various lattice forms shown in Fig. 1(b)-1(c) and bound states of skyrmions over a wider temperature range from 200 K to 310 K in a thin chiral-lattice magnet Co-Zn-Mn. In addition, the magnetization dynamics, such as the aggregation and collapse dynamics of skyrmions in non-equilibrium states[3], the dynamical topological phase transition among helical structure, conical structure and skyrmions with current flows[5], the current-driven skyrmion motion[3-4] have been directly captured with a real-space imaging technique - *in-situ* Lorentz transmission electron microscopy (Lorentz TEM). The control of skyrmion lattice form and metastable skyrmions as well as the current-driven skyrmion motion reported here reveals the particle nature for skyrmions and promises for the potential application of skyrmions to high-density and low-power-consumption magnetic memories. This work has been done in collabration with N. Nagaosa, Y. Tokunaga, Y. Taguchi, M. Kawasaki, T. Arima, F. Kagawa, W. Koshibae, N. Kanazawa, D. Morikawa, K. Shibata, Tomoyuki Yokouchi, M. Kubota, T. Inversion symmetry breaking has become a thriving research in modern magnetism with phenomena including Rashba effect, spin Hall effect and Dzyaloshinskii-Moriya interaction (DMI). The latter may stabilize chiral spin textures with topologically non-trivial properties, such as Skyrmions. So far, chiral spin textures have mainly been studied in helimagnets and thin ferromagnets with heavy-element capping. Little interest has been devoted to ferrimagnets in spite of their capability to bridge the gap between ferromagnetism and antiferromagnetism, which is a fundamentally interesting endeavor in view of chirality effects in spin orbitronics, spin caloritronics, all-optical switching and phase transitions. We show, on the example of chiral ferrimagnetism in amorphous GdCo, that the concept of chirality driven by interfacial DMI can be generalized to complex multicomponent systems. We utilize high resolution Lorentz microscopy with exit wave reconstruction and quantitative X-ray magnetic circular dichroism spectroscopy to probe the dependence of ferrimagnetic properties on thickness, capping and rare-earth composition. Our approach allows for reconstructing the electron phase and in-plane magnetic induction without the use of biprism electron holography offering yet similar quality. We find that Co and Gd moments are highly susceptible to capping and thickness variations, respectively, and that a 2nm-thick GdCo film preserves ferrimagnetism stabilizing chiral domain walls. The type of chiral domain walls depends on the rare-earth composition/saturation magnetization, enabling a possible temperature control of the intrinsic properties of ferrimagnetic domain walls. Supported by DOE BES MSED under contract #DE-AC02-05-CH11231.

In-plane magnetic induction (originating from domain walls) of symmetric and asymmetric layer stacks revealing achiral Bloch and chiral Neel walls. The data is retrieved from in-line holography/Lorentz microscopy. Scale bar is 200 nm.

Y4-04. Exploring chiral spin textures in in-plane magnets and graphene/metal bilayers. *G. Chen*[1,2] *1. Department of Physics, University of California, Davis, Davis, CA, United States; 2. Lawrence Berkeley National Laboratory, Davis, CA, United States*

Chirality in perpendicularly magnetized thin films is fundamentally interesting and holds potential for applications [1,2]. In in-plane magnetized thin films, energies of right- and left-handed spin structures are usually degenerate in in-plane Néel walls. Using spin-polarized low-energy electron microscopy [3], we recently found that out-of-plane domain walls can be stabilized by tuning the interplay between in-plane uniaxial anisotropy and effective anisotropy in Fe/Ni/W(110) system, where the right-handed chirality is observed in cycloidal-type walls [4]. We also found that the presence of graphene switches the magnetic chirality within domain walls in perpendicularly magnetized Co thin layer grown on top of Ru(0001), where left-handed walls in graphene/Co/Ru and right-handed walls in Co/Ru are observed. This result indicates significant Dzyaloshinskii-Moriya interaction at graphene/ferromagnetic metal interfaces in spite of the weak spin-orbit coupling of graphene [5]. First-principles calculations reveal that Rashba effect triggers such unexpected Dzyaloshinskii-Moriya interaction. These results exemplify the rich physics of chirality associated with interfaces of magnetic materials. This work was done in collaboration with S.P. Kang, H. Yang, A. Cotta, C. Ophus, H.Y. Kwon, S. Session Y5
FIRST PRINCIPLE SIMULATION OF HARD MAGNETIC PROPERTIES

Olga Vekilova, Chair
Uppsala University, Uppsala, Sweden

INVITED PAPER

1:30

Y5-01. Optimizing the magnetic performance of $REFe_{12-x}M_x$ phases – an ab initio study. *H.C. Herper*[1], O. Vekilova[1] and O. Eriksson[1] *1. Dept. of Physics and Astronomy, Uppsala University, Uppsala, Sweden*

The growing usage of green energies e.g. in hybrid cars has caused an increasing demand for new high performance magnets with magnetic properties comparable to commercial Nd-Fe-B magnets. Thereby a key task is the reduction of the amount of rare earth (RE). The tetragonal $REFe_{11}M$ (1:12) phase is viewed as a possible alternative since it has the lowest RE concentration of all known phases. However, the stabilizing nonmagnetic element M (e.g. Ti, V, Mo) reduces the magnetic performance and its concentration should be as small as possible. Here, we study a series of $(Nd_{1-x}Y_x)Fe_{12-y}M_y$ phases with M being a nonmagnetic transition metal atom such as Ti or V using state of the art density functional theory methods. We have investigated the phase stability and the magnetic properties depending on the concentration of the transition metal M and the RE elements. The geometry has been optimized using the VASP (PBE) code [1] with PAW potentials. For Nd the PAW potential which includes the 4f electrons in the core is employed for the structure optimization. Calculations have been performed for super-cells with up to 52 atoms. The magnetic properties have been obtained within the full potential LMTO code RSPt [2] treating the 4f electrons within the GGA+U formalism. We observe that partial replacement of Nd by Y leads to an uniaxial anisotropy even at low temperatures, e.g. K_1 = 1.3 MJ/m^3 for $NdYFe_{11}Ti$ without nitrogenation. Our results show further that for the whole concentration range of x the 1:12 is stable down to approximately y=0.5 for the NM element (see Fig. 1) which leeads to an increase of the magnetization by 17%. This work is supported by the European Research Project NOVAMAG (EU686056) and STandUP for energy (Sweden).

Y5-02. Theoretical study on the magnetic properties of $Sm(Fe_{1-x}Co_x)_{12}$ systems. *H. Tsuchiura*[1,2] and T. Yoshioka[1] *1. Department of Applied Physics, Tohoku University, Sendai, Japan; 2. Center for Spintronics Research Network, Tohoku University, Sendai, Japan*

There has been renewed interest in rare-earth based magnetic materials RFe_{12} as possible candidates for novel strong permanent magnets. For example, $NdFe_{12}$ and its derivative materials as $NdFe_{12}N$ or $NdFe_{11}TiN$ have been studied experimentally and theoretically to figure out the magnetic properties. Now it is clear that nitrogenation is inevitable for them to exhibit uniaxial magnetocrystalline anisotropy. This is not a favorable fact as a permanent magnet because incorporated nitrogen will easily desorb in high temperature situations such as in motors in electric vehicles. $SmFe_{12}$ is also a family member of the RFe_{12} compounds and by virtue of the prolate 4f electronic cloud of Sm ions, it exhibits large uniaxial magnetocrystalline anisotropy without nitrogenation. $SmFe_{12}$ itself is also thermodynamically unstable as other RFe_{12} compounds, and its Curie temperature (T_c=583K) is not high enough for permanent magnetic applications. However, it has been shown experimentally that Co substitution for Fe in the $SmFe_{12}$ thin films enhances their magnetic properties, such as Curie temperature and also magnetocrystalline anisotropy [1]. Thus, $Sm(Fe_{1-x}Cox)_{12}$ system is one of the most promising hard magnetic materials, and the question we have to address theoretically here is how and why does Co substitution improve the magnetic properties. In this talk, first we construct an effective spin model for the $Sm(Fe_{1-x}Cox)_{12}$ system based on the information obtained by first-principles calculations, and analyze the magnetic properties of the system using this model. Figure 1 shows the results of the temperature dependences of the magnetic anisotropy constants K_1 and K_2. We can see that the Co substitution considerably enhances K_1, which is quantitatively consistent with the experimental results [1]. We also show the magnetization curves for several temperatures and discuss the mechanisms of the Co substitution based on electron theory.

Tokyo Tech, Yokohama, Japan*

In the 1970's, rare-earth-Fe based magnetic compounds R_2Fe_{17} (R = rare earth) were not capable of becoming strong magnets due to their low Curie temperatures. Sagawa, who is the inventor of Nd-Fe-B sintered magnets, came up with the idea of adding boron into Nd_2Fe_{17}, to enhance the ferromagnetism of Nd_2Fe_{17} through volume expansion [1]. This led to the discovery of $Nd_2Fe_{14}B$, known as the main phase of Nd-Fe-B magnets. Recently, there is a more growing demand for Nd-Fe-B magnets for use in high-performance motors, which are needed to accelerate technologies and save energy resources. Based on Sagawa's idea and other theoretical assumptions, boron is still thought to enhance the magnetic moment and magnetization of $Nd_2Fe_{14}B$ [2, 3]. However, these theoretical speculations cannot explain the first-principles result that shows a decrease in the magnetic moment, as well as the magnetization in $Y_2Fe_{14}B$ with the same crystal structure as $Nd_2Fe_{14}B$ [4]. The previous first-principles study partially considered structural optimizations, which should be considered to understand the chemical and magnetovolume effects of B. Therefore, the role of B in $Nd_2Fe_{14}B$ is still unclear decades later. In this study, we investigated the effect of B on the electronic states and magnetism of $Nd_2Fe_{14}B$ through first-principles calculations. We used the computational package OpenMX which is based on pseudopotentials and pseudo-atomic-orbital basis functions [5]. Our results show that B does not improve the magnetic moment and magnetization of $Nd_2Fe_{14}B$ from a chemical and magnetovolume effect aspect, although it does stabilize the structure of $Nd_2Fe_{14}B$. The effects of other light elements, C, N, O, and F, on $Nd_2Fe_{14}X$, have also been presented systematically in terms of the system's stability, magnetic moment, magnetization, and magnetic anisotropy of $Nd_2Fe_{14}X$. Figure 1 illustrates the calculated formation energies of $Nd_2Fe_{14}X$ by referring to the total energies of $Nd_2Fe_{17}X$. This result is consistent with experimental results showing that $Nd_2Fe_{14}B$ and $Nd_2Fe_{14}C$ can exist stably.

Volatile prices of the rare-earth elements have motivated search for the new permanent magnets which are using little or none of rare-earth elements. The late 3*d* transition elements are primary candidates for such materials, however weak spin-orbital interaction typically causes low magnetocrystalline anisotropy energy (MAE), which means that 3*d*-materials often lack of appreciable coercivity. However, under certain circumstances, the MAE of 3*d* compounds can be substantial. Two promising materials are Fe_5SiB_2 and Fe_5PB_2, as well as their alloys with Mn and Co [1-6]. Our investigations start from synthesis and magnetic measurements of Fe_5SiB_2. The measured saturation magnetization M_{sat} = 0.92 MA/m at T = 300 K. The M versus T curve shows a broad peak around T = 160 K. The anisotropy constant K_1, estimated at T = 300 K, is 0.25 MJ/m^3. Theoretical analysis of Fe_5SiB_2 system has been also carried out and extended to the full range of $Fe_5Si_{1-x}P_xB_2$, $Fe_5P_{1-x}S_xB_2$, and $(Fe_{1-x}Co_x)_5SiB_2$ compositions. The electronic band structures have been calculated using the full-potential local-orbital minimum-basis scheme (FPLO-14). In agreement with experiment, magnetocrystalline anisotropy energies (MAEs) calculated for 0 K change from a negative (easy-plane) anisotropy for Fe5SiB2 to positive (easy-axis) anisotropy for Fe_5PB_2. Further increase of the number of p electrons in $Fe_5P_{1-x}S_xB_2$ leads to an increase of MAE up to 0.77 MJ/m^3 for the hypothetical $Fe_5P_{0.4}S_{0.6}B_2$ composition. Volume variation and fixed spin moment calculations for Fe_5SiB_2 show an inverse relation between MAE and magnetic moment in a region down to about 15% reduction of spin moment. The alloying of Fe_5SiB_2 with Co is proposed as practical realization of the magnetic moment reduction, which ought to increase MAE. The calculations indicate the $(Fe_{0.7}Co_{0.3})_5SiB_2$ composition as our best candidate for the rare-earth free permanent magnet applications.

Y5-05. Calculating the Temperature Dependence of the Magnetocrystalline Anisotropy in Rare-Earth-Transition-Metal Ferrimagnets. *C.E. Patrick*[1], S. Kumar[1], G. Balakrishnan[1], R.S. Edwards[1], M.R. Lees[1], L. Petit[2] and J.B. Staunton[1] *1. Department of Physics, University of Warwick, Coventry, United Kingdom; 2. Daresbury Laboratory, Warrington, United Kingdom*

We present a first-principles theory of the magnetocrystalline anisotropy (MCA) of the prototypical rare-earth-transition-metal (RE-TM) magnets YCo_5 and $GdCo_5$. We show that, while a "standard" calculation [1] of the temperature-dependent MCA of the ferromagnet YCo_5 agrees well with experimental measurements, applying the same procedure to the *ferri*magnet $GdCo_5$ gives numbers which are larger than experimentally-reported anisotropy constants and exhibit the wrong temperature dependence. We show that this apparent failure is due to the standard calculations not accounting for the field-induced canting of the Gd and Co sublattices [2]. Specifically, the external magnetic field breaks the ideal antiferromagnetic alignment of the RE-TM moments, which results in a softening of the effective anisotropy constants measured in experiments. In order to make a suitable comparison with such experiments we have developed a "first-principles magnetisation vs field" (FPMVB) approach to mirror the experiments used to measure the MCA [3]. By performing a Sucksmith-Thompson analysis [4] on the FPMVB curves we extract anisotropy constants which can be compared directly to previously-published experimental reports and to new measurements made on a single crystal of $GdCo_5$ recently grown by us [5]. We further use our first-principles calculations, which are based on self-interaction-corrected density-functional theory in the disordered local moment picture [5], to resolve a past controversy regarding the role of anisotropic exchange in GdCo5 [2]. The present work forms part of the PRETAMAG project, funded by the United Kingdom Engineering and Physical Sciences Research Council, Grant no. EP/M028941/1.

Y6-01. Spin torque control of antiferromagnetic moments in NiO.
T. Moriyama[1] *1. Kyoto University, Uji, Japan*

For a long time, there have been no efficient ways of controlling antiferromagnets. Quite a strong magnetic field was required to manipulate the magnetic moments because of a high molecular field and a small magnetic susceptibility [1]. It was also difficult to detect the orientation of the magnetic moments since the net magnetic moment is effectively zero. Nevertheless, the microscopic magnetic moments should in principle exhibit a similar spintronic effect, such as various magnetoresistance effects and the spin torque effect, as seen in ferromagnets [2,3]. In this talk, we show our recent results of the spin torque switching and magnetoresistive detection of the magnetic moments in antiferromagnets [4], leading to novel antiferromagnetic spintronic applications. Pt 4 nm/ NiO t_{NiO} nm/ Pt 4 nm multilayers were formed by magnetron sputtering. Figure 1 (a) shows the basic principle of the spin torque rotation of the antiferromagnetic moments in a Pt/ NiO/ Pt multilayer structure where the bipartite magnetic moments rotate without a cost to increasing the exchange energy. To experimentally demonstrate, we used the Hall bar structure with the measurement procedure described in Fig. 1 (b). A writing current I_w flowing from the electrode 2 and 3 to the electrodes 1 and 4, as represented by write "1", rotates the magnetic moments and stabilizes them orthogonal to the direction of I_w. In the same manner, the other current flow of I_w writes "0". The orientation of the magnetic moments is read, after each write, by the transverse resistance (R_{Hall}). We took advantage of the spin Hall magnetoresistance (SMR) to read out the orientation of the magnetic moments. Figure 1 (c) shows representative results of the sequential write-read operation in Pt/ NiO /Pt as well as Pt/ SiO / Pt with I_w = 38 mA. The operation of write "1" results in a high resistance state and "0" in a low state, which is coherently explained by the spin torque rotation of the magnetic moments and the change of R_{Hall} due to SMR.

Y6-02. Enhancement of spin transfer torque in antiferromagnetic barrier-based magnetic tunnel junctions. *Y. Cheng*[1], W. Wang[1] and S. Zhang[1] *1. Physics, University of Arizona, Tucson, AZ, United States*

Spin transfer torque (STT) induced magnetization switching in MgO barrier based magnetic tunnel junction (MTJ) has drawn intensive research interest over the past decade for the application of magnetic random-access memories (MRAM). In the direct STT switching under a typical switching voltage across barrier about 0.5 V, each tunnel electron transfers its spin angular momentum \hbar, but the accompanying energy of 0.5 eV is wasted. Recently, incoherent magnons in ferromagnetic and antiferromagnetic insulators have been demonstrated to be efficient angular momentum transport carriers in the presence of a temperature gradient. We thus theoretically propose a magnetic tunnel junction with an antiferromagnetic insulator (AFI) as the tunnel barrier for an efficient magnetization switching. The essential idea is that the energy lost by tunneling electrons will heat up more to the magnetic metal layer with a higher voltage than that with a lower voltage, and therefore, a temperature asymmetry across the tunnel barrier naturally appears by the wasted energy. Since the barrier is antiferromagnetic, the magnon current will flow across the barrier and thus provides an additional angular momentum transfer torque. We have calculated the temperature asymmetry and the magnon transfer torques. We have found that an order of magnitude enhancement is possible for such MTJs. We hope this work provides a motivation to the experimental search for MTJs beyond the MgO-based barrier. The antiferromagnetic insulator may have smaller tunnel magnetoresistance, but it offers a critical advantage on the reduction of the switching current. This work was partially supported by the U.S. National Science Foundation under Grant No. ECCS-1708180.

Y6-03. Angular dependence of magnetoresistance in asymmetric and symmetric nonmagnet/antiferromagnet metallic heterostructures.

S. Duttagupta[1], A. Kurenkov[2], R. Itoh[2], A. Okada[2], S. Fukami[2,3] and H. Ohno[2,4] *1. CSRN, Tohoku University, Sendai, Japan; 2. RIEC, Tohoku University, Sendai, Japan; 3. CSIS, Tohoku University, Sendai, Japan; 4. CIES, Tohoku University, Sendai, Japan*

Utilization of antiferromagnets (AFMs) as active components of spintronic devices offers unique advantages complementing ferromagnet (FM) based devices [1,2]. One of the challenges in such approach is an electrical detection of magnetic orientation in AFMs that possess no net magnetization. While earlier researches revealed anisotropic magnetoresistance (AMR) [3] and tunneling AMR effects [4], recent studies have shown a possibility to utilize spin Hall magnetoresistance (SMR) effect, which arises from spin-orbit torques in magnetic heterostructures and was initially observed in nonmagnet (NM)/FM systems [5,6]. The physics of SMR in NM/AFM is expected to be different from the NM/FM systems [7,8]. While magnetoresistance (MR) effect in NM/AFM insulator systems have been studied [9,10], no research has been conducted for metallic NM/AFM systems, where interplay of AMR and SMR is expected. Here we study MR effect in AFM PtMn based asymmetric (MgO/PtMn/Pt) and symmetric (Pt/PtMn/Pt) metallic heterostructures. The polycrystalline metallic multilayer films are grown by sputtering and patterned into μm-sized devices. We measure the longitudinal resistance (R_{XX}) under rotating magnetic field in x-y, x-z and y-z planes (Fig. 1). Note that x-y and x-z scans are subject to AMR whereas x-y and y-z scans are subject to SMR. We define MR ratio as $MR_{XX} = \Delta R_{XX}/R_0$ (in %), where $R_0 = R_{XX}(\theta = 0)$ and $\Delta R_{XX} = R_{XX}(\theta)-R_0$. Figures 2(a)-(c) and (d)-(f) show the results for asymmetric and symmetric structures, respectively. A large MR effect is observed in y-z scan for both the samples (Fig. 2(c),(f)), indicating sizable SMR in the studied system. It is also noted that the sign of SMR is negative, which is opposite to NM/FM [5,6] and the same with NM/AFM insulators [9,10]. The obtained results direct towards utilization of SMR as a new detection scheme for AFM metallic heterostructures. A portion of this work was supported by the ImPACT Program of CSTI, JST-OPERA, and JSPS KAKENHI 17H06093 and 17H06511.

Y6-04. Current-induced spin-orbit torques in antiferromagnets.

C. Song[1], X. Zhou[1], P. Zhang[1], X. Chen[1] and F. Pan[1] *1. Tsinghua University, Beijing, China*

Antiferromagnets with zero net magnetic moment, strong anti-interference and ultrafast switching speed have potential competitiveness in high-density information storage. Electrical switching of antiferromagnets is at the heart of device application. We will present our recent progress in the current-driven magnetization switching through spin-orbit torque (SOT) in two antiferromagnetic systems, including Mn_2Au and [Co/Pd]/Ru/[Co/Pd] synthetic antiferromagnets (SAF). Body centered tetragonal antiferromagnet Mn_2Au with opposite spin sub-lattices is a unique metallic material for Néel-order SOT switching. The SOT switching in quasi-epitaxial (103), (101) and (204) Mn_2Au films prepared by a simple magnetron sputtering method will be discussed. We demonstrate current induced antiferromagnetic moment switching in all the prepared Mn_2Au films by a short current pulse at room temperature, whereas different orientated films exhibit distinguished switching characters. Also, we will present the SOT in a perpendicularly magnetized Pt/[Co/Pd]/Ru/[Co/Pd] SAF structure, which exhibits completely compensated magnetization and a high exchange coupling field above 2 kOe. The magnetizations of two Co/Pd layers can be switched by SOT between two antiparallel states simultaneously, while the system exhibits a high spin-torque efficiency becaused of reduced magentic moment. The magnetization switching can be read out due to much stronger spin-orbit coupling at bottom Pt/[Co/Pd] interface compared to its upper counterpart without Pt. The efficient switching of antiferromagnets by current would advance magnetic memory devices with high density, high speed and low power consumption.

Norwegian University of Science and Technology, Trondheim, Norway; 5. University of Utrecht, Utrecht, Netherlands*

While ferromagnetic materials have been the pillars in the emergence of spintronic, they have a number of drawbacks which limit the development of spintronic devices. The parasitic magnetic stray fields of ferromagnets, their intrinsically low characteristic frequencies of a few GHz and their energy consuming high magnetic damping respectively limit their density integration, operation speed and use as long-range carrier of information. The two key challenges are thus to design devices that *remove stray fields* and *charge transport*. Theoretically it was predicted that pure spin currents could be generated, transported and employed in antiferromagnetic insulators [1-3]. Here, we achieve spin transport in insulating antiferromagnets over micrometer distances, which is 2-3 orders of magnitude larger than previous reports. In our study, we develop non-local geometries to study high frequency magnon propagation in an antiferromagnet. Our devices consist of platinum (Pt) strips, deposited on different insulating antiferromagnetic compounds. When we apply a current in a platinum stripe, we generate injection of magnon by both thermal effect and by spin Hall effect, and detect their propagation in a second platinum stripe by Inverse spin Hall effect. We demonstrate that the spin signal is dependent on the direction of the Neel vector of the antiferromagnet and the thermal signal to the field induced magnetization. Based on the geometry of our system, we also unambiguously distinguish long-distance transport based on equilibrium (Bose-Einstein condensate) or non-equilibrium magnons. The physical mechanisms at stake in our experiments allow us to observe the persistence of the two signals for distances larger than a micron (see Fig.1.ii), demonstrating long distance magnonic transport in antiferromagnetic insulators.

Magnetoresistive random-access memory (MRAM) [1,2] is poised to become a next-generation information storage device. Yet, many materials challenges remain unsolved before it can become a widely used memory storage solution. Among them, an urgent need is to identify a material system that is suitable for downscaling and is compatible with low-power logic applications. Self-assembled, vertically-aligned $La_{2/3}Sr_{1/3}MnO_3$:ZnO nanocomposites [3], in which $La_{2/3}Sr_{1/3}MnO_3$ (LSMO) matrix and ZnO nanopillars form an intertwined structure with coincident-site-matched growth occurring between the LSMO and ZnO vertical interfaces, may offer new MRAM applications by combining their superior electric, magnetic (*B*), and optical properties. In this talk, we will present the results of electrical current induced magnetic hysteresis in magneto-resistance measurements in these nanopillar composites [4]. We observe that when the current level is low, for example, 1 μA, the magneto-resistance displays a linear, negative, non-hysteretic *B* field dependence. Surprisingly, when a large current is used, $I > 10$ μA, a hysteretic behavior is observed when the *B* field is swept in the up and down directions. This hysteresis weakens as the sample temperature is increased. A possible spin-valve mechanism [5-7] related to this electrical current induced magnetic hysteresis is proposed and discussed. This work was supported by an LDRD project at Sandia National Laboratories (SNL). SNL is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525. This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy Office of Science by Los Alamos National Laboratory (Contract DE-AC52-06NA25396) and Sandia National Laboratories (Contract DE-NA0003525). A portion of this work was performed at the National High Magnetic Field Laboratory, which is supported by National Science Foundation Cooperative Agreement No. DMR-1157490 and the State of Florida.

Paris-Sud, Université Paris-Saclay, ORSAY, France; 4. ALS, Lawrence Berkeley National Laboratory, Berkeley, CA, United States*

Nowadays magnetic memories are based on the manipulation of magnetization in nano-magnets by electric currents, resulting in high energy consumption. Accordingly, a new paradigm based on the control of magnetization by an electric field is highly desirable. This seems to be possible in multiferroic systems [1], where both the ferromagnetic (FM) and the ferroelectric (FE) order parameters are present and are coupled to each other. In particular, multiferroic hetero-structures consisting of a FM thin film deposited on top of a FE $BaTiO_3$ (BTO) substrate have been reported to have a strong magneto-elastic coupling at the interface between the two materials which dominates the magnetic anisotropy in the ferromagnet [2,3]. The very stable one-to-one correspondence between the FE and FM domain state observed in those systems allows to obtain a fully deterministic control of magnetism by electric fields at the micro-\nano-scale, something that is totally new if compared with what has been obtained with other multiferroic hetero-structures [4,5]. Here we report about the electric field-controlled magnetization switching and magnetic domain wall (DW) motion in FeCo micro-\nano-structures on top of a BTO single crystal substrate. By XLD- and XMCD-PEEM, we directly image the FE state at the top surface of the BTO substrate and the FM state of the FeCo magnetic structures patterned on top of the single crystal, while the electrically induced magneto-elastic anisotropy is characterized by Kerr microscopy. On the as-grown sample, we observe a direct link between the magnetic uni-axial anisotropy in the patterned FeCo structures and the FE domains. Furthermore, during the application of an electric field through the substrate thickness, we observe the motion of FE DWs and the consequent motion of FM DWs. This induces a 90 degrees re-orientation of the magnetization state in the magnetic structures lying on top of the moving DWs. The observed magnetization switching process is highly reliable, and thus has a high potential for applications.

Contrary to current-controlled magnetic random access memory devices utilizing spin transfer torque (STT) or spin-orbit torques (SOT), voltage-induced magnetization switching can lead to a new paradigm enabling ultralow-power and high density instant-on nonvolatile magnetoelectric random access memory (MeRAM) devices. In recent theoretical research, *ab initio* electronic structure calculations in our group for Ta/FeCo/MgO[1] and Au/FeCo/MgO[2] junctions predict a V- or Λ-shape voltage-controlled magnetic anisotropy (VCMA) behavior with VCMA coefficients of −648 (486) and 1871 (-101) $fJV^{-1}m^{-1}$, respectively, under negative (positive) electric field. On the experimental side, Ta (3 nm)/CoFeB (2 nm)/MgO (3 nm)/Cr(10 nm)/Ir (10 nm)/CoFe (1~3 nm)/MgO (3 nm)/Ta (3 nm) magnetic tunnel junctions (MTJs) shows giant VCMA coefficients of around 1,000 fJ/Vm[3]. Employing *ab initio* electronic structure calculations we have investigated the effect of epitaxial strain on the VCMA behavior in Ir/FeCo/MgO heterostructures. We employed a slab supercell structure along [001] direction consists of three monolayers (MLs) of fcc Ir, three MLs of B2-type FeCo, seven MLs of rock-salt MgO and 19 Å-thick vacuum regions separating the periodic slabs. The calculation reveal that the magnetic anisotropy energy varies under electric field with giant VCMA efficiency in the range of -1,267 to -367 $fJV^{-1}m^{-1}$ in agreement with recent experiments. The underlying mechanism is that interfacial Fe atom with Ir cap plays a significant role in determining the MCA value under biaxial strain, contrary to other capped materials (Ta, Au), where the interfacial Fe atom in the vicinity of the cap has minor MCA contribution. Furthermore, we predict an electric-field-induced spin-reorientation which depends on epitaxial strain. These findings open interesting prospects for exploiting strain engineering and the appropriate heavy metal cap to harvest higher efficiency VCMA for the next-generation MeRAM devices. This research was supported by NSF ERC-TANMS Grant No. 1160504 and by NSF-PREM Grant No. DMR-1205734.

Y7-04. Robust Room Temperature Magnetoelectric Coupling in Multiferrioc Materials for Ultralow Energy Spintronic Applications. *B. Prasad*[1], H. Taz[2], Y. Huang[1], Z. Chen[1], V. Thakare[1], S. Hsu[1], R. Kalyanaraman[2,3] and R. Ramesh[1,4] *1. Department of Materials Science and Engineering, UC Berkeley, Berkeley, CA, United States; 2. Bredesen Center, University of Tennessee, Knoxville, TN, United States; 3. Department of Materials Science and Engineering, University of Tennessee, Knoxville, TN, United States; 4. Department of Physics, University of California, Berkeley, CA, United States*

The electric-field manipulation of magnetism in mutltiferrroic based devices promises to reach atto-Joule (aJ) per bit operation in logic and memory devices [1]. Among all multiferroic materials, $BiFeO_3$ (BFO) exhibits robust magnetoelectric coupling at room temperature [2, 3]. The canted antiferromagnetically aligned spins in BFO, give arise to the weak ferromagnetism due to the Dzyaloshinskii–Moriya(DM) interaction, causes strong exchange interaction with ultrathin ferromagnet, e.g. CoFe, which can be exploited to electrically control a spin valve device [4]. Nevertheless, fatigue and reliability are the key challenges for the integration of these heterostructure systems in microelectronic devices, when contacted with such metallic ferromagnets. We are exploring a novel magnetic oxide, comprised of an amorphous Fe-Dy-Tb oxide (FDTO) thin film, as the top ferromagnetic layer that couples to the underlying BFO. Amorphous FDTO has been shown to possess a combination of low sheet resistance (<200 ohm/sq) and room temperature magnetism with coercivity of around 40 Oe [5, 6]. The FDTO films were deposited by pulsed laser deposition on top of epitaxially grown BFO films at room temperature, in the presence of an in-plane and out-of-plane magnetic field, under varying oxygen pressures. Temperature dependent magnetic measurements demonstrated an increase in the coercive field of FDTO to 1300 Oe on BFO films indicating that the FDTO layer couples to the BFO. The ferroelectric property of BFO was found to be retained for over 10^8 switching cycles with the FDTO as a top electrode, suggesting the possibility of using this amorphous semiconducting oxide as a contact ferromagnet. Finally, electric filed control of giant magnetoresistance response of the spin-valve devices, structured on FDTO/BFO bilayer, have shown evidence for ME coupling in FDTO/BFO heterostructures at room temperature. In addition to these findings, reduction of switching voltages to sub-volt regime with the strain and interface engineering, and also chemically manipulating the ferroelectric property of BFO provides a pathway to integrate FDTO/BFO as the key component in the fabrication process for ultra-low energy, non-volatile beyond-CMOS computing.

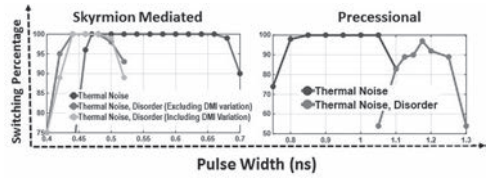
Y7-05. Switching error analysis in skyrmion mediated VCMA switching. *D. Bhattacharya*[1], P. Sutradhar[1] and J. Atulasimha[1] *1. Virginia Commonwealth University, Richmond, VA, United States*



Memory devices based on magnetization reversal induced by voltage control of magnetic anisotropy (VCMA) are potentially 2 orders of magnitude more energy efficient than Spin Transfer Torque (STT) based devices [1]. However, experimentally observed write error rate (WER) are substantially

high (4×10^{-3}) owing to incoherent switching due to thermal perturbation and presence of defects [2]. Therefore, this technique requires an iterative approach to lower the WER. In this work, we present an alternative, skyrmion mediated pathway for magnetization reversal that has the capability to eliminate or at least reduce the number of iterations in the write process [3]. Hence, it can potentially lower the write time and energy dissipation. In a system with Dzyaloshinskii-Moriya Interaction (DMI), reduction of perpendicular magnetic anisotropy (PMA) can drive the magnetization to a skyrmionic state [4]. Once formed, the skyrmion breathes (i.e. shrinks and expands). Successful switching can be accomplished if PMA is restored when skyrmion is inbreathing (i.e. shrinking) as PMA restoration promotes further shrinkage of the core (Fig. 1). We provide a comprehensive error analysis of our proposed method and compare it against the conventional precession based scheme. To simulate a real scenario, we perform error calculation in a disordered system with different grain sizes having intergranular variation of PMA and easy axis orientation. Room temperature thermal noise and perturbative spin current were also considered (Fig. 2). Motivated by recent demonstrations of STT switching of 11 nm p-MTJ with WER ~ 10^{-10} [5], we will further evaluate the feasibility of scaling skyrmions mediated VCMA switching by calculating WER in different sized devices. This systematic study will identify important sources as well as quantify WER for both VCMA switching mechanisms at different length scales. We acknowledge NSF CAREER grant CCF 1253370, VCU Quest Commercialization grant and Virginia Microelectronics Seed grant.

Y7-06. Voltage-driven high speed skyrmion motion in skyrmion shift device. *N. Lei*[1], Y. Liu[1], W. Kang[1], X. Zhang[2], Y. Zhou[2], Y. Zhang[1] and W. Zhao[1] *1. Beihang University, Beijing, China; 2. Department of Physics, The University of Hong Kong, Hong Kong, Hong Kong*

Magnetic skyrmions are promising information carriers for building future high-density and high-speed spintronic devices. However, to achieve a current-driven high-speed skyrmion motion, the required driving current density is usually very large, which could be energy inefficient and even destroy the device due to Joule heating. Here, we propose a voltage-driven skyrmion motion approach in a skyrmion shift device made of magnetic nanowires. In this work, a series of equidistant identical electrodes on the nanowire with uniform thickness structure is proposed for high-speed skyrmion motion. A voltage-induced energy barrier and energy well on the sides of the skyrmion drive its directional motion to the addressable position along the nanowire. An analytical model is developed to describe the spin texture in skyrmion profile passing through an energy step induced by VCMA. To realize high-speed data delivery, parameters are optimized with and a solution is proposed for long-range skyrmion motion. With that optimization, the maximum velocity reaches 259 m/s when 0.45 V voltage is applied. Under 0.2 V voltage, only 7.5 aJ is consumed for one shift of a single skyrmion with an average velocity of 70 m/s. Our approach uncovers valuable opportunities for building skyrmion racetrack memories and logic devices with both ultra-low power consumption and ultra-high processing speeds, which are appealing features for future spintronic applications.

Y8-01. Topological magnon Dirac points in a three-dimensional antiferromagnet. W. Yao[1], C. Li[1], L. Wang[1], S. Xue[1], Y. Dan[1], K. Iida[2], K. Kamazawa[2], K. Li[3], J. Hu[3], C. Fang[3] and *Y. Li[1] 1. International Center for Quantum Materials, Peking University, Beijing, China; 2. Neutron Science and Technology Center, Comprehensive Research Organization for Science and Society, Tokai, Japan; 3. Institute of Physics, Chinese Academy of Sciences, Beijing, China*

The recent discovery of topological semimetals, which possess distinct electron-band crossing with non-trivial topological characteristics, has stimulated intense research interest. By extending the notion of symmetry-protected band crossing into one of the simplest magnetic groups, namely by including the symmetry of time-reversal followed by space-inversion, we predict the existence of topological magnon-band crossing in three-dimensional (3D) antiferromagnets. The crossing takes on the forms of Dirac points and nodal lines, in the presence and absence, respectively, of the conservation of the total spin along the ordered moments. In a concrete example of a Heisenberg spin model for a "spin-web" compound, Cu_3TeO_6, we theoretically demonstrate the presence of Dirac magnons over a wide parameter range using linear spin-wave approximation [1]. Inelastic neutron scattering experiments have been carried out to detect the bulk magnon-band crossing in a single-crystal sample. The highly interconnected nature of the spin lattice suppresses quantum fluctuations and facilitates our experimental observation, leading to remarkably clean experimental data and very good agreement with the linear spin-wave calculations. The predicted topological band crossing is confirmed [2].

Y8-02. Observation of Direct Pu-239 Nuclear Magnetic Resonance in PuB_4. *E. Bauer*[1], A. Dioguardi[1], H. Yasuoka[1], S.M. Thomas[1], S. Cary[1], S. Kozimor[1], J. Thompson[1], T. Albrecht-Schmitt[2] and F. Ronning[1] *1. Los Alamos National Laboratory, Los Alamos, NM, United States; 2. Florida State University, Tallahassee, FL, United States*

Since its discovery in 1946, nuclear magnetic resonance (NMR) spectroscopy has become a powerful technique for probing the local structure, electronic structure, bonding, and dynamics of molecules and extended solids. It has developed into a cornerstone of chemistry and medicine for determination of the structure of chemical and biological systems through spin-1/2 ^{1}H and ^{13}C NMR, and for imaging the body (MRI). From the approximately 90 nuclear isotopes that are known to have a non-zero magnetic moment, about 30 have a nuclear spin of I=1/2. The spin-1/2, Pu-239 NMR signal was only recently observed in cubic PuO_2, despite more than 50 years of effort on a range of Pu compounds [1]. We report the second observation of a Pu-239 NMR signal in a tetragonal compound PuB_4. This compound is predicted to be a topological insulator [2] and measurements of the NMR shift reveal a significant difference (~25%) in the shift between PuO_2 and PuB_4, suggesting large changes in bonding in the two materials. We will discuss the properties of PuB_4 and our discovery of the direct Pu-239 NMR signal, which provides new way to investigate the electronic structure, chemical bonding, and behavior Pu's 5f electrons.

Y8-03. Resonant inelastic X-ray scattering studies of correlated rare-earth systems. *J. Hancock[1,2] 1. Department of Physics, University of Connecticut, Storrs, CT, United States; 2. Institute of Materials Science, University of Connecticut, Storrs, CT, United States*

Resonant inelastic X-ray scattering (RIXS) is a truly 21st-century technique which has a strong running record of discovery in the context of transition metal oxides and high-temperature superconductivity. These achievements have incentivized beamline and endstation development permitting investigations of f-electron materials with unprecedented energy resolution and kinematic control of the RIXS scattering process. In this talk, we present new results to this end, surveying the abilities of both hard- and soft-X-ray RIXS probes of Kondo correlations in rare-earth-based electronic systems. We compare and contrast RIXS spectra collected at the L and M edges crossing the valence instability of $YbInCu_4$. We find the L edge spectrum ($2p_{3/2}\rightarrow d\rightarrow 2p_{3/2}$) shows significant band reconstruction of 5d-derived states and therefore samples the itinerant states of this Kondo lattice system.

In contrast, the M edge RIXS spectra ($3d_{5/2}\rightarrow f\rightarrow 3d_{5/2}$) are sensitive to the more localized electronic states and we reveal our findings regarding the momentum-resolved hybridization gap of this material and lay out new opportunities. These two significant results enlighten the mechanism of the transition in $YbInCu_4$. In a second study, we have explored the RIXS response of rare-earth hexaborides YbB_6, EuB_6, and SmB_6, where we find that the inelastic X-ray scattering cross section at the divalent resonance of the L edges can be simply related to the unoccupied 5d density of states in an effective f-d transition as the primary excitation with quantitative agreement with electronic structure calculation. In addition, we find anomalous RIXS signal at a higher incident energy where there is no clear absorption resonance. These two different excitations have different dependences on scattering geometry and we provide an interpretation based on these findings, wherein the higher energy feature corresponds to a photon scattering process with enhancement through intermediate states that are photoemission final states. Together, these results pave a pathway toward future RIXS investigations of materials in the mixed-valent and heavy fermion class.

Département de Physique de la Matière Condensée, University of Geneva, Geneva, Switzerland*

The electronic ground state of correlated electron systems, often manifests a granular texture across a broad range of length scales. Antiferromagnetic order is a common instability of these materials, however, its nanoscale spatial organization has not been systematically studied. In this talk, I will present our recent result using a resonant soft X-ray scattering nanoprobe to image the bulk magnetic landscape in $NdNiO_3$ thin films. Our measurements provide direct evidence for a highly textured magnetic fabric, that further exhibits return memory effects across the Neel transition. The scale-free distribution of antiferromagnetic domains and its non-integral dimensionality, together reveal an unprecedented magnetic fractal geometry near criticality, which reflects the interplay between electronic correlations and an intrinsic local parameter. Our observations expose new essential details of the nanoscale anatomy of strongly correlated electronic systems.

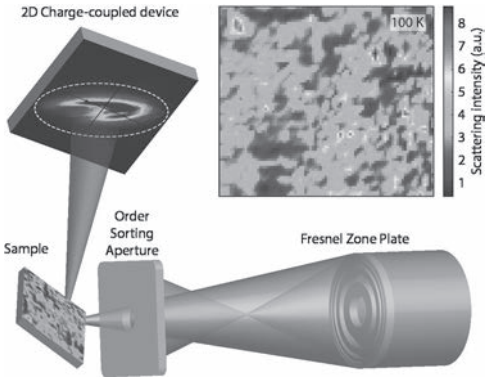

Figure 1. Experimental setup and nanoscale antiferromagnetic landscape in $NdNiO_3$. The combination of Fresnel zone plate and order sorting aperture delivers a focused soft X-ray spot at the sample. The magnetic Bragg diffraction are visualized with a fast 2D charge-coupled detector. Top right inset shows the spatial map of magnetic scattering intensity displaying a highly inhomogeneous electronic landscape at the nanoscale.

Beijing Computational Science Research Center, Beijing, China*

In this paper, we present the electronic structures and orbital-resolved electronic properties of structurally distorted 1T -TaS2 bulk and monolayer within density functional theory approaches. The relaxed commensurate-charge-density-wave (CCDW) structure shows that 13 Ta atoms condense into a star-of-David cluster, accompanied by a buckling of neighboring S planes. Through detailed analyses to the orbital characters near the Fermi level, we show that there exists an orbital-density-wave (ODW) order, which is predominantly contributed by Ta-5d3z2−r2 orbital in the central Ta of the star-of-David cluster. We further demonstrate that the structural distortion, together with the Coulomb interaction, stabilizes the CCDW insulating ground state with an ODW order. The results obtained from dynamical mean-field theory confirm the role of the electronic correlation. Moreover, such an ODW ground state favors an intralayer ferromagnetic order in bulk and monolayer 1T -TaS2, and an interlayer antiferromagnetic order in bulk. We propose that 1T -TaS2 monolayer may pave new ways to study exciton physics, flat-band physics, and potential applications in luminescence.

Y9-01. A new Ce-based heavy fermion system close to a possibly multipolar Quantum Critical Point: $CeRh_2As_2$. *S. Khim*[1], J. Banda[1], D. Hafner[1], U. Stockert[1], D. Jang[1], M. Brando[1] and C. Geibel[1] *1. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany*

We have discovered a new heavy fermion system close to a quantum critical point, $CeRh_2As_2$. It shows an unusual magnetic phase diagram and unusual properties which points to a possible involvement of quadrupolar degree of freedoms. Therefore, $CeRh_2As_2$ is a new candidate for multipolar quantum criticality and associated superconductivity. We have grown single crystals of $CeRh_2As_2$ and studied its physical properties. The high-T magnetic susceptibility shows a Curie-Weiss behavior with an effective moment of 2.55 μB/Ce, indicating a trivalent Ce state. However, the resistivity presents a temperature dependence typical of a system with strong Kondo interaction. This is supported by specific heat $C(T)$ results which indicate a Sommerfeld coefficient of the order of 1 J/molK^2, as well as a Kondo temperature T_K of the order 20 K. At low T the $C(T)$ data revealed two successive transitions at $T_1 \sim 0.25$ K and $T_2 \sim 0.4$ K in zero field. T_1 and T_2 much smaller than T_K implies that this system is very close to a hybridization induced quantum critical point (QCP). The magnetic phase diagram deduced from $C(T)$ data shows an unusual behavior for field applied in the basal plane. While T_1 decreases monotonously and disappears at $B = 2$ T as expected e.g. for an antiferromagnetic state, T_2 first stay constant and then increases weakly but continuously up to $T_2 = 1$ K at $B = 14$ T. Such a phase diagram with a significant increase of the transition Temperature with applied magnetic field is reminiscent of systems with quadrupolar order, as e.g. CeB_6. A possible quadrupolar order is supported by the magnetic 4f entropy which continuously increases and approaches Rln4 at 60-80 K, without showing a leveling at Rln2. This indicate a quasi-quartet crystal electric field (CEF) ground state carrying a finite quadrupolar moment. On the other hand, T_1 and/or T_2 may also be attributed to unconventional magnetic states resulting from the absence of inversion symmetry at the Ce site in the $CaBe_2Ge_2$-type structure. Thus, the unique magnetic phase diagram of $CeRh_2As_2$ makes it a very promising compound in the field of multipolar quantum criticality.

Y9-02. Single-site non-Fermi liquid behaviors in a diluted Pr system $Y_{1-x}Pr_xIr_2Zn_{20}$. *Y. Yamane*[1], T. Onimaru[1], K. Wakiya[1,3], K. Matsumoto[1,2], K. Umeo[4] and T. Takabatake[1] *1. Graduate School of Advanced Sciences of Matter, Hiroshima University, Higashi-Hiroshima, Japan; 2. Ehime University, Matsuyama, Japan; 3. Department of Physics, Yokohama National University, Yokohama, Japan; 4. Cryogenic and Instrumental Analysis Division, N-BARD, Hiroshima University, Higashi-Hiroshima, Japan*

Non-Fermi liquid (NFL) behaviors in U or Pr systems with f^2 configuration have received considerable attention since Cox proposed a single-site quadrupole Kondo effect to describe the NFL behaviors found in a heavy fermion compound UBe_{13} [1]. However, the single-site quadrupole Kondo effect has not been established yet because of inevitable atomic disorder and/or uncertainty of crystalline electric field (CEF) levels of the f^2 electrons. Recently, NFL behaviors of the specific heat C and electrical resistivity ρ were observed in a cubic $PrIr_2Zn_{20}$ with the Γ_3 doublet ground state carrying active quadrupoles, suggesting a possible formation of the quadrupole Kondo lattice [2, 3]. If this is the case, a single-site quadrupole Kondo effect could manifest itself when the Pr^{3+} ions are diluted with elements without 4f electrons. Bearing this in mind, we have measured C and ρ of a diluted Pr^{3+} system $Y_{1-x}Pr_xIr_2Zn_{20}$ for $0.024 \le x \le 0.44$. The magnetic specific heat C_m/T exhibits $-\ln T$ dependence at $T < 2$ K. A characteristic temperature of the single-site quadrupole Kondo effect T_0 is defined as the temperature where the magnetic entropy S_m reaches 75% of Rln2 expected for the doublet ground state. This method gives T_0 for $x = 0.024$ as 0.34 K, which value is monotonically increased to 1.26 K for $x = 0.44$. The normalized C_m/T data for all x by the absolute values at T_0 agree well at $T/T_0 \le 3$. Moreover, the normalized data of the differential electrical resistivity $\Delta\rho$ (= $\Delta\rho(T) - \Delta\rho(3\text{ K})$) for all x converge well at $T/T_0 \le 3$. The scaling of both C_m/T and $\Delta\rho$ data indicates the NFL behaviors originate from an identical mechanism. Furthermore, the normalized C_m/T and $\Delta\rho$ data for $x < 0.05$ follow $-\ln T$ and the square root of T at $T/T_0 \le 1$, respectively, which temperature dependences are consistent with those expected from the single-site quadrupole Kondo theory. Therefore, we infer that the observed non-Fermi liquid behaviors result from the single-site quadrupole Kondo effect.

Y9-03. A Realistic Model for Ferrohastatic Order in Cubic Pr-based Materials. J. van Dyke[1], G. Zhang[1] and *R. Flint*[1] *1. Iowa State University, Ames, IA, United States*

Heavy fermion physics has recently taken a new direction with the synthesis of non-Kramers doublet materials with significant hybridization leading to non-Kramers doublet Kondo physics [1]. We address the critical question: "what does the heavy Fermi liquid look like in non-Kramers doublet materials?" This question is particularly important to understand the phase diagrams and quantum criticality of the superconducting Pr "1-2-20" compounds, such as PrV_2Al_{20} [2-4]. The non-Kramers ground state doublet ensures that the heavy Fermi liquid must be an exotic 'hastatic' order that breaks symmetries [5,6]. We elucidate the physics of spinorial 'hastatic' hybridization order in cubic systems, as relevant for the Pr 1-2-20 [$Pr(Ti,V)_2Al_{20}$, $Pr(Ir,Rh)_2Zn_{20}$] compounds. We derive a simple mean-field picture for spatially uniform 'ferrohastatic' order, treated within a realistic spin-orbit coupled Anderson model, and identify its experimental consequences [7]. The properties of ferrohastatic order, grounded in spontaneous time reversal symmetry breaking, can explain the unusual behavior of several of these materials in magnetic field and motivate further experimental work on these compounds.

Y9-04. Theoretical Study of Non Fermi Liquid and Ordered States in Pr 1-2-20 Systems. *A. Tsuruta*[1] and K. Miyake[2] *1. Materials Engineering Science, Osaka University, Toyonaka-City, Japan; 2. Center for Advanced High Magnetic Field Science, Osaka University, Toyonaka, Japan*

Non-Fermi liquid behaviors in the resistivity have been reported in PrV_2Al_{20} [1] and $PrIr_2Zn_{20}$ [2]. Namely, the electrical resistivity is proportional to T^0.5. The Specific heat increases like C_0-$C_1T^{0.5}$ as T decreases. The ground state of the crystalline-electrical field (CEF) of the local f-electron is considered to be the Γ_3 non-Kramers doublet in $4f^2$ configuration. Such a system with the Γ_3 CEF ground state in f^2 configuration is expected to exhibit an anomalous behavior associated with the two-channel Kondo effect. Tsuruta et al. investigated electronic states in the M-channel Anderson lattice model using the expansion from the limit of large spin-orbital degeneracy N (1/N-expansion) [3]. The inclusion of the self-energy in $O((1/N)^0)$ leads to heavy electrons with degeneracy of channel and spin-orbit. In the single channel case, the imaginary part of the self-energy of conduction electrons (ISE) shows the Fermi liquid behavior: i.e. ISE is given by a form proportional to T^2 owing to the inter-site correlation effects in higher order terms in power of 1/N. In the two-channel case, however, a T-linear term in ISE at the Fermi level, in contrast to a T^2 -term in the Fermi liquid is found. However, the T-linear dependence of ISE is restricted in the asymptotic region of T=0, but a $T^{0.5}$-dependence appears in a rather wide temperature region. Because of the anomalous T-dependence of ISE, the chemical potential is given by μ_0-$\mu_1T^{0.5}$, and the specific heat is given by C_0-$C^1T^{0.5}$. We also obtain the scaling behavior f(T/T_K), T_K is the quadrupole Kondo temperature, in electrical resistivity, chemical potential, specific heat and magnetic susceptibility, explaining non-Fermi liquid properties observed in Pr 1-2-20 compounds [4]. Futhermore we investigate the quadrupole and superconducting ordered state in two-channel model.

Y9-05. Elastoresistivity as a probe of the diverging quadrupole-strain susceptibility approaching the ferroquadrupolar phase transition in $YbRu_2Ge_2$. *E. Rosenberg*[1], J. Straquadine[1], A. Hristov[1] and J. Palmstrom[1] *1. Stanford University, Stanford, CA, United States*

Elastoresistivity relates changes in resistivity ρ_{ij} to strains ε_{kl} experienced by a material. For a tetragonal system, the B1g and B2g components of this 4th rank tensor m_{ijkl} are proportional to the nematic susceptibility in these symmetry channels. Hence, measurements of the elastoresistivity can provide insight to nematic (quadrupole) fluctuations. This quantity has been recently probed in the iron based superconductors, for which a divergence of m_{xyxy} has revealed that the tetragonal-to-orthorhombic phase transition in those materials is driven by nematic order in the B2g symmetry channel. In principle, elastoresistivity measurements can also be used to probe quadrupole fluctuations in other materials, including heavy fermion systems. Here we apply a modified AC elastoresistivity technique to measure the quadrupole-strain susceptibility of $YbRu_2Ge_2$, a material that exhibits a tetragonal to orthorhombic phase transition at 10 K that is understood to arise from 4f ferroquadrupole order with a B1g symmetry. In order to measure this quantity, several technical advances were necessary. In particular, a Focused Ion Beam (FIB) was used to etch Hall bar patterns such that the B1g, A1g, and B2g quadrupole –strain susceptibilities could be separately obtained with negligible cross-contamination. The elastoresistance in all three symmetry channels grows rapidly towards the phase transition, but the B1g response is uniformly larger than the B2g response.

Y9-06. Theory of Valence Fluctuation and Unconventional Heavy Fermion in Sm compounds. *R. Shiina*[1] *1. Physics, University of Ryukyus, Nishihara, Japan*

In this presentation, we will discuss the origin of a new low-temperature phenomenon of Sm compounds, namely field-insensitive heavy-fermion (HF) states. It was reported first for the skutterudite $SmOs_4Sb_{12}$ [1] that the γ and A values in specific heat and resistivity show the HF behavior with a very large effective mass. A remarkable feature is an insensitivity of the HF state to the external magnetic field; the γ and A values were found to be almost unchanged up to 15T of the field strength. This is apparently inconsistent with the common knowledge on the Kondo effect that the field easily destroys the state of such a large effective mass associated with a small Kondo temperature. Recently, similar phenomena have been discovered for $SmTa_2Al_{20}$ and $SmTi_2Al_{20}$ in the so-called 1-2-20 compounds [2,3]. In order to understand the origin of those exotic HF states, an importance of valence fluctuation (VF) has recently been pointed out through an analysis of the X-ray scattering spectrum [4,5]. Thus, it is needed at this stage to clarify the nature of VF between f^5 and f^6 configurations in Sm ions, which must be different from the conventional one in Ce ions. As a first step to explore this problem, we consider a two-orbital impurity Anderson model in Γ_8 orbitals of Sm ions; it is mapped from the realistic model with a strong crystal field (CF) potential, where the CF-split 4f states in different J multiplets are mixed. This model exhibits a quantum critical point (QCP) between the local-singlet and the Kondo-singlet states in the variation of the c-f hybridization [6]. We then study the Fermi-liquid properties around the QCP by using the numerical renormalization-group (NRG) method. It is shown that the γ value of specific heat is definitely enhanced around the QCP, associated with a significant suppression of the Wilson ratio, thus realizing a field-insensitive HF state. It is also shown that the parameter region in which the HF state appears is of intermediate valence and is enlarged as the local excitation energy in the effective f^2 configuration is increased. The relevance of these results to the experimental results is also discussed.

INVITED PAPER

1:30

Y10-01. Spin-orbital Singlet, Spiral Spin-liquid And Novel Vortex States In Magnets With Spinel Structure. *C. Rüegg[1,2] 1. Neutrons and Muons, Paul Scherrer Institute, Villigen PSI, Switzerland; 2. Quantum Matter Physics, University of Geneva, Geneva, Switzerland*

Magnets with spinel structure AB_2S_4 and magnetic ions on their A-sites have been proposed theoretically to realize exotic magnetic states like spin-orbital singlets (SOS) and spiral spin-liquids. Application of magnetic field or pressure to control spin-orbit coupling may further lead to emergent new phases near quantum critical points. $FeSc_2S_4$ is a candidate material to realize a nearly quantum critical spin-orbital singlet state, where entangled spin and orbital moments fluctuate in a global singlet state at the boarder of spin and orbital order. We observe the magnetic excitations in this material by inelastic neutron scattering and find that spin-orbital triplon excitations of an SOS state can capture well key aspects of the spectrum in both zero and applied magnetic fields [1]. Using neutron scattering techniques, we experimentally prove the existence of a spiral spin-liquid in $MnSc_2S_4$ by directly observing a continuous 'spiral surface' of spiral propagation vectors in reciprocal space [2]. In the same material we discover a vortex-like triple-q phase on application of a magnetic field and hence demonstrate a new mechanism to realize a magnetic vortex lattice through frustrated interactions.

Y10-02. Study of magnetic Weyl semimetals. *E. Lachman[1]*, J. Analytis[1] and G. Lopez[1] *1. University of California, Berkeley, Berkeley, CA, United States*

Materials with topologically non-trivial band structure are of great interest in recent years as these non-trivial band structures support preferred, non-dissipating conduction modes. The unique band structure is usually the result of a combination of interactions. These can be the atomic lattice structure, the electronic states of the original elements that make the material, the spin of the electrons and others. For many applications, combining an element of magnetism in these materials is favorable, either by incorporating magnetic elements in the material itself, or by inducing magnetism via a collective mode of the spins. This is also a worthwhile effort for studying the different effects of magnetism on the non-trivial band structure, and for another axis in the parameter space in which new materials are studied. In this study, we present a variety of measurements conducted on materials which are considered to be a magnetic Weyl semi-metals, such as $Co_3Sn_2S_2$. In these materials, the magnetic atoms are arranged in layers, resulting in a ferromagnetic material. In addition to the topologically non-trivial band structure, these materials are also half-metallic ferromagnets. Our aim is to explore the intricate interactions between the electrons and the magnetic atoms. To do so, we use a number of tools including magnetic measurements, magneto-transport measurements, straining the material in an applied magnetic field and so on. Several results will be presented, in addition to a discussion on future efforts and directions.

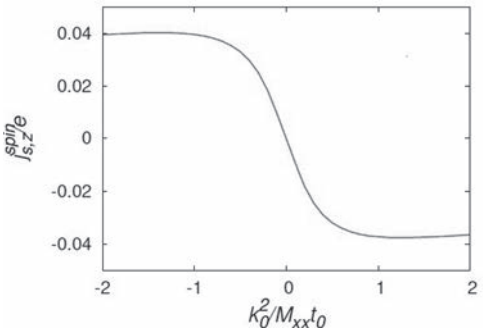
Y10-03. Spin/Charge supercurrent flow akin to chiral magnetic effect in Dirac/Weyl superconductor. *T. Matsushita[1]*, T. Liu[2,3], T. Mizushima[1] and S. Fujimoto[1] *1. Material Engineering Science, Osaka University, Toyonaka, Japan; 2. Physics and Astronomy, University of British Columbia, Vancouver, BC, Canada; 3. Quantum Matter Institute, University of British Columbia, Vancouver, BC, Canada*



The effective theory of Dirac/Weyl metals is described by Dirac/Weyl Hamiltonian. There exist the degrees of freedom of a monopole charge in momentum space, which induces an effective magnetic field in momentum space. This feature leads to the chiral anomaly phenomena in Dirac/Weyl metals, i.e. anomalous Hall effect and negative magnetoresistance. On the other hand, a strain induced pseudo-magnetic field was proposed and demonstrated in graphene, a classical Dirac system [1]. This pseudo-magnetic field is associated with chirality and behaves as an axial magnetic field. Recently, the concept of the strain induced axial magnetic field has been generalized to three-dimensional Dirac/Weyl systems [2]. The chiral anomaly phenomena associated with the emergent axial gauge field have been investigated [3,4]. However, the physical consequences of the axial magnetic field in Dirac/Weyl superconductor have not yet been well understood. In this presentation, we discuss effects of strain induced by axial magnetic fields in Dirac/Weyl superconductors using the quasiclassical Eilenberger formalism. We demonstrate that Cooper pair dynamics is affected by a pseudo-Lo-

rentz force due to the axial magnetic field in a dramatic way. In the case of Weyl superconductors, supercurrent flow parallel to the axial magnetic field is induced by the pseudo-Lorentz force. This effect is akin to the chiral magnetic effect in Weyl semimetal [5]. This implies that the pseudo-Lorentz force stabilizes the Fulde-Ferrell state where Cooper pairs have center of mass momentum along the axial magnetic field in the case that supercurrent flow is prohibited by a boundary condition. In the case of Dirac superconductors, the spin dependent Fulde-Ferrell state is realized and spin supercurrent flow appears. In addition, we show that neither Meissner effect nor vortex state due to the emergent axial gauge field occurs.

Y10-04. Quantum Kinetic Theory of the Chiral Anomaly in Topological Semimetals. *A. Sekine*[1], D. Culcer[2] and A.H. MacDonald[1]
1. Department of Physics, The University of Texas at Austin, Austin, TX, United States; 2. School of Physics, The University of New South Wales, Sydney, NSW, Australia

Three dimensional Weyl and Dirac semimetals have attracted great attention recently because of their topological nature, which is experimentally manifested by the presence of chiral anomalies, in particular by a quadratic negative magnetoresistance (positive magnetoconductance) for parallel electric and magnetic fields. Although several theoretical studies have derived expressions for the chiral-anomaly induced magnetoconductance [1,2], the conditions required for its appearance have not yet been fully understood. In this talk, we present a general theory of low-field magnetotransport in weakly disordered crystals based on a quantum kinetic equation [3]. The quantum kinetic equation determines a steady-state Bloch-state density matrix, and is a matrix generalization of the semiclassical Boltzmann equation, which is described by covariant derivatives involving momentum-space Berry connections. Our theory naturally incorporates the Berry phase effects that arise from topologically nontrivial band structures and are often discussed in terms of semiclassical wave-packet dynamics, and properly accounts for their subtle interplay with electron scattering effects. For example, the Berry phase correction to the momentum-space density of states in the presence of an external magnetic field implied by semiclassical wave-packet dynamics is captured by our theory as an intrinsic density-matrix response to a magnetic field. We propose a simple and general procedure for expanding the linear response of the Bloch-state density matrix to an electric field in powers of magnetic field. As an illustration, we apply our theory to magnetotransport in Weyl semimetals. We show that the chiral anomaly (positive magnetoconductivity quadratic in magnetic field) that appears when separate Fermi surface pockets surround distinct Weyl points survives only when intervalley scattering is very weak compared to intravalley scattering.

Y10-05. Vanishing Quantum Oscillations in Dirac Semimetal $ZrTe_5$. J. Wang[1], J. Niu[1], B. Yan[1], X. Li[1], R. Bi[1], Y. Yao[3], D. Yu[4] and *X. Wu*[1,2]
1. Physics, Peking University, Beijing, China; 2. Collaborative Innovation Center of Quantum Matter, Peking University, Beijing, China; 3. Institute of Physics, Chinese Academy of Sciences, Beijing, China; 4. Physics department, Southern University of Science and Technology of China, Beijing, China

One of the characteristics of topological materials is their non-trivial Berry phase. Experimental determination of this phase largely relies on a phase analysis of quantum oscillations. We study the angular dependence of the oscillations in a Dirac material $ZrTe_5$ and observe a striking spin zero effect in certain field directions, i.e., vanishing oscillations accompanied with a phase inversion. This indicates that the Berry phase in $ZrTe_5$ remains non-trivial for arbitrary field direction, in contrast with previous reports. The Zeeman splitting is found to be proportional to the magnetic field based on the condition for the spin zero effect in a Dirac band. Moreover, it is suggested that the Dirac band in $ZrTe_5$ is likely transformed into a line-node other than Weyl points for the field directions at which the spin zero occurs. The results underline a largely overlooked spin factor when determining the Berry phase from quantum oscillations.

Z1-01. Skyrmions in Chiral Multiferroic Insulators. *S. Seki[1] 1. Center for Emergent Matter Science (CEMS), RIKEN, Wako, Japan*
2018 IUPAP Young Scientist Prize in Magnetism

Magnetic skyrmion is a topologically stable particle-like object, which appears as nanometer-scale vortex-like spin texture in a chiral-lattice magnet[1]. In metallic materials, electrons moving through skyrmion spin texture gain a nontrivial quantum Berry phase, which provides topological force to the underlying spin texture and enables the current-induced manipulation of magnetic skyrmion[2]. Because of such electric controllability, small size, and particle-like nature, skyrmion is now rapidly attracting attention as a potential information carrier for high-density magnetic storage devices[3]. However, the above current-driven approach inevitably involves joule heat loss, and the development of alternative approach with improved energy efficiency is highly demanded. Recently, we newly discovered the emergence of skyrmions in an insulating chiral-lattice magnet Cu_2OSeO_3[4]. We found that skyrmion in insulators can induce electric polarization, whose origin can be ascribed to the relativistic spin-orbit interaction associated with the magnetically-induced symmetry breaking[5]. Such a strong coupling between skyrmion spin texture and electric polarization enables the control of stability and dynamics of skyrmions by external electric field without joule heat loss[6, 7]. The present finding of skyrmions in multiferroic insulators suggests energetically more efficient way for the electric manipulation of skyrmions. Moreover, such insulating magnets are also characterized by the low spin wave damping, which offer an ideal material platform to investigate the collective spin excitation in the skyrmion state[8]. In the three-dimensional system, skyrmion forms a flexible string structure in analogy with the vortex-line in superconductors / superfluids or cosmic string in the universe, and we have recently discovered that the resonant spin excitations in such skyrmion strings show nonreciprocal propagation character with extremely long propagation distance. Since these spin excitations are expected to propagate through any arbitrarily curved string path, skyrmion strings may serve as the robust and flexible information transmission line for the coherent unidirectional signal transfer.

Z1-02. Current-induced skyrmion dynamics probed by resistance noise spectroscopy. *T. Sato[1]*, A. Kikkawa[1], T. Yokouchi[2], H. Oike[1,2], Y. Taguchi[1], Y. Tokura[1,2] and F. Kagawa[1,2] *1. RIKEN Center for Emergent Matter Science, Wako, Japan; 2. Univ. of Tokyo, Hongo, Japan*

Magnetic skyrmions, which are topologically stabilized in some ferromagnets without inversion symmetry, such as MnSi, have been extensively studied with a focus on the manipulation of their dynamics induced by electric current or thermal gradient [1,2]. Because magnetic skyrmions act as an emergent magnetic field for conducting electrons as evidenced by topological Hall effect, moving skyrmions are expected to induce an emergent electric field [2], possibly resulting in considerable fluctuations in resistivity [3]. Here, we report resistance noise measurements on microscale-fabricated MnSi that exhibits a signature of dynamical phase transition. We obtain a road-band noise (BBN) originating from depinning of skyrmions (Fig. 1), followed by a formation of distinct narrow-band noise (NBN) (Fig. 2), which provides unambiguous evidence of dynamical coherence in moving skyrmions. The resultant NBN spectrum exhibits clear harmonics of up to 6 peaks. To the best of our knowledge, this is a first observation of washboard noise of current-induced motion of skyrmions in all skyrmion-forming materials. Given many results previously reported in sliding charge density wave or vortex flow, the NBN in the present system is also expected to originate from a washboard modulation of the translational velocity of the driven skyrmions in the form of lattice. The value of NBN frequency is, however, on the order of 100 Hz, thus a corresponding skyrmion velocity is only ~2 μm/sec, which is several orders of magnitude smaller than the previously reported for bulk samples. We believe that this large discrepancy highlights an importance of boundary effects on skyrmion motion; in our case, each skyrmion can not be ceaselessly destructed at sample edge because of their strong topological protection, reducing an averaged velocity to be a considerably smaller value. In the symposium, we present the detailed noise spectra and discuss the dynamics in the system.

We report the experimental observation of the chiral bobber (ChB) - a novel type of localized particle-like object predicted in chiral magnets exhibiting bulk-type Dzyaloshinskii-Moriya interaction [1]. ChB can be regarded as hybrid soliton composed of magnetic singularity (Bloch point) coupled to continuum magnetization vector fields near the free surface of the sample (Fig. 1a). It is shown that ChBs are able to coexist with skyrmion tubes (SkTs) over a wide range of temperature and magnetic field, suggesting their possible application in novel solid state memory devices, in which binary data bits could be encoded by a sequence of SkTs and ChBs (Fig. 1b). The imaging of ChBs is performed in thin plates of B20-type FeGe by means of off-axis electron holography [2], which provides quantitative measurements of the phase shift of an incident electron wave in a transmission electron microscope with high spatial resolution (Figs 1c-e). We identify the part of the temperature-magnetic field phase diagram, in which ChBs exist (Fig. 1f) and distinguish two mechanisms for their nucleation: spontaneous nucleation during the cooling process and nucleation from an edge dislocation in the helical state in an inclined external magnetic field.

Z2-01. Magnetic properties of FeO_2 and FeO_2H_x - novel constituents of Earth's lower mantle. *S. Streltsov*[1], A. Shorikov[1], A. Poteryaev[1] and D. Khomskii[2] *1. M.N. Miheev Institute of Metal Physics UB of RAS, Ekaterinburg, Russian Federation; 2. Universität zu Köln, Cologne, Germany*

The recent discovery of FeO_2 [1], which can be an important ingredient of the Earth's lower mantle and which in particular may serve as an extra source of oxygen and water at the Earth's surface and atmosphere [2], opens new perspectives for geophysics and geochemistry, but this is also an extremely interesting material from physical point of view. We found that in contrast to naive expectations, its properties are very different from the well-known pyrite FeS_2. FeO_2 turned out to be metallic with Fe ions nearly 3+, while FeS_2 is an insulator with Fe ions having 2+ oxidation state. Moreover, while FeS_2 is diamagnetic, FeO_2 is magnetic, with nontrivial temperature dependence of the magnetic susceptibility [3]. There also exist hydrate FeO2Hx at conditions of the Earth's lower mantle [4]. This hydrate is now considered as one of the candidates forming so called D'' layer separating Earth's core and lower mantle [5]. We show that magnetic properties of FeO_2 and FeO_2H_x are completely different [6]. FeO_2 is itinerant, band magnet, while spin moments in FeO_2H_x are localized. We discuss physical origin of this difference and an interplay between magnetic and electronic properties in these two compounds highly important for the geoscience. The work has been supported by the Russian science foundation through grant 17-12-01207.

Z2-02. The magnetic exchange parameters for the quasi-two-dimensional antiferromagnet $NiPS_3$. D. Lançon[1,2], R. Ewings[3], T. Guidi[3], F. Formisano[4] and *A.R. Wildes*[1] *1. Institut Laue-Langevin, Grenoble, France; 2. Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; 3. ISIS, Rutherford Appleton Laboratory, Didcot, United Kingdom; 4. Consiglio Nazionale delle Ricerche, Istituto Officina dei Materiali, Grenoble, France*

$NiPS_3$ is quasi-two-dimensional antiferromagnet with a honeycomb lattice. It orders below a Néel temperature of 155 K, forming ferromagnetic zig-zag chains that are antiferromagnetically coupled. The moments lie in the two-dimensional planes, pointing almost along the axis of the chains [1]. We have measured the neutron inelastic scattering from a powdered sample and have fitted the data to estimate the strengths of the magnetic exchange parameters and anisotropy (c.f. Figure 1). The data show clear, dispersive magnons and careful inspection shows no spectral weight for energy transfers between 0 and approximately 6 meV. A simple Hamiltonian with a single-ion easy axis anisotropy was used to model the magnon dynamics. Exchange interactions up to the third nearest-neighbour needed to be included to model the data, in a manner consistent with the analysis of sister compounds $MnPS_3$ and $FePS_3$. The results suggest that the nearest neighbour interaction is relatively strong and, surprisingly, ferromagnetic. However, the second and third neighbours have very strong antiferromagnetic interactions, giving rise to the antiferromagnetic structure and to the semblance of a nearest-neighbour antiferromagnetic interaction from the analysis of the magnetic susceptibility. The results are discussed in the context of other magnetic members of the transition metal-PS_3 family of compounds.

Z2-04. Magnon Scatterings in van der Waals Magnets. *C. Gong*[1] and X. Zhang[1] *1. University of California, Berkeley, Berkeley, CA, United States*

Magnon scatterings with different particles and quasi-particles are critical for the magnon dynamics and the resultant spin-related properties in magnetic materials. In this talk, I will present our discovered intrinsic ferromagnetism in 2D van der Waals (vdW) crystal $Cr_2Ge_2Te_6$,[1] including the prominent dimensionality effect and unprecedented magnetic field control of the Curie temperature in the nearly-ideal 2D Heisenberg ferromagnet. In this system, magnon softening arising from magnon-magnon interaction is suggested to play a significant role in renormalizing the magnon spectra and reducing the Curie temperature in 2D regime. Further work indicates that magnons also interact with other particles in vdW magnets. Our work reveals the plethora of inter-particle interactions in 2D magnetic systems and provides insightful guidance for designing magnonic devices based on emergent vdW magnets.

Z2-05. Carrier and strain tunable intrinsic magnetism in two-dimensional MAX_3 transition metal chalcogenides. B. Chittari[1], D. Lee[1], A. MacDonald[3], E. Hwang[2] and *J. Jung*[1] *1. Department of Physics, University of Seoul, Seoul, The Republic of Korea; 2. Sungkyunkwan University, Suwon, The Republic of Korea; 3. University of Texas at Austin, Austin, TX, United States*

We present a density functional theory study of the carrier-density and strain dependence of magnetic order in two-dimensional (2D) MAX3 (M= V, Cr, Mn, Fe, Co, Ni; A= Si, Ge, Sn, and X= S, Se, Te) transition metal trichalcogenides. Our {\em ab initio} calculations show that this class of compounds includes wide and narrow gap semiconductors and metals and half-metals, and that most of these compounds are magnetic. Although antiferromagnetic order is most common, ferromagnetism is predicted in MSiSe3 for M= Mn, Ni, in MSiTe3 for M= V, Ni, in MnGeSe3, in MGeTe3 for M=Cr, Mn, Ni, in FeSnS3, and in MSnTe3 for M= V, Mn, Fe. Among these compounds CrGeTe3 and VSnTe3 are ferromagnetic semiconductors. Our calculations suggest that the competition between antiferromagnetic and ferromagnetic order can be substantially altered by strain engineering, and in the semiconductor case also by gating. The associated critical temperatures can be substantially enhanced by means of carrier doping and strains.

Z4-01. Spin Hall Effect Induced Magnetism in Nonmagnetic Metals.
C. Stamm[1] 1. ETH Zurich, Zurich, Switzerland

The conversion of charge current into spin current transverse to the current direction, as described by the spin Hall effect, is a key consequence of the spin-orbit coupling. It leads to an accumulation of spins at the surface of the conductor, where it induces a local magnetic moment. Here we use magneto-optical Kerr microscopy to directly measure the spin Hall effect induced spin accumulation on the surface of Pt and W stripes of several nm thickness [1]. We find that the accumulated moment is oriented parallel to the surface and transverse to the current direction, and that its strength scales linearly with the applied current density. In combination with ab-initio calculations of the spin Hall effect and the magneto-optical response function, we quantify the induced moment at the Pt surface as $5x10^{-5}$ μ_B for a current density of 10^7 A/cm^2. In a thickness dependent study which takes into account the depth sensitivity of MOKE and the spin accumulation profile along the stripe thickness, we find a spin diffusion length of 11±3 nm for bare Pt. This is significantly larger compared to diffusion lengths reported for Pt adjacent to a magnetic layer.

Spin Hall effect (SHE)[1] originated from the spin-orbit interaction in nonmagnetic heavy metals has been attracting much attention as an operating principle in spintronic devices[2]. Very recently nevertheless, it has been theoretically predicted that replacing the nonmagnetic heavy metal with a ferromagnet and using the anomalous Hall effect (AHE) as a spin current source could offer potential advantages over the SHE in practical applications, such as the reliable switching of a perpendicular ferromagnet[3]. However, the spin current generation by the AHE has not been observed yet. In this work, we report the observation of spin-current generation by AHE, a phenomenon we term the spin anomalous Hall effect (SAHE)[4]. We performed spin-torque ferromagnetic resonance (FMR) experiment in CoFeB/Cu/NiFe trilayer structure, as schematically shown in Fig. 1. We apply an in-plane alternative current and external magnetic field in the direction of the film-plane with the angle ϕ_H. An oscillating magnetic field exerted by the alternative current induces an oscillation of the magnetization in NiFe. As a result of the rectification of the alternative current by the anisotropic magnetoresistance in NiFe, a direct voltage having the shape of an antisymmetric Lorentzian spectrum is obtained. Applying an in-plane direct current simultaneously, CoFeB injects the spin current into NiFe via the AHE. The spin current excites a direct spin-transfer torque acting on the magnetization in NiFe, and modifies the FMR linewidth. We observed the clear change in the linewidth of NiFe by the direct current flowing in CoFeB as shown in Fig. 2, indicating the spin injection from CoFeB to NiFe by AHE. Analyzing the current dependence of the linewidth, the efficiency of the spin injection, named as spin anomalous Hall angle, from CoFeB was evaluated to be -0.14, which is comparable to the spin Hall angle reported in nonmagnetic heavy metals.

4:15

Z4-03. Spin galvanic effect with spin rotation symmetry. W. Aljuaid[1,2], S. Allen[1], A. Humphries[1] and *X. Fan*[1] *1. Physics and Astronomy, University of Denver, Denver, CO, United States; 2. Department of Mechanical and Materials Engineering, University of Denver, Denver, CO, United States*

Spin galvanic effect (SGE) converts a spin current into a charge current due to spin-orbit interaction in a nonmagnetic material. In these effects, the spin current, spin polarization and the resultant charge current are expected to be orthogonal with each other. SGE should also exist in a magnetic material. However, because the magnetization breaks certain mirror and rotational symmetries, new spin galvanic effect with spin rotation symmetry (SGE-SR) is expected [1]. The symmetry of the SGE-SR is as if the charge current is rotated about the magnetization from that of the SGE with conventional symmetry. We have experimentally observed this SGE-SR in a spin valve with orthogonal magnetization configuration, PML/Cu/FM, where PML is a perpendicularly magnetized layer and FM is an in-plane magnetized free layer. By applying a perpendicular temperature gradient, which generates spin currents via the spin Seebeck effect, we are able to detect the SGE with conventional symmetry (dominated by the anomalous Nernst effect) as shown in Fig. 1 (a), and the SGE-SR as shown in Fig. 1(b). The SGE-SR signal observed in Fig. 1 (b) should consist of two components: (i) the spin seebeck effect in the FM generates a spin current, which is converted into a charge current by the SGE-SR at the surface of PML (Fig. 2(a)), and (ii) the spin seebeck in the PML generates a spin current, which is converted into a charge current by the SGE-SR at the surface of the FM (Fig. 2(b)). Process (i) is related to the spin diffusion length of FM while process (ii) should be an interface effect of the FM. In order to confirm this hypothesis, we carried out a FM thickness-dependent study using Ta(3)/Pt(3)/Co(1)/Cu(4)/Co(1-40)/SiO_2(4), where the Pt/Co is the PML and the second Co is the FM and the numbers in parenthesis are in nanometers. As shown in Fig. 2 (c), the result agress with our hypothesis that there are two processes contributing to the SGE-SR signal. If time permitting, I will also discuss the direct detection of spin memory loss at Cu/Pt interface, via the SGE-SR.

Z4-04. Magnetic transport properties of platinum in contact with polycrystalline antiferromagnetic NiO. M. Gamino[1], D.S. Maior[1], L.H. Vilela-Leão[3], R. Rodriguez[2], F.L. Machado[1], *A. Azevedo*[1] and S.M. Rezende[1] *1. Departamento de Física, Universidade Federal de Pernambuco, Recife, Brazil; 2. Physics, Pontificia Universidad Católica de Chile, Santiago, Chile; 3. Centro Acadêmico do Agreste, Universidade Federal de Pernambuco, Caruaru, Brazil*

We have investigated the magnetic transport properties of platinum in Pt/NiO bilayers as a function of temperature. Well-textured polycrystalline films of NiO were fabricated by the rf magnetron sputtering technique where most of the crystalline grains were oriented in the {111} and {100} planes. We show that the magnetoresistance behavior arises from two sources, the spin Hall magnetoresistance (SMR) and the anisotropic magnetoresistance (AMR). The AMR is explained as due to the magnetic proximity effect of Pt in atomic contact with the antiferromagnetic NiO, which is clearly demonstrated by the hysteresis of the MR versus magnetic field data at low temperatures. On the other hand, the SMR signal is produced by the charge current generated in the Pt layer by the spin current back reflected from the

antiferromagnetic insulating (AFI) NiO film through the inverse spin Hall effect (ISHE). As previously observed in Pt deposited on NiO in the form of bulk crystals or epitaxial films, here the SMR exhibits oscillations in the field angle variation shifted by 90 deg relative to that observed in the insulating ferrimagnet yttrium iron garnet (YIG). Measurements in the temperature range 10-300 K show that the AMR contribution increases with temperature while the SMR remains constant up to around 200 K and decreases at higher temperatures. The total magnetoresistance of Pt/NiO measured at room temperature with well textured NiO polycrystalline films is substantially larger than the values reported for crystalline or epitaxial NiO.

Z5-01. Magnetic and dielectric properties of manganese and neodymium doped calcium molybdato-tungstates. P. Urbanowicz[1], E. Tomaszewicz[2], M. Pawlikowska[2], *T. Gron*[1], M. Berkowski[3], M. Glowacki[3], M. Oboz[1], J. Kusz[1] and B. Sawicki[1] *1. Institute of Physics, University of Silesia, Katowice, Poland; 2. Inorganic and Analytical Chemistry, West Pomeranian University of Technology, Szczecin, Poland; 3. Institute of Physics, Polish Academy of Sciences, Warszawa, Poland*

Alkaline earth metal molybdates and tungstates with scheelite-type structure constitute an important group of inorganic materials. They have been used in various fields such as electro-optics, lasers, amplifiers, and microwave ceramics. Among of them, single crystals of calcium molybdate ($CaMoO_4$) and calcium tungstate ($CaWO_4$) deserve a special attention mainly because of their application as scintillation materials in cryogenic (millikelvin temperatures) experiments searching for rare events such as neutrinoless double beta decay or dark matter particle detection [1-3]. Our earlier studies showed that microcrystalline manganese-doped calcium molybdato-tungstates ($Ca_{1-x}Mn_x(MoO_4)_{0.50}(WO_4)_{0.50}$, where $0.01 \le x \le 0.15$) reveal a weak *p*-type electrical conductivity, a change in the short-range interactions from ferromagnetic to antiferromagnetic as well as an increase in orbital contribution to magnetic moment, resulting in a strong spin-orbit coupling [4]. Single crystals of $Ca_{1-3x-y}Mn_y[]_xNd_{2x}(MoO_4)_{1-3x}(WO_4)_{3x}$ (x = 0.005, 0.0099; y = 0.005, where [] denotes cationic vacancies) were successfully grown by the Czochralski method. The X-ray diffraction analysis confirmed that both single crystals belong to scheelite-type structure (s.g. $I4_1/a$). The electrical conductivity was measured by the DC method using a KEITHLEY 6517B Electrometer/High Resistance Meter. Broadband dielectric spectroscopy measurements were carried out using pellets, polished and sputtered with (~80 nm) Ag electrodes in the frequency range from 500 Hz to 2 MHz with a Novocontrol Alpha Impedance Analyzer and in the temperature range of 76–400 K. Magnetic properties were measured using a Quantum Design MPMS-XL-7AC SQUID magnetometer in the temperature range of 2–300 K and in magnetic fields up to 70 kOe. The results of electrical and magnetic measurements showed ferrimagnetic long-range and antiferromagnetic short-range interactions as well as insulating properties. In the single crystals under study, the relative permittivity reached values of 9 and 11 along axes [001] and [100], respectively, in a wide range of temperature and frequency. Their loss was below 0.05. Materials with such properties colud be applied in broadband capacitors.

The Heusler alloys are denoted as X_2YZ, here, X and Y are the transition metal elements and Z is a part of the main group elements. Recently, half-metallic or spin-gapless-type electronic states have been reported theoretically in many kinds of quaternary Heusler alloys [1-5]. The quaternary Heusler alloys are identified by $XX'YZ$ with 1:1:1:1 stoichiometric composition and thought to crystalize in LiMgPdSn-type structure. Because the electronic state is very sensitive to the atomic configurations, magnetic properties and electronic state of CoVMnAl alloy were investigated by means of powder neutron diffraction (ND), magnetic measurements and the firstprinciple calculations. Saturation magnetization measured at 5 K is quite small of 0.04 μ_B/f.u. in the specimen, which is obtained by annealing at 873 K, being closed to the expected value from the Slater-Pauling rule [6]. Since the intensities of superlattice diffractions of 111 and 200 are strong in ND, the atomic configuration of the CoVMnAl can be accurately decided. The best fitting was obtained in the structure of $L2_{1b}$-type, in where, Co and Mn atoms randomly occupy in 8*c* site in the Wyckoff position. The magnetic properties of the specimen, which is obtained by a quenching at the temperature above order-disorder phase transition, induces quit a small ferromagnetism. The specimen exhibits to *B*2-like atomic configuration, where V and Al partially distributed. The electronic states are calculated by using the KKR-CPA method based on LDA. Here, the lattice parameter was fixed as 0.580 nm, which is obtained by the analyzing of ND. In the obtained density of states (DOS), the fermi level (E_F) locates at the bottom of the pseudo-gap when the structure of the CoVMnAl alloy is assumed to have the LiMgPdSn-type ordering, and the situation brings a very low total DOS at E_F. For the electronic state with the $L2_{1b}$-type, although the E_F is kept in the position at the valley of the DOS, the total DOS at the E_F becomes to heighten.

Z5-03. Magnetization process and martensitic microstructure of Ni-Mn-Ga epitaxial films. *F. Casoli*[1], S. Fabbrici[1], M. Takhsha Ghahfarokhi[1], L. Nasi[1], R. Cabassi[1], F. Celegato[2], P. Tiberto[2], G. Varvaro[3] and F. Albertini[1] *1. CNR - IMEM, Parma, Italy; 2. INRIM, Torino, Italy; 3. CNR - ISM, Rome, Italy*

Magnetic shape memory materials show outstanding and multifunctional properties (e.g. magnetomechanical, magnetocaloric, magnetoresistive), originating from the occurrence of both a martensitic transformation and magnetically ordered states [1]. Thin films of these materials have a great potential for different applications, such as microactuators, valves and solid-state microrefrigerators [2]. We have demonstrated that a huge and reversible magnetization jump can be achieved in 200 nm epitaxial Ni-Mn-Ga films [3, Figure 1]. This is possible when the proper microstructure is obtained: growth conditions and a stress applied to the substrate enable the proper microstructure, where differently twinned martensitic regions are aligned anisotropically. In addition, we have found that lateral confinement in patterned thin films is able to influence the twin variants configuration [4]. We here examine the correlation between martensitic microstructure and magnetization process in Ni-Mn-Ga films epitaxially grown on MgO(100) or Cr/MgO(100) by r.f. sputtering. We have obtained a variety of martensitic patterns by modifying the growth conditions, applying a stress during or after growth and annealing the films. The patterns are different in orientation and spatial organization of the martensitic twin variants and give rise to distinctive magnetization processes, with magnetization jumps of variable intensity along different crystallographic directions. The occurrence of magnetization jumps is typically attributed to the magnetically induced reorientation of twin variants, similarly to what occurs in bulk materials [1 and references therein]. We have instead simulated magnetization processes of purely magnetic origin in films with different martensitic patterns by the OOMMF code [5]. The micromagnetic simulations demonstrate that magnetization jumps of purely magnetic origin and with variable intensity can occur in the first quadrant of the (M,H) diagram, showing a good agreement with the experimental results (Figure 1).

Z5-04. Temperature-dependent interlayer exchange coupling strength in synthetic antiferromagnetic $[Pt/Co]_4/Ru/[Co/Pt]_4$ multilayers. *P. Pan*[1], Y. Li[1], X. Jin[1], N. Zhang[1] and F. Ma[1] *1. School of Physics and Technology, Nanjing Normal University, Nanjing, China*

Perpendicularly magnetized tunneling junctions that contain synthetic antiferromagnetic (SAF) structures show promise as reliable building blocks to meet the demands of perpendicular magnetic anisotropy-based spintronic devices. However, the widespread Pt/Co based SAF multilayer with a nonmagnetic Ru spacer is still a challenge due to the structural discontinuity or intermixing that occurs at high temperature. In this work, the thermally robust characteristics of the interlayer exchange coupling (IEC) strength J_{ex} for sputtered SAF $[Pt/Co]_4/Ru/[Co/Pt]_4$ multilayer with strong perpendicular anisotropy has been investigated. The magnetization hysteresis (MH) loop of the SAF multilayer was measured using VSM at the temperature range from 100K to 800K. Both the out-of-plane and in-plane MH loops at room temperature were shown in Figure 1, which indicates the perpendicular anisotropy property of the SAF multilayer. Sharp spin-flips appear at the exchange coupling filed H_{ex} with a small net moment at low perpendicular field. The temperature-dependence of H_{ex} and J_{ex} were shown in Figure 2. It is demonstrated that the H_{ex} and J_{ex} of our SAF multilayer is very sensitive to the temperature variation, which depends not only on the spacer Fermi surface, but also the degree of the confinement of carriers in the quantum well of spacer. As shown in Figure 2, the H_{ex} and J_{ex} decrease from 6.17 kOe and -4.49 erg/cm^2 to 1.80 kOe and -0.83 erg/cm^2, respectively, when the temperature increases from 100K to 700K. It's worth pointing out that our SAF multilayer shows high thermal stability even at 700K (H_{ex} = 1.80 kOe and J_{ex} = -0.83 erg/cm^2) in comparison with other reports (*i.e.* [Pd/Co]/Ru(1.3)/[Co/Pd], J_{ex} = -0.38 erg/cm^2 at 673 K, *Sci. Rep. 6, 21324, 2016*). These experimental results would provide useful information for the design of SAF structures with better magnetic performance and thermal stability.

Z5-05. Metallic and Half-Metallic Materials with Ultra-Low Magnetic Damping. *J. Shaw*[1] *1. NIST, Boulder, CO, United States*

The phenomenology of magnetic damping is of critical importance to devices which seek to exploit the electronic spin degree of freedom since damping strongly affects the energy required and speed at which a device can operate. However, theory has struggled to quantitatively predict the damping, even in common ferromagnetic materials. This presents a challenge for a broad range of applications in data storage, magnonics, spintronics and spin-orbitronics that depend on the ability to precisely control the dynamics of a device. Complicating the situation is the need to simultaneously control many other magnetic properties, such as anisotropy and saturation magnetization, that may or may not be independent of the damping. I will discuss our recent work to precisely measure the intrinsic damping in several metallic and half-metallic material systems and compare experiment with several theoretical models.[1-7] This investigation uncovered a metallic material composed of Co and Fe that exhibit ultra-low values of damping that approach values found in thin film YIG.[8-10] Such ultra-low damping is unexpected in a metal since magnon-electron scattering dominates the damping in conductors. However, this system possesses a distinctive feature in the bandstructure that minimizes the density of states at the Fermi energy $n(E_F)$. This behavior can be seen in Figure 1 which shows the compositional dependence of the intrinsic damping in the Fe-Co alloy system. $n(E_F)$ is also included in the figure and exhibits a proportionality with the damping. These findings provide the theoretical framework by which such ultra-low damping can be achieved in metallic ferromagnets and may enable a new class of experiments where ultra-low damping can be combined with a charge current. Half-metallic Heusler compounds by definition have a bandgap in one of the spin channels at the Fermi energy. This feature can also lead to exceptionally low values of the damping parameter as a result of the reduced value of $n(E_F)$ and the reduced number of scattering channels. Co_2MnGe is a particularly promising Heusler material for applications in spintronics due to its low ordering temperature.[11] As a result, we achieve an intrinsic damping parameter as low as 0.001 in B2 ordered, polycrystalline Co_2MnGe films. Comparison with ab initio calculations reveal a strong correlation of $n(E_F)$ with the damping parameter, both of which vary with the order parameter. In addition, I will show that excellent quantitative agreement between theory and experiement can be obtained when the damping parameter was directly calculated by use of linear response theory. Physics Department, Georgetown University, Washington, DC, United States*

Electrical control of exchange bias is of key interest for spintronic applications due to the potential to substantially lower the power consumption in spin-valve type devices. Here we report ionic control of exchange bias, where ionic transport across a metal/oxide interface offers a highly effective means to tailor the exchange bias. In a recent experiment, we have demonstrated a controllable positive exchange bias in GdFe/NiCoO due to redox-driven oxygen migration [1]. The exchange bias characteristics are shown to be the result of an interfacial layer of elemental nickel and cobalt, a few nanometers in thickness (Fig. 1). This interface layer is attributed to a redox-driven oxygen migration from NiCoO to the gadolinium. We further show that the oxygen migration across the metal/oxide interface can be (semi-)reversibly controlled by an electric field in relatively thick AlO_x/GdO_x/Co(15 nm) films [2]. In the latest experiment we have investigated a series of NiCoO / getter (Gd, Ti, Ta) films. Our results show the presence of an interfacial FM layer with large exchange bias in three separate samples, even in nominally non-magnetic samples of NiCoO/Ti and NiCoO/Ta. This demonstrates an interesting emergence of ferromagnetism in originally non-magnetic oxide/metal heterostructures, which depends sensitively on the sample structure and field cooling conditions. Electric field control of exchange bias is also explored in these systems. These results demonstrate an effective path to tailoring the interfacial characteristics and interlayer exchange coupling in metal/oxide heterostructures. Z6-02. Imaging the Magnetization Reversal in Strongly Exchange-coupled Bilayers of TbFe and Co/Pt. *A. Mandru*[1], X. Zhao[1], M.A. Marioni[1] and H.J. Hug[1] *1. Empa, Swiss Federal Laboratories for Materials Science and Technology, Dübendorf, Switzerland*

Exchange-coupled systems with perpendicular magnetic anisotropy, consisting of a rare earth-based ferrimagnet (amorphous TbFe) and a transition metal-based ferromagnet (crystalline Co/Pt), are promising candidates for a variety of applications ranging from spin valves to heat-assisted magnetic recording. Due to the amorphous and ferrimagnetic nature of TbFe, which affects the magnetization reversal of the ferromagnet differently compared to an antiferromagnet-based system, strong and interesting coupling interactions at the interface occur [1,2]. Macroscopic magnetization measurements alone cannot account for all the details behind these interactions, thus studying the reversal locally is crucial. In this work, the reversal mechanism is understood by high-resolution and quantitative magnetic force microscopy (MFM). The $Tb_{25}Fe_{75}/[Co/Pt]_{\times 5}$ films are prepared at room-temperature using DC magnetron sputtering on Si substrates. The imaging is performed in a home-built low temperature UHV MFM at 10.5K and in high fields of up to 7T. Using a novel tip-sample distance control method [3], a quantitative analysis of our images is possible. Images of the TbFe layer alone are shown in panels a and b, with no change in the domain structure between 0 and 2T. Due to the high coercivity (~6T) of TbFe at low temperatures, we can detect the behavior of Co/Pt over a large field span. The net moments of TbFe and Co/Pt are antiparallel aligned and as the field increases, the reversal of Co/Pt is known to be accompanied by the formation of an in-plane domain wall (iDW). We find evidence of such an iDW, but instead of the expected lateral domain motion in fields of 1-2T,

the reversal of Co/Pt happens through the switching of isolated grains (panel d) followed by an inhomogeneous compression of the iDW at the interface for higher fields. These results point towards nanoscale inhomogeneities in TbFe that can easily affect the interface coupling. We have therefore extended our studies to a larger compositional spectrum of the TbFe system. Using vibrating sample magnetometry together with MFM imaging, we have studied TbFe alone and also explored its impact on the adjacent Co/Pt for each composition. These results will also be discussed.

Z6-03. Field-dependent magnetic helices in ternary magnetic heterostructures. *T. Gurieva*[1], K. Schlage[1], L. Bocklage[1,2] and R. Roehlsberger[1] *1. FS-PS, Deutsches Elektronen-Synchrotron (DESY), Hamburg, Germany; 2. Hamburg Center for Ultrafast Imaging, Hamburg, Germany*

Due to their technical relevance for spin based devices the field dependent spin structures of antiferromagnetic multilayers (AFMLs) were extensively studied during the last decades and revealed phenomena like the surface and bulk spin flop. One of the possible configurations in these AFMLs that is not only interesting from a scientific point of view but also for application is a helical structure of the magnetic moments. Recent calculations predicted that magnetic helices in such AFMLs can even be used for energy storage [1, 2]. In this contribution we investigate to which extend such helical structures can be realized in polycrystalline AF coupled Fe/Cr multilayers. To implement a helical structure, we magnetically fix the AFML at one side using a hardmagnetic FePt layer. A relatively thick Fe layer is attached to the other side of the Fe/Cr layer stack with the aim to wind up a spiral structure via rotation of an external magnetic field (Fig. 1). We used nuclear resonant reflectometry [3] to precisely study the depth dependent spin structure in the Fe/Cr multilayer stack as a function of the external rotary magnetic field and found a rather complex behavior. We observed the formation of a helical structure in the AFML which was wound up to an angle of 230°. Our experimental findings indicate that a further rotation of the external field causes a symmetrical spin flip in the helical spin structure. These results are supported by micromagnetic simulations based on a one-dimensional model. We further found that the reorientation of the magnetic spin structure in general does not only depend on the strength of the external magnetic field but also on the velocity of its rotation. This behavior can be due to the magnetic viscosity effect. This study presents valuable insight into the helical behavior of magnetic moments on the nanoscale and offers an advanced tool for further optimizations regarding potential applications.

Z6-04. Decoupling exchange bias and coercivity in perovskite oxide heterostructures. *A. Kane*[1], R.V. Chopdekar[1], A.T. N'Diaye[3], E. Arenholz[4] and Y. Takamura[1] *1. University of California, Davis, Davis, CA, United States; 3. Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA, United States; 4. LBNL, Berkeley, CA, United States*

Perovskite oxide heterostructures present a uniquely tunable materials system due to the complex interplay between their lattice, charge, orbital, and spin degrees of freedom, rendering them attractive from both fundamental and application-based perspectives. Previous studies on hard/soft ferromagnetic (FM) bilayers consisting of $La_{0.7}Sr_{0.3}CoO_3/La_{0.7}Sr_{0.3}MnO_3$ (LSCO/LSMO) layers revealed a soft FM layer characterized by Co^{2+} ions (s-LSCO) near the LSCO/LSMO interface, resulting in a s-LSCO/LSMO hybrid magnetic layer with Co/Mn ions switching simultaneously. The underlying LSCO sublayer retained its hard FM character (h-LSCO) and biased the soft layer in an exchange spring model [1, 2]. In this work, a comprehensive investigation of magnetic behavior as a function of LSCO thickness was performed on LSCO/LSMO exchange springs using a wedge bilayer and x-ray absorption/x-ray magnetic circular dichroism (XA/XMCD) spectroscopy. Minor Mn-XMCD hysteresis loops (Fig. 1) display that after biasing the h-LSCO layer, the exchange bias and coercivity both systematically change with LSCO thickness, but in opposite directions. Total electron yield (TEY) XA spectra show that this departure from expected behavior of exchange coupled systems coincides with an increase in the Co^{2+} to Co^{3+}/Co^{4+} ion ratio at the LSCO/LSMO interface (Fig. 2). We propose that the increased concentration of Co^{2+} ions in the thinnest LSCO layer provides a larger proportion of s-LSCO/h-LSCO magnetic interactions, leading to the increased coercivity of the hybrid soft FM layer. The increase in exchange bias shift results from the increase in volume of the underlying h-LSCO sublayer as the total LSCO thickness increases. This work demonstrates that the complex interactions in perovskite oxide heterostructures allows us to delicately control technologically relevant properties such as coercivity and exchange bias shift through parameters such as layer thickness.

Kneller and Hawig's theoretical work on exchange-spring magnets heralded a big leap forward in the field of advanced permanent magnets. [1] However, accomplishing an effective coupling between hard and soft magnetic phases has proven rather challenging in practice. After decades of intensive research on the subject, the mechanisms governing the phenomenon in real systems still puzzle the magnetic community. Despite the moderate hardness of the cobalt spinel, the $CoFe_2O_4$ (hard)/Co-Fe alloy (soft) system has recently drawn special attention, as a controlled reduction of $CoFe_2O_4$ nanoparticles directly leads to coexistence of the two magnetic species, maximizing the likelihood of structural coherency between them, and thus the probability of exchange-coupling. [2] Here we present what we believe is the first neutron powder diffraction (NPD) study on exchange-spring magnets. A series of $CoFe_2O_4$/Co-Fe composites were characterized combining NPD, powder X-ray diffraction (PXRD) at two different wavelengths, and magnetometry measurements. Refined nuclear and magnetic structures of the individual phases were obtained from a joint Rietveld analysis of all the diffraction patterns (see figure). The refinements revealed that the alloy tends to emerge in a Co-rich form, triggering a Co-deficiency on the remaining spinel, which induces a magnetic softening in the material. [3] The magnetic contributions from the spinel and the alloy were calculated from the atomic moments refined for each phase, yielding values of 3.54(6)-3.63(3) μ_B and 2.39(8)-2.60(9) μ_B, respectively. The total sample magnetization, $M_{Rietveld}$, was determined by weighting the individual phase contributions by the refined weight fractions of the given sample. The calculated $M_{Rietveld}$ values are in excellent agreement with the measured magnetic saturation, M_s, of the samples under an externally applied magnetic field of 2 T. The authors would like to thank financial support from the European Commission through the project AMPHIBIAN (H2020-NMBP-2016-720853).

Z7-01. Topology and Antiferromagnetic Proximity Interactions at $(Bi,Sb)_2Te_3$-based Interfaces. *Q. He*[1,2], G. Yin[2], A.J. Grutter[3] and K.L. Wang[2] *1. International Center for Quantum Materials, School of Physics, Peking University, Beijing, China; 2. Electrical Engineering, University of California, Los Angeles, Los Angeles, CA, United States; 3. NIST Center for Neutron Research, Gaithersburg, MD, United States*

Introducing magnetism into topological insulators (TIs) opens a non-trivial exchange band gap, which provides an exciting platform for versatile time-reversal symmetry-breaking physics. The surface spins of an antiferromagnetic thin film can magnetize the surface states in TIs through proximity couplings. Using this manner, emergent interfacial magnetic effects can be tailored through artificial structural engineering, and the magnetic properties such as the surface magnetization and the Curie temperature of the TI can be enhanced [1]. More interestingly, due to the vanishingly small stray field in antiferromagnets, the magnetization reversals of the top and bottom TI surfaces can be individually controlled, giving rise to intermediate spin configurations and topological transitions. The topological order is thus allowed to be manipulated using antiferromagnets [2]. Constructing TI-heterostructures using antiferromagnets with different anisotropies can further modulate the spin-texture topological transition according to the polarization of anchoring spins in the antiferromagnetic layer. This suggests that the topological charges with Chern numbers of +1 or -1 can thus be exchange-biased. Interfacing the TI with antiferromagnets unveils new avenues towards topological antiferromagnetic spintronics.

Z7-02. Coherent quantum control and magnetism on atoms on surfaces. *T. Choi*[1] *1. Physics, Ewha Womans University and Quantum Nanoscience, Seoul, The Republic of Korea*

Magnetometry having both high magnetic field sensitivity (energy resolution) and nanoscale spatial resolution has been of great interest and an important goal for applications in diverse fields covering physics, chemistry, material science, and biomedical science. The scanning tunneling microscope (STM) has been one of the most versatile tools for atomic-scale imaging, manipulation, and tunneling spectroscopy. Here, we successfully combine electron spin resonance (ESR) and STM, coherently driving spin resonance of individual iron (Fe) atoms on surfaces (MgO/Ag(100)) [1]. A radio-frequency electric field (~20 GHz), applied at the tunneling junction, modulates the spin state of the Fe atoms. The spin resonance signal is detected by a spin-polarized tunneling current. The ESR signals from individual Fe atoms differ by a few GHz (~10 μeV) while the ESR linewidth is in the range of only a few MHz (~10 neV). Such a high energy resolution enables us to distinguish spin distributions down to single-atom level and to investigate weak magnetic interactions. When we placed two Fe atoms close together with controlled atom manipulation, we found that the ESR signal from each Fe atom splits into doublet, of which separation depends on the distance between two atoms. Our measurements show $r^{-3.024\pm0.026}$ distance-dependent splitting, in excellent agreement of magnetic dipole-dipole interaction. We utilized this precisely measured dipolar interaction to determine the location and magnetic moment of unknown spin centers with sub-angstrom and one hundredth of Bohr magneton precision [2]. Our ESR-STM may promise the STM as a new and unique platform for a quantum sensor, investigating spin-labeled molecular structures and a quantum information processor, modeling quantum magnetism.

Z7-03. Long range magnetic order in 2D, fully-organic, structures on graphene. *R. Miranda*[1,2], M. Garnica[1], F. Calleja[1], A.L. Vázquez de Parga[1,2], D. Stradi[3] and F. Martin[2,1] *1. IMDEA Nanociencia, Madrid, Spain; 2. Universidad Autónoma de Madrid, Madrid, Spain; 3. Synopsys QuantumWise, Copenhagen, Denmark*

The search for long range magnetic order in 2D systems has a long history, spanning from single monolayers of magnetic metals epitaxially grown on non-magnetic metal substrates [1] to recent reports of ferromagnetic order for single monolayers of van der Waals crystals, such as $Cr_2Ge_2Te_6$ [2] or CrI_3 [3]. In all these cases the magnetic properties are associated with metal atoms with d or f electrons that provide the individual magnetic moments. A fully spin-polarized ground state based on π electrons was rigorously predicted long ago in half-filled flat-band organic materials [4]. Recently, we showed by STM and DFT that a self-assembled monolayer of organic molecules (tetracyano-p-quinodimethane, i.e. TCNQ) deposited on graphene epitaxially grown on Ru(0001) acquire charge from the n-doped graphene substrate and develop a magnetic moment of 0.18 μB per molecule [5]. The TCNQ monolayer develops spatially extended spin-split electronic bands, and a ground-state spin alignment visualized using spin-polarized Scanning Tunneling Spectroscopy (STS). The ferromagnetic order is due to the direct Heisenberg exchange interaction mediated by overlapping frontier orbitals of the molecules [6]. The magnetic anisotropy required for a 2D system to display long range magnetic order provides an easy axis in the surface plane, along the intermolecular bands where the electrons can be delocalized. The requirements to observe this magnetic order in a purely organic system are: i) the formation of spatially extended, spin-split intermolecular bands; ii) the appropriate population of these bands by charge transfer from the graphene substrate. This is demonstrated by TCNQ/gr/Ir(111), a system with intermolecular band formation, but no charge transfer from the p-doped graphene substrate, which, accordingly, does not develop magnetic moment, nor long range magnetic order. On the other hand, F4-TCNQ/gr/Ru(001), a system

where the molecules acquire charge (and magnetic moment) but do not form intermolecular bands, does not show long range magnetic order, with the F4-TCNQ molecules remaining as isolated, non-interacting magnets.

The fabrication of new magnetic devices with desired properties requires accurate control on the competing contributions to the magnetic anisotropy (MA) [1]. In this respect, magnetic structures capped by a two dimensional material provide an extremely appealing platform for future developments [2]. For instance, graphene has been shown to induce stabilization of out of plane MA in Co films supported on Ir and in gr/Co heterostrucutres, which may find use as spin torque devices and spin filters [2,3]. Here, we report on a method to deposit atomic carbon and form graphitic overlayers on top of a ferromagnetic layer, Co(0001) on Re. Our method uses intense micro-focused electron beams to stimulate the dissociation of carbon monoxide, which eventually produce the accumulation of carbon on the surface of the ferromagnetic film. XMCD-PEEM imaging shows that carbon atoms, either forming carbides or graphene, induce an in-plane to out of plane spin reorientation transition in Co. A key aspect of our method is that it enables to lithographically graft carbon patterns (see Fig 1) which modify the electronic and magnetic properties of the Co film [4]. As will be shown, our approach provides a non-invasive method to gain *local* control on the film MA, permitting to print out of plane magnetic domains with nm-sharp transition boundaries onto an in-plane magnetized support (see Fig 1-2). Interestingly, chiral domain walls are observed in the out-of-plane magnetized Co film under the graphene patterns (see details in Fig 2), suggesting that skyrmions may nucleate here and become stabile [5]. Further, *in situ* field dependent measurements will be reported, focusing in particular on the modification of the magnetic domain size.

Institute of Physics, Polish Academy of Sciences, Warszawa, Poland*

In ferromagnets magnetization reversal can be realized either by the external magnetic field or by the spin-polarized current. The manipulation of magnetization by spin-current occurs through the spin-transfer torque (STT) effect.

In this effect the spin angular momentum of electrons current is transferred to the magnetic moments of the ferromagnetic (FM) film. However, the current density required for inducing STT is of the order of 1×10^6 A/cm^2, or about $1x10^{25}$ electrons/sec cm^2. This relatively high current density significantly affects the devices' structure and performance. Here a new effect is presented: magnetization switching of FM thin layers induced solely by adsorption of chiral molecules (magnetism induced by a proximity of adsorbed chiral molecules - MIPAC), where about 10^{13} electrons per cm^2 are sufficient to induce the magnetization reversal. The local magnetization switching is achieved by adsorbing the chiral molecules as a self-assembled monolayer (SAM) on a gold-coated FM layer with perpendicular magnetic anisotropy. The direction of the magnetization depends on the handedness of the adsorbed chiral molecules. Owing to spin-selective electron transfer, the FM layer underneath the SAM molecules becomes spin polarized, and hence magnetization direction is determined. In the present work we combined the two effects, the electron transfer due to SAM formation and the chiral-induced spin selectivity (CISS) effect (where the spin is polarized either parallel or anti-parallel to the electrons' velocity vector according to the handedness of the molecules) in order to demonstrate the ability to control magnetization direction in a FM layer, by adsorption of SAM made from chiral molecules [1,2,3]. The FM thin films used in the experiments were a sandwich type epitaxial nanostructures: Al_2O_3/Pt/Au/Co (thickness1.5-2.2 nm)/Au 5 nm with the easy magnetization axis in the out-of-plane (OOP) direction. Different Co layers thicknesses were used, resulting in different coercive fields and domain sizes. The SAMs were made with two enantiomers of the oligopeptide, which are based on α-helix polyalanine L and D. The oligopeptides were adsorbed on predetermined areas on the top gold layer.

Z8-01. Scale-Invariant transport in high-temperature superconductors.
A. Shekhter[1] *1. NHMFL, Tallahassee, FL, United States*

The origin of the anomalous relaxation dynamics and the very nature of charge carriers in the "strange metal" state are among the most pressing open questions in the high-temperature superconductors. Measurements indicate enhanced electronic correlations approaching critical doping as well as zero-temperature collapse of a line of phase transitions suggesting a quantum critical point inside superconducting dome. To explore dynamic consequences of quantum criticality, such as scale invariance, in the high-temperature superconductors we have performed a series of high-magnetic-filed transport measurements in LSCO cuprates superconductor near critical doping (x=0.20). The observed resistivity is linear-in-field at very high magnetic fields (up to 93T) and exhibits a characteristic temperature-field competition at lower fields. Such scale-invariant behavior of magneto-transport in a broad range of temeperatures and magnetic fields is incompatible with quasiparticle transport in the strange metal state.

Pulsed Field Facility, Los Alamos National Laboratory, Los Alamos, NM, United States; 5. University of California, Berkeley, Berkeley, CA, United States*

Even after decades of research on the high-T_c cuprates, several parts of their phase diagrams remain mysterious, especially the normal state above T_c near optimal doping, a region commonly referred to as the strange metal phase. The urgency of this problem grew when the iron-based high-T_c superconductors were discovered and it was found that they exhibited very similar properties in the analogous part of their phase diagrams. In particular, they displayed very similar behavior in their charge transport coefficients, including a T-linear resistivity and a roughly 1/T Hall coefficient.[1] Although the list of materials exhibiting this behavior has grown considerably, the list of anomalous transport properties that might guide theory development has not. In recent work on the ultra high field (up to 92 Tesla) magnetoresistance of the iron-pnictide superconductor $BaFe_2(As,P)_2$, we extended the picture of charge transport in the strange metal state by finding an analogous B-linear resistivity that is connected to the T-linearity by an unusual scaling relationship.[2] In this talk I will present extensions of this work to the Hall coefficient, in which we also find an important parallel between the field and temperature dependences. As with the field-temperature scaling in the resistivity, this behavior is difficult to obtain in a simple quasiparticle picture and presents another concrete challenge for candidate theories of the strange metal state to overcome. Intriguingly, the strength of this anomalous Hall behavior also seems to be related to the strength of the superconductivity, in a manner similar to that in which the T-linear resistivity has been found to be associated with superconductivity,[3][4] underlining the particular significance of the strange metal charge transport behavior for our understanding of high-T_c superconductivity.

Karlsruhe Institut für Technologie, Karlsruhe, Germany; 5. National High Magnetic Field Center and School of Physics, Huazhong University of Science and Technology, Wuhan, China*

Previous high magnetic field experiments on the underdoped cuprates led to a debate about the ground state of the pseudogap regime in these materials. Whilst a conventional metallic state was suggested by measurements of properties such as ohmic resistivity, quantum oscillations, and density wave signatures, contrasting measurements of properties such as diamagnetism and the Nernst effect suggested a vortex liquid state. I will present electrical transport and magnetic torque measurements in the pseudogap regime of the underdoped cuprates that reveal the ground state to be an unusual magnetic field-resilient bulk superconductor. We uncover this state by performing measurements down to millikelvin temperatures and unprecedented low measurement currents on a range of YBCO dopings in the highest available DC magnetic field of 45 T. This novel state evolves to robust pairing correlations that we find to persist in the pseudogap regime up to high magnetic fields and elevated temperatures.

Z8-05. Electron-phonon coupling and superconductivity in doped $SrTiO_3$. *H. Yoon*[1], A.G. Swartz[1,2], H. Inoue[1], Y. Hikita[2] and H. Hwang[1,2] *1. Geballe Laboratory for Advanced Materials, Applied Physics, Stanford, CA, United States; 2. Stanford Institute for Materials and Energy Sciences, SLAC National Accelerator Laboratory, Menlo Park, CA, United States*

The dilute oxide semiconductor $SrTiO_3$ exhibits superconductivity at extremely low carrier densities (10^{17}-10^{21} cm^{-3}) and outside of the Bardeen-Cooper-Schrieffer (BCS) and Migdal-Eliashberg theories for conventional superconductors. In fact, bulk doped $SrTiO_3$ exhibits a superconducting dome spanning several orders of magnitude in carrier density and Fermi level. In addition, in this range, the Fermi level crosses a variety of vibrational modes in the system and therefore spans the widest range of adiabatic parameter (ω/E_F) of any material, making it an ideal choice to study the problem of dilute superconductivity. Recently, we have developed an approach using atomically controlled oxide heterostructures to enable access to the electronic structure of $SrTiO_3$ in planar tunneling junctions [1, 2]. With this technical improvement, we examine superconductivity and electron-phonon coupling of bulk doped $SrTiO_3$ across the superconducting dome by electron tunneling spectroscopy. We find strong coupling to the high-energy longitudinal optic phonon modes with increasing coupling strength towards lower carrier densities. Remarkably, we find that despite this strong coupling, the superconducting state corresponds nearly identically to the thermodynamic relationship of BCS weak-coupling theory. The possible scenarios of this discrepancy will be discussed.

Z8-06. Controlling iron-based superconductivity with spin currents. *J. Lee*[1] *1. Physics, KAIST, Daejeon, The Republic of Korea*

We have explored a new mechanism for switching magnetism and superconductivity in a magnetically frustrated iron-based superconductor using spin-polarized scanning tunneling microscopy (SPSTM) [1,2]. Our SPSTM study on single crystal Sr_2VO_3FeAs made of alternating self-assembled FeAs monolayer and Sr_2VO_3 bilayers shows that a spin-polarized tunneling current can switch the FeAs-layer magnetism into a non-trivial C_4 (2×2) order, which cannot be achieved by thermal excitation with unpolarized current. Our tunneling spectroscopy study shows that the induced C_4 (2×2) order has characteristics of plaquette antiferromagnetic order in the Fe layer and strongly suppresses superconductivity. Also, thermal agitation beyond the bulk Fe spin ordering temperature erases the C_4 state. These results suggest a new possibility of switching local superconductivity by changing the symmetry of magnetic order with spin-polarized and unpolarized tunneling currents in iron-based superconductors [3,4]. We also performed high-resolution quasiparticle interference (QPI) measurements, self-consistent BCS-theory-based QPI simulations and a detailed e-ph coupling analysis to provide direct atomic-scale proofs of enhancement of iron-based superconductivity due to the BCS mechanism based on forward-scattering interfacial phonons [5].

INVITED PAPER

3:30

Z9-01. Coherent Band Excitations Studied With Inelastic Neutron Scattering. *R. Osborn*[1], E.A. Goremychkin[2], H. Park[1,4], J. Lawrence[3], S. Rosenkranz[1], A. Christianson[5] and V.R. Fanelli[5] *1. Materials Science Division, Argonne National Laboratory, Argonne, IL, United States; 2. Joint Institute for Nuclear Research, Dubna, Russian Federation; 3. University of California, Irvine, Irvine, CA, United States; 4. University of Illinois at Chicago, Chicago, IL, United States; 5. Oak Ridge National Laboratory, Oak Ridge, TN, United States*

In strongly correlated electron systems, there is evidence of a crossover between regimes characterized by coherent quasiparticle bands at low temperature and incoherent electronic fluctuations at high temperature. This crossover has been invoked to explain both bulk properties such as transport measurements and spectroscopy such as ARPES. Realistic calculations that combine Density Functional Theory with Dynamical Mean Field Theory (DFT+DMFT), which treats both local correlations and itinerant bands on an equal footing, predict a gradual loss of quasiparticle spectral weight at the Fermi energy with increasing temperature. However, in cerium compounds, many of the relevant electronic states are unoccupied and therefore inaccessible to ARPES, so it is not possible to make a detailed comparison with theory. We have recently proposed that inelastic neutron scattering measurements of the dynamic magnetic susceptility, $\chi''(Q,\omega)$, can provide an alternative spectroscopic probe of electronic coherence [1]. With non-interacting bands, $\chi''(Q,\omega)$ is proportional to the joint electronic density-of-states, which depends on both occupied and unoccupied states and so probes the entire electronic spectrum near the Fermi energy. This produces systematic variations across the Brillouin zone, with enhancements whenever the momentum (Q) and energy transfer (ω) connects regions with relatively flat energy band dispersion. DMFT+DFT calculations on a canonical intermediate valence compound, $CePd_3$, show that, at low temperature, $\chi''(Q,\omega)$ is indeed modulated in this way but it is also enhanced substantially by strong electron-hole interactions. At high temperature, the quasiparticle spectral weight is heavily damped close to the Fermi energy, which suppresses the Q-dependence, *i.e.*, the fluctuations have become incoherent. With recent advances in neutron instrumentation at pulsed neutron sources, it is now possible to measure 4-dimensional volumes of $\chi''(Q,\omega)$ across multiple Brillouin zones on an absolute scale for direct comparision with the calculations. The excellent agreement between experiment and theory in $CePd_3$ shows that we have a robust first-principles understanding of how *f*-electron coherence evolves with increasing temperature. We acknowledge the contributions of John-Paul Castellan and Matthew Stone in the experiments, and Eric Bauer, Kenneth McClellan and Darrin Byler for single crystal synthesis. Work at ANL was supported by U.S. DOE, BES, DMSE. Research at ORNL's Spallation Neutron Source was sponsored by the U.S. DOE, BES, SUF. Experiments were also performed at the ISIS Pulsed Neutron and Muon Source, UK.

Institute of Physics II, University of Cologne, Dresden, Germany*

Intermediate valence (IV) materials represent one of the longest-standing issues in quantum materials physics [1,2]. In $CePd_3$, the correlation of localized and itinerant electrons results in an ambivalent state that strongly fluctuates between the Ce^{4+} ($4f^0$) and Ce^{3+} ($4f^1$) configurations. The most striking manifestation of this Kondo hybridization of 4f electrons with a sea of transition metal states occurs at low temperatures, where the valence fluctuations may form an unusual coherent state. The few available neutron spectroscopic studies of such coherent *Anderson lattices* have revealed that the phenomenon is associated with unusual quasiparticle excitations across the hybridization gap [3]. The dynamic magnetic susceptibility thus acquires a characteristic energy-/momentum-space texture. The recent advances in soft x-ray resonant inelastic scattering (RIXS) are among the most anticipated developments at 3rd generation synchrotrons. With an energy resolution on the order of E/dE=30000, soft RIXS is now able to address the small energy scale of this IV phenomenon. We present the first use of Ce *M*-edge RIXS to reveal the evolution of a low-temperature coherently hybridized state in $CePd_3$. The interpretation of these results is aided by an LDA+DMFT computational model of the electronic spectral function, which we verify by high-resolution vacuum ultraviolet angle resolved photoemission spectroscpy (VUV ARPES).

Z9-03. XMCD Studies of Actinide Compounds with Formally Nonmagnetic 5f-electron Ground States. *R. Caciuffo*[1], N. Magnani[1], E. Colineau[1], R. Eloirdi[1], J. Griveau[1], G.H. Lander[1], A. Rogalev[2], F. Wilhelm[2] and A.B. Shick[3] *1. Joint Research Centre, European Commission, Karlsruhe, Germany; 2. ESRF, Grenoble, France; 3. Institute of Physics, Czech Academy of Sciences, Prague, Czechia*

Determining the orbital and spin magnetic moment components in actinide compounds has been of interest for several decades, but it is still a formidable experimental and theoretical challenge. XMCD turned out to be a very efficient tool to determine these quantities for magnetic compounds by using two "sum rules" that correlate these moments to the measured dichroic signal at the M_4 and M_5 spectral edges [1]. Here, we show that this technique can also give important results for compounds where the actinide centers display a formally nonmagnetic ground state, such as $AmFe_2$ [2] and $PuCoGa_5$ [3]. In $AmFe_2$ the iron sublattice orders ferromagnetically around 700 K, but trivalent americium has a J = 0 ground state arising from the cancellation of the orbital and spin moments. Nevertheless, neutron diffraction data [4] suggest that a 5*f* magnetic moment is present. Since XMCD is a shell- and element-specific technique, we have been able to confirm this result directly; moreover, we found that the spin component is exactly twice as large as the orbital one and that the total Am moment is opposite to that of Fe, as expected under the assumption that the former is induced by the large molecular field arising from the latter [2]. $PuCoGa_5$ is an unconventional superconductor with a critical temperature of 18.7 K. We studied the vortex phase below T_c by XMCD and found that an external magnetic field induces a Pu 5*f* magnetic moment at 2 K equal to the temperature-independent moment measured in the normal phase up to 300 K by a SQUID device. This observation is in agreement with theoretical models [5] claiming that the Pu atoms have a nonmagnetic singlet ground state resulting from the hybridization of the conduction electrons with the intermediate-valence 5*f* electronic shell. Unexpectedly, however, the orbital component of the 5*f* magnetic moment increases significantly between 30 and 2 K; the antiparallel spin component increases as well, leaving the total moment practically constant. We suggest that this indicates a low-temperature breakdown of the complete Kondo-like screening of the local 5*f* moment.

Z9-04. Tests for Magnetoelectric Effects on Antiferromagnetic Metals. *H. Amitsuka*[1], H. Saito[1], N. Shikanai[1], M. Yamamoto[1], H. Hidaka[1], T. Yanagisawa[1], C. Tabata[2], H. Nakao[2], H. Tanida[3], T. Matsumura[4] and M. Sera[4] *1. Graduate School of Science, Hokkaido University, Sapporo, Japan; 2. IMSS CMRC, KEK, Tsukuba, Japan; 3. Graduate School of Engineering, Toyama Prefecture University, Toyama, Japan; 4. Graduate School of Advanced Sciences of Matter, Hiroshima University, Higashi Hiroshima, Japan*

We present our recent studies of experimental tests for a new magnetoelectric (ME) effect of "electric-current-induced magnetization" expected in certain antiferromagnetic (AF) metals. This phenomenon was theoretically predicted to occur when the global inversion symmetry of a system is spontaneously broken by the AF ordering, where the ordered state can be described as possessing a uniform component of a toroidal moment *t* [1, 2]. We have thus far investigated three AF metals, UNi_4B (Space group: *Cmcm*, No. 63, $D_{2h}{}^{17}$; T_N = 20.4 K) [3, 4], $CeRh_2Si_2$ (*I4/mmm*, No. 139, $D_{4h}{}^{17}$; T_{N1} = 35 K, T_{N2} = 24 K) [5], and $CeRu_2Al_{10}$ (*Cmcm*, No. 63, $D_{2h}17$; T_N = 27 K) [6, 7], and found that all of them show such a ME effect in their AF ordered states. Common characteristics among observed behaviors are (i) the current-induced magnetization ΔM is perpendicular to the direction of electric currents *I*, (ii) ΔM is directly proportional to *I*, and (iii) the rate of induction of ΔM is on the order of $\sim 10^{-7} - 10^{-9}$ μ_B/(U or Ce) per unit current density (in units of kA/m^2). The obtained experimental results have confirmed that a uniform magnetization component can be induced by applying electric currents in certain types of AF metals, and its magnitude and direction are closely coupled with the magnetic structure. This feature is considered to be essentially consistent with the theoretical prediction [2]. However, we also observed some inconsistencies that ΔM is induced in an unexpected geometry between *I* and *t* in UNi_4B [8], and moreover, in $CeRh_2Si_2$ and $CeRu_2Al_{10}$ ΔM occurs in the AF states where the global space-inversion symmetry is conserved if the known magnetic structures are correct. We will discuss the implications of these results and future research direction.

INVITED PAPER

3:30

Z10-01. Magnetic Excitations in the Itinerant Electron Ferromagnet Iron Measured Throughout the Brillouin Zone by Neutron Scattering. *T. Perring*[1], A. Buts[1] and M. Lueders[2] *1. ISIS Facility, STFC Rutherford Appleton Laboratory, Didcot, United Kingdom; 2. Scientific Computing Department, STFC Daresbury Laboratory, Warrington, United Kingdom*

As canonical examples of strongly correlated electron magnetism, the spin dynamics of the transition metal ferromagnets have been addressed both theoretically and experimentally for decades. Understanding of the spin dynamics of these elements is of interest not just because they are the classic examples of itinerant electron ferromagnets, but because they are model systems against which to test and benchmark the latest experimental and calculational tools. We report the results of a complete measurement of the spin wave excitations and imaginary part of the generalised magnetic susceptibility in elemental iron throughout the entire Brillouin zone and at energies up to 0.4eV, using the time-of-flight neutron spectroscopy. We compare the data with two different approaches to calculation of the generalised susceptibility. In contrast to earlier triple axis spectrometer (TAS) results [1], the lower energy spin waves do not show a marked decrease in intensity as they extend beyond 0.1 eV, a result which had been ascribed to the spin waves entering the Stoner continuum. Along the [111] direction the spin wave dispersion rises continuously to zone boundary energy 0.25 eV, in qualitative agreement with later TAS results [2], and along [110] the dispersion rises continuously to 0.35 eV at the zone boundary. However, we do not observe the break in the dispersion along [100] between 0.12-0.25 eV reported in Ref. 2. We discuss these differences, and compare the data with calculations of the generalised susceptibility we have performed using time dependent DFT implemented in the KKR package described in ref. [3], and also in the Questaal implementation [4]. We find that the computational results are robust, and that overall there is reasonable qualitative agreement between the calculations and the data once a scaling factor of » 0.75 is applied to the energy scale in the calculations. The major disagreement is that the calculations predict marked damping above 0.2 eV along [100] that is not observed in the data.

ISIS Facility, Rutherford Appleton Laboratory, Oxon, United Kingdom*

Mn_3Sn, a representative material of magnetic Weyl semimetal, has recently drawn considerable attention because of rather unusual transport anomalies resulting from the topology of its band structure. With this topological property arising from the chiral anomaly of the magnetic structure, exploring the magnetic Hamiltonian will be an important exercise in order to get insight into the magnetic Weyl fermions. By performing inelastic neutron scattering experiments, we investigated the spin waves spectra of Mn_3Sn over the full Brillouin zone. Using a linear spin wave theory, we obtained the complete Magnetic Hamiltonian that not only explains our data but also stabilizes the low temperature phase with the helical ordering. A comparison between RKKY exchange interaction and our exchange parameters with those from DFT calculations indicate the unusual aspect of the magnetic Weyl semimetal.

Z10-03. First-principle based simulations of longitudinal spin-fluctuations in metals and integration in classical space with variable spin amplitude. *S. Khmelevskyi*[1] *1. Center for Computational Materials Science, Vienna University of Technology, Vienna, Austria*

The classical Heisenberg type spin Hamiltonian is widely used for simulations of finite temperature properties of magnetic metals often using parameters derived from first principles calculations. In itinerant electron systems, however, the atomic magnetic moments vary their amplitude with temperature and the spin Hamiltonian should thus be extended to incorporate the effects of longitudinal spin fluctuations (LSF). Although the simple phenomenological spin Hamiltonians describing LSF can be efficiently parameterized in the framework of the constrained Local Spin Density Approximation (LSDA) and its extensions, the fundamental problem concerning the integration in classical spin space remains. It is generally unknown how to integrate over the spin amplitude. Two intuitive choices of integration measure have

been used up to date - the Murata-Doniach scalar measure and the simple three dimensional vector measure. Here we derive the integration measure by considering a classical limit of the quantum Heisenberg spin Hamiltonian under conditions leading to the proper classical limit of the commutation relations for all values of the classical spin amplitude and calculate the corresponding ratio of the number of quantum states. We show that the number of quantum states corresponding to the considered classical spin amplitude is proportional to this amplitude and thus a non-trivial integration measure must be used. We apply our results to the first-principles simulation of the Curie temperatures of the two canonical ferromagnets bcc Fe and fcc Ni using a single-site LSF Hamiltonian with parameters calculated in the LSDA framework in the Disordered Local Moment approximation and a fixed spin moment constraint. In the same framework we compare our results with those obtained from the scalar and vector measures.

4:30

Z10-04. Magnetic structures and magnetic phase transitions in RMn_2Si_2 intermetallics. *N.V. Mushnikov*[1] and E.G. Gerasimov[1] *1. Institute of Metal Physics UB RAS, Ekaterinburg, Russian Federation*

The $R$$Mn_2Si_2$ compounds (R is the rare earth metal) crystallize in the $ThCr_2Si_2$-type structure (space group $I4/mmm$) consisting of alternating atomic layers of R–Si–Mn–Si–R stacked along the tetragonal c-axis. We studied spontaneous and field-induced magnetic phase transitions in the $La_{1-x}Tb_xMn_2Si_2$, $La_{1-x}Sm_xMn_2Si_2$, and $La_{1-x}Gd_xMn_2Si_2$ compounds using quasi-single-crystal samples. The exchange interactions in the compounds strongly depend on the intralayer Mn-Mn distance and can be smoothly varied by changing relative concentrations of the rare-earth elements. In the compounds with small x, the intralayer Mn-Mn distance is larger than the critical value $d_c = 0.286$ nm, and the interlayer Mn-Mn exchange interactions are ferromagnetic. With increasing x, the Mn-Mn distance decreases below the dc value, and the moments of the Mn layers tend to order antiferromagnetically. The resultant magnetic order is determined by a competition of negative Mn-Mn and positive indirect Mn-R-Mn exchange interactions. The Mn-Sm interaction is relatively small, and a simple transition from ferromagnetic to antiferromagnetic state appears with increasing x [1,2]. The transition can be induced by magnetic field. It accompanies by large volume and anisotropic magnetostrictions. For the system with Gd, the competition of exchange interactions leads to formation of non-collinear magnetic order. The compounds with Tb exhibits strong uniaxial magnetic anisotropy. We demonstrate that at 4.2 K with increasing the Tb concentration a canted ferromagnetic structure of $LaMn_2Si_2$ changes to a canted antiferromagnetic structure at $x > 0.2$. The antiferromagnetic in-plane component of the Mn magnetic moment decreases with increasing x and vanishes at $x > 0.5$. Neutron diffraction study does not reveal a long-range magnetic order of the Tb moments for the compounds with $0.2 < x \leq 0.4$ [3]. A competition of the interlayer Tb-Mn and Mn-Mn exchange interactions and strong uniaxial magnetic anisotropy lead to formation of a frustrated magnetic state of the Tb ions, which prevents magnetic ordering in the Tb sublattice. The research was supported by RSF (project No. 15-12-10015).

Department of Physics & Astronomy, Louisiana State University, Baton Rouge, LA, United States*

Powder neutron diffraction experiments on $Ni_{50}Mn_{35}In_{14.25}B_{0.75}$ were carried out at a temperature between 7 and 375 K in 25 K increments to observe the evolution of the magnetic and crystal structures. The full proof analysis of neutron diffraction data reveals a clear structural transition from high temperature cubic to a monoclinic phase with significant temperature hysteresis. Traces of the low temperature phase were detected up to 380 K. Changes in the electronic structure of the elements of NiMnInB alloys at the phase transition were determined from XAS measurements from 80 to 380 K and compared with the parent compound. The change in intensity with temperature in $Ni_{50}Mn_{35}In_{14.25}B_{0.75}$ from XAS spectra shows that the magnetostructural transition as well as B doping results in the redistribution of d electrons. B substitution in NiMnIn Heusler alloys results in an enhancement of Ni covalency and stronger Ni-In chemical bond.
