Lorentz Force Velocimetry (LFV) is a non-contact electromagnetic flow measurement technique developed by Thess et al. [1]. LFV relies on the fundamental measurement principle of Lorentz forces generated by a magnetic system and the induced eddy currents in an electrically conducting fluid. This technique can be applied to measure the flow rate of aggressive fluid metal or high-temperature molten metal such as steel and to give information about the local flow. Furthermore, in metallurgy, particles are injected into the melt to refine or to remove impurities. Therefore we extend previous work [2] of the LFV by including a non-conducting particle passing near a cuboidal permanent magnet. We use the magnetic dipole theory to model the magnetic field, in which the permanent magnet is substituted with an assembly of magnetic dipoles. The main goal is to explore the magnetic field influence on particle-laden liquid metal flow, the induced eddy currents distribution, and the resulting Lorentz force. A three-dimensional numerical model that employs the moving frame shows how the lift and drag components of the Lorentz force signal change when the particle moves near to the magnet. The numerical results using the commercial code ANSYS FLUENT are verified by comparison with experimental results. The proposed numerical method enables the determination of Lorentz force profiles and can be used to detect accurately the presence of particle.

[1] A. Thess, V. Votyakov and Y. Kolesnikov, *Physical review letters*, Lorentz force velocimetry,96.16.164501, (2006). [2] N. Tran - T. Boeck - U. Lüdtke - Z. Lyu - C. Karcher, Numerical study of the interaction between a bubble rising in a column of conducting liquid and a permanent magnet, Magnetohydrodynamics 53, No. 4, 619-632, (2017).

Principle sketch of the numerical model: In a GaInSn alloy fluid container, a non-conducting spherical particle passes vertically near the horizontally magnetized permanent magnet. The force is produced by the interaction between the primary magnetic field and eddy currents induced by a magnetic dipole interacting with a displacement flow of the fluid metal.

The drag (in z-axis) and lift (in x-axis) force calculation and measurement in dependence of normalized time for particle rising velocity v=0.0123 m/s. The negative drag force pulse is produced when the particle passes the permanent magnet (PM). The lift force is symmetrical when the particle enters and exits the PM.

L3-09. Magnetization detected in a single particle without mass measurement using a niobium permanent magnet. *C. Uyeda*[1] *1. Graduate School of Science, Osaka University, Toyonaka, Japan*

In a standard magnetization measurement, it is necessary to know the mass of sample, and measurement becomes difficult with the reduction of sample size; for example, a saturated magnetization *M*s is difficult to determine when sample mass is below the level of 1μg. A new method to detect magnetization of a single particle was recently developed based on translational velocity of a particle that was induced by a field gradient force in a monotonically decreasing field distribution [1]. The measurement is realized in *M*s [2] as well as susceptibility χ of weak magnetic (i.e. diamagnetic & paramagnetic) materials[1][3] using a micro-gravity condition. Further more, heterogeneous particles were separated into groups of different materials, and χ was obtained for individual group [1]; it is generally believed that a dynamic motion of a diamagnetic material requires a strong field above several Tesla [4]. In the above methods, magnetizations can be obtained from a translation particle because its value is generally proportional to mass of particle *m*; e.g. diamagnetic magnetization is proportional to intrinsic susceptibility χ (per unit mass) of material, field intensity *B* and *m*. According to a energy conservation rule, terminal velocity v_T of the translating particle out side the field is described as $v_T = \chi^{1/2} B_0$ [1][3] where B_0 denote field intensity at initial position. Hence, χ can be measured without the knowledge of *m*, provided that v_T is observable. Value of *M*s was obtained in a similar manner [2]. In the present report, the validity of the proposed method is examined based on the observed data obtained in the extending experiments; here, field gradient produced by a Nd magnetic circuit is enhanced to increase translating velocity. In order to put the system to practical use, the efficiency of distinguishing two particles with small variance of χ should be improved considerably.

L3-10. A Versatile Demagnetization Refrigerator. *A. Regnat*[1], J. Spallek[1], C. Duvinage[1], T. Schulz[1] and C. Pfleiderer[1] *1. Physics Department, Technical University of Munich, Garching, Germany*

Cooling devices providing temperatures well below 1 K are a key prerequisite for modern research and development, e.g., in materials science, quantum applications and the cooling of sensors and detectors. Here we present a versatile and compact demagnetization refrigerator for the cryogen-free generation of sub-Kelvin temperatures.

L3-11. A torque compensation control scheme of permanent magnet synchronous motor considering wide variation of permanent magnet temperature. *S. Cho*[1] *1. Electric Powertrain R&D Center, Korea Automotive Technology Institute, Cheoan-si, The Republic of Korea*

Increasing number of studies attempting to improve output density and miniaturize size and volume of motor has reported the problem of heat generation due to rotor-mounted permanent magnet loss in the motor. Unlike stator's winding temperature, rotor permanent magnet temperature cannot be measured directly under rotating situation. Temperature rising of rotor permanent magnet is attributed to iron loss by high frequency harmonic magnetic flux linkage and high conductivity of NdFeB magnet material. Change in the magnetic flux according to the rotor permanent magnet temperature appears as a decrease in magnetic flux linkage with increase in temperature, which decreases the torque, which leads to a lower output power. Residual flux density and intrinsic coercivity of NdFeB permanent magnet change by operating temperature, according to each temperature coefficients. If magnetic flux linkage changes by rotor permanent magnet temperature, magnetic saturation level in the stator iron core change as well. This magnetic saturation level in the stator iron core changes the magnetic permeability of the magnetic flux path and it changes inductances. From this cause, it is possible to indirectly reflect rotor permanent magnet temperature variation, which cannot be directly measured, by on-line estimation of the permanent magnet flux linkage and inductances. The steepest descent method was used to estimate permanent magnet flux linkage. In order to estimate d-q axis inductances, affine projection algorithm(APA) was used. APA is one of the adaptive filter methods. APA offers less computational complexity and fast convergence. The estimated parameters were used to achieve a torque compensation control scheme based on the torque feedback control of permanent magnet synchronous motor considering wide variation of permanent magnet temperature. The proposed control scheme was verified by dynamometer test of the test motor under rotor-mounted permanent magnet temperature conditions.

L4-01. Frustration induced topological order. *C. Agrapidis*[1], J. van den Brink[1,2] and S. Nishimoto[1,2] *1. Institute for Theoretical Solid State Physics, Leibniz Institute for Solid State and Materials Research (IFW) Dresden, Dresden, Germany; 2. Department of Physics, Technical University Dresden, Dresden, Germany*

The J_1-J_2 ferromagnetic (FM) frustrated spin-1/2 chain is a minimal model for some cuprate materials (e.g. Li_2CuO_2, $LiCuVO_2$). We define the degree of frustration as $J_2/|J_1|=\alpha$. It's known that the system is in a FM state for $\alpha<1/4$, while the nature of the state after the phase transition is still not established. Mean field theory predicts an exponentially small gap opening at $\alpha\sim3.3$ [1], however it fails in making predictions for $1/4 < \alpha < 3.3$. There have been different suggestions pointing to a gapped state for $\alpha>1/4$, based on spin-spin correlations or calculation of the string-order parameter. Using the density matrix renormalization group (DMRG), we compute spin-gap, dimer order parameter, string order parameter and dimer-dimer correlations. We explicitly show the presence of a spin gap of the order of $\sim10^{-3}$. Moreover, we investigate the mechanism leading to the formation of the spin-gap, discussing the formation of an Affleck-Kennedy-Lieb-Tasaki (AKLT)-like state.

L4-02. Frustrated magnetism in the chiral system $EuIr_2P_2$. *D.G. Franco*[1] and C. Geibel[1] *1. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany*

While frustration in insulating magnetic systems is a topic of strong interest because of very unusual ground states with intriguing properties, frustrated metallic systems remain largely unexplored. Interesting effects may be expected for this case from the interplay between itinerant electrons and frustrated magnetic degrees of freedom. A further topic of strong interest is the presence of chirality, which can also lead to unusual ground states, like the formation of a skyrmion lattice as observed e.g. in MnSi [1] in a given temperature and magnetic field region. Therefor we got interested in the compound $EuIr_2P_2$, since it crystallizes in the trigonal chiral structure $P3_221$. Early work evidenced an Eu^{2+} state [2], which bears a large, isotropic magnetic moment. However the magnetic properties were only poorly investigated. We synthesize polycrystalline samples of $EuIr_2P_2$ and studied its magnetic properties. The results indeed suggest unusual magnetic states and magnetic transitions, and reveal evidence for important frustration effects. Specific heat, magnetization, and susceptibility data conclusively prove that $EuIr_2P_2$ orders antiferromagnetically at $T_{N1} = 5$ K, and not ferromagnetically as suggested in [2]. In addition we observe a second magnetic transition to a different AFM state at $T_{N2} = 3$ K. The size of the specific heat anomaly at T_{N1} is small compared to other S = 7/2 Eu^{2+} or Gd^{3+} systems. Furthermore we observe a large tail in the specific heat above T_{N1} indicative of strong magnetic fluctuations. These effects point to a significant degree of frustration due to different competing magnetic interactions. Preliminary resistivity measurements show a semiconducting behavior with a small gap. Further measurements are now in progress to determine the nature of the different AFM phases as well their interaction with conduction electrons.

L4-03. Magnetocaloric effect in exactly solvable spin-1/2 Ising-Heisenberg double tetrahedral chain. *L. Galisova*[1] *1. Technical University of Kosice, Kosice, Slovakia*

We present magnetocaloric properties of the frustrated spin-1/2 double-tetrahedral chain, in which three-site Heisenberg clusters regularly alternate with single Ising spins. The model has been originally proposed by V. Ohanynan *et al.* [1,2] as a simpler variant of the pure Heisenberg chain [3] and belongs to the class of lattice-statistical models that can be exactly solved by two analytical approaches at finite temperatures, namely by the classical transfer-matrix technique [4] and also the generalized decoration-iteration mapping transformation [5]. Both the methods result in the closed-form analytical expression for the partition function, which allows one to rigorously calculate all thermodynamic quantities useful for creating a complete picture about magnetic behaviour of the model at finite temperatures. The knowledge of the thermodynamic quantities gives an opportunity to rigorously determine some basic magnetocaloric characteristics. In the present work, we rigorously calculate the isothermal magnetic entropy change and the adiabatic (isentropic) change of the temperature during the varying magnetic field in order to discuss a relation between cooling/heating efficiency of the model and its ground-state spin ordering. Special attention is paid to comparision of the cooling/heating ability of the model in a proximity of the quantum critical points separating two non-chiral phases with that one which can be observed near quantum critical points separating uncommon chiral phase from non-chiral one. We also demonstrate that temperature isotherms have most steep gradients when the entropy is set to be sufficiently close to the residual value observed at the appropriate critical point corresponding to the field-induced phase transition between different ground states. When the entropy takes the residual value, the isentropic temperature of the model falls down infinitely fast up to the zero at the relevant critical value. The results are completed by low-temperature field dependencies of the magnetic Grüneisen parameter, which gives the quantitative information about the cooling/heating rate of the model during the adiabatic (de)magnetization process.

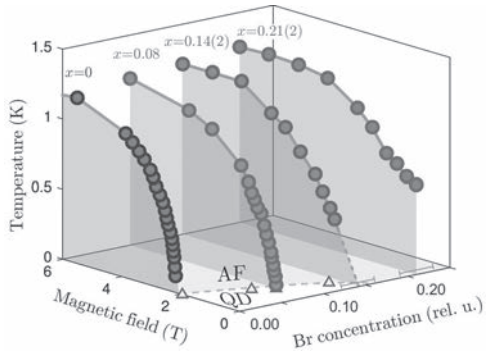
L4-04. Quantum Criticality in a Three-Dimensional Spin System at Zero Field and Pressure. *K. Povarov*[1], A. Mannig[1], G. Perren[1], J. Möller[1], E. Wulf[1], J. Ollivier[2] and A. Zheludev[1] *1. Laboratory for Solid State Physics, ETH Zurich, Zurich, Switzerland; 2. Institut Laue-Langevin, Grenoble, France*



Quantum phase transitions between the quantum disordered and semiclassical Neel phases, which are of great current interest, are usually achieved either by application of external field or pressure to the model material. However, it was recently found that in a well-known gapped 3D XY quantum antiferromagnet $Ni(Cl_{1-x}Br_x)_2$-4SC$(NH_2)_2$ (abbreviated DTNX) the Br content strongly influences the critical field needed to overcome the gap and induce ordering [1]. We show that in this case the chemical composition can be used as the "handle" controlling the spin gap and the ground state, allowing one to achieve a 3D quantum critical state in absence of external

stimuli [2,3]. The overall effect of varying DTNX chemical composition is qualitatively similar to the application of hydrostatic pressure to the spin gap magnet: the magnetic excitations spectrum gets gradually deformed (Fig. 1), and finally the spin gap dissapears and the material orders magnetically. The resulting phase diagram (Fig. 2) also bears apparent similarities with the pressure-induced ordering, as e.g. in $TlCuCl_3$ [4]. However, in DTNX the ordering happens at ambient pressure as the function of intrinsic parameter *x,* and no extrinsic tuning is needed. This allows us to conveniently probe thermodynamic properties of the seemingly critical material with *x*~0.14. From analyzing the specific heat and magnetization we conclude that this material exhibits the critical behavior indeed, although the particular scaling laws are somewhat different from the idealized case. Therefore, this DTNX family member is a unique example of a 3D antiferromanget, that has a quantum critical ground state under the ambient conditions.

L4-05. Stabilizing the Skyrmion Phase in Cu_2OSeO_3: The Influence of Field, Temperature and Time. *J.D. Reim*[1], K. Makino[1], D. Higashi[1], D. Okuyama[1], T.J. Sato[1], Y. Nambu[2], E.P. Gilbert[3], N. Booth[3], S. Seki[4] and Y. Tokura[4] *1. Institute of Multidisciplinary Research for Advanced Materials, Tohoku University, Sendai, Japan; 2. Institute for Materials Research, Tohoku University, Sendai, Japan; 3. ACNS, Australian Nuclear Science and Technology Organization, Kirrawee DC, NSW, Australia; 4. RIKEN Center for Emergent Matter Science (CEMS), Saitama, Japan*

In recent years intensive research has been conducted on the compound Cu_2OSeO_3 since it was found to feature lattices of topologically protected spin-swirlings called skyrmions. Among the compounds exhibiting skyrmion lattices, Cu_2OSeO_3 has attracted particular interest because of its insulating nature resulting in multiferroic properties.[1] However, previous studies reported somewhat contradicting phase diagrams regarding the presence of two different skyrmion phases.[2-4] Using small angle neutron scattering we have investigated the thermodynamic stability of these phases and were able to relate the deviations to a difference in the stabilization process.[5] By cooling under finite magnetic field (FC), the so-called skyrmion 2 phase is stabilized (see Fig. 1b), whereas the 30°-rotated skyrmion 1 phase can be stabilized by heating the sample under finite field from the ordered conical phase (FW, see Fig. 1c). The zero-field-cooling protocol (ZFC) results in the co-existence of the two phases (see Fig. 1d). It is further found that once one of the skyrmion phases is formed, it is hardly destabilized on an experimental time scale even in the vicinity of the phase boundary. This indicates unusual thermal stability of the skyrmion lattice phases, possibly related to the topologically protected nature. When using the ZFC protocol the stabilization of either SkX(1) or SkX(2) can be tuned either by applying the magnetic field directly or with intermediate steps. Also the introduction of waiting times at intermediate temperature steps into the FC and FW protocol significantly influences the skyrmion-lattice stabilization. While extrinsic temperature equilibration effects cannot be excluded (for FC and FW), the influence of temperature and magnetic field sweep rate indicates the relevance of slow kinetics on the order of a few minutes for the stabilization process.[6]

L4-06. Chirality domain walls in frustrated spin system. *P. Rusek*[1] *1. Wroclaw University of Technology and Science, Wroclaw, Poland*

In noncollinear(NC)(frustrated) spin system, states have additional quantum number - the chirality: spins can rotate clock- or counter-clock-wise on plaquette. The relevant order parameter of frustrated spins is rotation matrix O~ SO(3). In this case the space of degeneracy is the manifold of SO(3) group and it is disconnected Pi_1 (SO(3))=Z_2 . Consequently *linear* topological defects - Z_2 vortices can be spontaneously excited in a system[1]. We present the general solution for Z_2 vortex in NC spin system in terms of variable closely related to the chirality. We have found that If a chirality distribution in long distance from the vortex is uniform (by inclusion the spin orbit interaction) the Z_2 vortex generates the singular planar defect that is terminated on the vortex- the chirality domain wall(ChDW). In the ChDW the chirality changes its sign. In 2d the CHDW is the flat band terminated on Z_2 vortex core. We argue that ChDW has peculiar topology: in ChDW one

can go from the ground state with the given chirality to the ground state with the opposite one *continueosly*, encircling the Z_2 vortex. We claim that this feature of ChDW topology gives rice to spontaneuos creation of holes which edge is(closed) Z_2 vortex. Thus ChDW can colapse to the Z_2 vortex and the barrier energy that stabalized ChDW is equal to the nucleation energy of Z_2 loops with diameter of order of the thickness of ChDW. This, in turn, is equal to the spin orbit length, i.e. the ChDW thickness as well as the energy barrier stabilizing ChDW are *not* macroscopically large. The application our ideas to the 2d quantum frustrated antiferromagnet (in underdoped La-based cuprates in spiral phase) and in the canonical 3d spin glass with spin-orbit interactionis is discussed.

Quantum magnets exhibit exotic ground states and novel elementary excitations, complex correlations and generic quantum critical points. Phenomena like frustration, condensation and quantum disorder are at the very heart of this field. Here we present an example, which explores the possibility of a spin nematic phase in a low dimensional frustrated magnet [1-4]. The highly frustrated $BaCdVO(PO_4)_2$ was believed to be a J_1-J_2 system however our recent data show that it is more complex than originally expected. While it is still two dimensional, more magnetic interactions are at play. The low energy scale of the system allows for experimenting with externally applied fields. We will show some experimental hints, backed by theory, pointing towards the long-sought field-induced spin nematic phase for this system.

L4-09. The new WAND² diffractometer at HFIR - ideal for magnetism. *M. Frontzek*[1] *1. Neutron Scattering Division, Oak Ridge National Laboratory, Oak Ridge, TN, United States*

The Wide Angle Neutron Diffractometer (WAND) at the High FLux Isotope Reactor (HFIR) at the Oak Ridge National Laboratory (ORNL) has been part of HFIRs instrument suite since the 1980s. In October 2017, the last phase of the planned upgrade program had begun and the 120 degree, 2-dimensional position sensitive detector from Brookhaven National Laboratories (BNL120) had been installed at the HB-2C beamport. The updated instrument has been named WAND² and took it's first general users from the call for 2018A in May this year. WAND² is positioned as a thermal, multi-purpose, high throughput powder-/single crystal diffractometer. The instrument can use a large portion of HFIRs sample environment, allowing measurements from mK to 1500 K, magnetic fields up to 6 T and high pressures (~ 10 GPa). The large area coverage allows efficient collection of powder data in short time and is combined with the possibility to event filter to external synchronized parameters. We installed two time domains, one for slow controls with time resolution of ms and one synchronized domain with ~100ns resolution for stroboscopic measurements. For single crystal diffraction the instruments strenght is the mapping of a large area in reciprocal space with an excellent noise to background ratio. This allows for instance the search for weak magnetic signals when the propagation vector is unknown and the mapping of diffuse scattering. In our contribution we review the improvements on WAND² implemented during the upgrade and review some of the challenges we encountered. We will review a selection of the first experiments and will be able to gauge the performance of the new instrument. We hope that the we can illustrate the unique capabilities of a 2D-PSD instrument at a monochromatic steady beam which has been missing in the neutron scattering suite on the American continent.

Session L5
HEAVY FERMIONS IV: NOVEL MATERIALS
(Poster Session)

Heike Pfau, Chair
SLAC & Stanford, Menlo Park, CA, United States

L5-01. Quantum Criticality below the Néel temperature in a frustrated heavy fermion magnet. *C. O'Neill*[1], J. Schmehr[1], H. Keen[1], D.A. Sokolov[1], A. Hermann[1], P. Manuel[2], D. Wermeille[3] and A. Huxley[1] *1. Physics and Astronomy, University of Edinburgh, Edinburgh, United Kingdom; 2. ISIS Pulsed Neutron Facilty, Rutherford Appleton Laboratory, Chilton, United Kingdom; 3. ESRF, Grenoble, France*

When materials that contain ions with local moments (such as Ce or U) are cooled, a winner takes all competition exists between (1) the ordering of the local moments at the Néel temperature, T_N, and (2) the Kondo screening of the same moments by conduction electrons that gain a mass below T_K. The transition between these two outcomes is described by Doniach's seminal phase diagram[1]. If Kondo-screening wins these itinerant heavy conduction electrons can still order magnetically at lower temperature. However previously there have been no definite examples with $T_K \leq T_N$. Here we present our results on a previously overlooked heavy fermion compound with an exceedingly simple crystalline structure comprised of columns arranged in a simple triangular lattice. The stacked triangle lattice raises the prospect of magnetic frustration. Neutron scattering results show a clear transition to an antiferromagnetic state on cooling where the moments on each of the 3 columns order incommensurately with different phases $\theta = \{0, 120^o, 240^o\}$. Upon further cooling we find evidence for quantum critical behaviour at temperatures an order of magnitude below T_N, suggesting Kondo screening occurs with $T_K << T_N$. Frustration prevents the modulated structure from squaring up to fully accommodate the local moments, leading to a new low temperature state that combines both Kondo screening and local moments. Our neutron and X-ray scattering experimental results will be discussed showing clearly the magnetic structure of this material. Low temperature resistivity, magnetisation and heat capacity results will also be presented that demonstrate quantum critical behaviour deep within this already ordered state. Our experimental results are complimented by density functional theory results.

L5-02. Magnon Bose-Einstein Condensation in a Metal: Implications for Magnetically Frustrated Heavy Fermion Metals. S. Gazit[1] and *J. Pixley*[2] *1. University of California, Berkeley, Berkeley, CA, United States; 2. Rutgers University, Piscataway, NJ, United States*

Motivated by magnetically frustrated heavy fermion metals [1,2], we theoretically study the phenomena of field-driven Bose-Einstein condensation of magnons immersed in a metallic environment. We construct a simplified model Hamiltonian that captures this behavior and we solve it using the density matrix renormalization group. We determine the overall phase diagram and investigate critical properties with regards to this new type of transition. Implications of our results for experiments on the heavy fermion systems YbAl3C3 [3] and CeAgBi2 [4] are discussed. [1] Q. Si, Phys. Status Solidi B 247, 476-484 (2010). [2] P. Coleman and A. L5-03. The Effect of Rashba Spin-Orbit Coupling on f-electron Materials. *Y. Michishita*[1] and R. Peters[1] *1. Kyoto University, Kyoto, Japan*

Recently, the effect of the spin-orbit coupling(SOC) on transport, which can be used for spintronics, has been studied intensively [1,2]. Besides weakly interacting systems, the combination of strong correlations and SOC leads to the emergence of novel phenomena, such as spin liquid behavior and unconventional superconductivity. [3,4] Particular, non-centrosymmetric f-electron materials, such as CePt3Si or CeCoIn5/YbCoIn5-supperlattice, are interesting examples in which the interplay between asymmetric SOC (e.g. the Rashba spin-orbit interaction) and strong correlations can be studied. The properties of these f-electron materials are determined by the competition of the two effect, namely the Kondo effect, which results in the formation of heavy-fermions and the RKKY interaction [5]. Therefore the study of the effect of SOC on the Kondo effect and RKKY interaction in heavy fermion materials is important to understand recent experiments and predict new phenomena. Here, we study the effect of the Rashba spin-orbit coupling(RSOC) in f-electron materials, particular the impact on the Kondo coupling, the Kondo temperature, the RKKY interaction, and the magnetic order in f-electron materials by using perturbation theory and numerical calculations with DMFT/NRG. The results demonstrate the emergence of a second energy scale and a general enhancement of the Kondo temperature due to the RSOC which is consistent with the result of reference [6]. Besides analyzing the impact on the Kondo effect, we study the influence of the Rashba interaction on the magnetic order by using perturbation theory and numerical calculations. We show that the Neel state still appears at half-filling in the case with RSOC, similar to the centrosymmetric case. However, the Neel phase shrinks with increasing strength of the RSOC. We combine these results into the Doniach phase diagram and elucidate the effect of RSOC on the quantum critical point(QCP). Finally, we also discover that strong RSOC can result in a gap closing of the Kondo insulator. [7] Thus, I will explain the following three topics at the Poster session: effect of RSOC on the Kondo temperature, RKKY interaction and magnetic order, and gap closing due to RSOC.

L5-04. Valence-Bond-Solid State in Shastry-Sutherland Tetrahedron Lattice Ce_5Si_3. *R. Kobayashi*[1], K. Nakahara[1], K. Chinen[1] and S. Yano[2] *1. Department of Physics and Earth Sciences, University of the Ryukyus, Nishihara, Nakagami, Japan; 2. NSRRC, Hsinchu, Taiwan*

We have investigated the magnetic structure of Ce_5Si_3 by powder neutron diffraction technique. Tetragonal Cr_5B_3-type Ce_5Si_3 has two inequivalent Ce sites: Ce1-site with high-symmetry (Wyckoff 4*c*) and Ce2-site with low-symmetry (Wyckoff 16*l*)[1]. Previous studies with macroscopic measurements (resistivity, specific heat, and magnetization) proposed that the Ce1-site orders antiferromagnetically below T_N = 11.6 K and the Ce2-site forms valence-bond-solid (VBS) state around T_V = 3.9 K, respectively[2]. However, the origin of the VBS is not well understood. Very recently, our detailed structure analysis clarified that the Ce2-site forms

Shastry-Sutherland tetrahedron lattice (SSTL) described by orthogonalized two-layer Shastry-Sutherland lattice (SSL) system (Figure 1). The ground state of SSL system is well known as VBS; therefore, SSTL may be the origin of VBS at the Ce2-site. In SSL system however, the VBS ground state is only valid in two-dimensional system. The Ce2-site in Ce_5Si_3 has four SSL layer (two SSTL layer) per unit cell. The fact implies that the interplanar interaction between SSL layers in Ce_5Si_3 is ignorable for some reason or other. In addition, the internal magnetic field coming from the ordered Ce1-site impedes the formation of VBS state in the Ce2-site. In the first place, there is no microscopic evidence of the VBS state. Therefore, we need the certain evidence that the Ce2-site forms the VBS state around T_V in order to forward the study of this material. The powder neutron diffraction pattern below T_N clearly indicates magnetic satellite peaks which can be explained by the propagation vector k = (0, 0, 1). Rietveld refinement using the model where only Ce1-site orders magnetically shows good agreement with the data. The result supports the hypothesis that Ce2-site can not order magnetically due to the geometrical frustration coming from SSTL system. This may be the first Ce compound which has VBS grand state in heavy fermion system. In the current day, I will also show the results of neutron inelastic scattering experiments.

L5-05. Dense Kondo Behavior in the Low Temperature Resistivity and Specific Heat for Amorphous $Ce_{50}Al_{50}$ Alloy. S. Ito[1], K. Seki[1], *Y. Amakai*[1], S. Murayama[1], H. Takano[1], N. Momono[1] and T. Kuwai[2]
1. Muroran Institute of Technology, Muroran, Japan; 2. University of Toyama, Toyama, Japan

Ce-Al bulk-metallic-glasses which made by a single-roller melt-spinning have two amorphous phases under high-pressure[1]. On the other hand, another group have reported that a metastable phase of a novel cubic CeAl exists in an amorphous matrix[2]. In contrast to these researches, we have studied magnetic and transport properties of amorphous (*a*-)$Ce_{50}Al_{50}$ alloy which made by a dc high-rate sputter method, recently[3]. The *a*-$Ce_{50}Al_{50}$ have no magnetic transition down to 2 K. Low-temperature resistivity follows a –log T dependence and the specific heat C_p/T increases rapidly with decreasing temperature and tends to a saturation about 560 mJ/molK^2 at 2 K. From these results, we have concluded that *a*-$Ce_{50}Al_{50}$ have a Kondo interaction at low-temperature. In this study, in order to investigate the Kondo behavior at low-temperature of *a*-Ce-Al alloy made by sputter, we have measured the low-temperature resistivity and specific heat at T < 2 K. The amorphous $Ce_{50}Al_{50}$ was obtained by a dc high-rate sputtering method from arc-melted ingot onto the water-cooled Cu substrate. Figure 1 shows the temperature dependence of the resistivity ρ for the *a*-$Ce_{50}Al_{50}$ from 0.5 to 10 K. ρ(T) exhibits a –log T dependence in 2 K < T < 10 K, and this behavior is similar to previous report. ρ at T < 2 K increases with a –T-linear behavior. In amorphous alloys case, a –log T dependence of electrical resistivity also is observed by the scattering of electrons due to the amorphous structure. So, we have measured the magnetoresistance Δρ/ρ for *a*-$Ce_{50}Al_{50}$. Δρ/ρ at 50 K for the *a*-$Ce_{50}Al_{50}$ is independent in magnetic fields. However, Δρ/ρ at 2 K increases negative with increasing magnetic fields. Therefore, it is considered that the negative increase of Δρ/ρ at 2 K is due to the magnetic scattering, not due to the amorphous structure. In the specific heat C_p at T < 10 K, a deviation from the phonon contribution for C_p increases with decreasing temperature, and exhibits a large maximum around 3 K. ρ and C_p behaviors at T < 10 K of *a*-$Ce_{50}Al_{50}$ are considered to be due to the dense Kondo effect realized by a Kondo interaction in the amorphous structure.

L5-06. Pressure Effect on Ce-based Kondo Approximant Crystal. T. Sawano[1], Y. Shinagawa[1], *T. Shiino*[1], K. Imura[1], K. Deguchi[1] and N. Sato[1] *1. Department of Physics, Graduate School of Science, Nagoya University, Nagoya, Japan*

Since the discovery of unconventional quantum criticality in a Yb-based quasicrystal (QC) and its approximant crystal (AC) [1,2], QCs and ACs have attracted a great deal of attention. Recently, a Ce-based AC that shows heavy-fermion and spin-glass features were discovered by Imura *et al.* [3]; measurements of magnetic and thermal properties and hard x-ray photoemission spectroscopy were performed on $Ag_{50}In_{36}Ce_{14}$ (Ag-In-Ce hereafter), which is the only Ce-based Kondo AC so far, and the results indicate the heavy-fermion nature of the 4*f* electrons and a magnetic transition into a spin-glass-like short-range-ordered state at the freezing temperature, $T_f \sim 0.3$ K. Here, we show the effect of hydrostatic pressure on Ag-In-Ce AC. The spin-glass features remain to be observed under pressure: for example, ac magnetic susceptibility exhibits a frequency dependent cusp near T_f and the increase of T_f with an external magnetic field. We also report that C/T (C is the specific heat) logarithmically increases with decreasing temperature for $T > T_f$. What is unexpected is that T_f increases as pressure increases, because Ce-based *f*-electron systems favor nonmagnetic Ce^{4+} states under pressure and thus the application of external pressure would make them nonmagnetic. We discuss possible origins of this unusual pressure dependence of the Ag-In-Ce AC.

L5-07. Point-contact Andreev reflection spectroscopy of Ce compound/ superconductor interface. *M. Shiga*[1], H. Takata[1], Y. Inagaki[1], F. Iga[2], Y. Onuki[3] and T. Kawae[1] *1. Department of Applied Quantum Physics, Kyushu University, Fukuoka, Japan; 2. College of Science, Ibaraki University, Mito, Japan; 3. Faculty of Science, University of the Ryukyus, Okinawa, Japan*

Heavy fermion compound forms a Kondo-singlet state at low temperature, where the effective mass of conduction electrons are enhanced. According to the theory, the Andreev reflection is suppressed at superconductor / heavy fermion interface due to the difference of fermi velocity. However, Andreev signal of $CeRIn_5$ (R = Co, Rh, In) / Nb interface was not reduced [1]. In this presentation, we study CeB_6/ superconductor interfaces using point-contact spectroscopy to deeply understand of the influence of heavy fermion system on Andreev reflection. Figure 1 shows the temperature dependence of differential conductance at a CeB_6/Nb interface. A zero bias conductance peak (ZBCP) is seen below $T \sim 7$ K. As the temperature is decreased, the intensity of the ZBCP is increased, and is saturated at $T \sim 1.5$K which is almost same with the Kondo temperature of CeB_6 (T_K = 1~2 K). At normal-metal /superconductor interface, on the other hand, such ZBCP is not observed. These results suggest that the ZBCP at the CeB_6/Nb interface is related to a Kondo-singlet state and Andreev reflection. To confirm the origin of ZBCP, we study a $CeCu_6$/Nb interface, which will be shown in the presentation.

L5-09. Magnetic Phase Transitions in Single Crystalline Non-centrosymmetric URhSn under Pressure. *A. Maurya*[1], F. Honda[1], Y. Shimizu[1], A. Nakamura[1], Y.J. Sato[1], Y. Homma[1], D. Li[1] and D. Aoki[1] *1. Institute for Materials Research, Tohoku University, Higashiibaraki, Japan*

We report the effect of hydrostatic pressure on a well characterized single crystal of URhSn, which crystallizes in a non-centrosymmetric ZrNiAl- type structure with the U-atoms forming a quasi-kagome lattice. URhSn is known to exhibit magnetic transitions at $T_1 = 54$ K and $T_2 = 17$ K with a ferromagnetic ground state [1,2,3]. We have measured electrical transport in the c-plane of single crystalline URhSn in a Bridgman anvil cell attached with a lead manometer to explore the evolution of these phase transitions up to a pressure of 5.9 GPa and temperatures down to 3 K. We find that the T_1 is monotonically suppressed to 37 K, while the T_2 first decreases at 1 GPa, shows a maximum and attains a value of 18 K with a declining trend at 5.9 GPa (Fig. 1). From the temperature-pressure phase diagram, a critical pressure of ~ 8 GPa is anticipated. A least square fitting of the equation $\rho = \rho_0 + AT^2$ to the resistivity vs. temperature data in temperature range 3-5 K reveals a diverging trend in the A coefficient as well as in the residual resistivity (ρ_0). This indicates an enhancement in the quasiparticle mass and presence of a possible quantum critical point at a higher pressure in URhSn.

L5-11. Novel Heavy-Fermion Compound $U_{11}Hg_{45}$. *E. Svanidze*[1], A. Amon[1], R. Borth[1], M. Nicklas[1], A. Leithe-Jasper[1] and Y. Grin[1] *1. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany*

The field of heavy-fermion physics emerged nearly four decades ago and has since become one of the most prominent research directions of condensed matter physics. However, while significant progress has been made in understanding heavy-fermion behavior and accompanying phenomena, the global trends still remain unclear. In this work, we present the discovery of a new heavy-fermion antiferromagnet - $U_{11}Hg_{45}$. The Sommerfeld coefficient $\gamma = 630$ mJ $mol^{-1}{}_U K^{-2}$ places this material as the second heaviest U-based heavy-fermion compound. Antiferromagnetic $U_{11}Hg_{45}$ orders below $T_N = 2.2$ K, with a high degree of itineracy of the \textit{5f} electrons, as suggested by the small entropy of the antiferromagnetic transition ($S_m = 0.08R\ln 2$) and the reduction of γ below the antiferromagnetic transition. However, a large effective magnetic moment $\mu_{eff} = 3.43\ \mu_B$/U points to a local moment scenario. These features altogether advocate dual nature of 5f electrons in $U_{11}Hg_{45}$.

L5-12. Tracking aluminum in UBe_{13} single crystals. A. Amon[1], I. Zelenina[1], P. Simon[1], M. Bobnar[1], M. Naumann[1], E. Svanidze[1], F. Arnold[1], H. Borrmann[1], U. Burkhardt[1], W. Schnelle[1], E. Hassinger[1], A. Leithe-Jasper[1] and *Y. Grin*[1] *1. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany*

The influence of Al incorporation on the heavy fermion superconductor UBe_{13} was investigated to explain the sample dependence of physical properties. Clear evidence for incorporated Al in flux-grown UBe_{13} single crystals is presented by results from X-ray diffraction, nuclear magnetic resonance and X-ray spectroscopy. The increase of the lattice parameter and the concomitant change of the superconducting properties are caused by substitution of Be by 1 - 2 at.% Al. Furthermore it was possible to locate the minute amounts of Al in the structure by atomic resolution transmission electron microscopy. Specific heat measurements reveal the strong influence of incorporated Al on the physical properties of UBe_{13}. Upon long-term annealing, Al incorporated in single crystals can leave the structure, restoring properties of Al-free polycrystalline UBe_{13}.

L6-01. Insights into the Origin of Room Temperature Ferromagnetism in SnO_2 and Mn doped SnO_2 Quantum Dots. *D. Manikandan*[1], A. Yadav[2], S. Jha[2], D. Bhattacharyya[2] and R. Murugan[1] *1. Department of Physics, Pondicherry University, Puducherry, India; 2. Atomic& Molecular Physics Division, Bhabha Atomic Research Centre, Mumbai, India*

Influence of dilute Mn on the structural, microstructure, electronic, magnetic and local structure properties of SnO_2 and Mn doped SnO_2 quantum dots (QDs) synthesized using high pressure microwave synthesis technique has been investigated. Powder X-ray diffraction, Raman, HRTEM and XPS in combination with first principle modeling investigations reveal single phase of tetragonal SnO_2 and ruled out the secondary phases. X-ray absorption near edge structure (XANES) spectra for Mn doped SnO_2 QDs measured at Mn K-edge were compared with standards of Mn metal foil, MnO, Mn_2O_3 and MnO_2. The Mn valence state mostly as +3 in lower dopant concentration (2 % Mn) and moved to +2 valence state at higher Mn dopant concentration (10 % Mn). Extended X-ray absorption fine structure (EXAFS) spectra show that Mn-O bond length decreases from 2% Mn doped QDs to the 6% Mn doped QDs, however for the 10% Mn doped QDs a small increase in bond length was observed. The Debye-Waller factor (σ^2) increases gradually with increase of Mn doping concentration also disclose the Mn incorporation in to the Sn site. The oxygen coordination in the nearest neighbor coordination shell around Mn site however remains constant over the whole Mn doping concentration range. Since Mn^{3+} is replacing Sn^{4+} in the present samples, it is expected to have oxygen vacancy in the lattice to maintain charge balance. However as seen in other cases also oxygen vacancies are generally created near the host sites rather than near the dopant sites. The observed EPR signal at room temperature in these QDs clearly indicates the intrinsic ferromagnetic nature. The experimental and theoretical investigations suggest that the oxygen vacancies and configuration of Mn ($Mn^{2+}$and Mn^{3+}) might be the origin of ferromagnetic order in these QDs. Our results provide an insight into the origin of observed room temperature ferromagnetism.

L6-02. Magnetic Interaction and Spin Dynamics in Cr doped 3C-SiC. *G.p. Moharana*[1], S. Singh[2] and H. Narayanan[3] *1. Physics, IIT Madras, Chennai, India; 2. CSIR Innovation Centre For Plasma Processing, IMMT, Bhubaneswar 751013, India, IMMT Bhubaneswar, Bhubaneswar, India; 3. Physics, IIT Madras, Chennai, India*

Undoped and Cr (1%, 3%, 5%) doped 3C-SiC polycrystalline samples have been prepared by Thermal plasma technique. X-Ray Diffraction and Raman studies confirm the incorporation of Cr ion into host matrix. DC magnetic measurement reveals the ferromagnetic nature of the sample. Among all the three samples 3% Cr doped 3C-SiC exhibits highest magnetic moment and Curie temperature indicating that this is the optimum solubility limit. The site occupancy and oxidation state of Cr ion have been confirmed by Temperature variation of electron paramagnetic resonance study. Cr^{3+} ion substitutes for the Si^{4+} ion resulting in the generation of holes. The variation of g value, Resonance field (H_r) and Integrated intensity with temperature and concentration have been studied in detail. The long range ferromagnetic order observed in the system might be due to Carrier (hole) mediated interaction.

L6-03. *ac* magnetic susceptibility in GaMnAsP films with perpendicular anisotropy. J.K. Furdyna[2], *X. Liu*[2], S. Bac[1,2], S. Dong[2], S. Lee[1] and M. Dobrowolska[2] *1. Physics, Korea University, Seoul, The Republic of Korea; 2. Department of Physics, University of Notre Dame, Notre Dame, IN, United States*

The dynamics of domain wall (DW) nucleation, motion and/or rotation is studied in GaMnAsP films with anisotropy perpendicular to the film plane, using *ac* magnetic susceptibility measurements[1]. To carry out these measurements, we have grown a series of thin film $Ga_{1-x}Mn_xAs_{1-y}P_y$ epilayers on GaAs (100) substrate by MBE, with film thicknesses ranging from 50 and 75 nm and with different nominal phosphorous concentration y from 0.10 to 0.30, while keeping the Mn content constant at $x = 0.06$. The samples were annealed at 270°C for 1 hour. *dc* and *ac* magnetization measurements were performed by a superconducting quantum interference device (SQUID) with the *ac* magnetic field applied along the [001] crystallographic direction (i.e., along the easy axis of GaMnAsP film, normal to the film plane). The *ac* driving field was applied at various frequencies, from 0. 1 Hz to 1000 Hz, at an amplitude of 3.77 Oe. Characteristic dynamic modes in the *ac* spectra were mapped in all GaMnAsP samples at temperatures near T_C, where the coercive field is comparable to the *ac* driving field, as illustrated in Fig. 1 for a 48 nm an annealed $Ga_{0.94}Mn_{0.06}As_{0.90}P_{0.10}$ film. Note that both the peak profile and its intensity show clear dependences on the frequency of the *ac* driving field. More significantly, we were able to identify DW relaxation, sliding, and switching using Cole-Cole plots[2] (shown in Fig. 2). Specifically, a switching mode (Debye semicircle) is observed in *ac* spectra in the temperature range between 76K and 90K; and a slide mode is observed just below T_C. The observation of a crossover between switching and slide regimes suggests a complicated feature of the phase transition below T_C. To further illustrate this complicated behavior, we will also discuss the DW segmental relaxation in GaMnAsP films with higher P concentrations, when the coercive fields are enlarged as the P concentration increases.

L6-04. Magnetic anisotropy of GaMnAsP ferromagnetic semiconductor films grown by MBE with a graded phosphorus concentration. *S. Dong*[1], X. Liu[1], S. Bac[1,2], T. Yoo[1], S. Lee[2], X. Li[1], M. Dobrowolska[1] and J.K. Furdyna[1] *1. Department of Physics, University of Notre Dame, Notre Dame, IN, United States; 2. Physics, Korea University, Seoul, The Republic of Korea*

GaMnAs is a widely investigated ferromagnetic semiconductor, holding significant promise for spintronic applications [1]. It is now well established that strain effects play an important role in determining the magnetic anisotropy of epitaxial III-Mn-V films. Specifically, the magnetic easy axis of GaMnAs films grown GaAs substrates lies in the film plane because of the compressive strain in the film. However, replacing a small fraction of As by P is known to change the strain to tensile, leading to an out-of-plane

orientation of the magnetic easy axis [2]. In this work, we investigate the effect of grading the concentration of P along the growth direction in this quaternary alloy. A graded $(Ga_{0.94}Mn_{0.06})(As_{1-x}P_x)$ film has been grown by low-temperature molecular beam epitaxy. This was accomplished by growing eight successive layers of 13-nm thickness with different P content (x = 0.03, 0.06, 0.10, 0.14, 0.18, 0.21, 0.25 and 0.28, respectively) while keeping the Mn concentration fixed to a total thickness 104 nm. From dark-field cross-sectional transmission electron microscope images, the 8-layer structure with increasing phosphorous concentration can be clearly seen, as also confirmed by X-ray diffraction results shown in Fig. 1. Although there are 8 layers with different content of P, the specimen shows only one Curie temperature at about 52 K and the magnetic properties shown from the magnetization vs. magnetic field curves (see Fig. 2) also behave like a single-phase film, indicating that the eight layers are magnetically coupled with each other. Most interestingly, the magnetic easy axis is remains in the film plane instead of normal to the film, although the average phosphorous content of the layer as a whole is about $x \sim 0.16$. By measuring the angle-dependent Hall resistance, the profile of the magnetic anisotropy has been obtained. These results suggest that one can design ferromagnetic semiconductor structures with different types of magnetic anisotropy by such graded strain effects.

L6-05. Characterization of ternary alloys (III-V) Mn deposited by magnetron sputtering. *J.G. Doria Andrade*[1,2], C.A. Pulzara-Mora[2], A. Pulzara-Mora[2], R.A. Bernal Correa[5] and A. Rosales Rivera[6] *1. Laboratorio de Materialografia, Facultad de Ingenieria, Institución Universitaria Pascual Bravo, Medellin, Colombia; 2. Departamento de Física, Universidad Nacional de Colombia, Manizales, Colombia; 5. Universidad Nacional de Colombia, Arauca, Colombia; 6. Laboratorio de Magnetismo y Materiales Avanzados, Universidad Nacional de Colombia, Sede Manizales, Manizales, Colombia*

The search for new materials for spintronics devices has generated much of the real research work to concentrate on the study and development of magnetic semiconductors [1-2]. The inclusion of a small fraction of magnetic atoms in a semiconductor matrix. This fraction must be small so that the structure of the bands of the material remains almost unchanged and remains a semiconductor, so these materials are called diluted magnetic semiconductors (SMD). For the growth of these alloys, several growth techniques have been used such as molecular beam epitaxy (MBE), metal phase vapor phase epitaxy (MOVPE) among others. Therefore, the growth technique is an important factor to take into account in the subsequent production of integrated circuits on semiconductor crystal filmes. For the growth of thin filmes of III-V (Mn), the sputtering technique was used due to its low cost. This technique has developed a lot during the last decade, until establishing itself as the processes chosen for the deposit of a wide range of industrially important research and with a growing demand for films of high functional quality in many sectors of the market. In the Raman spectra, the TO and LO modes of GaSb are also observed in positions 226 cm^{-1} and 231 cm^{-1} respectively. These semiconductor alloys intentionally doped with Mn and a change in the relative intensities LO/TO, which may be associated with a structural rearrangement in the alloy itself of the inclusion of Mn atoms in a substitutional manner. The Raman measurement also showed a 230 cm^{-1} vibratory mode associated with the coupled LO-Phonon-Plasmo mode (CLOPM) [3]. The ferromagnetic behavior of the samples was also analyzed from measurements of hysteresis cycles M vs H for different growth temperatures.

L6-06. Interlayer exchange coupling between Fe and GaMnAs ferromagnetic semiconductor. K. Tivakornsasithorn[2], S. Lee[1], S. Bac[1], S. Choi[1], *S. Lee*[1], X. Liu[3] and J.K. Furdyna[3] *1. Physics, Korea University, Seoul, The Republic of Korea; 2. Physics, Mahidol University, Bangkok, Thailand; 3. Department of Physics, University of Notre Dame, Notre Dame, IN, United States*

Interlayer exchange coupling (IEC) between ferromagnetic metal Fe and ferromagnetic semiconductor GaMnAs has been investigated by using magnetotransport measurements. For this investigation, we have grown two layered structures involving Fe and GaMnAs on GaAs (001) substrate with molecular beam epitaxy technique. One is a Fe/GaMnAs bilayer, in which Fe and GaMnAs layers are directly contact to each other, and the other is a Fe/GaAs/GaMnAs structure, in which 4 nm GaAs spacer separate Fe and GaMnAs layers. The planar Hall effect measurements were used to observe the magnetization reversal process of the structures. The transition steps corresponding to the reorientation of magnetization in Fe and GaMnAs layers are clearly resolved in the hysteresis observed from both samples. The orientations of magnetization in Fe and GaMnAs layers are carefully identified during the magnetization reversal process by considering magnetic anisotropy of each layers. Such identification of magnetization direction reveals diverse magnetization alignments, including collinear and non-collinear configurations, between Fe and GaMnAs layers. In order to investigate IEC between Fe and GaMnAs layers, we have performed minor loop scans in which only GaMnAs layer experiences reorientation of magnetization while that of Fe is fixed. While the Fe/GaMnAs bilayer shows shift of the minor hysteresis, the Fe/GaAs/GaMnAs structure does not show shift of the minor loop. This indicates that the IEC between Fe and GaMnAs present only when they are directly interfaced with each other. The direction of the minor loop shift in Fe/GaMnAs bilayer further revealed that the type of IEC between Fe and GaMnAs layers is ferromagnetic.

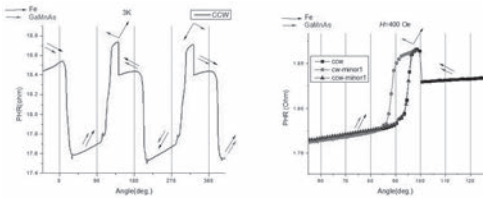

Fig1. (left) Magnetization reversal processes measured with rotating magnetic field. Various magnetic alignments are realized during the magnetization reverals process. (right) Minor loop scan obtained during the reorientation of magnetization in GaMnAs layer while the magnetization of Fe is fixed. The minor loop shifted toward the perpendicular alignment indicating the presence of ferromagnetic IEC between Fe and GaMnAs layers.

L6-07. Magnetic properties of (Ga, Mn)As films epitaxied on GaAs (110). *J. Ma*[1], H. Wang[1], X. Wang[1] and J. Zhao[1] *1. State Key Laboratory of Superlattices and Microstructures, Institute of Semiconductors, Chinese Academy of Sciences, Beijing, China*

(III, Mn)V dilute magnetic semiconductors (DMSs) featuring carrier-mediated ferromagnetism have been acting as an ideal playground for the exploration of many novel concepts in spintronic devices [1]. (Ga, Mn)As films previously studied were mainly deposited on GaAs (001) substrates, and their magnetic properties have been thoroughly investigated. However, the T_C is still lower than the room temperature [2], and the magnetic anisotropy of (Ga, Mn)As also needs to be further elucidated [2], especially for the bulk uniaxial magnetic anisotropy [3]. Considering the different incorporated ability of substitutional Mn and diffusion efficiency of interstitial Mn, GaAs substrates with different orientations may probably lead to (Ga, Mn)As films with very different magnetic properties. In this work, the magnetic anisotropies of (Ga, Mn)As (110) epitaxial films with different Mn concentrations have been systematically investigated by both superconducting quantum interference device (SQUID) magnetometry and magneto-transport measurements. Dominant in-plane magnetic anisotropies are found by both magnetic and magneto-transport measurements. Moreover, obvious spin reorientation transition has been observed for as-grown samples, which disappears after annealing. Figure 1 presents the angle dependent planar Hall resistance and fitting curves for the as-grown and annealed samples at 5 K and 40 K, clearly showing the change of magnetic easy axis by varying temperature and hole density. The above phenomena are shown to be correlated with the competition between the cubic and the uniaxial magnetic anisotropy, as presented in table I. Our work provides useful information for the understanding of the magnetic anisotropies in (Ga, Mn)As films.

L7-01. Effect of Graphene on Magnetocaloric Properties of $La_{0.7}Ca_{0.3}MnO_3$ Perovskite Manganese Oxide. K. Sarlar[1,3], *E. Civan*[2], N. Kucuk[1] and I. Kucuk[1] *1. Physics Department, Uludag University, Bursa, Turkey; 2. National Defence University, Izmir, Turkey; 3. Physics Department, Karamanoglu Mehmetbey University, Karaman, Turkey*

In this work, $La_{0.7}Ca_{0.3}MnO_3$ perovskite manganese oxide powders were produced incorporating small amounts (0.1 to 1 wt%) of graphene. The powders were prepared by wet chemical method. Magnetic transition temperature (T_C) and magnetic entropy change (ΔS_M) for the perovskite manganese oxides were determined from the minimum of the dM/dT versus T curve and isothermal magnetisation curves. Magnetisation (M)-Temperature (T) measurements were performed under an applied magnetic field of 0.01 T and revealed that the ferromagnetic-paramagnetic transition temperature changed from 253 to 260 K with increasing graphene content from 0 to 1 at.%. With increasing graphene content to 1 at.%, the $-\Delta S_M^{max}$ values were increased to 0.92, 2.09, 3.28 and 4.36 $Jkg^{-1}K^{-1}$ for a magnetic field change of 0.5, 1, 1.5 and 2 T (Fig.1). The refrigeration capacity (RC) values calculated from the experimental data under an applied magnetic field change of 0-2 T, were increased from 128 (undoped) to 324 J/kg by doping 1 % graphene by weight. Furthermore, the gradual increase of the RC similar to $-\Delta S_M$ has been observed as a function of H for $La_{0.7}Ca_{0.3}MnO_3$, 0.7 and 1% graphene-doped, which is illustrated in the Fig. 2.

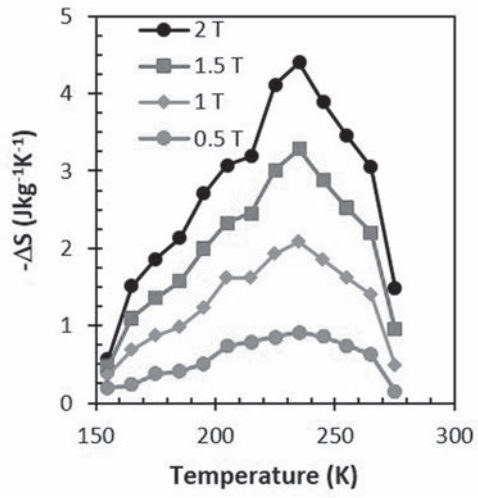

Fig. 1 Temperature dependence of magnetic entropy change for 1% graphene-doped $La_{0.7}Ca_{0.3}MnO_3$ under 0.5, 1, 1.5 and 2 T magnetic field-changes.

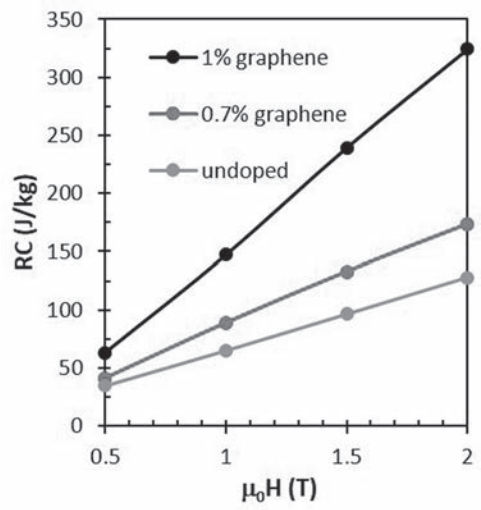

Fig. 2 The refrigeration capacity (*RC*) as a function of magnetic field change for $La_{0.7}Ca_{0.3}MnO_3$, 0.7 and 1% graphene-doped perovskite manganese oxide powders.

L7-02. Magnetocaloric effect in promising magnetocaloric materials in cyclic magnetic fields. *A. Aliev*[1], A. Gamzatov[1], A. Batdalov[1], L. Khanov[1], A. Mukhuchev[1], V. Koledov[2], V. Shavrov[2], A.P. Kamantsev[2], G. Govor[3], K.P. Skokov[4] and O. Gutfleisch[5] *1. LTP&M, Amirkhanov Institute of Physics of Daghestan Scientific Center of RAS, Makhachkala, Russian Federation; 2. Scientific-Practical Materials Research Centre of the National Academy of Sciences of Belarus, Minsk, Belarus; 4. FM, TU Darmstadt, Darmstadt, Germany; 5. Fb11, FG FM, TU Darmstadt, Darmstadt, Germany*

From a practical point of view there is a substantial need for studying the magnetocaloric effect (MCE) in promising magnetocaloric materials under prolonged exposure to the cyclic magnetic fields. Most promising magnetocaloric materials are materials with the first-order magnetostructural phase transitions. The value of MCE in these materials for the first application and under prolonged exposure to cyclic magnetic fields can vary considerably. In this work, we present results of studying the magnetocaloric properties in various families of promising magnetic materials (La(FeSi)13-H, MnFe(AsP), FeRh, Gd5(GeSi)4, Ni-Mn-X Heusler alloys and manganites (Fig.1)). The influence of hysteresis on the magnetocaloric properties of materials, the dependence of the MCE on the frequency of alternating magnetic field, the effect of prolonged action of cyclic magnetic field are studied in detail. For some materials, the ratios of magnetic and lattice contributions to the total magnetocaloric effect are defined. The explanation of differences in the values of MCE in the heating and cooling runs, as well as the effect of degradation of MCE under prolonged action of cyclic magnetic field are given. Various mechanisms for MCE reduction with a magnetic field frequency are proposed. This work is supported by RFBR grants ## 17-02-01195 and 18-08-01434.

L7-03. Mechanical alloying influence on the preparation of single-phase Mn-Fe-P-Si magnetocaloric compounds. *J.H. da Silva*[1], A. Davarpanah[1], F. Mohseni[1], J.S. Amaral[1] and V.S. Amaral[1] *1. CICECO & Physics Dept., Universidade de Aveiro, Aveiro, Portugal*

The Mn-Fe-Si-P together with the La-Fe-Si compounds are currently the most promising magnetocaloric materials to be used in magnetic refrigeration (MR) at room temperature (RT). Their tunable Tc, high magnetocaloric effect (MC) and their inexpensive constituent elements qualify them as versatile and cheap candidate materials [1]. Unfortunately, their preparation requires multiple steps that account for a long overall preparation time. It comprises mechanical alloying via Ball Milling (BM) of the chemical reagents for at least 10h[1] followed by the sintering that can last from 20 hours up to one week [2,3] and typically involves a two-step thermal treatment. Despite its critical importance on the materials MC properties, there are few studies dedicated to the evaluation and control of the various preparation parameters. One interesting exception is the recent report by Fries and co-workers, where they have studied the influence of metal/non-metal ratio on the materials microstructural, structural and magnetic properties and found that a small percentage such as 6% of secondary phase can lead to a 25K Tc change [2]. In this work we focused on the study of the influence of the BM time on the final material properties. Hence, powders of Fe2P, Mn, Si, P and B were mixed to achieve a final stoichiometry of $Mn_{0.88}Fe_{1.07}P_{0.59}Si_{0.34}B_{0.07}$. Preliminary results highlight the influence of BM time in the completeness of the mechanical alloying. After 10h, the resultant powder spectrum still showed XRD peaks associated with pure Mn and Si, whereas after 25h these peaks were absent (Figure 1). Two bulk samples were prepared following the same and the typical procedure reported in the literature: pressing followed by a two-step annealing and a slow-cooling to RT. There was a drastic impact of the BM time on both the structural (down to 15% less secondary phase) and magnetic (up to 100K higher Tc) properties A detailed assessment of the BM time influence on the microstructural, structural and magnetic properties of the final materials is currently underway.

L7-04. Influence of the characterization protocols for erasing the thermal and magnetic history on the direct-ΔT_{ad} of FOPT magnetocaloric materials. L.M. Moreno-Ramírez[1], A. Delgado-Matarín[1], J. Law[1], *V. Franco*[1], A. Conde[1] and A. Giri[2] *1. Universidad de Sevilla, Sevilla, Spain; 2. Weapons and Materials Research Directorate, US Army Research Laboratory, Aberdeen, MD, United States*

In the direct magnetocaloric characterization, ΔT_{ad} is directly measured under adiabatic conditions during the variation of magnetic field. For materials with first order phase transitions (FOPT), the effects of temperature and field are not reversible due to the intrinsic hysteresis of the transition. This implies that, for subsequent measurements in the hysteretic range, the sample could have been partially transformed due to its previous measurement conditions. Hence, to obtain experimental data with physical meaning, the effects of partial transformations during each measurement should be removed by erasing the thermal and field history. This is done by cooling/heating the sample well below/above the transition with the simultaneous application of different magnetic fields before starting the characterization at the desired temperature. The influence of previous measurements on the determination of ΔS_M from magnetic measurements has been profusely discussed [1,2]. However, its influence on the direct measurement of ΔT_{ad} has been mostly disregarded in the literature. In this work, we analyze the influence of erasing memory protocols on the direct ΔT_{ad} measurements of FOPT Heusler alloys [3]. We observe that ΔT_{ad} values are underestimated when the thermal history of the samples is not accounted for. One example is shown in Fig 1, wherein $Ni_{49}Mn_{36}In_{15}$ exhibits lesser amount of austenite phase that transforms into martensitic phase when its previously thermal history was not erased (ΔT_{ad} decreases by 40 %). Tuning the temperature span of the hysteretic region, it is shown that the importance of this protocol for erasing the memory of the sample is more crucial with increasing thermal hysteresis. This work was supported by AEI/FEDER-UE (project MAT-2016-77265-R) and the PAI of the Regional Government of Andalucía. L. M. acknowledges a FPU fellowship from MECD.

L7-05. Dynamic Magnetic Losses along different Directions in Hi-B GO Laminations. *C. Appino*[1], E. Ferrara[1], L. Rocchino[1], F. Fiorillo[1] and C. Ragusa[2] *1. Nanoscience and Materials Division, Istituto Nazionale di Ricerca Metrologica, Torino, Italy; 2. Energy Department, Politecnico di Torino, Turin, Italy*

Magnetic cores of medium-large rotating machines are increasingly made with grain-oriented (GO) Fe-Si laminations, as they display good torque and efficiency, in spite of the high directional properties of material [1][2]. However, when assessing the power loss behavior in directions different from RD, ambiguities may derive from the experiments, because they reflect both the geometrical features of the samples and the intrinsic properties of the material. One finds, in particular, that magnetization curve and losses measured along directions different from RD and TD using either Epstein or Single Sheet Testing largely depend on strip width and flux closure along the strip edge [3]. In this work we investigate the magnetic loss vs. frequency f (DC – 400 Hz) and peak induction (0.15 T - 1.4 T) of high-permeability GO sheets tested both as conventional 30 mm wide Epstein strips and 120 mm wide strips. The wider strips are characterized, in particular, adopting the X-stack configuration, ensuring flux closure at the sample edges. The samples are cut at different angles q with respect to RD, from 0° to 90°. For a same cutting angle, large differences arise, at all frequencies, between single strip and X-stack. For a lamination in a core, intermediate behavior is expected. It is shown how the presence (Epstein) or the absence (X-stack) of a transverse demagnetizing field $H_{d,}$ makes the magnetization process to pass from unidirectional to two-dimensional. The H_d-influenced mechanism of domain transition between different [100] easy axes determines a q dependent hysteresis loop shape, area, and evolution with frequency. While the quasi-static response vs. q can be assessed in the frame of Néel's phase theory, the dynamic behavior calls for loss separation with two-dimensional magnetization reversal. This requires first the prediction of the classical loss (longitudinal plus transverse), where only the longitudinal magnetization is controlled sinusoidal and the net transverse component relates to 180 °domain wall motion only, to disappear upon transition between easy axes. The corresponding excess loss shows a deviation from the usual $f^{½}$ behavior, pointing to a non-uniform distribution of the local coercive fields.

Both FeNi and MnAl phases with $L1_0$ crystal structure have promising potential for advanced permanent magnet applications due to low costs and moderately high magnetic anisotropy that are combining with its large corrosion resistivity and high Curie temperature. In our talk, we will focus on searching of novel synthesis routes of these FeNi- and MnAl(C)-based alloys. Particular emphasis will be done on severe plastic deformation that can be induced in the alloys by: (1) Mechanical alloying, in order to achieve a metastable (partially amorphous) state with anomalous high mutual solubility of elements and with high mobility of atoms; (2) High pressure torsion, of $Fe_{50-x}Ni_{50-y}Z_xW_y$ and $Mn_{50-x}Al_{50-y}Z_xW_y$ alloys where Z and W are different 3*d*, 4*d*, 5*d* metals and some rare-earth elements; (3) High-energy explosion, that detonate in a closed steel chamber filled with water (ice) coolant in order to stabilise new intermetallic phases under high pressure (above 200 GPa).

L7-07. Vibration Analysis, Calculation, and Reduction in Surface-mounted Permanent Magnet Motors. *J. Hong*[1] and S. Wang[1] *1. Tsinghua University, Beijing, China*

Because of the high performance of PM material, PM motors have many advantages, the applications of PM motors get wider and wider. In some applications, the vibration and noise recution techniques are the continually increasing requirements. Electromagnetic excited vibration is one main reason of noise. Based on the MMF and magnetic permeance of air-gap, the magnetic flux density in the airgap is obtained, including the features of pole pair number, rotating speed and amplitude. Then the typical contents of electromagnetic excited force on the stator are derived, also including the mode number and frequency. The relationships between the different magnetic field components and different components of electromagnetic excited force are discussed. Also, finite element method (FEM) is used to compare the analytical results. To reduce vibration and noise, a method skewing the magnet shape is proposed in this paper. The correlation between the skew structure, the radial electromagnetic force, and the acceleration is described in detail, including cogging torque. The optimal skew angle does not equal to the one teeth width, but to the pole width. A structural finite element model of the SPM motor composed of stator iron is built. In order to validate the model results and get the damping ratio used to calculate the deformation, modal test is conducted. In the modal testing, the test SPM motor is suspended by the elastic rope to simulate the free support-condition. The 13 accelerometers are evenly attached to the surface of the stator in the circumferential direction. In the modal test, the hammer is used to hit the point close to the accelerometer. This hit repeats from the first accelerometer to the last one. The effective frequency band of the measured modal parameters is from 10 to 6400Hz. In order to verify the calculation and analysis, the prototype motor of SPM is specially designed and manufactured, as shown in Fig. 1. The experiments of vibration signal under different speeds and different load are carried out. The experimental results are compared with the FEM analysis and calculation. Fig.2 shows the experimental results of the two sample motors.

L7-08. Recovering of REE from Waste Magnets and End-of-life Devices: A Novel Acid Free Method. D. Prodius[1] and *C.I. Nlebedim[1] 1. Critical Materials Institute, Ames Laboratory, US Department of Energy, Ames, IA, United States*

Rare earth elements are widely used for permanent magnets in modern high-tech applications. They are essential for national energy, technological and manufacturing competitiveness, and security. Recycling permanent magnets offers an opportunity to apply circular economy to rare earth elements by recovering them to be used as secondary raw materials. Many proposed hydrometallurgical recycling methods typically dissolve magnets in large volumes of mineral acids and generate significant amounts of acid contaminated wastes. This creates obvious environmental, cost and safety concerns. Our process dissolves magnets in water-based solutions, applies to both Nd-Fe-B and Sm-Co magnets and recovers high purity rare earth elements and Co. It is also energy efficient and demonstrated to be economically profitable. In addition, this novel technology directly recovers rare earth elements from permanent magnets, including those contained in shredded magnetic devices. This means that it omits pre-sorting, demagnetization or some other pre-treatment of the waste stream material typically done in other technologies. In this talk, we will present pathways for recycling permanent magnets, such as grinding swarfs, scrap magnets from magnet manufacturing or post-manufacturing processing operations and magnets from end-of-life products (e.g., hard disk drives). Examples of different recycling methods, including the possibility for direct reuse and elemental separations into metals and oxides, will be discussed. Emphasis will be on permanent magnets containing neodymium, praseodymium, dysprosium and samarium. The talk will also provide insights into how the states of the magnets to be recycled influence the choice of recycling pathway and the targeted recycling end products. Acknowledgement This work is supported by the Critical Materials Institute, an Energy Innovation Hub funded by the U.S. Department of Energy, Office of Energy Efficiency and Renewable Energy, Advanced Manufacturing Office.

L8-01. Chaotic magnetization dynamics in elliptical nanodots excited by spin transfer torque. *E.A. Montoya*[3], S. Perna[1], M. d'Aquino[2], C. Serpico[1] and I. Krivorotov[3] *1. DIETI, Università di Napoli Federico II, Napoli, Italy; 2. Dipartimento di Ingegneria, Università degli Studi di Napoli "Parthenope", Napoli, Italy; 3. Physics and Astronomy, University of California, Irvine, Irvine, CA, United States*

Recent theoretical work has shown that ac-driven magnetization dynamics near saddle equilibria in magnetic elliptical nanodots exhibits chaotic behavior, even for moderately low excitation power [1]. The chaotic magnetization dynamics in this regime can be studied with tools of nonlinear dynamical systems such as the Poincarè map [2]. Such analysis allows the definition of the concept of erosion of the stability region of magnetic equilibria in absence of the ac drive [1]. From an energy perspective, the effect of the erosion is similar to a reduction of the magnetic potential barrier separating two stable equilibrium states of the nanodot, as exploited in energy assisted magnetic reversal schemes (HAMR [3] and MAMR [4,5]). In this framework, we study experimentally this phenomenon by measuring thermal telegraph noise of the free magnetic layer in nanoscale elliptical magnetic tunnel junctions (MTJs) in the presence of ac drive. In these studies, the ac excitation is provided by the spin transfer torque arising from radio-frequency (RF) current applied to the MTJ. We follow the switching rate of the free layer, which serves as an indicator for the occurrence of chaotic dynamics as a function of both the frequency and power of the applied microwave excitation. It is found that microwave excitations below the ferromagnetic resonance frequency lead to rapid increases in the switching rate in the MTJs, as shown in Figure 1. The results indicate that the threshold power increases with increasing microwave frequency and matches well to analytical theory as shown in Figure 2. The experimental results are compared to analytic theory and simulation and show good agreement. These results are relevant for spin torque memory (STT-MRAM) based on nanoscale MTJs, where it is of great interest to lower the threshold current for the MTJ free layer switching.

Threshold ac drive voltage as a function of microwave frequency for experiment (blue dots) and theory (black line).

L8-02. Excitation of Short Spin-Wave Packets by Pure Spin Current. *B. Divinskiy*[1], V.E. Demidov[1], S. Demokritov[1] and S. Urazhdin[2] *1. Institute for Applied Physics, University of Muenster, Muenster, Germany; 2. Emory University, Atlanta, GA, United States*

Downscaling poses a number of new challenges for the implementation of magnonic devices. In particular, the traditional inductive method for spin wave excitation becomes inefficient at nanoscale. An alternative approach to the excitation of spin waves can utilize the spin-transfer torque generated by local spin current. Here, we use time- and space-resolved micro-focus Brillouin light scattering spectroscopy to study the excitation of propagating spin waves by pure spin currents, generated by the nonlocal spin injection (NLSI) mechanism. By applying the driving dc current in the form of short pulses, we show that the NLSI mechanism is sufficiently fast to

enable generation of short spin-wave packets with the duration down to 2 ns. Moreover, we find that the intense spin-wave packets generated by the pure spin current experience a nonlinear compression while propagating in the magnonic nano-waveguides, which further reduces their temporal width. The nonlinear compression can compensate the dispersive broadening of spin-wave packets, allowing on to engineer the nonlinear characteristics of magnonic transmission lines with improved information flow capacity. Our findings clearly demonstrate the unique benefits of NLSI oscillators as the nanoscale sources of short spin-wave packets for the implementation of high-speed magnonic devices. Our results should stimulate further developments in magnonics, and bring this area of research closer to the real-world applications.

Measured maps of the spin-wave intensity recorded at delays of 1.6, 2.4 and 3.2 ns with respect to the start of the driving current pulse, as labeled. The temporal width of the spin-wave packet is 2.1 ns, and its center frequency is 8 GHz. The nano-waveguide is outlined in dashed lines.

L8-03. Increased Gilbert Damping at Low Temperature in Polycrystalline YIG Films with Pt Capping layer. *S. Pati*[1] and Y. Endo[1,2] *1. Department of Electrical Engineering, Tohoku University, Sendai, Japan; 2. Center for Spintronics Research Network (CSRN), Tohoku University, Sendai, Japan*

Yittrium-Iron-Garnet (YIG) is one of the suitable candidates for spin-wave based devices, due to its ultra-low damping and electrically insulator. Magnetization dynamics of YIG films have been studied immensely for the scientific points of view. Recently, as reported by Haider et.al.[1], the damping of YIG film decreases in the low temperature range, which may be attributed the suppression of thermal scattering of magnon and phonon. Contrarily, Jermain et.al. reported the damping was enhanced by the spin relaxation via impurities at the low temperature [2]. Thus, the magnetization dynamics of YIG film at the low temperature still remains unclear. Herein, we studied the magnetization dynamics of Pt/YIG(t_{YIG})/Pt trilayer films in various temperatures between 50 – 300 K and discussed their dynamics behaviors in details. It was found that the resonance field shifted towards low field and the resonance linewidth broadened with decreasing temperature. Using these parameters, effective Gilbert damping (α_{eff}) was evaluated as a function of temperature. Fig. 1 shows the variation of α_{eff} with temperature for 100nm YIG film. α_{eff} increased from 1.1×10^{-3} to 3.4×10^{-3} as the temperature was decreased was varied from 300 K to 50 K. To understand the reason for enhancement of α_{eff} at the low temperature, we measured α_{eff} at 300 K and 50 K as a function of the inverse of YIG thickness (the inset of Fig 1). The enhancement of α_{eff} at the low temperature is more pronounced in lower thickness region of YIG, which may be attributed to the structural and/or magnetic inhomogenities at the YIG/Pt interface. On the basis of these results, it is revealed that YIG/Pt interface plays an important role for the enhancement of the Gilbert damping in YIG films at the low temperature. S. P. Pati would like to thank JSPS for the international post-doctoral research fellowship (ID no: P17070). We would like to thank Quantum Design for PPMS-FMR measurement. This work was partly supported by JSPS KAKENHI Grant Number JP17H03226, JP17F17070 from MEXT, Japan and ASRC in Japan.

L8-04. Ferromagnetic Resonance and Spin Pumping in Heterostructures with $SrIrO_3$. *S. Crossley*[1], A.G. Swartz[1], K. Nishio[2], Y. Hikita[2] and H. Hwang[1,2] *1. Applied Physics, Stanford University, Stanford, CA, United States; 2. Stanford Institute for Materials and Energy Sciences, SLAC National Accelerator Laboratory, Menlo Park, CA, United States*

Resonant excitation of magnetic films is an attractive source of pure spin current for spintronics applications. Exploiting this spin pumping effect in heterostructures of transition metal oxides, with tunable spin-charge-orbital degrees of freedom, could lead to novel physical probes of these materials and new operational regimes for spintronics devices. By pulsed laser deposition, we have incorporated epitaxial films of the prototypical high spin-orbit semimetal $SrIrO_3$ into heterostructures with either manganite or cobalt ferromagnetic layers. Ferromagnetic resonance (FMR) damping and two-magnon scattering are studied at room temperature and at low temperature, revealing large changes linked to the presence of $SrIrO_3$.

L8-05. Enhanced Gilbert Damping Due to the Oxide Interface in $Py/LaTiO_3/SrTiO_3$ Trilayers. *M.J. Veit*[1], J. Wisser[1], S. Emori[1,2], Y. Deng[1], M. Chan[3], B. Ramshaw[3,4], R. Arras[6], R. Pentcheva[5], S. Wang[1] and Y. Suzuki[1] *1. Stanford University, Stanford, CA, United States; 2. Virginia Tech, Blacksburg, VA, United States; 3. Emergent metallic behavior at the interface of the Mott insulator $LaTiO_3$ (LTO) and the band insulator $SrTiO_3$ (STO) has been explained in terms of charge redistribution at the interface combined with strain-induced electronic structure modification. We have previously shown that the interface has a large Rashba effect and therefore enhanced spin-orbit coupling although these effects do not exist in the bulk of the film. Because of this large spin-orbit coupling, it is possible that the interface can be used in spintronic devices as a spin sink or to convert spin current to charge current. Here we perform ferromagnetic resonance (FMR) measurements on permalloy/LTO/STO structures to determine the increase in damping in the permalloy due to the LTO. We find a large enhancement of the FMR damping in LTO films just a few unit cells thick. The damping decreases as the films are made thicker. This is in contrast to typical metals which show an increased damping with thicker films. This implies that the interface acts as a better

spin sink than the bulk of the film. These results suggest that large Rashba oxide systems are promising for spin current based spintronic devices.

Damping factor of the permalloy as determined by the FMR linewidth for a variety of LaTiO3 thicknesses. The red line is a fit to a trilayer model which considers the interface as a spin sink and spins diffuse through the bulk of the film.

L8-06. $Mg(Al, Fe)_2O_4$: A New Magnetic Insulator for Spin Pumping. *L. Riddiford*[1], S. Emori[3], J. Wisser[1] and Y. Suzuki[2] *1. Applied Physics, Stanford University, Menlo Park, CA, United States; 2. Stanford University, Stanford, CA, United States; 3. Virginia Tech, Blacksburg, VA, United States*

In spin-based electronics, magnetic insulators are crucial to energy-efficient information transfer because they can carry a pure spin current without a dissipative charge current. We have developed epitaxial films of the ferrimagnetic insulator $Mg(Al,Fe)_2O_4$ (MAFO) with low magnetic damping. Additionally, MAFO crystallizes in a spinel structure which can be coherently interfaced with perovskites and other materials for spin pumping applications. Toward this purpose, we have synthesized MAFO thin films on (001) $MgAl_2O_4$ (MAO) single crystal substrates via pulsed laser deposition. To characterize the structural properties, we used x-ray diffraction and atomic force microscopy (AFM). X-ray diffraction measurements indicate epitaxial growth with only the (00l) family of film peaks appearing. Rocking curves with a mosaic spread of $\Delta\omega$=0.06° indicate excellent crystallinity, and reciprocal space mapping shows the film is coherently strained to the MAO substrate. Atomic force microscopy shows a typical sub-unit cell rms roughness of 0.8 Å. Magnetic properties were studied using ferromagnetic resonance (FMR) and SQUID magnetometry. We collected FMR spectra which demonstrate an exceptionally narrow linewidth of 0.58 mT at 10 GHz. From frequency-dependent linewidth measurements, we calculate a Gilbert damping parameter of 0.0015. Finally, SQUID magnetometry shows a saturation magnetization of ~100 kA/m at 300 K. These promising results indicate MAFO can eventually be integrated into new, low-loss spin pumping systems.

L8-07. The dc voltage induced by Nonuniform microwave power in YIG/NM system. *H. Zhou*[1,2], Q. Zhang[1], X. Fan[1], D. Xue[1] and L. Ma[4,3] *1. Spin pumping is a fundamental approach for generating pure spin currents. The precessing spins in ferromagnets (FMs) act as peristaltic pumps, adiabatically injecting spins out of the FM layer into the adjacent normal metal (NM) without charge transport [1–5]. Therefore, spin pumping can be understood as the inverse effect of spin torque and provides access to the physics of spin dynamics, damping, and spin current. The resonant dc voltage spectrum induced by spin pumping effect and inverse spin Hall effect shows a "symmetric" (Lorentz) lineshape. In many spin Hall angle measuring experiments, this characteristic was used to separate the spin pumping signal and the spin rectification signal[6]. However, we found an "antisymmetric" resonant peak in a typical spin pumping system YIG/NM (yttrium iron garnet/normal metal). This special lineshape was proved to be the integrated result of two resonant signal: a traditional spin pumping signal and an uncharted signal. The later one shows many characteristics: a $\cos^3\theta$ angle dependence, related with spin Hall angle, and exists in xz plane, as shown in Fig 1. Finally, we demonstrated that the uncharted signal originates from non-uniform distribution of microwave.

L8-08. Caustic-like Spin Transport by Hybrid Magneto-Elastic Bosons in a Ferrimagnetic Film. *D.A. Bozhko*[1], P. Frey[1], A.A. Serga[1] and B. Hillebrands[1] *1. Physics, Technische Universität Kaiserslautern, Kaiserslautern, Germany*

An ensemble of spin-wave quanta — magnons — can be treated as a Bose gas of weakly interacting quasiparticles. An external injection of magnons causes an increase in the chemical potential of a thermalized magnon gas. When it reaches the minimal magnon energy a Bose-Einstein condensate (BEC) forms at this spectral point [1,2]. However, magnon-phonon interaction processes can significantly modify this scenario. Our recent observations of an overpopulated magnon gas in a single-crystal film of yttrium iron garnet ($Y_3Fe_5O_{12}$, YIG) by means of wavevector-resolved Brillouin light scattering (BLS) spectroscopy resulted in the discovery of a novel condensation phenomenon: A spontaneous accumulation of hybrid magnon-phonon bosonic quasiparticles at the intersection of the lowest spin-wave mode and a transversal acoustic wave [3]. As opposed to the classical magnon BEC, these hybrid quasiparticles posses a nonzero group velocity, making them promising data carriers in prospective magnon spintronics devices. In order to determine a two-dimensional transport characteristics

of the magnon-phonon hybrids, we parametrically injected magnons in a point-like 100μm-wide area by 200ns-long microwave pump pulses. By performing two-dimensional space-resolved BLS probing, we show that the emission of the accumulated quasiparticles from the injection area is highly anisotropic. We observed six propagation directions (see Figure). Two hybrid wave packets contra-propagate along the magnetic field with a group velocity of 3500m/s, independent on the applied pumping power. In contrast, the other four packets propagate at angles of 58 degrees to the direction of the bias magnetic field. Although their group velocity is changed from 200 to 500m/s with fourfold increase in the pump power, the propagation directions remain constant. The revealed propagation dynamics can be understood as caustic-like phenomenon [4], which can be utilized for a long distance spin transport in future two-dimensional magnonic cirquits. The work is supported by the ERC within the AdG "Supercurrents of Magnon Condensates for Advanced Magnonics" and DFG within the SFB/TR49 (project INST 161/544-3).

In the backward volume (BV) geometry of a ferromagnetic film, spin waves propagate in plane and parallel to an external magnetic field. In this geometry, the mode has the unusual property that the frequency initially *decreases* with increasing wavevector and therefore the group velocity is directed *opposite* to the wave vector, and hence the designation. Inclusion of the exchange interaction causes this downward trend of the mode frequency to go through a minimum at some wave vector, k_{min}, after which it increases approximately as k^2. Recently two groups have reported that under heavy two-magnon pumping, followed by approximately-number conserving interactions among the excitations so produced, that a macroscopic *condensation* occurs into the two states lying at $k=\pm k_{min}$, a phenomena that they refer to as Bose-Einstein condensation [1,2]. Later theoretical work, which accurately reproduces the observed time dependence of the magnon spectrum following pumping, argues that the phenomena should more appropriately be termed a Rayleigh-Jeans condensation [3] since it occurs in the classical region of the Bose distribution. Regardless of the terminology, this is a clearly an unusual phenomenon and hence it is important to have a more complete characterization of the spectrum in the vicinity of where condensation occurs. We will report measurements of the dispersion of the BV mode for a discrete set of wavevectors lying in the vicinity of as well as that of the higher-lying, exchange-split, branches for the same wavevectors. These data are acquired as microwave resonances using multi-element antennas patterned on the magnetic layer, the spacing of which fixes the wavelength. * Work at Northwestern supported by the US Department of Energy under grant DE-SC0014424. The study of nonlinear magnetization dynamics in periodically-driven nanoscale magnetic particles plays a central role in both fundamental and technological research areas of applied magnetism[1]. Single-domain magnetic particles represent the simplest theoretical systems which exhibit non trivial nonlinear effects such as nonlinear resonance, synchronization and chaos[2] and are at the basis of magnetic recording technologies[3]. In the last decades, there has been a renewed interest in nonlinear FMR[4] in connection with the technique of microwave assisted switching[5]. The FMR occurs when AC-driven magnetization oscillations are excited around a stable equilibrium. The small oscillations amplitude as function of the frequency follows the usual resonance curve peaked around the Kittel frequency[6]. When the AC power is increased, nonlinear phenomena produce multiple steady periodic regimes, accompanied by hysteresis phenomena in amplitude versus frequency response, usually referred to as fold-over phenomenon[7]. However, while classical FMR and fold-over studies have focused on frequency ranges close to the Kittel frequency, it turns out that complex nonlinear phenomena associated with multiplicity of stable regimes may occur, for instance, when the frequency is significantly reduced at sufficiently large AC excitations. In this work, we propose an exact analytical treatment enabling one to make a complete broadband study of nonlinear FMR excited by AC magnetic fields with moderately large amplitudes and frequency not necessarily close to the Kittel frequency. Such analytical treatment is possible when one considers the idealized situation of single domain nanomagnets, with uniaxial shape and crystalline anisotropy, and subject to circularly polarized fields rotating in the plane perpendicular to the symmetry axis[2]. In this situation, chaos is precluded and the only possible regimes are either periodic (P-modes) or quasiperiodic (Q-modes) magnetization oscillations. By using bifurcation theory, the complete phase-diagram of P and Q modes as function of frequency and amplitude of the AC field is derived and all the possible hysteretic transitions among these regimes are elucidated.

L8-11. Analysis of Transient Chaos in Nanomagnets Subject to Time-harmonic excitations. *M. d'Aquino*[1], C. Serpico[2], A. Quercia[2], S. Perna[2], P. Ansalone[3] and I. Mayergoyz[4] *1. Dipartimento di Ingegneria, Università degli Studi di Napoli "Parthenope", Napoli, Italy; 2. DIETI, Università di Napoli Federico II, Napoli, Italy; 3. INRIM, Torino, Italy; 4. ECE Department, University of Maryland, College Park, MD, United States*

One of the basic operations on magnetic nanosystems used in magnetic and spintronic technologies is the application of external excitations, such as applied magnetic fields or injected currents, in order to move magnetization direction from one metastable state to another[1]. An important aspect of these processes is the nature and the time scale of the transient magnetization dynamics. In this work, we analyze transient evolutions of magnetization in nanomagnets subject to weak time-harmonic (AC) external fields. More specifically, we analyze how the magnetization direction in a uniformly magnetized nanomagnet, initially tilted to an arbitrary direction, relaxes toward one of the coexisting AC-driven asymptotic regimes. It turns out that this transient dynamics has a chaotic character at moderately low power level. The chaotic and fractal nature of the transient AC is due to the phenomenon of heteroclinic entanglement which is produced by the combined effect of AC-excitations and saddle type dynamics[2]. The latter occurs at the top of potential barrier separating different metastable states. By using an analytical technique based on perturbation, and usually referred to as Melnikov function technique[2], we are able to derive analytical formulas which provide the values of critical applied fields necessary to create the heteroclinic entaglement. These critical values are expressed as function of frequency, direction and generic (elliptical) polarization of the applied fields. Then, by means of numerical simulations, we discuss how transient chaos is accompanied by the erosion of the safe basin around the stable regimes. The concept of basin erosion can be regarded as an effective reduction of the stability margin (extending the notion of potential barrier in Kramers-Brown theory[3]) of the steady AC-driven regimes with respect to both deterministic as well as thermal perturbation[4]. Finally, implications of this phenomenon on the microwave and thermal assisted switching are pointed out.

LB-13. Spin wave propagation in the nanostripes – tuning of dynamical coupling. *J.N. Rychly*[1,2], G. Centala[2], J.W. Klos[2] and V. Novosad[1] *1. Materials Science Division, Argonne National Laboratory, Argonne, IL, United States; 2. Faculty of Physics, Adam Mickiewicz University in Poznan, Poznan, Poland*

We have explored theoretically 1D magnonic crystals (MCs) and magnonic Fibonacci quasicrystals (MQ) in the form of sequences of infinitely long stripes, magnetically saturated by the external magnetic field directed along the stripe axis. The material parameters and geometry of the studied structures are the same as in Ref. [1]. We have studied the frequency spectrum of spin wave (SW) eigenmodes and their spatial profiles in dependence on the value of the wave vector for propagation along the stripes - $k_{||}$. We showed the existence of surface states [2] in the band gap regions of spin wave spectra for short MCs in dependence on the value of a tangential component of wave vector $k_{||}$. We will show additionally that with the increase of $k_{||}$, the frequencies of spin waves are decreasing. Moreover, for the SWs of the lowest frequency, the group velocity for the propagation between the stripes v_g is decreasing with the increase of the tangential component wave vector $k_{||}$. We are observing the widening of the SWs bands while increasing the $k_{||}$. Usually widening of the bands in periodic structures is connected to the increase of the interaction between elements of the structure. We are presenting, for comparison, the additional study of the stripes separated by air gaps. By reducing the distance between two stripes, we enhance the coupling between them. The similar effect of tunable interaction (visible in the change of the bandwidth) is obtained by adjusting the value of $k_{||}$. *This work has received funding from National Science Centre Poland grant UMO-2016/21/B/ST3/0045; J.R. would like to acknowledge National Science Centre Poland grant - UMO-2017/24/T/ST3/00173, support from the Adam Mickiewicz University Foundation; work at Argonne was supported by U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, under contract no. L9-01. Manufactured Easy-Plane Spin Hall Oscillator. *E.A. Montoya*[1], C.J. Safranski[1], A. Smith[1], J. Chen[1] and I. Krivorotov[1] *1. Physics and Astronomy, University of California, Irvine, Irvine, CA, United States*

Spin torque oscillators (STOs) are nanomagnetic sources of microwave radiation driven by spin currents. A promising type of STO, the spin Hall nano-oscillator (SHNO), is based on a bilayer of a ferromagnet (F) and a non-magnetic metal (N) having large spin-orbit interaction. Owing to the spin Hall effect (SHE), a direct current in the N layer induces a transverse spin current that can drive auto-oscillations of the F layer magnetization [1,2]. Requisites for high microwave power generated by a SHNO are large device magnetoresistance and large precession cone angle of the magnetic auto-oscillations. Large precession cone angle can also lead to reduction of the SHNO phase noise [3]. Ferromagnets with easy-plane magnetic anisotropy are predicted to exhibit precession cone angle near 90 degrees when spin current polarized perpendicular to the easy-plane is injected into the F layer [4]. Thin F films exhibit natural easy-plane anisotropy, however spin current polarization in F|N thin-film bilayers lies within this easy-plane, resulting in excitation of auto-oscillations of relatively small amplitude [1,2]. Here we present a SHNO system where the easy-plane of the F layer is perpendicular to the sample plane, which allows injection of spin Hall current polarized perpendicular to the easy-plane. This SHNO device shown in Fig. 1 consists of a 50 nm wide Pt|Co|Ni|Ta nanowire with two electric leads separated by a 300 nm gap. In this device, the large interfacial perpendicular magnetic anisotropy in the Pt|Co|Ni structure [5,6] is used to tune the out-of-plane anisotropy while the nanowire width is used to tune the in-plane anisotropy. Careful control of these anisotropies allows us to manufacture an easy-plane for the Co|Ni magnetization that is defined by the wire axis and the sample normal (the x-z plane in Fig. 1). We have found that such easy-plane Pt|Co|Ni|Ta nanowire SHNOs can support large-amplitude magnetic auto-oscillations with low phase noise as illustrated in Fig. 2.

L9-02. Coupled dynamics of magnetizations in spin-Hall oscillators via spin current injection. *T. Taniguchi*[1] *1. Spintronics Research Center, AIST, Tsukuba, Japan*

Coupled dynamics of magnetizations between spin torque oscillators has attracted much attention from view points of magnetism, nonlinear science, and practical applications[1]. The coupled dynamics is excited as a result of electric and/or magnetic interactions[2]. On the other hand, a coupled magnetization dynamics excited by spin current has been investigated in ferromagnetic resonance only[3]. In this work, we propose a theoretical framework for spin-current driven synchronized oscillations of the magnetizations in spin Hall geometry[4]. The system in this study is schematically shown in Fig. 1, where two spin-Hall oscillators are connected by a nonmagnetic top electrode. Each spin-Hall oscillator consists of a bottom nonmagnetic heavy metal driving the spin Hall effect and a metallic ferromagnet having the oscillating magnetization due to spin-transfer torque excited by the spin Hall effect. The spin current generated by the spin Hall effect simultaneously creates spin accumulation inside the ferromagnet, whose magnitude and direction depends on the magnetization direction. Therefore, by connecting the top surfaces of the ferromagnets by the top electrode, another spin current flows according to the gradient of the spin accumulations between the ferromagnets; see Fig. 1. This additional spin current excites an additional spin-transfer torque leading to a coupled motion of the magnetizations. We derive the theoretical formula of this additional spin-transfer torque from the spin transport theory, and solve the Landau-Lifshitz-Gilbert equations of the magnetizations with this additional torque. It was found that this additional torque induces an antiphase synchronization in the spin-Hall oscillators, as shown in Fig. 2.

The spin transfer torque nano-oscillators (STNOs) have been studied for the last two decades due to their several potential technological applications[1,2]. These structures are composed by two ferromagnetic layers, the "fixed" and the "free" layers, separated by a nonmagnetic spacer. The spin transfer torque[3,4] has an anti-damping effect, then at critical values of the dc current, the normal modes of the free layer reach auto-oscillation regimes. Recently, there has been an interest in understanding the magnetization dynamics in these structures since they may emulate neuron and synapse behaviour[5]. In our work, a detailed analytical and numerical study of the spin wave modes of two STNOs has been performed as a function of the relative position between them described by the variable θ (see Fig. 1). By using a standard Hamiltonian formalism[6] and the macrospin approximation, we obtain analytical expressions for the eigenfrequencies, while the critical current densities to induce self-oscillations of the magnetization are obtained numerically. We observe that there are two normal modes in the system, called in-phase and anti-phase modes. In particular, we observe that the frequency variation, as a function of θ, for the in-phase mode is larger than the frequency variation for the anti-phase mode. This can be explained by an analysis of the magnetic charges on the surfaces of the free layers. These results may be useful to perform a nonlinear study of the synchronization of two STNOs and then for the implementation of an associative memory, in which a recognition is obtained when a oscillator network converges to a synchronized state[5]. A recent technological realization of perpendicular magnetic tunnel junctions (MTJs) with two perpendicular reference layers has opened a new route for scaling the overall size of spin-transfer torque MRAM. This is because for an antiparallel configuration of the magnetization of the reference layers (RL) the two spin-transfer torques add constructively, giving rise to more efficient switching processes of the free layer (FL) magnetization as compared to a single MTJ [1-3]. Here, we use a full micromagnetic code to study a double MTJ with two in-plane RL in antiparallel configuration, generating microwave signals at low drive currents and external magnetic fields. The geometry and the physical parameters of the device under investigation are similar to the ones studied experimentally by Zeng et al. [4] with the adding of the second RL. We used a full micromagnetic code to show the persistent oscillation of the FL magnetization at very low external field and source current. The device has an elliptical cross section of 70x40 nm^2 and the thickness of t=1.60 nm. A sketch of the device together with the indication of the angle between FL and RL are shown in Fig. 1. Our micromagnetic simulations show that it is possible to obtain persistent magnetization oscillations by applying a very low external field (10 mT) and for current densities in the range of J_{MTJ}=0.4 – 1.6 MA/cm^2, as shown in Fig. 2(a). Fig. 2(b) shows that the power as a function of the source current describes a very similar behaviour of that reported in a previous experimental study for single RL MTJ (see Fig. 2 of Ref. 4). From the comparison between the MTJ devices with single [4] and double RL, we see that the source current is decreased of a factor 5 (from about 3.0 to 0.6 MA/cm^2). A predicted advantage of the reduced bias current well below 10^6 A/m with an output power that can approach the microwatt opens the direction of low dissipation power oscillator for IoT applications.

In the analytical study of spin-torque nano-oscillators[1], both those based on uniformly magnetized free layer and those with free layer in a magnetic vortex state, one is naturally led to the derivation and the use of simplified models of self-oscillating systems (see [2] and references therein). Such models can be derived by appropriate simplification of the Landau-Lifshitz equation based on time scale separation[3] between the fast precessional motion and slow dynamics due to nonconservative effects such as damping and spin transfer torque. These oscillator models include universal features such as nonlinear dependence of frequency with respect to the amplitude of oscillations, and presence of positive and negative damping effects[2]. In this respect, by using appropriate change of variable, nonlinear oscillator models can be put in standard (normal) forms. In this work, we propose a normal form for the study of nonlinear self-oscillating systems subject to external AC excitation. By using combined numerical and analytical techniques based on bifurcation theories we show that the deceivingly simple structure of the nonlinear oscillator equation actually encompasses a very rich and nontrivial bifurcation patterns which include both local (saddle-node and Hopf) and nonlocal (homoclinic connection) bifurcations[4]. In this respect, while the role of local bifurcation has been studied in detail[2], the important role of homoclinic phenomena in synchronization problems have been largely overlooked. In this work, the full range of possible bifurcations of the standard nonlinear oscillator model is studied. The various regimes in the control plane (frequency, ac magnitude) are identified (Fig. 1). This bifurcation diagram enables one to have a comprehensive understanding of phase-locking and nonlinear resonance phenomena. The relevance of this analysis in the area of spin-torque nano-oscillators is discussed.

Spin torque nano-oscillators (STNOs) are strong potential candidates for high-frequency devices applications thanks to their exceptional features: frequency signal and frequency tunability on the order of Gigahertz, narrow linewidth, nanometric scale size, and broad working temperature [1]. Here we numerically analysed the steady state excitations of a STNO based on fully perpendicular magnetic tunnel junctions (MTJs) as they exhibit large magnetoresistance, better thermal stability and smaller dimensions than other spin valves or MTJs configurations. Our simulations are based on the Landau-Lifshitz Gilbert equation in the macrospin approach, and take into account both damping-like and the field-like spin transfer torque terms [2]. In these all perpendicular nanostructures the STT induced dynamics is generally triggered by thermal fluctuations. However, the out of plane symmetry can be balanced by an in-plane applied magnetic field or by considering a second order anisotropy contribution, as recently measured in perpendicular MgO-based MTJs [3]. The static and dynamic states of the free layer (FL) magnetization are studied as a function of the second order anisotropy energy, K_2, and of the out of plane q angle of the applied field (varying from 0^0 to 30^0 from the in-plane OX axis). The simulations show the existence of two in-plane stable state (IPS+/-) for which the FL magnetization lies in-plane, parallel or anti-parallel to the field direction (OX), two out of plane stable states (OPS+/-) for which the FL magnetization is parallel/anti-parallel to the polarizer fixed magnetization direction (OZ), and two dynamic states, the in-plane precession state (IPP) and the out of plane precession state (OPP) having oscillation frequencies up to 14 GHz. The regions of the voltage-field diagram exhibiting dynamic states strongly depend on the K_2 amplitude and on the q field angle. Several numerical predicted features are compared against the experimental measurements. L9-07. Asymmetric and partial injection locking of a three-terminal spin-torque oscillator. *E. Jué*[1], M. Pufall[2,1] and W. Rippard[1] *1. National Institute of Standards and Technology, Boulder, CO, United States; 2. NIST, Boulder, CO, United States*

Beyond their nanoscale size and their tunability in frequency, spin-torque oscillators are of interest for their ability to lock to an external microwave signal or to mutually synchronize. In this work, we measure the injection locking of a three-terminal STO excited by spin-orbit torque [1]. The three-terminal device consists of a magnetic tunnel junction (MTJ) on a Pt wire. A DC and microwave (MW) current are applied through the Pt wire to induce the oscillations and injection lock the device, respectively, whereas the precessional signal is measured via a spectrum analyzer through the MTJ. We study the injection locking at $f_{MW} \approx f_0$ and at $f_{MW} \approx 2f_0$, where f_0 is the free running frequency of the STO and f_{MW} is the MW frequency. Interestingly, we observe a frequency response that is different from the injection locking of STO generally reported in the literature. Whereas typical phase locking behavior is observed at $f_{MW} \approx 2f_0$ (figure 1), the injection locking at $f_{MW} \approx f_0$ exhibits a strong asymmetry (figure 2). By analyzing the power transferred from f_0 to f_{MW} in the vicinity of $f_{MW}=f_0$, we show that the oscillator is locked to the MW signal only 75% of the time. In this presentation, we give a qualitative and quantitative description of the injection locking in the three-terminal STO.

The concept of spin torque driven high frequency magnetization dynamics, especially in spin-torque nano-oscillators (STNOs), has opened up the field of spintronics to nonlinear (NL) physics as these oscillators' key property is their high NL [2] which gives rise to very rich physics and manifold phenomena [3] but also to a relatively poor spectral coherence and coupled noise behavior [4]. While the noise distribution for offset frequencies far from the carrier frequency is reasonably well understood [4] and described by the general NL autooscillator theory [2], low frequency noise remains under investigation as it limits the oscillator's frequency stability. Extensively studied in GMR and TMR sensors [5], this work addresses the low frequency Flicker noise of a TMR-based spin-torque vortex oscillator (STVO) [6] in the regime of large amplitude steady oscillations. We present a thorough experimental study of the STVO's low frequency noise, which remains poorly investigated. In complement to the experimental measurements, we developed a phenomenological theory aiming to classify the low frequency flicker noise in STVOs. Starting from the corresponding NL Langevin equations and a colored noise distribution, we predict flicker noise contributions to amplitude (AN) and phase noise (PN), including NL noise conversion. Noteworthy, we find that this prediction agrees well to our experimental results of the gyrotropic mode's low frequency noise (fig. a). Furthermore, we analyze the noise dependence on the operating dc current and the STVO's active magnetic volume, reflected by the Hooge-formula for TMR sensors [7], and the oscillator's NL itself (fig. b). We find the NL properties being dominant against the Hooge-proportionality α and identify the low frequency noise's important dependencies.

L9-09. Discovery of chiral Majorana fermion. *X. Sun*[1] *1. Physics, Stanford University, Palo Alto, CA, United States*

Majorana fermion is a hypothetical fermionic particle which is its own anti-particle. Intense research efforts focus on its experimental observation as a fundamental particle in high energy physics and as a quasi-particle in condensed matter systems. We have theoretically predicted the chiral Majorana fermion in a hybrid structure of quantum anomalous Hall thin film coupled with a conventional superconductor, and proposed the half-integer quantized conductance plateau as its compelling signature. Recently, this theoretical prediction has been experimentally realized in magnetically doped topological insulator coupled with Nb superconductor and the half plateau quantization has been observed near the magnetic flipping under magnetic field. Furthermore, we propose to braid the chiral Majorana fermion in a Corbino device geometry, which could have potential application in quantum computation.

The half conductance signature of chiral Majorana fermion.

L9-10. Ferromagnetic resonance linewidth in nanoscale magnetic tunnel junctions. *C. Sha*[1] and I. Krivorotov[2] *1. Physics & Astronomy, University of California, Irvine, Irvine, CA, United States; 2. Physics and Astronomy, University of California, Irvine, Irvine, CA, United States*

Nanoscale magnetic tunnel junctions (MTJs) with strong perpendicular magnetic anisotropy (PMA) are the core building blocks of spin torque memory (STT-MRAM). The Gilbert damping constant a of the MTJ free layer is the key parameter that determines the write voltage of an STT-MRAM cell, and thus precision measurements of a at the cell level are important for understanding of STT-MRAM performance. Spin torque ferromagnetic resonance (ST-FMR) [1-3] can potentially be employed for such measurements because ST-FMR spectral linewidth Δf_0 of the free layer spin wave modes in a nanoscale MTJ is expected to be directly proportional to the product of a and the resonance frequency f_0 [1,2]. However, our measurements of Δf_0 and f_0 in a nanoscale perpendicular MTJ with a CoFeB free layer performed as a function of out-of-plane magnetic field (Fig. 1) clearly show that this simple proportionality between Δf_0 and f_0 is broken, and the dependence of Δf_0 on f_0 shows a non-zero intercept $\Delta f_i = 0.039$ GHz in the limit of zero f_0. In order to understand the physical origin of this intercept, we employ micromagnetic simulations of ST-FMR resonance linewidth as a function of out-of-plane magnetic field. As expected, our simulations show $\Delta f_i = 0$ for spatially uniform parameters of the free layer (saturation magnetization M_S, PMA constant K_u and exchange parameter A_{ex}). We then introduce a random distribution of magnetic anisotropy constants K_u among the micromagnetic cells in order to simulate random distribution of the PMA values among the crystallographic grains of the free layer. We find that a physically reasonable spread of the K_u values is unable to give rise to a significant value of Δf_i as long as bulk value of A_{ex} is assumed. However, simulations with a physically reasonable distribution of K_u and A_{ex} that is 25% of the bulk value give rise to $\Delta f_i = 0.041$ GHz, which is in good agreement with the measured intercept. Our ST-FMR measurements combined with micromagnetic analysis shed light onto the properties of exchange, PMA and Gilbert damping in nanoscale MTJs, and pave the way towards quantitative measurements of these parameters at the individual STT-MRAM cell level.

L9-11. Irreversible Thermodynamics and Transverse Magnetization in Spintronics. *W. Saslow*[1] *1. Physics, Texas A&M University, College Station, TX, United States*

Irreversible Thermodynamics describes interfacial currents via various contact resistances: electric currents driven by voltage differences, heat currents driven by temperature differences, and longitudinal spin currents from a ferromagnet driven by longitudinal effective field differences. In 1979 Silsbee, Janossy, and Monod (SJM) employed an s-d model to consider

how ferromagnetic resonance (FMR) of a ferromagnet F adjacent to a normal metal N leads to a transverse spin current j_S from F to N, with an additional FMR linewidth. They employed transverse components of an immobile magnetization M_d (equivalent to the usual magnetization M) and mobile M_s (equivalent to the spin accumulation m); irreversible thermodynamics ideas were applied to j_S and *m*, both in bulk and across the F/N interface, with a frequency-independent interfacial driving term given by the exchange field λM due to the transverse FMR-tipped *M* (Fredkin 1976). [In 1987 Johnson and Silsbee studied, for an F/N system with charge-carriers from F to N, the related *longitudinal* spin transfer adjustment from F to N.] In 2002 Zhang, Levy, and Fert (ZLF) also employed an s-d model to study how transverse spin from N adjusts (transfers) to F, emphasizing bulk behavior, in 2004 justifying the model with Fermi liquid theory. Recently we argued that Fermi liquid theory indeed applies to a conducting ferromagnet, and we derived its equations of irreversible thermodynamics. We present a physical picture for transverse spin accumulation m as well as for transverse M. We confirm the general equations of SJM and ZLF, and find two new Onsager-related cross-decay terms between transverse M and m. Because transverse M and m interact via exchange, and because of both the non-uniform exchange field AMxΔM in dM/dt, and the diffusion term DΔm in dm/dt, the system has two coupled transverse modes with distinct wavevectors. These two degrees of freedom enable the system to adjust to the boundary conditions on M and on m. The parameters in the theory can be expressed in terms of correlation functions.

Saslow, Phys.Rev. B 95, 184407 (2017). Appendix A considers magnetic insulators.

Fermi Liquid Theory gives two ways to get transverse total magnetization; rotate to get tipped M, or excite above Fermi sea, to get transverse spin accumulation m.

L9-12. Magnetostatic interaction between closely located magnetic tunnel junction. H. Kubota[1], *T. Taniguchi*[1], A. Fukushima[1], K. Yakushiji[1] and S. Yuasa[1] *1. National Institute of Advance Industrial Science and Technology (AIST), Tsukuba, Japan*

Magnetic dot array has been investigated as a logic device called magnetic cellular automata (MCA)[1, 2], where digital information is transferred via magnetostatic interaction. Magnetization of the dots has so far been detected by using magneto-optical effect [1] or magnetic force microscopy[2]. From a viewpoint of compatibility, improvement of performance is expected by implementing magnetic tunnel junction (MTJ) as magnetic dots. Increasing the density of MTJ, gap length between dots becomes smaller [3], resulting in the issue of interference between dots due to the magnetostatic interaction. In this study we investigated the effect of the magnetositatic interaction between closely located MTJs on their magnetization process through MR effect. We prepared magnetic multilayer of a buffer layer/IrMn/CoFe/Ru/CoFeB/MgO/FeB/MgO/cap layer on a thermally oxidized silicon substrate. Both reference and free layers were in-plane magnetized. The multilayer was fabricated into array of two MTJs with elliptical shape: one is ellipsoid with the dimension of 150 nm x 50 nm; another is also ellipsoid but with the dimension of 450 nm x 150 nm. Gap length (G) between the two MTJ was varied from 30 nm to 800 nm. The two MTJs were sandwiched between common bottom and top leads. Single MTJ with 150 nm x 50 nm or 450 nm x 150 nm was also fabricated as a reference. We observed the shape of the arrays before depositing the top electrode by electron microscopy. The array with G<50 nm showed direct connection between the dots. Complete separation was observed in the array with G>=75 nm. MR ratio of the arrays was about 100% regardless of G, which was identical to those of single MTJs. Resistance of the array with G<50 nm showed rather small values, indicating wider area of junction due to direct connection. MR curve of the arrays with G=75 and 100 nm showed single and sharp transition of resistance change, suggesting simultaneous switching of the two MTJs due to strong magnetostatic coupling. In contrast, clear two-step resistance change was observed in the array with G>=100 nm, implying independent switching of the two MTJs because of weaker interaction at larger G. This research and development were supported by the MIC.

The search for quantum spin liquid states is a major challenge in condensed matter research [1]. The prime candidate to host this state of matter is the *S=1/2* kagome antiferromagnet (KAFM) in two dimensions. Nevertheless, the nature of this ground state, with gapped or gapless excitation spectrum, is still subject to debate. On the experimental side, only few candidates exist. Various experiments on herbertsmithite have pointed out a gapless excitation spectrum, but recent NMR investigations on a single crystal revealed a gapped excitation. Further, understanding the influence of the different deviations to the ideal Heisenberg Hamiltonian on the ground state remains a difficult issue [2]. Among the rare experimental realizations of the *S=1/2* KAFM model the recently synthesized compound, $[NH_4]_2[C_7H_{14}N][V_7O_6F_{18}]$ (DQVOF) [3], is the first one to host magnetically active V^{4+} (d^1) ions rather than more common Cu^{2+} (d^9). Further, this compound seems to be the first experimental realization of the breathing Kagome model, formed by two different equilaterals triangles with two different interactions, J_Δ and $J\bigtriangledown$, which may stabilize a gapped or gapless ground state [4]. Our low temperature magnetization and specific heat results suggest that DQVOF is a good candidate for the *S=1/2* KAFM physics despite a complex structure with mixed V^{4+} (*S=1/2*) in the kagome planes and nearly free interlayer V^{3+} (*S=1*) [5]. Besides, the low temperature specific heat and μSR studies evidence a gapless spin liquid behavior down to 20 mK [6]. Our ^{17}O NMR studies unveil the intrinsic susceptibility of the kagome layers. The high temperature series analysis of this latter reveals a ratio $J\bigtriangledown/J_\Delta \approx 0.5$ and a mean interaction J_m= 60(7) K in the kagome planes. Moreover, our spin lattice time relaxation measurements points out a gapless state ($\Delta \approx 0.007(7)\ J_m$) [7]. Our NMR results call for more calculations on the breathing kagome lattice. Further, the dominant perturbation in DQVOF is likely the interaction between the interlayer V^{3+} and the kagome V^{4+} which remains difficult to estimate. Recently, new compounds of the DQVOF family have been synthesized [8]. Studying them could reveal the role this interaction plays in the selection of a ground state.

L10-03. Quantum Fluctuations on a Hyperkagome Lattice. *L.Ø. Sandberg*[1], K. Lefmann[1], M. Ciomaga Hatnean[2], G. Balakrishnan[3], G. Ehlers[4], G. Sala[4] and P. Deen[5,1] *1. Niels Bohr Institute, University of Copenhagen, Copenhagen, Denmark; 2. Physics, University of Warwick, Coventry CV4 7AL, United Kingdom; 3. Physics, University of Warwick, Coventry CV4 7AL, United Kingdom; 4. Spallation Neutron Source, Oak Ridge, TN, United States; 5. European Spallation Source, Lund, Sweden*

Quantum spin liquid (QSL) states are exotic states of matter that feature strong quantum fluctuations leading to a disordered ground state at zero temperature with emergent quasiparticles that exhibit fractionalised excitations. The search for QSL states has been heavily focussed on lattices comprised of 2 dimensional (2D) corner sharing triangular structures of which the kagome system is most common. It is widely considered that equivalent 3 dimensional (3D) compounds would also display novel ground states. The pyrochlore and spinel structures that display a network of corner-sharing tetrahedra have been most heavily studied. In contrast, experimental examples of geometric frustration on a 3D networks of corner sharing lattices are less common, yet are theoretically considered to be highly promising for exotic states. A second example for a 3D QSL is the rare earth based hyperkagome system $Yb_3Ga_5O_{12}$ (YbGG). The spin-orbit coupled Yb ions in YbGG realise a lattice of two interpenetrating hyperkagome structures. The specific heat indicates that the ground state is a Kramers doublet, separated from the excited doublet which can be found at 546 cm^{-1} [1] thus providing a pseudo quantum spin, S = 1/2. Magnetisation measurements determine a Curie-Weiss temperature θ_{CW} = -118 K with no indication of long range order down to T_N = 54 mK [2] which gives YbGG an unusually high frustration index of $\theta_{CW} / T_N \approx 2100$. Specific heat measurements determined the development of short range magnetic correlations below 0.5 K and a lambda-transition at 54 mK while 170-Yb Mossbauer spectroscopy, determined no static magnetic order at temperatures below the lambda-transition. Indeed the specific heat measurements indicate that only 20 % of entropy is frozen at the lambda point thus leaving the true ground state an open question [2,3]. It has recently been possible to synthesise YbGG and grow a single crystal suitable for neutron scattering studies. Recent neutron scattering results confirm the short range nature of the spin-spin correlations with unusual diffuse scattering features in both the elastic and inelastic channels. The implication for a QSL state in YbGG will be discussed.

L10-04. Majorana Representations of Spin and an Alternative Solution of the Kitaev Honeycomb Model. *J. Fu*[1], J. Knolle[2] and N. Perkins[1]
1. School of Physics and Astronomy, University of Minnesota, Minneapolis, MN, United States; 2. Blackett Laboratory, Imperial College London, London, United Kingdom

Based on the Dirac spinor representation of the SO(4) group, we discuss the relationship between three types of representation of spin in terms of Majo-

rana fermions, namely the Kitaev representation, the SO(3) representation and the SO(4) chiral representation. Comparing the three types, we show that the Hilbert space of the SO(3) representation is different from the other two by requiring pairing of sites, but it has the advantage over the other two in that no unphysical states are involved. As an example of its application, we present a new alternative solution of the Kitaev honeycomb model. Our new solution involves no unphysical states which enables a systematic calculation of physical observables. Finally, we discuss an extension of the model to a more general exactly soluble Z_2 gauge theory interacting with complex fermions.

L10-05. Dilute Magnetic Impurity Effect on a Quantum Spin Liquid Candidate $Ba_3ZnRu_2O_9$ with $S = 3/2$ Dimer Lattice. *T. Yamamoto*[1], H. Taniguchi[1] and I. Terasaki[1] *1. Department of Physics, Nagoya University, Nagoya, Japan*

The impurity effect on a magnetic matter with a quantum spin often leads us to discover exotic physical phenomena, e.g., the impurity-induced antiferromagnetism in spin gapped (SG) systems [1]. In this context, a quantum spin liquid (QSL) material is one of intriguing targets but the effect of intentional impurity doping on the system has never been investigated. For this purpose, we will focus on a 6H hexagonal perovskite ruthenate $Ba_3ZnRu_2O_9$, which is a QSL candidate that we have recently discovered [2]. This material is a member of the compounds with a general formula $Ba_3MRu_2O_9$, which is composed of the three-dimensional network of Ru_2O9 dimers interconnected by MO_6 octahedra with corner sharing. The M site can be occupied by various divalent ions, and the magnetic ground state depends on the species of M, from a non-magnetic SG state for M = Ca, Sr, and Mg [3] to an antiferromagnetic ordered state for M = Co, Ni, and Cu [4]. In all the cases, the Ru^{5+} ions ($S = 3/2$) are mainly responsible for the magnetism. Here we report a dilute magnetic impurity effect on the magnetic properties of $Ba_3ZnRu_2O_9$ through the comparison with $Ba_3CaRu_2O_9$. We find that the magnetic ground state of each compounds stands against 2% substitution of magnetic impurities of Cu, Ni, and Co for Zn or Ca and these impurities behave as paramagnetic spins. We further find that the magnetic response of these impurities is determined by the ground state of the host materials. The magnetic susceptibility and magnetization at low temperatures reveal that the difference between the two can be attributed to the Weiss temperature of the magnetic impurities: the magnitude of which observed in the substituted QSL candidate is 3-5 times larger than that in the substituted SG system of about 1 or 2 K. Such a large value of the Weiss temperature observed in the QSL candidate is difficult to be explained by only dilute magnetic impurities and suggests a contribution from the Ru^{5+} ions consisting of the QSL state, a possible origin of which is discussed in this talk.

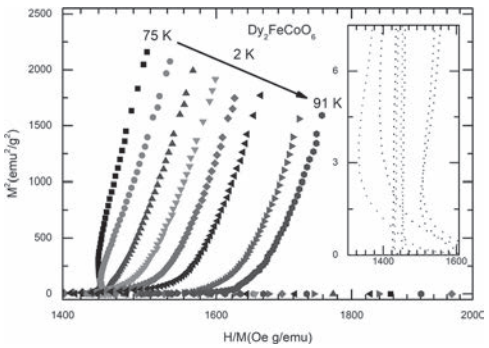
L10-06. Electronic Nematicity in Strongly Correlated Layer-Frustrayed $In_3Cu_2VO_9$. S. Jia[1], *H. Lin*[2] and L. Zou[1] *1. Research Laboratory of Computational Materials Sciences, Institute of Solid State Physics, Chinese Academy of Sciences, Hefei, China; 2. Beijing Computational Science Research Center, Beijing, China*



Electronic structure calculations show that three-dimensional layered honeycomb compound $In_3Cu_2VO_9$ is a strongly correlated Mott insulator with Neel antiferromagnetic order [1], however, it does not display any magnetic order down to 4 K [2]. In this work we explore the ground state of an interlayer-frustrated J_1-J_2-J_c Heisenberg model for honeycomb compound $In_3Cu_2VO_9$ by employing the *Schwinger* boson mean-field theory. We find that the spontaneous symmetry breaking occurs in the three directions of the intra-layer spin correlation functions at zero temperature, and decreases parabolically with the increasing temperature down to zero at a tranistion temperature T_n, suggesting that the ground state of $In_3Cu_2VO_9$ is likely to be a nematic phase. With the increase of interlayer coupling J_c from 0 to 3.6 meV, the zero-temperature spontaneous symmetry breaking lifts, but the Neel temperature gradually closes to the nematic phase transition temperature T_n. These indicate that the interlayer spin coupling J_c plays two competing roles: on the one hand, the increase of J_c strengthens the interlayer frustration; on the other hand, it also enhances the magnetic long-range order. When $J_c > 3.6$ meV, the symmetry breaking of three direction spin correlation functions disappears, and the C_3 rotational symmetry recoveries, suggesting that the system may be in the spin liquid phase.

L10-07. The Order of Magnetic Phase Transitions in Disordered Double Perovskite Oxides Sm_2FeCoO_6 and Dy_2FeCoO_6. *G. Haripriya*[1], P. R[1,2], S. K[1] and S. V[1] *1. Physics, Indian Institute of Technology Madras, Chennai, India; 2. Physics, National Institute of Technology Calicut, Kozhikode, India*

We present the results of the attempts made to evaluate the order of phase transitions using isothermal magnetization data performed on the sol-gel synthesized disordered double perovskite oxides Sm_2FeCoO_6 and Dy_2FeCoO_6. The temperature variation of the DC magnetization data of both the samples show that there are two magnetic phase transitions; one at the high temperature regime, the conventional PM to FM (FIM) and the other at low temperatures FM (FIM) to AFM. The spin reorientation transition due to the rare earth - Fe^{3+} interaction is also inferred in these compounds [1]. The one quadrant M vs H curves are recorded for the samples around the two magnetic transitions observed from the M vs T curves [1]. The Arrott plots are made for the low and high temperature regions at and around the transition temperatures with an interval of 3 K for the high temperature region and 2 K for the low temperature region. From the equation of the state, $H/M = a + b M^2$, it is found that the curves for the low temperature region of Dy_2FeCoO_6 show a negative slope ('S- shape behaviour') which is considered as a first order phase transition below the spin reorientation temperature 86 K (refer Fig. 1), while the high temperature region has positive slope behaviour inferring a second order phase transition (not shown) [2, 3]. For the sample Sm_2FeCoO_6, the transition at the low temperatures as well as the one nearer to spin reorientation (~210 K) have a first order behaviour (refer Fig. 2). The presence of disordered B-sites with the magnetic ions of Fe and Co in mixed valence states may be the cause for the complicated magnetic structure observed in these compounds.

L10-08. Probing the ground state magnetic structure of $M_2V_2O_7$ (M = Co, Mn). *J. Sannigrahi*[1], D. Adroja[1], D. Khalyavin[1], P. Manuel[1], M. Gutmann[1], S. Capelli[1] and R. Perry[1] *1. ISIS neutron and muon facility, Rutherford Appleton Laboratory, STFC, Harwell Campus, Didcot, Oxfordshire, United Kingdom*

This family of 3*d* transition metal pyrovanadate have attracted much interest due to their intriguing crystal structures where they can have low-dimensional to more complex three dimensional lattice with fascinating magnetic and electronic properties.[1] We systematically investigated the ground state magnetic structure of $Co_2V_2O_7$ and $Mn_2V_2O_7$. A canted antiferromagnetic state is observed below about T_C = 8 K in case of $Co_2V_2O_7$[2] which is found to be first-order in nature. The large value of effective moment (5.43 μ_B) of Co^{2+} ($3d^7$) compared to the spin-only value (3.87 μ_B) confirms the presence of unquenched orbital component. The proposed non-collinear magnetic structure, obtained from powder neutron diffraction, points to a presence of competing exchange interactions and magnetic anisotropies in the system. Two-dimensional honeycomb-lattice spin systems have attracted much interest because of novel ground states might be induced by frustration and enhanced quantum fluctuations which reflects in their rich structural features and magnetic properties. The 3*d* transition metal pyrovanadate $Mn_2V_2O_7$ has recently been identified as platforms for realizing the insights of these type of systems.[3,4] $Mn_2V_2O_7$ exhibits reversible structural transition from the high temperature β-phase (monoclinic, C2/m) to low temperature α-phase (triclinic, P-1) near room temperature. Mn^{2+} ions form regular honeycomb network in the β phase, while in the low-T α phase it is distorted. An antiferromagnetic-like magnetic ordering occurs below 20 K. From powder neutron diffraction measurements on $Mn_2V_2O_7$, two distinct magnetic phases have been identified. At 12 K the neutron diffraction data were well fitted with the commensurate propagation vector (0,0.5,0) and a collinear antiferromagnetic alignment of Mn^{2+} spins. But below 12 K splitting in magnetic peaks is observed and the magnetic reflections cannot be indexed properly with the commensurate propagation vector, which indicates a possibility of incommensurate nature of the magnetic ground state. The incommensurate magnetic structure has been resolved from single crystal neutron diffraction at 1.5 K where the incommensurate propagation vector, (0.37, 0.44, 0) is obtained.

L10-09. Long Wavelength Correlations in Ferromagnetic Titanate Pyrochlores as Revealed by Small Angle Neutron Scattering. *C.R. Buhariwalla*[2], Q. Ma[2], L. Debeer-Schmitt[4], K. Xie[3], D. Pomaranski[3], J. Gaudet[2], T. Munsie[2], H. Dabkowska[1], J. Kycia[3] and B. Gaulin[2,1] *1. Brockhouse Institute for Materials Research, McMaster University, Hamilton, ON, Canada; 2. Physics & Astronomy, McMaster University, Hamilton, ON, Canada; 3. Physics & Astronomy, University of Waterloo, Waterloo, ON, Canada; 4. Large Scale Structures Group, Oak Ridge National Laboratory, Oak Ridge, TN, United States*

We have carried out small angle neutron scattering measurements on single crystals of two members of the family of cubic rare-earth titanate pyrochlores that display ferromagnetic Curie-Weiss susceptibilities,$Yb_2Ti_2O_7$ and $Ho_2Ti_2O_7$. $Ho_2Ti_2O_7$ is established as displaying a prototypical classical dipolar spin ice ground state, while $Yb_2Ti_2O_7$ has been purported as a candidate for a quantum spin ice ground state. While both materials have been well studied with neutron scattering techniques, neither has been previously explored in single crystal form with small angle neutron scattering (SANS). Our results for $Yb_2Ti_2O_7$ show distinct SANS features below its Curie-Weisse temperarture of 0.50 K, with rods of diffuse scattering extending along <111> directions in reciprocal space, off-rod scattering which peaks in temperature near curie weiss temperature and quasi-Bragg scattering at very small angles which correlates well with T_C ~ 0.26 K. The quasi-Bragg scattering corresponds to finite extent ferromagnetic domains ~ 140 angstroms across, at the lowest temperatures. We interpret the < 111> rods of diffuse scattering as arising from domain boundaries between the finite-extent ferromagnetic domains. In contrast the SANS signal in $Ho_2Ti_2O_7$ is isotropic within the (HHL) plane around Q=0. However the strength of this overall SANS signal has a temperature dependence resembling that of the magnetic heat capacity, with a peak near 3 K. Below the break between the field-cooled and the zero-field cooled susceptibility in $Ho_2Ti_2O_7$ at ~ 0.60 K, the SANS signal is very low, approaching zero.

Comparison of SANS diffuse scattering features in $Yb_2Ti_2O_7$ compared with inset total scattering

Comparison of $Ho_2Ti_2O_7$ SANS scattering with MC electronic heat capacity (Bramwell 2001) and magnetic susceptibility measurements as a function of temperature.

L11-01. Stable Bloch point in helimagnetic nanostructures containing boundary between grains with different chirality. *M. Beg*[1,2], D.I. Cortés-Ortuño[2], R.A. Pepper[2], M. Bisotti[2], G. Downing[2], B. Atie[2], O. Hovorka[2] and H. Fangohr[1,2] *1. European XFEL GmbH, Schenefeld, Germany; 2. Faculty of Engineering and the Environment, University of Southampton, Southampton, United Kingdom*

Dzyaloshinskii-Moriya interaction (DMI) in helimagnetic materials can give rise to a large number of different non-trivial magnetisation configurations. One of them is the magnetic skyrmion. Recent research showed that confined helimagnetic nanostructures can host ground state skyrmionic states at zero external magnetic field and in the absence of magnetocrystalline anisotropy [1, 2]. However, the epitaxial growth of thin films from which the skyrmion hosting nanostructures are etched, are usually granular. More precisely, they contain grains with different chirality and consequently different sign of the DMI constant. In this work, we perform finite element micromagnetic simulations on a FeGe disk containing grains with different chirality. We find that for particular layer thicknesses, as shown in Figure 1, a stable Bloch point [3, 4] emerges and it is stable at zero external magnetic field. Secondly, we vary an external magnetic field and demonstrate that the system undergoes hysteretic behaviour and that it is possible to switch between two different types of Bloch points (head-to-head and tail-to-tail). Finally, we explore the mechanism of the Bloch point creation and show that it is formed at the boundary of the sample. Our demonstration of the stability and manipulation of Bloch point in a planar sample, apart from being of fundamental physical interest, suggests a possible use in future spintronics, data storage and processing devices. We acknowledge the financial support from the Horizon 2020 European Research Infrastructures project (676541). The work is also supported by the EPSRC CDT in Next Generation Computational Modelling EP/L015382/1, and the EPSRC grant EP/N032128/1.

(a) The skyrmion number *S* values for all individual layers in the studied structure. We notice a sharp decrease in the *S* value for the top layer. (b) Different magnetisation configurations of both layers. For smaller thicknesses the magnetisation in the top layer follows the magnetisation of the bottom layer. For larger thicknesses the orientation of the top layer reverses and a zero field stable Bloch point is formed. (c) Schematic representation of the Bloch point configuration.

L11-02. Micromagnetics of Anti-skyrmions in Ultrathin Films. L. Camosi[1], N. Rougemaille[1], O. Fruchart[2], *J. Vogel*[1] and S. Rohart[3] *1. Institut Néel, CNRS, Grenoble, France; 2. SPINTEC, CNRS, Grenoble, France; 3. Université Paris-Sud, Orsay, France*

We will present a combined analytical and numerical micromagnetic study of anti-skyrmions in thin magnetic films. Anti-skyrmions can be stabilized when the Dzyaloshinskii-Moriya interaction has opposite signs along two orthogonal in-plane directions, breaking the magnetic circular symmetry. We compare the equilibrium energy, size and shape of anti-skyrmions and skyrmions that are stabilized respectively in environments with anisotropic and isotropic Dzyaloshinskii-Moriya interaction, but with the same strength of the magnetic interactions. When the dipolar interactions are neglected the skyrmion and the anti-skyrmion have the same energy, shape and size in their respective environment. However, when dipolar interactions are considered, the energy of the anti-skyrmion is strongly reduced and its equilibrium size increased with respect to the skyrmion. While the skyrmion configuration shows homochiral Néel magnetization rotations, anti-skyrmions show partly Néel and partly Bloch rotations. The latter do not produce magnetic charges and thus cost less dipolar energy. Upon increasing the spontaneous magnetization M_s, the shape of the anti-skyrmion changes in order to increase the ratio between Bloch-like and Néel-like rotations. Since the DMI favors these Bloch-like rotations along directions intermediate between the two main axes the ASk has the tendency to acquire a square shape. Both skyrmions and anti-skyrmions are stable when the magnetic energies almost cancel each other, meaning that a small variation of one parameter can drastically change their shape, size and energy.

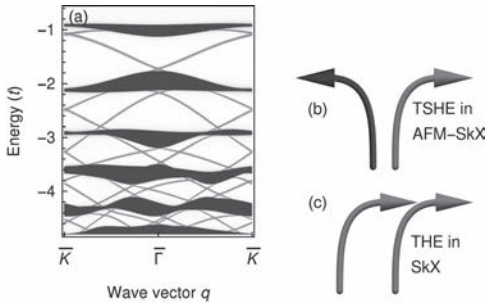
L11-03. Antiferromagnetic and conventional skyrmion crystals: Generation, topological Hall and topological spin Hall effect. *B. Göbel*[1], A. Mook[2,1], J. Henk[2] and I. Mertig[2,1] *1. Max Planck Institute for Microstructure Physics, Halle (Saale), Germany; 2. Martin-Luther University, Halle, Germany*



Skyrmions are topologically nontrivial, magnetic quasiparticles that are characterized by a topological charge. A regular array of skyrmions — a skyrmion crystal (SkX) — features the topological Hall effect (THE) of

electrons, and the Hall effect of the skyrmions themselves, called skyrmion Hall effect [1]. We show via calculations of the Berry curvature in reciprocal space that the spin-polarized THE is quantized in an unconventional way. It shows step heights of different magnitude (multiples of the conductivity quantum) and can change sign at the energy of a van Hove singularity of the structural lattice's band structure. Therefore the topological Hall conductivity strongly depends on the geometry of the structural lattice [2,3]. Furthermore, we present a generally applicable method to create stable antiferromagnetic skyrmion crystals (AFM-SkXs) by growing a two-sublattice SkX onto a collinear antiferromagnet (Fig. 1). As an example, we show that both types of skyrmion crystals — conventional and antiferromagnetic — exist in honeycomb lattices. While AFM-SkXs do not show a THE, they exhibit a topological spin Hall effect [4] (Fig. 2). The zero skyrmion Hall effect carries over to isolated AFM skyrmions as well. They can move in straight lines, at higher velocities and need lower driving currents compared to conventional skyrmions [5,6].

L11-04. Magnetic Globule – New particle-like object for three-dimensional nanomagnetism. *G.P. Müller*[2,1], F. Rybakov[3], H. Jónsson[1], S. Blügel[2] and N.S. Kiselev[2] *1. Science Institute, VR-III, University of Iceland, Reykjavik, Iceland; 2. Peter Grünberg Institut and Institute for Advanced Simulation, Forschungszentrum Jülich, Jülich, Germany; 3. Department of Physics, KTH-Royal Institute of Technology, Stockholm, Sweden*

In nanomagnetism, spintronics and microelectronics conventional two-dimensional systems have, due to their relative simplicity, been explored to far greater extent than three-dimensional systems. It is obvious that, for a full understanding of nanomagnetism, the natural expansion to 3D is inevitable, especially in the face of recent advances in techniques for 3D imaging and structuring of nanoscale magnetic objects [1]. Recently we have theoretically predicted [2] and experimentally proven [3] the existence of the chiral bobber, a three-dimensional hybrid particle-like object localized at a free surface of the cubic chiral magnet. Here, we present a novel, truly three-dimensional particle-like object, hosted by cubic chiral magnets, which does not require a free surface and is therefore, in general, less constrained. We call these objects chiral magnetic globules as they consist of two singularities coupled by a continuous vector field with a usually elliptical isosurface. We further show their ability to couple to edge states as well as three-dimensional skyrmion tubes and show how globules may be related to skyrmion annihilation mechanisms in 3D. We apply the recently proposed geodesic nudged elastic band method [4], implemented into our open source spin simulation framework *Spirit* [5] to explore different skyrmion nucleation/annihilation mechanisms cubic chiral magnets by calculating corresponding minimum energy transition paths.

L11-05. Collective excitations of magnetic bubble domains in an antidot lattice. *A. Laurenson*[1], A. Marchenko[2], V. Krivoruchko[2], J. Bertolotti[1] and V. Kruglyak[1] *1. Physics, University of Exeter, Exeter, United Kingdom; 2. National Academy of Sciences of Ukraine | ISP, Kiev, Ukraine*

Collective excitations in periodic magnetic media (magnonic crystals) are widely explored as constituents of future magnonic technologies[1]. Their spectrum is characterized by the presence of magnonic bands and band gaps, with some of the bands formed as a result of the splitting of oscillatory eigenmodes of such magnetic textures as domain walls, vortices, skyrmions etc[2]. The use of the collective excitations as information carriers may be especially promising because their dispersion depends on the static magnetic configuration and could in principle be reconfigured by changing the magnetic state of the device[3]. We use micromagnetic simulations to calculate the spectrum of collective excitations of identical magnetic bubble domains, which have a skyrmion winding number of 1. They are confined to form a honeycomb lattice within the hexagonal lattice of magnetic antidots

(Fig. 1). We observe that the width of bands formed from different modes of an isolated bubble domain decreases dramatically as the mode number increases, with only the band associated with the m=0 "breathing" mode showing a significant group velocity. A theory based on the magneto-dipole coupling between the excited nearest neighbor bubble domains agrees qualitatively with the simulation results, suggesting the coupling as the principal mechanism of the collective mode formation at low frequencies.

Magnetic skyrmions[1] are topologically stable spin textures. They are generally stabilized by Dzyaloshinskii-Moriya interactions[2] that mainly arise due to the spin-orbit coupling and the lack of structural inversion symmetry. Skyrmions are a promising candidate for low dissipation magnetic information storage devices because of their small size and facile current driven motion. However, skyrmions have been observed to achieve a transverse velocity when displaced by a current, which is known as the skyrmion Hall effect. Key challenges regarding the skyrmion motion are to stabilize, confine and control the movement of these skyrmions at room temperature. One of the possible ways to control the skyrmion motion will be to introduce magnetic topological defects in the form of magnonic crystals[3]. The aim of the present work is to stabilize and confine the magnetic skyrmions by patterning a nanometer size antidot lattice in high perpendicular magnetic anisotropy films. For this purpose, circular antidots of about 200 nm diameter and an edge separation of about 1 μm have been fabricated from $[Pt(3\ nm)/Co(0.9\ nm)/Ta(4\ nm)]_{12}$ multilayer stacks with high perpendicular magnetic anisotropy using focused ion beam lithography (Fig. 1a). The magnetic configuration of the continuous and patterned film was investigated with scanning transmission x-ray microscopy as a function of applied out-of-plane magnetic field. For the continuous film, a worm domain structure is observed which transforms into skyrmions on application of a magnetic field (Fig. 1b)). A similar worm domain structure is stabilized in the magnetic antidot arrays. However, due to the pinning caused by the presence of antidots, a higher magnetic field was necessary to cause the collapse of the worm domains into magnetic skyrmions (Fig. 1c), which are stable over a range of a few mT. These experimental observations are a first step toward future magnon spintronic devices based on skyrmion lattices.

L11-07. Hybrid Magnetic Skyrmions.
B. Miao[1], H. Wu[1], L. Sun[1], D. Wu[1] and H. Ding[1] *1. Department of Physics, Nanjing University, Nanjing, China*

Skyrmions show great potential for future information technology due to their small size and to the small current densities needed to displace them. Fundermentally, skyrmion is of particular interest as it carries a topological charge and Berry phase in real space and is anticipated to produce unconventional spin-electronic phenomena. Typically, skyrmions emerge from the Dzyaloshinskii–Moriya interaction (DMI) in a finite magnetic field, at low temperature (natural skyrmion materials). Alternatively, a growing group of artificially designed magnetic superstructures allowing for the existence of skyrmions without the need for a microscopically built-in DMI mechanism (artificial skyrmion materials). Artficial skyrmions signficantly expand the phase diagram, and has been deomonstrated at room temperature and in the absence of magnetic field. The mobility of the artificial skyrmion, however, is restricted by the patterned disks. Here, we present a novel design of building on the advantages of both the natural and the artificial skyrmion materials from the available skyrmion physics toolbox. We denote the emerging novel material as hybrid magnetic skyrmions (HMS). The proposed HMS can be driven by an electrical current to a speed of 850 m/s. We further demonstrate the viability of information encoding and propagation with the HMS in a nano-track. With a high current pulse, isolated skyrmions can be created individually due to the spin transfer torque. With a low steady current, the skyrmions can then be driven with relatively high speed. As individual skyrmions can be detected by a simple Hall geometry via the topological Hall effect, the proposed hybrid structure allows the construction of the HMS racetrack memory that can work at higher temperature and with higher speed compared to skyrmion stablized by the DMI with the same magnitude only. Our approach pave a new pathway of material engineering for the skrymion-based applications.

Magnetic skyrmions [1] are topologically protected inhomogeneous spin textures on the nanoscale, currently widely investigated due to their unusual fundamental properties and their potential applications in memory storage devices or spintronics. With their small sizes and high mobility under low current densities, skyrmions are envisaged as information carriers in the racetrack memory type devices. In this sense, control over the formation and manipulation of skyrmions, particularly in confined geometries [2], becomes of uttermost importance [3]. Most of the works in the literature report on skyrmions in systems with Dzyaloshinskii–Moriya exchange interaction (DMI) either in ultra-thin multilayers of transition metals and materials with strong spin-orbit coupling [4]. Moreover, non-chiral Bloch skyrmions (or bubble domains) can be stabilized in films with out-of-plane magnetic anisotropy by the dipolar interactions without the need of DMI. Nobody so far assumed that stabilization of the Néel skyrmions in confined systems without magnetic anisotropy is possible. In this work, we studied permalloy (Py) sub-100 nm diameter particles (nanodots) with no perpendicular uniaxial magnetic anisotropy or DMI. Due to the low magnetocrystalline anisotropy, vortex or a single domain (with in-plane magnetization) state is expected [5,6]. However, Néel (hedgehog) skyrmion spin textures were detected in the present study through Magnetic Force Microscopy. The magnetization configuration of these Néel (hedgehog) skyrmions [7] is characterized by spins rotating in radial planes from their cores to the boundaries, in contrast to Bloch skyrmions, where spins form a close-flux. The evolution of the magnetic configuration under external applied in-plane [8] fields leaves no doubt of the existence of hedgehog skyrmions in such Py dots. Analytical calculations showed that these magnetization textures are metastable high-energetic states and micromagnetic simulations confirmed this fact.

L12-01. 3D Ferromagnetism in Bulk $Cr_2Ge_2Te_6$. *C. Nelson*[1], Y. Liu[2] and C. Petrovic[2] *1. NSLS-II, Brookhaven National Laboratory, Upton, NY, United States; 2. Condensed Matter Physics, Brookhaven National Laboratory, Upton, NY, United States*

Cr K edge resonant x-ray scattering is used to probe the ferromagnetism in a bulk, single-crystal platelet of $Cr_2Ge_2Te_6$-- a semiconductor that remains ferromagnetic in the 2D limit,[1] and is therefore of interest both fundamentally and for potential device applications.[2] An MgO(220) analyzer crystal provides sufficient suppression of the structural scattering to reveal magnetic scattering in the rotated polarization channel. Temperature-dependent studies are consistent with magnetization measurements,[3] and reciprocal space scans indicate 3D ferromagnetism below T_c. These studies exemplify the utility of the resonant x-ray scattering capabilities that are available at NSLS-II beamline 4-ID.

Ternary silicides LnT_2Si_2 (Ln = lanthanide, T = transition metal) which crystallize in the bodycentered tetragonal $ThCr_2Si_2$ structure, have attracted much attention in the last decades as members of this family show exceptional magnetic properties. Single crystals of the 122 compounds, with Ln = Sm, Gd, Ho and T = Rh, Ir, were grown by a modified Bridgman method from indium flux. We report on their growth and their characterization by specific heat, magnetic and electrical transport measurements as well as by electron spin resonance [1-4]. Besides their unique bulk properties evolving from a delicate interplay of 4f and valence electrons, these materials serve as toy models for studying exotic surface physics within the Si-T-Si-Ln four layer of the Si-terminated surface. Applying angle-resolved photoelectron spectroscopy (ARPES), we could demonstrate that this silicon surface of $GdRh_2Si_2$ bears two distinct two-dimensional electron states that are created by Shockley and Dirac fermions [5]. These surface states exhibit pronounced spin splitting which arises from a strong exchange interaction with the ordered Gd 4f moments. Similar experiments were performed on the magnetically active, silicon-terminated surface of $HoRh_2Si_2$ single crystals [6]. Interestingly in this compound the crystal electric field lead to a tilting of the ordered moments upon decreasing temperature. This results in very specific changes in the momentum dependent splitting of the surface states, which can be precisely observed in our high resolution ARPES spectra. This allows for a very deep insight into of the effect of spin-orbit coupling and exchange interaction on itinerant electronic states. Our ARPES studies revealed that for Sm ions in $SmRh_2Si_2$, the electronic properties of bulk and surface are rather similar and they behave in both cases slightly mixed valent with a mean valence of about 2.94 at T = 10K [7]. Such a reduction of the valence of the Sm ion might be caused by a Kondo screening, but our characterization of the bulk properties did not show any signatures of the Kondo effect.

We used the muon-spin rotation technique (μSR) to refine the magnetic structures of the systems MnP, which presents at high pressure a transition towards a superconducting state, and MnSi, which exhibits a skyrmion state with the application of a magnetic field of about 0.2 T, embedded in a conical phase, just below T_N [1-3]. For MnP, at ambient pressure two phases with very different μSR responses are clearly detected. In the ferromagnetic state the Mn spins are all aligned along the crystallographic *b*-direction. At low-temperatures a double spiral helimagnetic structure is observed. This structure is characterised by an increased value by about 20% of the average magnetic moment compared to the high-temperature ferromagnetic phase. We found that an elliptical double-helical structure with a propagation vector Q = (0,0,0.117), an *a*-axis moment elongated by approximately 18% and an additional tilt of the rotation plane towards the *c*-direction describes best out data. The analysis of the high-pressure μSR data reveals that the new magnetic order appearing for pressures exceeding 1.5 GPa can not be described by keeping the propagation vector Q parallel to the *c*-axis. We show that this high-pressure magnetic phase, which is a precursor of superconductivity, is an incommensurate helical state with a propagation vector along the *b*-axis. For MnSi, we perform a quantitative analysys of zero-field μSR data by exploiting the result of representation theory as applied to the determination of magnetic structures. Instead of a gradual rotation of the magnetic moments when moving along a ⟨111⟩ axis as expected from a simple helical structure, we find that the angle of rotation between the moments of certain subsequent planes is essentially quenched. It is the magnetization of pairs of planes which rotates when moving along a ⟨111⟩axis, thus preserving the overall helical structure. By applying a magnetic field, we also show the magnetic structure in the conical

phase to strongly depend on the field direction and to deviate substantially from a conventional conical structure.

L12-06. Crystal structure and magnetic properties of oxyfluorides (Co, Ni)$_3$Sb$_4$O$_6$F. *S. Shimono*[1], H. Ishibashi[1], Y. Ishii[2], N. Otsuki[2], S. Kawaguchi[3], S. Mori[2] and Y. Kubota[1] *1. Department of Physical Science, Osaka Prefecture University, Sakai, Japan; 2. Department of Materials Science, Osaka Prefecture University, Sakai, Japan; 3. Japan Synchrotron Radiation Research Institute (JASRI), Sayo-cho, Japan*

Mixed-anion compounds exhibit a variety of physical phenomena caused by such as tuning crystal field splitting and local symmetry breaking in octahedral coordination [1]. For example, the spin crossover of cobalt from high-spin to low-spin state was reported in layered cobalt oxyfluoride under pressure [2]. Recently, the solid solution of new oxyfluorides (Co, Ni)$_3$Sb$_4$O$_6$F$_6$ were synthesized and antiferromagnetic order was observed in the temperature range from at 67 K to 170 K [3]. In this study, we have prepared $Co_3Sb_4O_6F_6$ and $Ni_3Sb_4O_6F_6$ by hydrothermal synthesis method, and investigated the crystal structure in detail and physical properties by high-resolution synchrotron powder diffraction (SPD), magnetization, and specific heat measurements. Antiferromagnetic order was observed at T_N ~ 70 K ($Co_3Sb_4O_6F_6$), and 155 K ($Ni_3Sb_4O_6F_6$) in temperature dependences of the magnetic susceptibility and specific heat. SPD experiments were carried out at the BL02B2 beamline of SPring-8, Japan [4]. Figure 1 shows the SPD patterns measured around the 400 cubic Bragg refection of $Co_3Sb_4O_6F_6$, and $Ni_3Sb_4O_6F_6$ at room temperature (red line) and 100 K (blue line), respectively. These compounds have the same crystal structure with cubic (*I*-43*m*) at room temperature. At 100 K, the crystal structure of $Ni_3Sb_4O_6F_6$ remains cubic, however, that of $Co_3Sb_4O_6F_6$ was found to be tetragonal since the peak splitting was observed. The structural phase transition of $Co_3Sb_4O_6F_6$ was observed at T_S ~ 180 K by the temperature dependences of the peak profiles and specific heat. In this presentation, we will discuss the details of structural phase transitions based on the coordination structure of Co and Ni.

Recently, antiferromagnetic (AFM) materials have drawn a lot of attention in spintronics because of possible device applications. Anisotropic magnetoresistance (AMR) and spin-orbit torque (SOT) can open the possibility for realizing AFM devices based on microelectronic designs. Although both SOT and AMR have been observed for a ferromagnetic (FM) Heusler alloy NiMnSb [1], AFM Heusler alloys are expected to reveal the same phenomena as the ferromagnetic one. However, almost all AFM Heusler alloys have relatively moderate Néel temperature (Ru_2MnGe:T_N~300K) compared to FM Heuser alloys with high Curie temperature (NiMnSb:T_C~700K). Quite recently V_3Al has been found to be an AFM spin-gapless semiconductor with significantly high T_N (~600K) [2]. Therefore, V_2 based, namely V_2YZ, AFM Heusler alloys have potentials for room-temperature AFM spintronics device applications. In this work, we investigate the magnetism and phase stability of AFM V_2 based Heusler alloys by using first-principles calculations. First, we find that V_2YAl (*Y*=V,Nb, and Ta) have higher phase stability than V_2YSi (*Y*=Ti, Zr, and Hf) from the analysis of cluster expansion. Calculated T_N of V_2TaAl, V_2TiSi, and V_2HfSi are much higher than V_3Al. In the case of V_2TaAl, the high T_N originates from the larger lattice constant than that of V_3Al. The expanded lattice constant enhances the localized character of the magnetic atoms. From the distance dependence of the exchange interaction, the first-nearest and third-nearest pairs are AFM coupled and the second-nearest interaction is FM coupled. These neighboring interactions totally stabilize a G-type AFM ordering. Finally, we discuss the origin of the strong AFM coupling between the V sites by using rigid-band models.

L12-08. The magnetic anomaly and the thermodynamic properties of the charge-ordered system $Ca_{1-x}Sr_xMn_{1-y}Sb_yO_3$. *H. Taniguchi*[1], A. Terui[1], S. Kobayashi[1], M. Matsukawa[1] and R. Suryanarayanan[2] *1. Department of Physical Science and Materials Engineering, Iwate University, Morioka, Japan; 2. Universite Paris-Sud, Orsay, France*

Perovskite manganites exhibit many interesting phenomena due to electron interactions: for example, charge-orbital ordering, magnetoelectric effect, colossal magnetoresistance, and phase separation. In previous studies, we have synthesized polycrystalline $Ca_{1-x}Sr_xMn_{1-y}Sb_yO_3$ and investigated the magnetic and dielectric properties [1]. With decreasing temperature, the magnetization exhibits a kink and a steep increase as shown in Fig. 1 (b). Moreover, the temperature dependence of the real part of the dielectric

constant exhibits a broad peak which is sensitive to a magnetic field. In this study, we measured the specific heat of $Ca_{1-x}Sr_xMn_{1-y}Sb_yO_3$ in order to discuss the magnetic and dielectric anomalies of this system from the thermodynamic viewpoint. As shown in Fig. 1 (a), the specific heat of $CaMn_{1-y}Sb_yO_3$ (y = 0.15, 0.2) exhibits a peak at the temperature of the magnetization kink, whereas clear thermodynamic anomaly is not observed at the magnetization increase and the dielectric peak. By analogy with similar electron-doped systems $Ca_{1-x}Ce_xMnO_3$ [2, 3] and $CaMn_{1-y}Mo_yO_3$ [4], it is expected that the magnetization kink results from a charge ordering which is accompanied by a canted zig-zag C-type antiferromagnetism, and the magnetization increase results from the growth of the canted component. Quantitatively, the entropy change ΔS related to the charge ordering is 0.53 and 0.28 J/Kmol at y = 0.15 and 0.2, respectively. The smaller ΔS at higher y indicates that introduced Sb ions work as a disorder on the Mn lattice and suppress the volume fraction of the charge ordering. Focusing on the *A*-site isovalent substitution, the peak of the specific heat disappears for $Ca_{0.7}Sr_{0.3}Mn_{0.85}Sb_{0.15}O_3$, although the temperature of the magnetization kink is enhanced more than 50 K. We consider that the former suppression effect is caused by the macroscopic disorder effect, whereas the latter enhancement effect is related to the relaxation of the local lattice distortion of MnO_6 octahedra around introduced Sr ions.

L12-09. Complex magnetic structure of the swedenborgite $CaBa(Co_3Fe)O_7$ derived by unpolarized neutron diffraction and spherical neutron polarimetry. *N. Qureshi*[1,2], M. Fernández Díaz[1], L. Chapon[3], A. Senyshyn[4], W. Schweika[5] and M. Valldor[6] *1. Institut Laue Langevin, Grenoble, France; 2. II. Physikalisches Institut, Universität zu Köln, Cologne, Germany; 3. Diamond Light Source Ltd, Didcot, United Kingdom; 4. Forschungs-Neutronenquelle Heinz Maier-Leibnitz, Garching, Germany; 5. Forschungszentrum Julich, Jülich, Germany; 6. Leibniz Institute for Solid State and Materials Research (IFW) Dresden, Dresden, Germany*

The magnetic swedenborgites, i.e. structural homologues to the hexagonal mineral $SbNaBe_4O_7$ [1], contain kagome layers with several different, similarly strong, competing spin interactions, which lead to a wide variety of ground states including chiral spin liquids [2,3], spin-glasses [4] and long-range antiferromagnetic order [5]. The slight structural distortions away from the hexagonal symmetry release the geometric frustration and the nature of

the distortion determines the ground state. As the spins are Heisenberg-like, a Néel order is not expected unless a significant magnetic coupling between the kagome layers is at hand, which is mediated by triangular layers in-between. Here we present an extensive study on the orthorhombic compound $CaBa(Co_3Fe)O_7$ combining powder and single-crystal neutron diffraction as well as spherical neutron polarimetry (SNP). A detailed analysis of the possible irreducible representations and the magnetic structure factors in combination with the observed polarization matrices of special reflections gave clear indications concerning the magnetic symmetry. The complex situation with the presence of three structural twins and four magnetic domains (two orientational and two chiral domains) was tackled with the development of a unique software, Mag2Pol [6], which permits the refinement of a magnetic structure model including domain populations to integrated intensity and SNP data simultaneously. We could therefore derive an interesting magnetic structure of magnetic superspace symmetry $P2_1$', which differs from any other member of the swedenborgite family, but which can be mapped onto the classical √3 x √3 structure of a kagome lattice. The resulting spin structure indicates an important interplay between the kagome and the triangular layers of the crystal structure.

L12-11. X-ray emission spectroscopy study of pressure-induced magnetic transitions in magnetite Fe_3O_4. *A. Efimenko*[1], S. Agrestini[2], S. Liao[3], S. Petitgirard[4], A.C. Komarek[3], C.J. Sahle[1] and Z. Hu[3] *1. ESRF (The European Synchrotron), Grenoble, France; 2. Experiments, ALBA Synchrotron Light Source, Barcelona, Spain; 3. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 4. Bavarian Research Institute of Experimental Geochemistry and Geophysics, University of Bayreuth, Bayreuth, Germany*

Magnetism was discovered first in magnetite (Fe_3O_4). The understanding of magnetite behaviour under high pressure brings the insights into the magnetism of Earth's mantle. Despite the continues studies of this material its high pressure state is still disputed. A high-spin (HS) S=2 to intermediate-spin (IS) S=1 state transition of Fe^{2+} ions in Fe_3O_4 has been proposed in the pressure range between 12 and 16 GPa based on the X-ray Magnetic Circular Dichroism (XMCD) measurements at the Fe-K edge and Fe-Kβ X-ray emission spectroscopy (XES) [1]. However, soon such a transition has been disputed by another XMCD study [2]. Here we report our XES study at the Fe-Kβ emission line of the high-quality single crystal and grinded powder Fe_3O_4 at room temperature. The experiments were carried out on the ID20 beamline at the ESRF. We were able to obtain XES spectra until 49 GPa. In XES spectrum the intensity of the Kβ′ satellite is related to the magnitude of the spin moment. Our data reveals that the apparent reduction in intensity of the satelite peak Kβ′ reported in [1] is actually due to a spectral gradual lineshape broadening without a significant change in intensity. In that respect our XES results rule out the proposed spin-state transition in ref. [1] and demonstrate that Fe^{2+} remains in the HS state at least up to 49 GPa. Our complementary data from X-ray absorption spectroscopy (XAS) at the Fe-K edge show changes above 29 GPa in correspondence with the previously observed structural transition.

Diluted magnetic semiconductors (DMSs) have attracted lots of attention due to their potential applications in various domains, such as Spin Field-Effect Transistors (Spin-FETs), Spin Light-Emitting Diodes (Spin-LEDs), Magnetoresistance Random Access Memory (MRAM), ultrafast optical switches, etc [1]. Among various DMS materials, ZnO-based DMSs with relatively high Curie temperature *Tc*, abundance in nature and absence of toxicity are considered an ideal candidate [2]. In order to improve the magnetic properties of ZnO, transition metal elements like Fe^{2+}, Co^{2+}, Ni^{2+}, Mn^{2+}, etc. have been proposed to be doped into ZnO. In 2005, Marcel H.F. Sluiter *et al* reported that both electron-doping and hole-doping with Zn interstitials or oxygen vacancies can improve the magnetic properties of ZnO:Co and ZnO:Mn [3]. A. Dinia *et al* also reported that high free-charge carriers produced by transition metal interstitials in ZnO thin films is desirable for a high Curie temperature [4]. In this context, ZnO with high carrier density co-doped by transition metals and the elements from the third group, such as B^{3+}, Al^{3+}, Ga^{3+} and In^{3+}, has been widely studied. In this study, (In, Co) co-doped ZnO films were produced by radio frequency (RF) magnetron sputtering. The influence of In content on the film's electrical and magnetic properties was investigated, and the mechanisms of ferromagnetism was also discussed. The results show that both the surface roughness and the particle size of ZnO decrease with increasing In content in the films, while the phase structure remains almost unchanged. As for the film's magnetic properties, ferromagnetic performance is detected at room temperature, displaying a carrier-concentration dependent behavior. Three distinct regions can be identified. With the carrier concentration varying, bound magnetic polaron (BMP) and carrier-mediated exchange contribute to the variation in the film's ferromagnetic behavior. Keywords: (In, Co)-ZnO films; electrical properties; magnetic properties; RF sputtering; ferromagnetic behavior.

L13-02. Magneto-optical Spectroscopy of Ferromagnetic Fe-Mn-Ga Heusler alloys. *D. Kral*[1], M. Veis[1], O. Heczko[2] and P. Cejpek[3] *1. Institute of Physics, Charles University in Prague, Prague, Czechia; 2. Department of Functional Materials, Institute of Physics ASCR, Prague, Prague, Czechia; 3. Department of Condensed Matter Physics, Charles University, Praha, Czechia*

Heusler alloys that undergo martensitic transformation (MT) are of scientific interest due to their vast application potential [1]. The most known member of this class is Ni-Mn-Ga, which has been intensively studied during the last decade as it exhibits magnetically induced reorientation (MIR) [2]. Recently, MT has been observed in another Heusler alloy, Fe-Mn-Ga [3]. Here, we present a systematic comparison of magnetic, optical and magneto-optical (MO) properties of both Ni-Mn-Ga and Fe-Mn-Ga. We focus mainly on their electronic structure, which influences MT via the Jahn-Teller effect. Polycrystalline samples of nominal composition $Fe_{40}Mn_{27}Ga_{33}$ and close to stoichiometry were prepared by arc melting, annealed and electropolished. Vibrating sample magnetometry indicated the ferromagnetic behavior of all samples. $Fe_{40}Mn_{27}Ga_{33}$ alloy exhibited saturation magnetic moment about 90 emu/g at 10K with estimated Curie point about 526 K. The optical response of the Fe-Mn-Ga alloys was obtained in the photon energy range from 0.7 to 6.5 eV. The spectral dependence of diagonal permittivity (shown in Fig. 1) was calculated from the experimental results using the Drude model. Results indicate a high concentration of free carriers as well as the presence of a 1 eV interband transition. The experimental results are confronted with ab initio calculations of the density of states. The spectral dependence of MO Kerr effect (MOKE) was obtained by a generalized MO ellipsometer in the spectral range from 1.2 to 5 eV. The MO response of Fe-Mn-Ga (see Fig. 2) differs substantially from Ni-Mn-Ga, where several interband spectral features are clearly noticeable. $Fe_{40}Mn_{27}Ga_{33}$ shows MOKE signal of rather low amplitude, implicating reduced magnetic moment and the possibility of antiferromagnetic ordering. This work was supported by Czech Grant Agency (grant No. 16-00043S) and Ministry of Education of Czech Republic (grant No. OP VVV CZ.02.1.01/0.0/0.0/15_003/0000487).

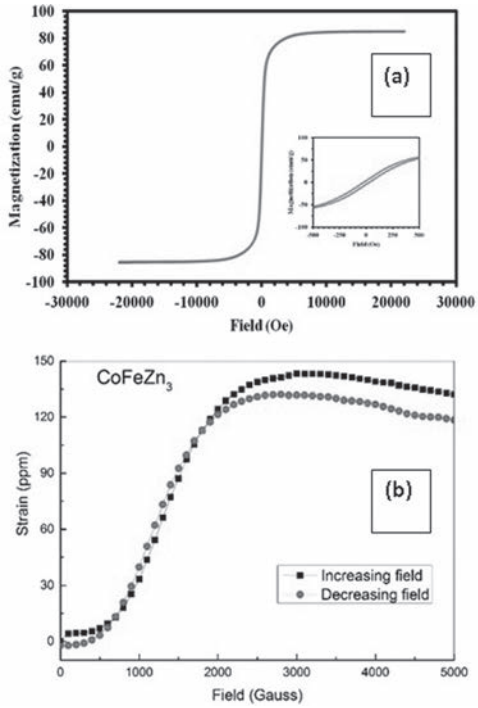
L13-03. Magnetic and electrical properties of (Al, Co) co-doped ZnO films deposited by RF magnetron sputtering. *S. Chen*[1,2], H. Sun[3], C. Wang[1], C. Wen[4] and T. Chuang[4] *1. Department of Materials Engineering and Center for Thin Film Technologies and Applications, Ming Chi University of Technology, New Taipei City, Taiwan; 2. Department of Electronic Engineering, Chang Gung University, Taoyuan 333, Taiwan; 3. School of Space Science and Physics, Shandong University at Weihai, Weihai 264209, China; 4. Institute of Materials Science and Engineering, National Taiwan University, Taipei 106, Taiwan*



Diluted magnetic semiconductors (DMSs) based on ZnO have attracted a great deal of attention due to their potential application in magnetic semiconductor devices. In particular, they are predicted to display ferromagnetic properties at Curie temperature above room temperature and have large magnetization. (Al, Co)-ZnO films for use as DMSs have been fabricated using various techniques, including sol-gel [1,2], pulsed laser deposition (PLD) [3], etc. However, there are very few reports about (Al, Co)-ZnO thin films deposited using radio frequency (rf) magnetron sputtering. In this study, (Al, Co)-ZnO [$Co_xAl_yZn_{(1-x-y)}O$] films with different Al contents are co-sputtered on glass substrates by rf magnetron sputtering. The *x* content [Co/(Al+Co+Zn)] in the films varies from 6.6 to 12.4 at.%. The content of *y* [Al/(Al+Co+Zn)] varies from 0 to 5.2 at.%. Using Hall effect analysis, the resistivity (ρ) of the film is 42.9 Ω-cm when the *y* content is 0. When the content of *y* increases to 5.2 at.%, the ρ value drops greatly to 8.04×10^{-3} Ω-cm. It is found that both the surface roughness and grain size of columnar (Al, Co)-ZnO films decrease significantly after Al addition into the films, but the phase structure remains almost unchanged. In magnetic properties analysis, two distinct mechanisms of bound magnetic polaron and carrier-mediated exchange lead to the films presenting different ferromagnetic behaviors in various carrier density regions. Keywords: rf magnetron co-sputtering, diluted magnetic semiconductors, (Al, Co) co-doped ZnO films, electrical properties, magnetic properties.

L13-04. Hysteresis-free Highly Magnetostrictive Ceramics. *A. Lisfi*[1], S. Pokharel[1], S. Alomari[1], A. Davis[1], A. Alqarni[1] and M. Wuttig[2] *1. Physics, Morgan State University, Baltimore, MD, United States; 2. Materials Science and Engineering, University of Maryland, College Park, ME, United States*

Hysteresis-free magnetic materials displaying a large mechanical response under the application of a small magnetic field are of a considerable interest to technological applications such as sensors and transducers [1-2]. Among the materials that can fulfill such requirements are ceramics such as cobalt ferrite, which is distinguished by its large magnetostriction and good chemical stability. However, its low magnetization and its large amount of hysteresis can limit its technological performance. This research work aims to synthesize new ceramic material in the bulk phase that can exhibit a high magnetization and low anisotropy together with a sizable magnetostriction. The material of interest consists of Zn-doped cobalt ferrite, which is expected to offer the following enhanced properties over pure cobalt ferrite. (1) Doping with Zn can produce a significant increase in the magnetization. (2) The doped ceramic can display nearly hysteresis-free magnetic character while inheriting a large magnetostriction from cobalt ferrite. A series of Zn-doped cobalt ferrite samples was prepared with ball milling. The doped samples with different Zn concentrations were compacted and annealed at different temperatures up to 1500 °C. A good illustration of the enhanced properties is displayed in Fig. 1, which depicts the field dependence of the magnetization and the magnetostriction of Zn-doped cobalt ferrite prepared at 1400 °C. As shown by Fig. 1(a), the saturation magnetization of the Zn-doped sample (86 emu/g) is larger than that of pure single crystal cobalt ferrite (80 emu/g) in addition to a reversible character of the magnetization with high magnetic susceptibility at low field. Moreover, Fig. 1(b) shows significantly large mechanical response at low magnetic field with saturation magnetotriction close to 150 ppm. The detail of this investigation will be presented and discussed under a full study, which corroborates the results of the enhanced doped ceramics.

Field dependence of (a) the magnetization and (b) the magnetostriction of Zn-doped polycrystalline cobalt ferrite prepared at 1400 °C. Both the magnetization and the magnetostrictions are nearly hysteresis free and display high saturation values.

L13-05. Anisotropy in Antiferromagnetic Thin films. *J. Sinclair*[1], A. Hirohata[2], J. Balluff[3], M. Meinert[3] and K. O'Grady[1] *1. Department of Physics, University of York, York, United Kingdom; 2. Department of Electronics, University of York, York, United Kingdom; 3. Center for Spinelectronic Materials and Devices, Bielefeld University, Bielefeld, Germany*

Antiferromagnetic (AF) thin films are of increasing importance due to their application in spintronic devices. The use of the AF IrMn in hard drive read heads and magnetic sensors to 'pin' the orientation of one or more ferromagnetic (F) layers is well established [1]. Due to the volatile price of Iridium there is considerable interest in replacing this material. Any AF materials suitable for integration into this type of device must meet a number of criteria, in particular thermal stability which is achieved via an anisotropy barrier of the form ΔE=KV due to the granular nature of the sputtered films used. The thermal stability of AF materials is controlled by their anisotropy which is strictly magnetocrystalline in nature. In the IrMn system, the anisotropy has been measured as 3.3×10^7 ergs/cc [2], associated with a strong (111) in plane texture. It has been demonstrated that in sputtered polycrystalline IrMn thin films this (111) texture gives rise to a 2D random system which exhibits uniaxial behaviour [3]. There are a number of materials considered as a replacement for IrMn. These include Heusler alloys such as Ru_2MnGe and the novel AF material MnN. In MnN the anisotropy is derived from a tetragonal structure, with a c/a ratio of 1.04 [4]. When the c axis is textured in plane the effective anisotropy is enhanced. Defects in the crystal lattice will lead to a distribution of anisotropy constants (K_{AF}), which together with the distribution of grain volumes gives rise to the blocking temperature distribution. Using a careful measurement protocol, the blocking temperature distribution can be determined. With a measurement of the grain size distribution in the film, the anisotropy constant can be obtained at the point where the exchange bias equals zero and hence all grains up to the median grain volume are activated. An example of such data for MnN is shown in Figure 1.

L13-06. Magnetic properties and magnetocaloric effect of Pd-Ni-Mn-Sn Heusler alloys. *H. Yako*[1], T. Shima[2] and M. Doi[3] *1. Tohoku Gakuin University, Tagajo, Japan; 2. Faculty of Engineering, Tohoku Gakuin University, Tagajo, Japan; 3. Tohoku Gakuin University, Tagajo, Japan*

Ternary Heusler alloys defined as the stoichiometric composition X_2YZ with the $L2_1$ structure have attracted considerable attention due to their valuable magnetic and transport properties. Previous study reported that the phase diagram of $Pd_2Mn_{1+x}Sn_{1-x}$ is similar to that of $Ni_2Mn_{1+x}Z_{1-x}$ (Z = Sn, In) although the transition temperature is different [1]. Furthermore, the magnetization of this system decreased with increasing Mn concentration x, while the martensitic transition was appeared only in the range x of 0.42 and 0.50. Then, the $Pd_2Mn_{1+x}Sn_{1-x}$ alloys are expected to be appeared the magnetocaloric effect. In this study, the effect of Ni substitution for Pd is performed in order to enhance the magnetization of $Pd_2Mn_{1+x}Sn_{1-x}$. Moreover, the magnetic properties of $Pd_{2-y}Ni_yMn_{1+x}Sn_{1-x}$ alloy with both low Ni and high Mn concentrations are investigated. Samples have been prepared by arc melting in an argon gas atmosphere. They were re-melted at four times for homogenization. The ingots were sealed in the quartz tube and annealed at 1123 – 1373 K for 84 hours and subsequent quenched into ice water. The structure was characterized by powder X-ray diffraction (XRD) with Cu K_α radiation at room temperature. Magnetization measurements were carried out using a superconducting quantum interface device (SQUID) magnetometer. XRD measurement revealed that $Pd_{2-y}Ni_yMn_{1.47}Sn_{0.53}$ alloys showed the $L2_1$ structure. A lattice parameter decreased and a spontaneous magnetization increased with increasing Ni concentration y. In addition, the martensitic transition couldn't observe for x from 0.1 to 1.5. The maximum isothermal magnetic entropy change estimated by the Maxwell relationship in a magnetic field of 2 T evaluated to about 2.7 J / kgK without Ni. The composition dependence of structure and magnetization will be discussed in detail.

L13-07. Helical magnetic ordering in epitaxial $SrFeO_3$ and $CaFeO_3$ heterostructures. P.C. Rogge[1], R.J. Green[2,3] and *S. May*[1] *1. Materials Science and Engineering, Drexel University, Philadelphia, PA, United States; 2. Department of Physics and Engineering, University of Saskatchewan, Saskatoon, SK, Canada; 3. Stewart Blusson Quantum Matter Institute, University of British Columbia, Vancouver, BC, Canada*

There is rapidly growing interest in non-collinear spin textures and their relationship to electronic transport in magnetic materials. The ability to synthesize epitaxial thin films of non-collinear magnets opens new scientific avenues to explore how interfacial perturbations, finite thickness, and epitaxial strain alter spin textures. Here, we report the synthesis and magnetic characterization of metallic $SrFeO_3$ and insulating $CaFeO_3$ thin films and superlattices, materials that exhibit incommensurate helical

magnetic ordering along the pseudocubic [111] direction in their bulk forms. The heterostructures, 20-30 nm in thickness, were deposited by oxygen plasma-assisted molecular beam epitaxy on (001) and (111)-oriented perovskite oxide substrates. Resonant soft x-ray magnetic scattering confirms the presence of helical ordering within the films. The measured helical periods, 17.5 Å and 13.7 Å, and the Néel temperatures of the films, 120 K and 100 K, are similar to bulk $SrFeO_3$ and $CaFeO_3$, respectively. Magnetoresistance measurements from $SrFeO_3$ films exhibit distinct sign changes as a function of temperature and field, which will be described within the context of previously reported magnetic transitions in bulk $SrFeO_3$ crystals. Magnetotransport and scattering data will also be presented from $CaFeO_3/SrFeO_3$ superlattices revealing how the helical ordering is altered by the presence of interfaces. P.C.R. and S.J.M. were supported by the Army Research Office, grant number W911NF-15-1-0133.

L13-08. Magnetic properties of quaternary silicide carbides RFe_2SiC (R= rare earth). *M. Ohashi*[1], K. Maeta[1] and S. Hirokawa[1] *1. Kanazawa University, Kanazawa, Japan*

The quaternary silicide carbides RFe_2SiC (R= rare earth) were refined from single crystal X-ray data of $ThFe_2SiC$ with space group *Cmcm* [1]. However, the physical properties of RFe_2SiC such as magnetic susceptibility and heat capacity have not been reported yet. In the present work, we report on the synthesis of RFe_2SiC and the magnetic properties. Polycrystalline sample of RFe_2SiC (R= Gd-Er) was synthesized by arc melting with a stoichiometric composition in an Ar gas atmosphere. To improve homogeneity, the sample was turned over and re-melted several times. These samples were sealed in evacuated quartz tubes and were annealed at 800 °C. The sample was characterized by X-ray powder diffraction experiments using a Rigaku MiniFlex II diffractometer with Cu-Kα radiation. Almost all the Bragg peaks of all compounds can be indexed as the orthorhombic structure. The cell volume of RFe_2SiC compounds show the usual lantanoid contraction, which is consistent with the previous report [1]. The dc magnetization was measured by using a Quantum Design MPMS-5 superconducting quantum interference device magnetometer. The magnetic susceptibility M/B(T) of all compounds follow the modified Curie-Weiss law $M/B = C/T\text{-}\Theta + \chi_0$. The effective magnetic moments were obtained from the Curie constant C in these compounds and rare-earth ions are close to those of free trivalent ions. The residual magnetic susceptibility χ_0 may be a Pauli-type contribution of these compounds, or may come from the magnetic moment of the impurity phase such as Fe. The cusp and the steep increase was observed in M/B(T) which correspond to antiferromagnetic and ferromagnetic transitions for all compounds at low temperature.

L13-09. Structural and Magnetic Properties of (111) $CaRuO_3/CaMnO_3$ Heterostructures. *M. Kane*[1], C. Flint[2] and Y. Suzuki[2] *1. Materials Science and Engineering, Stanford University, Stanford, CA, United States; 2. Stanford University, Stanford, CA, United States*

Emergent ferromagnetism has been observed at the interface of $CaRuO_3$ (CRO) and $CaMnO_3$ (CMO), which are a paramagnetic metal and an antiferromagnet insulator respectively in the bulk. We have shown that CRO/CMO (001)-oriented superlattices show a canted ferromagnetic moment isolated to the first unit cell, resulting in a magnetic moment of 1 μ_B/interfacial Mn ion [1]. This magnetic moment is significantly smaller than the 3 μ_B expected from Mn^{4+} ions. The emergent ferromagnetism has been explained in terms of a double exchange interaction among interfacial Mn ions, mediated by itinerant electrons leaking into the CMO. In order to increase the emergent moment at the interface, we have induced a larger transfer of charge by electrical gating to obtain 2.6 μ_B/interfacial Mn ion [2]. Since CMO has a G-type antiferromagnetic structure, the (001) surface is fully compensated while the (111) surface is fully compensated, and films grown in this orientation could possibly have an even higher interfacial moment. However, growing CRO/CMO superlattices in the (111)-orientation to explore the effects of the fully uncompensated surface on the interfacial magnetic moment has proven challenging. We have developed an interval pulsed laser deposition process that enables smooth growth in the (111) orientation. This process allowed us to successfully fabricate (111)-oriented $LaNiO_3/CaMnO_3$ superlattices [3], and using this interval pulsed laser deposition process, we have successfully grown (111)-oriented CRO and CMO bilayers with an rms roughness of less than a unit cell. X-ray diffraction shows the excellent crystallinity with rocking curves on the order of 0.020°. Since CMO and CRO are isovalent, CRO/CMO systems do not exhibit a polarity mismatch across the interface and provide a model system for the exploration of emergent ferromagnetism without a polarity mismatch. The CRO/CMO bilayers we have grown prove that smooth, (111)-oriented films can be grown, allowing us to next grow atomically smooth superlattices.

L13-10. Magnetic states and band gaps of $Ba_2Pr(Bi,Sb)O_6$ double perovskite oxide compounds. K. Onodera[1], M. Matsukawa[1], *H. Taniguchi*[2] and A. Matsushita[3] *1. Iwate University, Morioka, Japan; 2. Department of Physical Science and Materials Engineering, Iwate University, Morioka, Japan; 3. National Institute for Materials Science (NIMS), Tsukuba, Japan*

We demonstrated crystal structures, magnetic, and optical properties of the B-site substituted perovskite oxides $Ba_2Pr(Bi_{1-x},Sb_x)$ O6 (x=0, 0.05 and 0.15, 0.25, 0.3, 0.4, 0.5 and 1.0). Polycrystalline samples of Sb-substituted $Ba_2Pr(Bi_{1-x},Sb_x)$ O_6 were prepared with the conventional solid-state reaction technique. The X-ray diffraction data revealed that the polycrystalline samples with low Sb substitution for B site are an almost single phase with a monoclinic structure (C2/m). Substitution of smaller Sb ion at Bi site causes a monotonic decrease in both the lattice parameters and volume. The heavily Sb substituted samples crystallize in the hexagonal system accompanied by B-site disorder. Magnetization measurements on the lightly Sb substituted samples show that the effective magnetic moment is estimated to be around 3.15 μB, indicating the valence mixing between Pr^{3+} and Pr^{4+}. On the other hand, the magnetic moment with the heavy Sb substitution is close to the valence of Pr^{3+}. The low-temperature magnetic data are analyzed by considering the crystal filed effect of 4f electrons. Optical spectra at room temperature were measured using a diffuse-reflectance method. The band gaps were estimated from the optical data to be 1.11 eV and 2.24 eV, at x=0 and 1.0, respectively. The effect of band gap opening due to Sb substitution is examined by using the density functional theory. The lightly and heavily Sb doped compounds show typical absorption edges in indirect and direct semiconductors, which is qualitatively consistent with the calculated results.

L13-11. Highly sensitive flexible zero-biased magnetic sensor based on Metglas/poly(vinylidene fluoride) magnetoelectric heterostructures. *J. Qiu*[1], Y. Long[1], X. He[1], Q. Chang[1], Z. Hu[1] and H. Liu[1] *1. College of Optoelectronic Engineering, Chongqing University, Chongqing, China*

Magnetoelectric(ME) composites show increasing interest for a large number of applications, including energy harvesters, magnetic storage and magnetic sensors[1-3]. Recently, utilize ME laminate composites, consisting of piezoelectric ceramics (e.g., PZT)/magnetostrictive (e.g., Terfenol-D) to detect magnetic field has become a hot research topic, owing to their commendable ME coupling characteristic and high ME conversion coefficient. However, ceramic-based ME composites are usually brittle, non-bendable, fatigue and expensive, which are not applicable to wearable devices. Owing to without the above drawbacks, the polymer-based ME composites may be an appropriate solution for this limitation. Although several works have been focused on the polymer-based ME laminates and did proper optimization, to achieve those high ME coupling effect, the external dc bias magnetic

field (H_{dc}) is indispensable[4,5]. It will improve production costs and increase technical difficulty in industrial production. Actually, utilizing zero-bias ME coupling in polymer-based ME laminates is a feasible way to solve this problem. In this paper, the flexible magnetic sensors consisting of FeSiB/PVDF are presented. The zero-bias ME coupling characteristics under different bending angle have been investigated. It is found that the maximum zero-bias resonant ME voltage coefficient (MEVC) was 23.54V/cmOe. In addition, ac magnetic field H_{ac} sensing and current sensing properties of sensor have also been researched. The induced ME voltages exhibits a good linear relationship with the ac magnetic field and current both at resonant and low-frequency conditions in a wide range. The average sensitivity of composites reached 118 mV/Oe and 6.19 mV/Oe, with a linearity of 1.49% and 0.75%, at the low frequency (1 kHz) and the resonant frequency (57.3 kHz), respectively. Obviously, it indicates that the proposed flexible zero-bias magnetic sensor have great prospect of being applied to the field of highly sensitive ac magnetic field and current sensing.

L13-12. Study of highly uniform Heusler based Ni-Mn-Ga Nanowires fabricated by DC Electrodeposition. *K. Javed*[1,2], W. Li[2], N. Ahmad[3], S.S. Ali[2], U. Khan[2] and X. Han[2] *1. Department of Physics, Forman Christian College(University), Lahore, Pakistan; 2. Institute of Physics, Chinese Academy of Sciences, Beijing, China; 3. Department of Physics, FBAS, International Islamic University, Islamabad, Pakistan*

During last two decades, Heusler based Ni-Mn-X(Ga, In, Sn, Sb, Al) FSMAs (ferromagnetic shape memory alloys) have been studied extensively. Ni-Mn-Ga is a ferromagnetic martensitic alloy with the unique property of undergoing large strains when a magnetic field is applied. Ni-Mn-Ga Heusler based alloy is capable of reversible MFIS (magnetic field induced strain) while the magnetic shape memory effect is useful for actuation purpose, the inverse effect may be utilized for sensing and energy harvesting applications[1]. Ni-Mn-Ga FSMA have potential applications for magnetic field sensors, strain sensors, actuators and solid state refrigeration, because of its uniqueness in microstructure and multiple phases at different temperatures. To the best of our knowledge, synthesis of Heusler based Ni-Mn-Ga nanowires by DC electrodeposition using AAO (anodic aluminum oxide) templates has not been reported. In this talk, we will present synthesis of Ni-Mn-Ga nanowires using low cost dc electrodeposition in AAO templates. This method has been selected because of its simplicity, cost-effectiveness, and precise control over length, diameter and composition of nanowires/nanotubes [2-3]. The deposition potential was controlled carefully to have desired composition. Nanowires with different Ga concentration were obtained by controlling deposition potential. It has been found that Ga concentration is inversely proportional to deposition potential. The effect of deposition potential on morphology, chemical composition, crystal structure and magnetic properties has also been studied. The SEM (Scanning Electron Microscope) analysis show that diameter of nanowires is about 200nm and length of about 10 μm. The composition of nanowires was confirmed using EDS. The XRD (X-Ray diffraction) analysis exhibit a cubic crystal structure, with lattice constant of a=5.821Å at room temperature. The average grain size estimated from XRD peaks using Scherer equation is about 29 nm for $Ni_{70}Mn_5Ga_{25}$ sample. The MH loops show that Ni-Mn-Ga Heusler based nanowires have maintained ferromagnetic behavior form 10K to room temperature.

L13-14. Barkhausen noise analysis in Fe-Co magnetostrictive alloy wire for monitoring stress and damage accumulation. *T. Yamazaki*[1], Y. Furuya[2] and W. Nakao[1] *1. Department of Materials Science and Engineering, Yokohana National University, Yokohama, Japan; 2. Micro System Integration Center, Tohoku University, Sendai, Japan*

High strength magnetostrictive alloys have attracted much attention for wide variety of applications such as environmental mechanical energy harvesters, structure health monitoring sensors and damping actuators due to the magneto-mechanical energy conversion mechanism [1]. Here, we propose a novel multi-sensing system for real-time monitoring the stress and damage accumulation of embedded structures using magnetic Barkhausen noise (MBN) observed in annealed $Fe_{29}Co_{71}$ magnetostrictive alloy wire [2]. MBN is a compositional pulse generated due to the dynamic interaction between dynamic domain wall movement and microstructure factors (i.e. grain boundary, dislocations, etc.) [3]. Therefore, it could be possible to a large change of stress or a minute deformation and the damage accumulation) for target objects. In this study, the stress and damage dependence of the root-mean-square (RMS) value of MBN was investigated by applying an alternating magnetic field under tensile stress to the specimen until the specimen was raptured. MBN signals was measured by a microscopic magnetization measurement system constituted of two kinds of solenoidal coils and the other signal conversion apparatus. As a result, we revealed the stress effect of MBN shows a good sensitivity (0.18 mV/MPa) and a large linearity in the stress range of 0-400 MPa (Fig. 1a), which shows higher stress-sensitivity than that of the other steel specimens with low magnetostrictive constant. Also, we demonstrated that the RMS value of MBN was decreased with the increase of stress cycle (Fig. 1b). From these results, MBN was largely affected by the magnetostrictive constant and the number of defects in specimen, which were very well agree with the microstructure observation by scanning electron microscopy (SEM) and the dislocation density for each specimen calculated by Williamson–Hall method. The consideration of MBN generation mechanism will be discussed in my poster presentation.

L14-01. High Pressure Phases and Superconductivity in Cerium Hydrides. *B. Li[1] 1. Information Physics Research Center, Nanjing University of Posts and Telecommunications, Nanjing, China*

Recent discovery of high-temperature superconductivity in H3S at megabar pressures breaks the traditional belief on the Tc limit of 40 K for conventional superconductors. We use first-principles calculations to study structural, vibrational, and superconducting properties of cerium hydrides at megabar pressures. We report its high-pressure novel structural phases accompanied by electronic-structure calculations and electron-phonon couplings. Our simulations established the high temperature superconductive nature of cerium hydrides and provided useful route for experimental verification.

L14-02. Electron-Hole Asymmetry and Two Superconducting Phases in Carrier Doped Molecular Conductor κ-$(ET)_2X$. *H. Watanabe*[1], H. Seo[2,3] and S. Yunoki[2,3] *1. Waseda Institute for Advanced Study (WIAS), Waseda University, Tokyo, Japan; 2. RIKEN, Saitama, Japan; 3. RIKEN CEMS, Saitama, Japan*

Unconventional superconductivity (SC) is often observed around the Mott transition in strongly-correlated electron systems. In high-T_c cuprates, *d*-wave SC is induced by carrier doping to the parent Mott insulating copper oxides. On the other hand, in the family of molecular conductors κ-$(ET)_2X$, external pressure or chemical substitution of X to the dimer-Mott insulating state induces SC whose gap symmetry is still controversial [1]. Recently, carrier doping is also realized in κ-$(ET)_2X$ and the anomalous metallic behavior and significant electron-hole doping asymmetry have been reported [2,3], which are reminiscent of the cuprates. Although cuprates and κ-$(ET)_2X$ have similarities [4], there are also differences which should be carefully examined. In cuprates, a general understanding is that the strong AF fluctuation mediates the *d*-wave SC. In κ-$(ET)_2X$, however, SC can appear next to the nonmagnetic Mott insulators as well as the AF Mott insulators. It is not clear that the AF fluctuation mechanism in cuprates can directly be applied to κ-$(ET)_2X$. Moreover, κ-$(ET)_2X$ is originally 3/4-filled electron system and the intradimer charge degree of freedom, which is sometimes neglected for simplicity leading to a 1/2-filled situation, is considered to play important roles [5,6,7]. In this study, we investigate the extended Hubbard model for κ-$(ET)_2X$ where the intradimer charge degree of freedom and the intersite Coulomb interactions are explicitly considered. The detailed ground state properties are analyzed with variational Monte Carlo method. We obtain the ground-state phase diagram with significant electron-hole doping asymmetry. There appear various competing phases: dimer-AF phase (DAF), polar charge-ordered phase (PCO), two 3-fold charge-ordered phases (3-fold CO), and two SC phases with different gap symmetries. The "extended-s+$d_{x^2-y^2}$"-wave SC is favored for the electron-doped side and the "d_{xy}"-wave SC is favored for the hole-doped side; the latter is the counterpart to high-T_c cuprates. We discuss the origin of such an asymmetry and the two SC phases, and propose that they are controllable by chemical substitution of X or carrier doping.

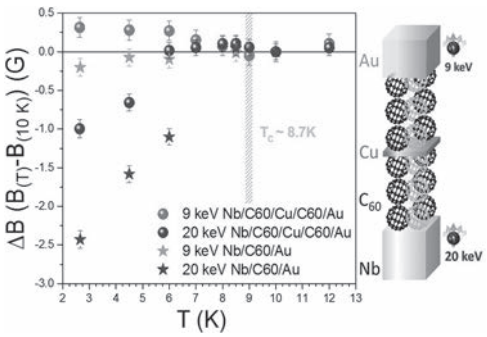
L14-03. Paramagnetic Meissner Effect in Metal-Molecule Hybrid Systems. *M.D. Rogers*[1], F. Al Ma'Mari[1,2], H. Bradshaw[1], S. Lee[3], R. Stewart[3], M. Flokstra[3], T. Prokscha[4], T. Moorsom[1], M. Ali[1], G. Burnell[1] and O. Cespedes[1] *1. Physics and Astronomy, University of Leeds, Leeds, United Kingdom; 2. Department of Physics, Sultan Qaboos University, Muscat, Oman; 3. School of Physics and Astronomy, University of St. Andrews, St. Andrews, United Kingdom; 4. Laboratory for Muon Spin Spectroscopy, Paul Scherrer Institut, Villigen, Switzerland*



The coexistence of magnetism and superconductivity observed in bulk materials and hybrid structures of conventional s-wave superconductors (SC) with ferromagnets (FM) is of relevance due to the possibility of generating spin-polarised supercurrents, enabling new opportunities for spin based electronics. The two states of matter are able to coexist due to the formation of spin-triplet Cooper-pair states.[1] Fullerene C_{60}, is diamagnetic and insulating. However, its large electron affinity and low LUMO can lead to considerable charge transfer into the molecule from metallic surfaces. It has been shown that for metal/C_{60} interfaces, significant charge transfer and orbital hybridisation can lead to emergent spin polarised interfaces and ferromagnetic ordering.[2] Here, we show that in Nb/C_{60}/Au systems, cooper pair leakage leads to a proximity induced SC state in the C_{60} with a coherence length, ξ_o, of 30±8 nm that is highly dependent upon growth conditions. By inserting a weakly magnetic C_{60}/Cu/C_{60} layer, we observe a massive enhancement to the measured magnetic moment by SQUID VSM below the T_C and H_C of the Nb. It is unlikely that this effect would arise due to vortex pinning as the field lies in plane to the niobium film, whose thickness is of the order of ξ_o. Probing the local magnetic field by Low Energy Muon Spin Rotation (LE-μSR) we observe conventional diamagnetic Meissner screening in the Nb/C60/Au stack extending into the Au layer. In a similar structure including the magnetic Cu layer the diamagnetic screening in the Nb is slightly supressed whereas the screening in the Au is now paramagnetic. In some hybrid SC/FM structures such effects have been attributed to the generation of odd-frequency triplet Cooper pairs[3]. Our initial results demonstrate the potential for forming unconventional Cooper pairs in systems that contain no intrinsic exchange splitting and instead rely on the emergent effects that occur at molecule/metal interfaces.

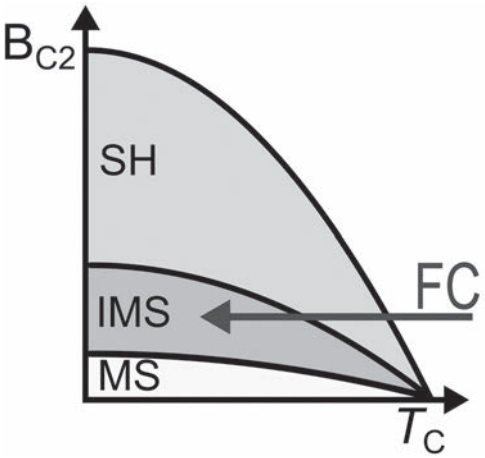
L14-04. Minimal microscopic model for the quasi-one-dimensional superconductor $K_2Cr_3As_3$. G. Cuono[1], C. Autieri[3], F. Forte[2,1], G. Busiello[1], M. Mercaldo[1,2], A. Romano[1,2], C. Noce[1,2] and *A. Avella[1,2] 1. Dipartimento di Fisica "E.R. Caianiello", Università degli Studi di Salerno, Fisciano, Italy; 2. UoS di Salerno, CNR-SPIN, Fisciano, Italy; 3. UoS dell'Aquila - Chieti, CNR-SPIN, Chieti, Italy*

We study the tight-binding dispersion of the recently discovered quasi-one-dimensional superconductor $K_2Cr_3As_3$, obtained from full-fledge Wannier projection of optimized ab initio results, characterizing it with respect to the Cr-d and the As-p orbitals of the several ions present in the unit cell. A minimal number of hopping terms, with respect to distances (in terms of neighbours per different type of ion) and energy values, is identified for the bands closer to the Fermi surface, which is satisfactorily reproduced. The orbital characterization of the band structure reveals that a reliable minimal model needs to take into account both the Cr-d and the As-p orbitals due to the high degree of covalency. Finally, a Löwdin reduction procedure is applied in order to take into account non-perturbatively relevant, but not essential, degrees of freedom and obtain a minimal model useful to perform further studies and identify the mechanism and the nature of the superconductivity in this material.

L14-05. ^{11}B NMR studies of YNiBC system. *P.L. Paulose*[1] and S.M. Patil[2] *1. Department of Condensed Matter Physics&MS, Tata Institute of Fundamental Research, Mumbai, India; 2. Department of Physics, Wilson College, Mumbai, India*



RNi_2B_2C (R= Y or rare earth compounds) are widely studied intermetallic system showing varied behavior of coexistence of superconductivity with magnetic order and relatively high superconducting transition temperatures. RNiBC compounds form in a structure closely related to RNi_2B_2C with an additional R-C layer in between the N_2 - B_2 layers. As a result, the body centered tetragonal structure of RNi_2B_2C (space group *I4/mmm)* changes into a simple tetragonal structure (*P4/nmm*) for RNiBC. RNiBC are metallic but superconductivity is observed only for the nonmagnetic Y and Lu but at very low temperatures. Band structure calculations predict a reduced density of states (DOS) at Fermi level for LuNiBC. We have carried out ^{11}B NMR studies on YNiBC to probe the spin dynamics and compared it with the YNi_2B_2C system. ^{11}B NMR was performed at a fixed frequency of 36 MHz using a conventional phase coherent pulse spectrometer. The nuclear spin-lattice relaxation was measured by the saturation recovery method. The spectral line-width was found to remain constant in the temperature range 5-300K. The magnitude of Knight shift at room temperature was smaller (about 0.02%) compared to 0.04% reported for YNi_2B_2C attributable to weak coupling of Boron nuclei in YNiBC system. The Knight shift shows a near linear dependence with temperature down to 5K. The spin lattice relaxation time is very large at 300K (~ 1500ms) and it increases monotonously with decreasing temperature. The temperature dependence of T1T is very weak. This contrasts with large enhancement of 1/T1T with decreasing temperature in YNi_2B_2C system.

L14-06. Vortex Lattice Domain Formation in the Type-II/1 Superconductor Niobium. *A. Backs*[2,1], T. Reimann[2,1], M. Schulz[2,1], V. Pipich[3], P. Böni[1] and S. Muehlbauer[2] *1. Physik-Department E21, Technische Universität München, Garching, Germany; 2. Heinz Maier-Leibnitz Zentrum (MLZ), Technische Universität München, Garching, Germany; 3. Jülich Centre for Neutron Science, Forschungszentrum Jülich GmbH, Garching, Germany*

Besides the well-known properties of vortex lattices (VL) of type II superconductors, type II/1 compounds exhibit the intermediate mixed state (IMS), where VL domains and Meissner domains coexist, caused by an attractive component of the VL interaction [1]. Despite some early work in the 1970s, the IMS bulk properties remain elusive. No detailed theoretical model for the IMS exists. Primary obstacles are the inapplicability of most standard models of superconductivity in the IMS regime, as well as demagnetization effects and vortex pinning which play a crucial role. We have readdressed the IMS in bulk niobium by combining several neutron based techniques [2],[3]. Using high resolution small angle scattering, we characterized the VL crystallography, yielding details on the VL spacing and correlation lengths. For the larger IMS domains, we used ultra-small angle scattering to investigate the domain size and morphology. Additionally, neutron grating interferometry was used to obtain spatially resolved information about the distribution of IMS domains over the sample. Focusing on several length scales, we have studied the formation of the IMS domains, following a field cooling protocol: We find that while the macroscopic magnetic properties remain homogeneous, vortices are gradually rearranged microscopically from a uniform VL to inhomogeneous domains. This transition also is seen in high resolution measurements of the VL correlation lengths. Surprisingly, this process takes place at temperatures below the macroscopic freezing transition of the VL. Upon lowering the temperature, the IMS domains form at a preferred length scale which remains nearly unchanged with temperature. Our study sheds new light on the detailed formation of the IMS domains otherwise inaccessible directly in bulk superconductors.

The primitive cubic (space group *Pm*-3*n*; a = 9.676 Å) $Yb_3Rh_4Sn_{13}$ type of structure was discovered in the early 1980s by Remeika and co-workers [1]. Investigating RE-Pt-Ge and Al-Pd-B systems we discovered numerous distorted variants of this simple structure type: cubic $Ca_3Pt_4Ge_{13}$ with doubled unit cell parameter, [3] rhombohedral high temperature (HT) $Y_3Pt_4Ge_{13}$, [4] tetragonal $Yb_3Pt_4Ge_{13}$ [3], monoclinic low temperature (LT) $Y_3Pt_4Ge_{13}$ [5] and even cubic anti-type $AlPd_{15}B_7$ (where larger Al atoms occupy the positions of smaller Rh in prototype) [6]. Noncentrosymmetric LT-$Y_3Pt_4Ge_{13}$ becomes superconducting below T_c = 4.5 K. Thermodynamic properties as well as transport measurements were conducted down to 0.4 K. The upper critical field B_{c2} is 3.8 T. The data are consistent with a single energy gap with *s*-wave symmetry for the superconducting phase. Body-centred $AlPd_{15}B_7$ is a strongly coupled BCS superconductors with T_c = 2.9 K and B_{c2} = 500 mT.

The spinel oxides display a wide range of interesting physical properties, e.g. exotic magnetism; charge ordering, and superconductivity. Among them, spinel lithium titanates have attracted a lot of attention, indeed, as a superconductor ($LiTi_2O_4$), but recently also as an electrode material for Li-ion batteries ($Li_4Ti_5O_{12}$). For $LiTi_2O_4$ the spinel crystal structure is face-centered cubic, the Li and Ti atoms are located at the positions of tetrahedral and octahedral sites, respectively. As a superconductor $LiTi_2O_4$ displays a transition temperature T_C » 12 K. Band calculations reveal that conduction band states are mainly coming from Ti-3*d* bands which lie about 2–3 eV above the O-2*p* bands. This is very different from other transition-metal spinels where *d* and *p* orbitals hybridize and cross the Fermi level. A complication with this material has been that the superconducting properties were shown to be very sensitive to the exact composition, Li vs. Ti ratio. For the present study high-quality stoichiometric $LiTi_2O_4$ epitaxial films were deposited by a pulsed laser deposition (PLD) technique using $MgAl_2O_4$ (111) substrates [1]. Substrate was chosen because spinel $MgAl_2O_4$ has a 4% smaller in-plane lattice constant than $LiTi_2O_4$. This is interesting since for other similar systems a compressive strain has been shown to increase the transition temperature. Magnetization measurements show that our present $LiTi_2O_4$ films display a very sharp superconducting transition at T_C = 12 K. We have performed a low-energy muon spin rotation studies of such $LiTi_2O_4$ films [2]. By employing both vortex and Meissner state protocols we extracted the superconducting properties including the London penetration depth as a function of both temperature and depth profile. For temperatures $T < T_c$ = 11.5 K the superconducting order parameter is well fitted to a two-fluid model. This research is funded by Swedish Foundation for Strategic Research (SSF) within the Swedish national graduate school in neutron scattering (SwedNess) and the Swedish Research Council (VR) through a neutron project grant (BIFROST, Dnr. 2016-06955).

L15-01. Magnetoresistance and Hall resistivity in $MoTe_2$ under pressure. *S. Lee*[1], T. Park[2], S. Jung[2], S. Kim[2], J. Kim[2], S. Cho[1], S. Kim[1], J. Jang[1] and J. Rhee[1] *1. Sungkyunkwan University, Suwon, The Republic of Korea; 2. Physics, Sungkyunkwan University, Suwon, The Republic of Korea*

We report magnetoresistance (MR) and Hall resistivity in the candidate Weyl semimetal $MoTe_2$ under pressure. At ambient pressure, $MoTe_2$ shows a structural phase transition from T'- to T_d-phase below 210 K. When subjected to pressure, the transition temperature decreases and the T_d-phase is completely suppressed at 1.4 GPa (=P_c). The pressure dependence of the MR and Hall resistivity in the T_d-phase is successfully explained up to P_c by using the two-band model, where compensation between the hole and electron carriers contributes to the large MR at the low-temperature and low–pressure regime. In the T'-phase ($P>P_c$), however, field-dependent transport properties cannot be explained by the two-band model, requiring four-band analysis. Ab initio calculation shows that the electronic band structure of $MoTe_2$ sharply changes at the critical pressure where the T_d- to T'-phase transition occurs. These results establish a comprehensive T-P phase diagram and suggest that the anomalously large MR in $MoTe_2$ is due to perfect electron-hole compensation.

L15-02. Shubnikov–de Haas oscillations in Weyl semimetal WTe_2 measured up to 56 T. *S. Onishi*[1], R. Jha[1], A. Miyake[2], R. Higashinaka[1], T. Matsuda[1], M. Tokunaga[2] and Y. Aoki[1] *1. Department of Physics, Tokyo Metropolitan University, Hachioji, Japan; 2. The Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan*

The observation of an extremely large and nonsaturating magnetoresistance (MR) in semimetallic WTe_2 [1] has attracted considerable attention in recent years. Angle-resolved photoemission spectroscopy confirmed the existence of Fermi arcs connecting Weyl points of opposite chirality [2], suggesting that WTe_2 is a type-II Weyl semimetal. In order to investigate the electronic state further through the Shubnikov–de Haas (SdH) oscillations, we have measured MR up to 56 T using a pulse magnet at the International MegaGauss Science Laboratory of the Institute for Solid State Physics, the University of Tokyo. We used high-quality single crystals grown by Te flux method. The residual resistivity ratio higher than 1300 confirms that the sample quality is in the highest class [3]. Figure 1 shows MR measured at 1.4 K. Clear large-amplitude SdH oscillations appear on the almost H^2 dependent background. No saturating behavior of the background suggests nearly perfect carrier compensation. Figure 2 displays the FFT spectrum of the MR data shown in Fig. 1. We can identify four distinct intrinsic frequencies (F^1 - F^4) corresponding to two pairs of electrons and hole pockets, in agreement with the reported results [4]. We have found that the intensity of the peak appearing at F^5 =255 T, which is close to F^1 +F^4, is largely enhanced in high applied fields. This feature agrees well with the interpretation that this peak originates from a magnetic breakdown effect [4]. We discuss the field dependence of the cyclotron mass, which has been determined for each branch using the temperature dependence of the peak intensity.

L15-03. Anisotropic electrical resistivity of Weyl semimetal WTe_2. *R. Jha*[1], S. Onishi[1], R. Higashinaka[1], T. Matsuda[1], R.A. Ribeiro[2] and Y. Aoki[1] *1. Department of Physics, Tokyo Metropolitan University, Hachioji, 192-0397, Japan; 2. CCNH, Universidade Federal do ABC, Santo Andre, 09210-580, Brazil*

The layered transition-metal dichalcogenide WTe_2 has attracted considerable attention in recent years since highly-mobile carriers exhibit extremely large nonsaturating magnetoresistance in this material [1]. The observation of Fermi arcs by ARPES [2] has confirmed that WTe_2 is a type-II Weyl semimetal in agreement with theoretical predictions [3]. Because of the layered crystal structure, anisotropic behaviors are expected in physical properties. In the electronic transport properties, however, the anisotropy has not been fully studied yet due to the difficulty caused by the thin plate shape of grown single crystals. Here we report measurements of the electrical resistivity with the flowing current for all the crystallographic directions using high quality single crystals. A large residual resistance ratio RRR=ρ(300K)/ρ(2K) larger than 1300, which is in the highest class in the literature, and Shubnikov-de Hass quantum oscillations appearing in non-saturated magnetoresistance

(MR%=1.5×10^6 at 2 K in 9 T) attest to the high quality of the single crystals [4]. The temperature dependences of the normalized resistivity ρ(T)/ρ(300K) for all the three directions and their ratio, ρ_b/ρ_a and ρ_c/ρ_a, are shown in Fig. 1 and Fig. 2, respectively. It has been found that the anisotropy in ρ develops with decreasing temperature and finally reach $\rho_a:\rho_b:\rho_c \approx 1:28:1400$ at 2 K. For the current flowing perpendicular to the layer structure (I//c), ρ is the largest. Even for I//c, the electronic conduction is found to be metallic. At low temperatures below 20 K, ρ(T) exhibits a power law temperature dependence expressed as $\rho(T)=\rho_0 + AT^n$ with n=2.65-2.9 for all the current directions. The deviation from n=2 (n=5) expected for electron-electron (electron-phonon) scattering suggests an unconventional inelastic scattering mechanism working in WTe_2.

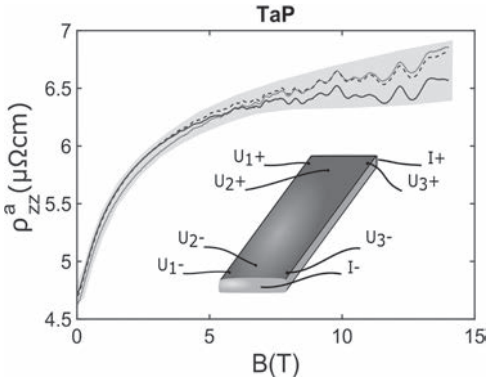
L15-04. Longitudinal magneto-thermopower in Weyl semimetal TaAs. A. Rudenko[1], J. Juraszek[1] and *T. Cichorek*[1] *1. Institute of Low Temperature and Structure Research, Polish Academy of Sciences, Wroclaw, Poland*



A topologically non-trivial semimetal hosts Weyl fermions as quasiparticle excitations and features Fermi arcs on its surface. One of the most intriguing property of a Weyl semimetal is chirality imbalance in parallel electric and magnetic fields. Tantalum arsenide TaAs, crystallizing in the tetragonal structure, is the first realization of a Weyl semimetal in a stoichiometric and inversion-breaking material [1]. Single crystals of TaAs were grown by means of an Iodine-vapor transport method. The thermopower *S* was measured along the [100], [111], and [531] directions with magnetic field $B \leq 7$ T parallel to a temperature gradient of about 10%. The voltage signal was measured at $T = 1.8$ and 4.2 K during a *B*-sweep rate of 1 Gs/s. Fairly well symmetric $S(B)$ curves were obtained for the opposite field orientations, indicative of a negligible contribution of the off-diagonal components. At $T = 1.8$ K, the zero-field thermopower of TaAs amounts for about 200 and 150 nV/K along the [100] and [111] direction, respectively. These values change to 300 and 80 nV/K at $T = 4.2$ K. While the thermopower of TaAs along the main crystallographic directions remains positive in finite fields, $S(B)$ dependencies are strongly anisotropic with an essentially featureless behavior along [111] and a complicated, strongly *T*-dependent variation along [100]. At $T = 1.8$ K, the $S(B)$ data rise by a factor of ~2.5 with increasing *B* up to 1 T where oscillatory behavior becomes evident. Amplitudes of quantum oscillations rapidly increase with field and are as large as 800 nV/K around $B = 7$ T. At $T = 4.2$ K, thermoelectric oscillations are very weak and thus, a negative contribution to $S(B)$ is unmasked for $B > 1$ T. Even more remarkable is an $S(B)$ variation along [531], the configuration determined by a crystal morphology. In addition to features along [100], the thermopower of TaAs experiences a very sharp drop from 400 nV/K to -500 nV/K at $IBI = 4.75$ T, i.e., much below the quantum limit of ~10 T [2]. All these observations for Weyl semimetal TaAs show an unusual field-induced anisotropy of $S(B)$ that appears to be associated with the chiral anomaly. Work supported by the Polish National Science Centre within Grant No. 2016/21/B/ST3/02361.

L15-05. Absence of the chiral anomaly – the longitudinal magnetoresistance in TaAs-type Weyl metals. *M. Naumann*[1,2], F. Arnold[1], K. Modic[1], M. Bachmann[1], P.J. Moll[1], B. Ramshaw[3], V. Süß[1], M. Schmidt[1] and E. Hassinger[1,2] *1. Max-Planck-Institut for Chemical Physics of Solids, Dresden, Germany; 2. Physik Departement, Technische Universität München, 85748 Garching, Germany; 3. Laboratory of Atomic and Solid State Physics, Cornell University, Ithaca, NY, United States*

The discovery of materials with linear dispersion close to the Fermi level such as Dirac and Weyl semimetals has offered the possibility to study relativistic fermions in solid state systems. Such physics was previously only accessible in high energy physics [1]. One consequence of Dirac or Weyl fermions is the 'axial' or 'chiral anomaly'. This effect manifests itself as a reduction of the longitudinal magnetoresistance, when the electric and magnetic fields are aligned. While the characteristic magnetoresistance was quickly discovered in TaAs [2], alternative scenarios leading to the same magnetoresistance behavior were proposed [3,4]. It was demonstrated in the 70s that in a configuration where the B-field and current are parallel, strong current inhomogeneities (i. e. current jetting) give rise to the same magnetoresistance behavior [5]. This imposes severe challenges on the accurate experimental determination of the longitudinal magnetoresistance. In this study we determine the intrinsic longitudinal magnetoresistance in order to check the existence of a chiral anomaly in the TaAs family (TaAs, TaP, NbAs, NbP) of Weyl semimetals. Here, the high mobility makes the aforementioned current inhomogeneities particularly pronounced. We reduced current jetting effects as much as possible by trying to achieve a homogeneous current injection and increasing the aspect ratio of our samples. For this, we employ soldered current contacts as well as FIB microstructured samples. Up to three voltage contact pairs distributed over the width of the samples are used to probe the current distribution. Furthermore, we complement this experimental study with extensive finite-difference simulations of the voltage distribution within the samples. The results show that there is an absence of the negative longitudinal magnetoresistance in the studied materials regardless of the existence of Weyl fermions at the Fermi level (see figure).

We report band structure calculations, angle-resolved photoemission spectroscopy (ARPES) and magnetotransport measurements on high quality RX (R = Pr, Sm; X=Sb, Bi) single crystals. By elemental substitution, the spin-orbit coupling (SOC), magnetism and electronic correlations can be tuned. We find that all the materials display a very large non-saturating magnetoresistance but the topological properties change. ARPES measurements see a crossover from a trivial topology in PrSb, which is consistent with the Landau index analysis from high field magnetotransport measurements[1], to a non-trivial topology in RBi, where bulk band inversions and topological surface states are revealed[2,3]. Meanwhile in SmSb, an anomalous discrepancy is found in the temperature dependence of quantum oscillation amplitudes between the SdH and dHvA effects at low temperature. Our results suggest that by varying the spin-orbit coupling, the band topology of the rare-earth monopnictides can be tuned through a topological phase transition from a trivial to non-trivial state.

School of Chemistry, The University of Sydney, Sydney, NSW, Australia; 6. Neutron Group, NSRRC, Hsinchu, Taiwan*

$Fe_4Si_2Sn_7O_{16}$ is a new Fe based kagome system with a frustration index $f = \theta/T_N \approx 3.6$. The system consists of alternate stacking of kagome layer formed from edge sharing FeO_6 ($S = 2$) and SnO_6 octahedra and stannate layer FeSn6 ($S = 0$) [1]. $Fe_4Si_2Sn_7O_{16}$ is a classical homologue to a famous kagome compound herbertsmithite, a suitable candidate to realize quantum spin liquid phase. $^{(119/117)}$Sn nuclear magnetic resonance (NMR) allows us to selectively probe the static and dynamic magnetism of different Fe-layers. While the NMR shift vs bulk susceptibility plot follows linear relation down to10 K confirming the absence of foreign phases in the vicinity of kagome plane, the considerable line broadening below 10 K [fig. 1] indicates the distribution of static internal field. NMR spin-lattice ($1/T_1$) reflects the slowing down of spin fluctuations at ~ 2.5 K associated with the static magnetism of Fe-kagome layer. Further, zero field (ZF) μSR spectra shows the presence of two relaxation channels with faster and slower relaxation rates (λ_1, λ_2) respectively. A peak in both λ_1, λ_2 is observed in the temperature range of 2-3 K associated with the static magnetism. λ_1 exhibits a constant value below 1.5 K down to 20 mK indicating the presence of dynamic magnetism in the system [fig. 2]. In AC-susceptibility, we observe a frequency dependent broad maximum which shifts from 3.5 K to 6 K (1.1 KHz). At low temperature below 0.15 K an upturn in the AC-susceptibility is evidenced. The combination of AC susceptibility and μSR data suggests the presence of two relevant energy scales in $Fe_4Si_2Sn_7O_{16}$.

NMR spectra of $Fe_4Si_2Sn_7O_{16}$ measured at 54 MHz. The broadening of spectra below 10 K reflects the formation of static ordering in the system.

Relaxation rate (λ) shows the persistence spin dynamics below 1.5 K.

L16-02. A Novel Kagome-like Cu_2OSO_4 Crystal. *V.Y. Favre*[1], G.S. Tucker[1], I. Zivkovic[1] and H.M. Ronnow[1] *1. Physics, EPFL, Lausanne, Switzerland*

Low dimensional, geometrically frustrated antiferromagnets are at the forefront of condensed matter research. Materials with antiferromagnetic interactions between spins on a triangle lattice inherently exhibit large frustration between similar energy ground states giving rise to new behavior. Recently, experimental and theoretical results indicate that the kagome lattice can host spin liquid state[1]. The kagome lattice is an enticing example; however, various effects hinder its highly degenerate spin-liquid state and instead select a single magnetic ground state. It is therefore worthwhile to study nearly-kagomé compounds in an attempt to discern what precisely stops formation of the spin-liquid. We successfully synthesised a novel kagome like single crystal of Cu_2OSO_4 and report here its magnetism, since it has strong antiferromagnetic interactions on a diamond-kagomé lattice. Very little was previously published and the only experiment performed were always done on powder samples[2]. We studied the magnetic excitation spectra of Cu_2OSO_4 in order to help elucidate the mechanisms by which spin-liquid formation fails. We will present thermodynamic measurements, such as specific heat and magnetisation results, as well as neutron and X-ray diffraction data. We also recently measured large swaths of reciprocal lattice, energy space thanks to time of flight, inelastic neutron scattering. We will thus present the latest results analysed on this compound and their interpretation, in order to explain why the spin-liquid state fails to form in this compound and understand better criteria for spin liquid formation on the kagome lattice.

The discovery of thermoelectricity and superconductivity in NaxCoO2 (NCO) has aroused a high interest for this triangular lattice compound from both scientific and industrial communities. The physical properties of NCO are governed by the number of conduction electrons in the CoO2 layers, but also by the Coulomb potential (U) caused by ordered Na ions. Upon Na doping, a plethora of magnetic and electronic ground states emerges leading to a very rich phase diagram. However, the present phase diagram is controversial. For specific Na concentration (e.g. x =0.5 - 0.7 or x =0.85), samples grown by the solid-state reaction method display inhomogeneous Na content, which makes the identification of the magnetic properties as function of doping challenging [1]. To obtain a better understanding of the magnetic and electronic states, we have performed muons spin rotation (μ+SR) experiments on NCO samples prepared by the electrochemical reaction technique [2]. This growth method gives a succession of single- and order-phases for various Na concentrations with high accuracy and reproducibility. Based on our μ+SR results, we re-establish a new NCO magnetic phase diagram [3] for $0.5 \leq x \leq 0.85$. In comparison with the original NCO phase diagram, we show that the antiferromagnetic order state only appears at specific Na doping (x = 0.72, 0.76 and 0.79), the ground state of Na0.85CoO2 is unlikely a random spin-glass, and the x range for the AF phase of Na0.5CoO2 is refined. Our results demonstrate the importance of having high quality samples to understand the intrinsic magnetic and electronic properties of materials. This research is funded by the Swedish Research Council (VR) through a Starting Grant (Dnr. 2017-05078), the Swedish Foundation for Strategic Research (SSF) within the Swedish national graduate school in neutron scattering (SwedNess), Marie. Technische Universität Dresden, Dresden, Germany; 7. University of Auckland, Auckland, New Zealand*

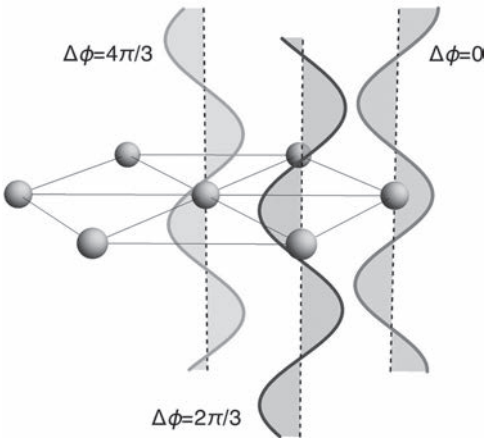
Bulk Characterisation, neutron powder diffraction and muon spin relaxation data has been used to determine the magnetic ground state of $Fe_4Si_2Sn_7O_{16}$. The only magnetic ions in this compound are layers of high-spin Fe^{2+} (d^6, S=2) arranged on a perfectly hexagonal kagome lattice. Below T_N=3.5 K, the spins partially order into canted antiferromagnetic chains, separated by paramagnetic spins on the geometrically frustrated lattice. An upturn in the low temperature a.c. susceptibility suggests a second transition occurs at 150 mK, however a static long-range ordered phase has not been observed down to 50mK in muon and neutron experiments. The magnetic structure determination was published recently in Phys. Rev. B 96, 180410 (2017) by us.

Proposed magnetic model from neutron refinement at 1.5K.



L16-05. Emergent Ising criticality in a magnetization process of the frustrated FM/AF spin-1/2 Heisenberg square bilayer.
K. Karlova[1] and J. Strecka[2] *1. Department of Theoretical Physics and Astrophysics, P. J. Safarik University in Kosice, Kosice, Slovakia; 2. P. J. Safarik University, Kosice, Slovakia*

Low-temperature magnetization curves and thermodynamics of the spin-1/2 Heisenberg square bilayer with the antiferromagnetic intra-dimer interaction and ferromagnetic inter-dimer interaction is investigated in a highly frustrated parameter region, where localized many-magnon eigenstates provide the most dominant contribution to a magnetothermodynamics. Low-energy states of the spin-1/2 Heisenberg square bilayer can be accordingly found from a mapping correspondence with the effective spin-1/2 Ising model on a square lattice. The description based on the effective Ising model implies that the spin-1/2 Heisenberg square bilayer displays in a zero-temperature magnetization curve discontinuous magnetization jump, which is reduced upon increasing of temperature until a continuous field-driven phase transition from the Ising universality class is reached at a certain critical temperature. The results obtained from Monte Carlo simulations of the effective Ising model are confronted with full exact diagonalization data for the Heisenberg triangular bilayer in order to corroborate these findings.

L16-06. Modulated magnetic order in a frustrated antiferromagnet.
H. Keen[1] and A. Hermann[1] *1. Physics and Astronomy, University of Edinburgh, Edinburgh, United Kingdom*

Actinide compounds exhibit strong electronic correlations that can lead to intriguing collective excitations such as unusual magnetism and heavy-fermion superconductivity [1]. These present challenges to modern electronic structure calculations. We present here density functional calculations on a prototypical actinide compound that combines frustrated magnetism on a triangular lattice with strong coupling along chains of magnetic atoms perpendicular to the plane of frustration. To account for on-site Coulomb repulsion we employ a general implementation of the DFT+U method with a Yukawa screening of the Coulomb interaction in the Slater integrals [2]. We analyse the Lindhard function obtained from the non-magnetic band structure to identify instabilities that can give rise to incommensurate moment modulations along the strongly coupled chains. We also extract exchange coupling parameters along the chains and within the triangular plane from a series of local moment arrangements, and use those in an effective local moment model to explore the potential formation of long-range modulated order.

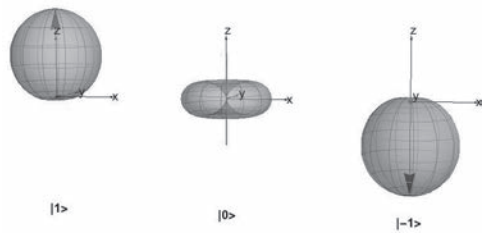
A frustrated arrangement of modulated chains.

L16-07. Magnetization plateaus of the spin-1/2 antiferromagnetic Heisenberg model on a square-kagome lattice with three nonequivalent exchange interactions. *K. Morita*[1] and T. Tohyama[1] *1. Tokyo University of Science, Katsushika, Japan*



Low-dimensional frustrated quantum spin systems give rise to novel quantum states such as quantum spin liquids and valence bond crystal states. The kagome lattice model is one of the best candidate with the novel quantum states. The square kagome lattice (SKL) is expected to have the quantum states because of having corner-sharing triangles similar to the kagome lattice. Very recently, a compound with the spin-1/2 SKL with three nonequivalent exchange interactions has been synthesized [1]. However, the SKL with the three nonequivalent exchange interactions has not been studied theoretically. Therefore, we investigate the phase diagrams and magnetization plateaus of the SKL using the exact diagonalization method [2]. We find four plateaus, one of which is a new 2/3 plateau that spontaneously breaks four-fold rotational symmetry by quantum fluctuations. The new plateau appears only in the case of three nonequivalent bonds. These four plateaus exist in wide regions for the exchange interactions. We propose that the newly discovered compound exhibits the plateaus.

L16-08. Equation of Motion for Spin-1 Magnets with Applications to Nematic Phases. *K. Remund*[1], R. Pohle[1], J. Romhanyi[1] and N. Shannon[1] *1. Theory of Quantum Matter Unit, Okinawa Institute of Science and Technology, Onna-son, Japan*

Frustrated magnetism is known to give rise to exotic and interesting phenomena, such as spin liquids or spin nematics, aside of conventional ordering. Obtaining a tool that would be able to describe the time evolution for both systems that do order conventionally and unconventionally, like a spin nematic, would therefore turn out to be very useful. We develop a simple equation of motion for calculating the dynamics of spin-1 magnets. This method is based on a treatment of quantum spin-1 moments in the group U(3) and allows to treat both dipolar and quadrupolar moments on an equal basis. Thanks to the embedding into the algebra u(3), the equations of motion take a very simple form. By applying this method to the ordered phases of the spin-1 bilinear biquadratic model on a triangular lattice, we can make explicit comparison with already published flavour-wave theory results [1,2]. We show that the method can be applied to the 3-sublattice anti-ferromagnetic phase of the spin-1 bilinear biquadratic model on the triangular lattice and predict spin-1 and spin-2 excitations dispersion relations, which could be compared directly with experiments. Moreover, the equation of motion is easy to integrate numerically, thanks to its simple form, and could be applied to study the dynamics of spin liquids and topological defects in spin nematics.

L16-09. A low-energy effective model for the S=1/2 Kagome-triangular-strip Heisenberg model. *K. Okunishi*[1], Y. Onozato[1] and K. Seki[1] *1. Physics, Niigata University, Niigata, Japan*

Recently, the cuboc order, which is a novel non-coplanar classical spin order observed for the Kagome-triangular lattice classical Heisenberg model, attracts much interest, while exotic ground states of S=1/2 Kagome lattice antiferromagnets have been extensively studied. In this work, we investigate effects of one-dimensional quantum fluctuations for the S=1/2 Kagome-triangular-strip Heisenberg model, which is defined as an S=1/2 Heisenberg model with ferromagnetic interactions between nearest neighboring (NN) spins on the Kagome lattice and antiferromagnetic interactions for triangles of next-nearest-neighboring (NNN) spins. Using the exact diagonalization, we show that spin-singlet ground sate appears, although the NN couplings are ferromagnetic. This is because the ferromagnetic Kagome couplings also cause frustration in connection with the antiferromagnetic NNN couplings of the triangle structure embedded in the Kagome lattice. Then, an essential point is that the doubly degenerating doublets of the unit triangle specified by the effective chirality (or parity) degrees of freedom play an essential role in formation of the spin-singlet ground state. By constructing the effective spin-chirality model based on the degenerating perturbation theory, we further discuss the role of the chirality in the ground state of the Kagome-triangular strip model.

L16-10. Z_6 Parafermions in the Triangular Lattice Ising Antiferromagnet. *G. Rakala*[2], S. Shivam[1] and K. Damle[2] *1. IIT Bombay, Mumbai, India; 2. Dept. of Theoretical Physics, Tata Institute of Fundamental Research, Mumbai, India*

Monte Carlo simulations using recently developed cluster algorithms for frustrated lattices have been used to study the phase diagram of a triangular lattice Ising antiferromagnet with ferromagnetic next-nearest and next-next-nearest interactions. In the presence of ferromagnetic next-nearest neighbour couplings, the spins form a three-sublattice ordered $\sqrt{3} \times \sqrt{3}$ state at low temperatures which melts via a two-step melting process. The intermediate power-law three-sublattice ordered phase is characterized by a temperature dependent exponent $\eta(T) \in (1/9,1/4)$. In this work, we study the nature of the melting transition as a function of increasing ferromagnetic next-next-nearest coupling strength. We find that the two-step melting pinches off, via a multicritical point M_c into a weak first-order transition which separates the ferrimagnetic three-sublattice ordered state and a paramagnet. We numerically obtain estimates of the multicritical exponents at M_c which are shown to match within error bars with the values for the Z_6 self-dual parafermionic conformal field theory constructed by Zamolodchikov and Fateev. We also demonstrate that the same exponents govern the behaviour of the corresponding pinch-off point of the power-law phase in the generalized six-state clock model studied by J. Cardy. Our results on the generalized clock model provide strong evidence in favour of a conjecture of Dorey et. al. identifying this pinch-off point with the Z_6 parafermionic conformal field theory.

L16-11. Ground state with nonzero spontaneous magnetization of the two-dimensional spin-1/2 Heisenberg antiferromagnet with frustration. *T. Sakai*[1,2] and H. Nakano[1] *1. Graduate School of Material Science, University of Hyogo, Ako, Japan; 2. QST SPring-8, Sayo, Japan*

The spin-1/2 Heisenberg antiferromagnet on a two-dimensional lattice with frustration is studied by the numerical-diagonalization method based on the Lanczos algorithm. The lattice is composed of square pyramids; each pyramid shares corners of its bottom face with its neighboring pyramids. The system includes two kinds of bonds of antiferromagnetic interaction: one is a bond between two spins at shared corners in a pyramid and the other is a bond connecting the spin at a shared corner in a pyramid and the spin at the top vertex of the pyramid. When the latter interaction is sufficiently larger than the former one, the model is reduced to the Lieb-lattice antiferromagnet. It is rigorously proven that, in the Lieb-lattice antiferromagnet, the Lieb-Mattis-type ferrimagnetic ground state is realized. This ferrimagnetic ground state in the Lieb-lattice antiferromagnet shows spontaneous magnetization with one-third magnitude of the saturation magnetization. When the former interaction is sufficiently larger than the latter one, on the other hand, the model is reduced to the square-lattice antiferromagnet accompanied by isolated spins at the top vertex of the pyramid. When the ratio of the former interaction divided by the latter one is controlled, we examine the behavior of the ground state and find various types of the ground state in the viewpoint of whether or not the state shows the spontaneous magnetization and of how the magnitude of the spontaneous magnetization changes if it appears. As the former interaction is increased, the spontaneous magnetization gradually decreases from the magnetization of the Lieb-Mattis-type ferrimagnetic ground state and disappears once. When the former interaction is further increased, another ground state with nonzero spontaneous magnetization appears but the spontaneous magnetization disappears again. Our diagonalization calculations clarify such complex phenomena in the present frustrated magnets.

L16-12. Frustration vs. magnetic Ordering in the Cr-Triangles of $TiCrIr_{2-x}Os_xB_2$. *J. Scheifers*[1], M. Küpers[2] and B.P. Fokwa[1] *1. Department of Chemistry, University of California, Riverside, Riverside, CA, United States; 2. IAC, RWTH Aachen University, Aachen, Germany*

We successfully synthesized and characterized a series of new compounds $TiCrIr_{2-x}Os_xB_2$ ($0 \le x \le 2$). These compounds crystallize in the hexagonal, non-centrosymmetric $Ti_{1+x}Os_{2-x}RuB_2$-type structure (space group *P2m*, no. 189, *h*P18) [1]. Like many other transition metal-rich borides, the atoms are arranged in layers perpendicular to c including a trigonal planar B_4 unit and triangles of magnetically active Cr [2]. Those two building blocks interact strongly as they are stacked alternatingly along the c-axis. We observed how the substitution of Ir by the electron poor Os affects the structure and studied the changes in the magnetic properties that occur for a decreasing Ir concentration. Magnetization measurements (H = 0.1 T) down to 2K revealed predominating antiferromagnetic interactions (Weiss constant Θ = - 755 K) and ferrimagnetic ordering below T_c = 275 K for $TiCrIr_2B_2$ (with 34 valence electrons). Despite the perfect triangular arrangement of the magnetically active Cr-atoms, the data suggest only weak frustration (f = 2.75) [3]. We show that the substitution of Ir by Os is accompanied by significant changes in the lattice parameters. The substitution causes a decrease in the aspect ratio resulting in smaller intra-triangle Cr-Cr but longer inter-triangle Cr-Cr distances for increasing x. If one of the Ir-atoms is replaced by Os leading to $TiCrIrOsB_2$ (x = 1, 33 valence electrons), the Weiss constant decreases drastically (Θ = - 1900 K) and no magnetic ordering is detected down to 2K resulting in f ≥ 1000. For the quaternary Os-containing compounds $TiCrOs_2B_2$ (x = 2, 32 valence electrons), the Weiss constant Θ is below -4000 K in the absence of magnetic ordering down to 2K. Such a high degree of frustration makes the two Os-containing compounds candidates for a spin liquid [4], but further measurements at lower temperatures are necessary.

The magnetic ordering is suppressed while frustration increases drastically with x in the boride series $TiCrIr_{2-x}Os_xB_2$ containing Cr-triangles (red) and trigonal planar B_4 units (green).

L16-13. Heat Capacity of the Highly Frustrated Triangulated Kagome Lattice $Cu_9X_2(cpa)_6$. *W.M. Farmer*[1], S.F. Skinner[1] and L.W. Ter Haar[1] *1. Chemistry, University of West Florida, Pensacola, FL, United States*

New physical property measurements on the tunable molecular magnet $Cu_9X_2(cpa)_6$, a metal organic framework (MOF) based on copper(II) and pentonic acid (henceforth CPA), suggest the framework could serve as a candidate for quantum spin liquids (QSLs) studies. The 2-D CPA framework has been previously described as a 'triangles-in-triangles' (TIT) Kagomé or triangulated-Kagomé-latttice (TKL) shown in Figure 1. [1] Theoretical studies [2] have attempted to describe the enigmatic ground state of this Kagomé Heisenberg antiferromagnet (KHAF), and chemical modifications to date have shown CPA an excellent candidate to expand this class of materials for studies concerning fundamental physics of frustrated spins, as well as applications based on the magnetocaloric effect (MCE) such as adiabatic demagnetization refrigeration (ADR). Of the chemical modifications investigated, intercalation of d- and f-metal ions into the voids of the framework (channels of 20 Å diameter) have offered an effective means of altering the magnetic properties of CPA. [3] To further elucidate structure-property relationships we report magnetic field dependent heat capacity of the CPA framework. Heat capacity in the range of 3.0K – 12K confirms the field independent nature of the spin lattice at higher temperatures and can be largely fit to a T^3 dependence. This is in agreement with magnetic susceptibility measurements in the temperature range 1.8 – 300 K, confirming that signature features of TKL magnetism persist, specifically: i) large negative Weiss constant (θ_{CW}); ii) absence of zero-field phase transition down to 1.8 K; iii) minimum in X_MT; iv) low temperature X_MT values increasingly divergent at low fields; and, v) field dependence of magnetization at low temperatures suggestive of intermediate plateaus, not saturation. Heat capacity studies in the temperature range 50 mK – 3.0 K in magnetic fields from 0T – 14T exhibit a field-induced phase transition that by extrapolation decreases to 0K in zero-field. These data produce a T-H phase diagram similar to Herbertsmithite [4], suggesting CPA is a candidate for further QSL studies. [5] Supported by NASA via grant #NASA-FSGC-11-NNX15-005.

L16-14. Ising versus Potts Criticality in Low-temperature Magneto-thermodynamics of a Frustrated Spin-1/2 Heisenberg Triangular Bilayer. *J. Strecka*[1], K. Karlova[2], V. Baliha[3] and O. Derzhko[3] *1. P. J. Safarik University, Kosice, Slovakia; 2. Department of theoretical physics and astrophysics, P. J. Safarik University in Kosice, Kosice, Slovakia; 3. Institute for Condensed Matter Physics, Lviv, Ukraine*

Low-temperature magnetization curves and thermodynamics of a frustrated spin-1/2 Heisenberg triangular bilayer with the antiferromagnetic intradimer interaction and either ferromagnetic or antiferromagnetic interdimer interaction are investigated in a highly frustrated parameter region, where localized many-magnon eigenstates provide the most dominant contribution to a magneto-thermodynamics. Low-energy states of the highly frustrated spin-1/2 Heisenberg triangular bilayer can be accordingly found from a mapping correspondence with the effective spin-1/2 Ising model on a triangular lattice. The description based on the effective Ising model implies that the spin-1/2 Heisenberg triangular bilayer with the ferromagnetic inter-dimer coupling displays in a zero-temperature magnetization curve discontinuous magnetization jump, which is reduced upon increasing of temperature until a continuous field-driven phase transition from the Ising universality class is reached at a certain critical temperature. The spin-1/2 Heisenberg triangular bilayer with the antiferromagnetic interdimer coupling contrarily exhibits multistep magnetization curve with intermediate plateaus at one-third and two-thirds of the saturation magnetization, whereas discontinuous magnetization jumps observable at zero temperature change to continuous field-driven phase transitions from the universality class of three-state Potts model at sufficiently low temperatures. The results obtained from Monte Carlo simulations of the effective Ising model are confronted with full exact diagonalization data for the Heisenberg triangular bilayer in order to corroborate these findings.

M1-01. Position Dependence of Spin Scattering in Lateral Spin Valves. *G. Stefanou*[1], J. Adams[1], K.A. Moran[1], M. Rosamond[2], M. Ali[1], G. Burnell[1] and B. Hickey[3] *1. Physics and Astronomy, University of Leeds, Leeds, United Kingdom; 2. Electronic and Electrical Engineering, University of Leeds, Leeds, United Kingdom; 3. Physics and Astronomy, University of Leeds, Leeds, United Kingdom*

The unexpected decrease of the spin signal (ΔRs) at low temperatures (T) has been shown to be the result of Kondo scattering from magnetic impurities in the normal metal (NM) channel of a lateral spin valve (LSV)[i]. Studies have mostly focused on the origin of these and suggested that they either pre-exist[ii] in the source material or get incorporated in the NM channel during its deposition[iii]. There remain interesting details in the nature of the scattering that have yet to be understood. A prediction[iv] was made in 2012 that the spin Hall angle could be enhanced by choosing the *position* at which impurities were embedded in a sample. Here we varied the position of impurities to study their effect on the transport of a pure spin current. Our LSVs consist of two 250 Å thick Py electrodes bridged by a 1000 Å thick Ag channel that, for the different sets of devices, was interrupted at different vertical positions by a dusting layer of 0.5 Å of Fe. The devices were grown by a combination of electron beam and thermal evaporation in a chamber with a base pressure of 10^{-10} mbar and the thickness of the Fe layer was controlled with the use of a mechanical shutter and a very low deposition rate (< 0.1 Å/s). Clean Ag channels do not have a Kondo minimum in the low T resistivity but after the addition of 0.5 Å of Fe, the resistivity has a clear upturn with a minimum of (7.4 ± 0.2) K (figure 1a). Furthermore, spin transport measurements revealed that the T dependence of the ΔRs as well as the T where the spin signal peaks, is strongly correlated to *the position* of the doping layer (figure 1b).

M1-02. Size-Dependent Elliott-Yafet Phonon Spin Relaxation in Al Non-Local Spin Valves. *J.D. Watts*[1,2], J. Batley[2], J.P. Hoch[3,2], L. O'Brien[4,2], J.S. Jeong[2], A. Mkhoyan[2], N.A. Rabideau[2], P.A. Crowell[1] and C. Leighton[2] *1. Physics and Astronomy, University of Minnesota, Minneapolis, MN, United States; 2. Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, MN, United States; 3. Materials Department, University of California, Santa Barbara, CA, United States; 4. Department of Physics, University of Liverpool, Liverpool, United Kingdom*

The Elliott-Yafet (EY) theory of spin relaxation is widely acknowledged to describe the relationship between spin relaxation rate τ_s^{-1} and elastic scattering rate τ_e^{-1} in metals, *via* $\tau_s^{-1} = \beta^{-1} \tau_e^{-1}$. However, even considering only phonon scattering, quantitative understanding of β is limited [1], particularly in the limit as thickness $t_N \rightarrow 0$. Considering other scattering sources, generalized EY relaxation with a different β for each defect has been postulated [2], but quantitative understanding of β values for important scattering sources remains elusive. Remarkably, our recent work on Cu-based non-local spin valves (NLSVs) showed that spin relaxation of EY form applies even to Kondo relaxation at *magnetic* impurities, where the EY parameter, $\beta_K = 3/2$, is much smaller than for phonons, $\beta_{ph} \approx 1{,}000$ [3,4]. In this work, we separately determine β for phonons and nonmagnetic defects in Al, using NLSVs with a significantly expanded range of Al t_N from 8 to 300 nm. As shown in Fig. 1, this allows us to test EY relaxation over a wide range of residual resistivity, ρ_0, scattering rate, and spin diffusion length, λ_N. We find defect spin relaxation is dominated by grain boundaries, with $\beta_{GB} \approx 4{,}500$ across the entire t_N range. Phonon spin relaxation, however, exhibits a very surprising t_N dependence (Fig. 2). Whereas for thick Al, $t_N \geq 100$ nm, we find $\beta_{ph} \approx 18{,}000$, as t_N is reduced to 25 nm β_{ph} is reduced by as much as a factor of 6. We have thus discovered an unanticipated finite-size effect in β_{ph}. Potential origins will be discussed, considering thickness, grain size, lattice softening in Debye temperature, phonon density-of-states, and spin relaxation hot spots on the Al Fermi surface. Our results not only highlight new physics in spin relaxation in Al, but are also directly relevant to applications, as $\beta_{ph}(t_N)$ dramatically impacts predicted $\lambda_N(t_N)$ scaling, which is critical for devices [5].

Materials Science and Engineering, Korea University, Seoul, The Republic of Korea; 4. School of Electrical and Computer Engineering, Purdue University, West Lafayette, IN, United States

In a strong Rashba system, the charge current induces a separation of the electrochemical potentials of spin-up and spin-down electrons. In this work, using an InAs HEMT (high electron mobility transistor) structure [1], we observed three resistance states exhibiting unequal antiparallel states ($R_{AP(1)} > R_P > R_{AP(2)}$) in a multi-terminal spin valve device. For a device with two NiFe patterns as ferromagnetic electrodes (FMs) and two non-magnetic electrodes (NMs) [2, 3], the current is applied from one NM to the other NM and the voltage is measured between the FMs as shown in Fig. 1a. In this experiment, the bias charge current creates spin splitting which leads to two separate electrochemical potentials and therefore the voltage probe detects the difference between the two potentiometric voltages. In the reciprocal configuration shown in Fig. 1b, two FMs were used as current terminals while the separate NMs were used as voltage terminals. Depending on the orientation of magnetization, FM current injectors shift the relative positions of the electrochemical potentials in the regions where $I = 0$ generating the three state signal. As show in Fig. 1, we observed identical magnitude of three states with opposite sign which are well explained by Onsager reciprocity relation. These result are strikingly different from conventional spin valve or magnetic tunneling junction devices, which have only two resistance states corresponding to parallel and antiparallel alignments of the ferromagnetic contacts. The observed signals are extremely long range in nature (up to few mm) without any degradation up to room temperature. This result is a clear demonstration of both direct (conversion of charge to spin) and indirect (conversion of spin to charge) effects in a quantum well system with a Rashba spin splitting.

M1-04. Out of plane superconducting Nb/Cu/Ni/Cu/Co triplet spin-valves. *Z. Feng*[1] and M. Blamire[1] *1. Material Sciences and Metallurgy, University of Cambridge, Cambridge, United Kingdom*

Superconducting spin electronics is of great potential for devices with faster performance and greater energy efficiency than current semiconductor architectures [1]. Recently, a more complete synergy between superconductivity and spintronics has been made possible through the discovery of mechanisms for the generation of odd frequency spin-triplet Cooper pairs at S/F interfaces[2,3]. The critical temperature of a triplet superconducting spin valve depends on the effectiveness of the conversion of singlet pairs in the superconductor into triplet pairs which can penetrate a ferromagnet and so drive a strong proximity effect. Here, we compare the out-of plane field dependence of the critical temperature in transition metal triplet spin valves with otherwise equivalent samples in which the singlet-triplet converting spin mixer ferromagnet layer is omitted. We report a significant field-dependent difference between the samples, which is consistent with a magnetisation orientation dependent spin mixing efficiency in the spin valve[4].

M1-05. Magnon auto-oscillation in domain walls. *N. Nishida*[1], T. Hache[1,2], P. Arekapudi[2], A.A. Awad[3], O. Hellwig[1,2], J. Fassbender[1] and H. Schultheiss[1] *1. Institute of Ion Beam Physics and Materials Research, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany; 2. Physics, Chemnitz University of Technology, Chemnitz, Germany; 3. Physics Department, Gothenburg University, Gothenburg, Sweden*

Magnons are the fundamental excitations in magnetic materials, and they can transport angular momentum without actual charge currents. Therefore, they are attractive for applications in energy efficient information technology, offering high operating frequencies up to the THz range. Here we present a novel scheme for magnon generation using spin currents and domain walls. When a charge current is applied to a bilayer consisting of a heavy metal and a ferromagnetic metal, the spin currents originating from the spin Hall effect in the heavy metal apply a spin transfer torque on the magnetization of the ferromagnetic layer. This allows driving efficiently auto-oscillations of magnetization [1]. We focused on domain walls as local nano magnon channels [2]. Since it is possible to move domain walls by electrical currents [3], domain walls are attractive for nano-sized reprogrammable circuits. A 370 nm wide boomerang structure was fabricated from a Pt/CoFeB bilayer (Fig.1). The sample was magnetized by applying an external magnetic field *H*. After the saturation, the external magnetic field was set to 0 Oe, and a dc current was applied to the sample. The magnon intensity at the apex of the boomerang structure was measured by Brillouin light scattering microscopy [4]. Figure 2 shows the dc current dependency of the magnon spectrum on the remanent state. Magnons were detected for currents between 3.6 mA and 4.5 mA, while no magnons were observed for any negative dc currents. A domain wall is generated at the apex for the remanent state because of the shape anisotropy of the boomerang structure. We succeeded to excite magnons under zero magnetic field due to the auto-oscillation of the magnetization by spin transfer torque.

M1-06. Effect of the electron-phonon scattering on the spin diffusion length and its effect on the spin mixing conductance at NiFe/Pt bilayers. *C.A. Gonzalez-Fuentes*[1] *1. Physics, UTFSM, Valparaiso, Chile*

We have performed broadband ferromagnetic resonance spectroscopy on a series of thin films made of NiFe (20nm) /Pt(t) bilayers with *t* varying from 1.5 to 10 nm, where a pure spin current is injected from NiFe to Pt. From the fitting of Gilbert's damping constant (α) variation vs *t* following the model of Tserkovniak et al. [1], we obtain both the spin diffusion length (λ_{sd}) of the Pt and the effective spin mixing conductance (g_{eff}) of the NiFe/Pt interface, at different temperatures varying from 50 to 300K. The results are shown in Figures 1 and 2. Both λ_{sd} and g_{eff} follow a $(C_0/(1+C_1T))^{1/2}$ law, where C_0 and C_1 are fitting constants. We found that these results are consistent the classic spin pumping model [1], combined with the assumptions that electron-phonon collision is the dominant momentum scattering mechanism in Pt, the spin current backflow is significative and the spin-flip time is roughly independent of temperature. These outcomes are in agreement with other recent ones employing different methodologies from this work [2,3]. Overall, our results provide a solid experimental evidence for understanding the disentanglement of the electron-phonon interaction from other spin-conserving momentum scattering mechanisms in Pt and its indirect influence on λ_{sd}.

Advances in thin-film deposition have enabled materials to be rationally designed at the atomic-scale to stabilize emergent phenomena. In particular, ferroelectric and ferromagnetic phases can be strongly modified in the ultra-thin film geometry due to applied strain from the substrate, size effects of the material and electronic charges induced at the interfaces. Here we construct superlattices based on the prototypical multiferroic material, $BiFeO_3$, and an adjacent dielectric layer. The strong depolarizing fields at the interface modifies the strongly crystallographic structure of the $BiFeO_3$ layer, driving the material from the ferroelectric ground state into a distinct antiferroelectric-antiferromagnetic state that has not been previously observed previously in (doped) $BiFeO_3$ films. Moreover, neutron diffraction results demonstrate an unusual magnetic field dependence of the expected G-type antiferromagnetic structure coincident with this antiferroelectric instability. Combined our results demonstrate the ability of interfacial electric fields to modify the crystal symmetry and in turn the electronic and magnetic properties of multiferroic materials.

M2-02. Fe/$BaTiO_3$ nanoengineering towards a switchable spin state multiferroic. C.d. Amorim[1], *J.S. Amaral*[1], J. Gonçalves[1] and V.S. Amaral[1] *1. Physics Department & CICECO, University of Aveiro, Aveiro, Portugal*

Novel multiferroic (magnetic/electric) memory devices are technologically promising due to their expected low energy, non-volatile, high speed, and high density performances. The main challenge on the development of high-performance multiferroics (MFs) for these device applications is achieving a high sensitivity of the measured magnetization value on a change of applied electrical field. Indeed, most MFs act through changes in exchange bias, weak ferromagnetism, spin-lattice interaction, magnetic anisotropy, with typical low changes in magnetization. Additionally, most of these potential coupling mechanisms occur below room temperature, limiting their technological appeal. In this work, we explore a novel magnetoelectric coupling mechanism, modeling an Fe monolayer sandwiched between a ferroelectric material that undergoes an electrical field-induced structural phase transition, in this case $BaTiO_3$. Our DFT calculations show that all atoms of the Fe monolayer change from a high spin state ($2\mu_B$/Fe) to a null spin state, fully coupled to the substrate's structure. This on-off magnetization switching occurs due to changes in the local environment of the Fe atoms, inducing changes to the crystalline field and therefore quenching their magnetic moment. As the field induced transition in $BaTiO_3$ occurs above room-temperature, a device based on this proposed concept would operate in temperature ranges adequate to consumer electronics. We propose a simple memory device based on the multiferroic coupling mechanism here presented.

State Key Lab of Magnetism, Institute of Physics, Chinese Academy of Sciences, Beijing, China*

With the fast development of information storage, exploiting new concepts for dense, fast, and non-volatile random access memory with low energy consumption is a significant and challenging task. To realize this goal, electric-field control of magnetism is crucial. In this regard, multiferroic heterostructures, composed of ferromagnetic (FM) and ferroelectric (FE) materials, are very unique and have attracted much attention [1,2]. We have carried out electric-field control of magnetism in different FM/FE heterostructures in our previous work [3,4]. For the first time, we reported a large and nonvolatile *loop-like* bipolar-electric-field-controlled magnetization at room temperature in $Co_{40}Fe_{40}B_{20}$(/$Pb(Mg_{1/3}Nb_{2/3})_{0.7}Ti_{0.3}O_3$(001) (CoFeB/PMN-PT(001)) and it was proposed that the unusual nonvolatile behavior is related to the 109° FE domain switching in PMN-PT[4]. So far, CoFeB/PMN-PT(001) has been one of the widely studied multiferroic heterostructures. However, one important issue remains to be solved — the magnetic responses of CoFeB corresponding to the different FE domain switching of PMN-PT(001) under bipolar electric fields. We patterned the CoFeB film of CoFeB/PMN-PT(001) into separated and small non-interacting discs whose size is comparable to the FE domains [5]. By using spatially-resolved techniques including magneto-optic Kerr effect (MOKE) and scanning electron microscopy with polarization analysis (SEMPA) with in situ electric fields, we uncover the distinct behaviors of electric-field control of magnetism corresponding to the different types of FE domain switching in CoFeB mesoscopic discs on PMN-PT(001). For the first time, the 90° rotation of the magnetic easy axis induced by 109° FE domain switching was observed. In addition, for the first time, we systematically studied the variations of effective magnetic anisotropy field with electric field and correlated them with the proposed different FE domain switching paths. This work is significant for understanding the distinct magnetic responses to different FE domain switching, and shedding light on the path of FE domain switching.

M2-04. The multicaloric effect in multiferroics: recent developments and future directions. *M.M. Vopson*[1] *1. University of Portsmouth, Portsmouth, United Kingdom*

The surge of interest in multiferroic materials over the past 15 years has been driven by their fascinating properties, as well as their huge suitability for technological applications. In fact, multiferroics have the potential to deliver a new wave of technological advances and economic impact, comparable to the silicon industrial revolution of the 1950s. The possible applications of multiferroic materials cover a wide range of topics and technologies including sensors, microwave devices, energy harvesting, photovoltaic technologies, data storage recording technologies, random access multi-state memories and magneto-electric opto-electronic modulators, as detailed in a recently published review article [1]. Recently, a new application of multiferroic materials to solid-state refrigeration has been made possible by the 2012 discovery of a new solid-state caloric effect, the multicaloric effect [2,3]. In this lecture, the theory behind the solid-state refrigeration based on the multicaloric effect is presented in detail, with emphasis on possible improvements of the existing solid-state refrigeration technology, material synthesis challenges that must be further addressed and the benefits of composite multiferroics to the practical implementation of this new effect.

M3-01. Magnetic sensor system for real-time marine animals monitoring. *A. Kaidarova*[1], M.A. Karimi[1], S. Amara[1], A. Shamim[1], N. Geraldi[2], C.M. Duarte[2] and J. Kosel[1] *1. CEMSE, King Abdullah University of Science and Technology (KAUST), Thuwal, Saudi Arabia; 2. RSRC, King Abdullah University of Science and Technology (KAUST), Thuwal, Saudi Arabia*

The quantification of marine animals' interactions with their environment, as well as their physiological state, physical performance, and behavior, is crucial for conservation efforts and understanding the functioning of ecosystems [1-3]. The existing biologging devices use heavy, bulky and rigid systems, which considerably limit the diagnostic capacities of underwater animal monitoring and the range of species they can be applied to. To accommodate animal's comfort and free movement, we have developed flexible, lightweight and minimally intrusive composite magnets and combined them with a magnetic tunnel junction sensor as well as a miniaturized wireless data acquisition system. The fabrication process of NdFeB-PDMS composite magnets is highly versatile concerning the shape and size of the magnets (Fig. 1a). The dramatic weight reduction (>10 times) of composite magnets poses less burden to the animals' movements. The stray magnetic field of the composite magnets is sensed by the magnetic sensor integrated into a PCB and wirelessly transmitted using Bluetooth low energy communication standard to a smart phone and dashboard server (Fig. 1b). The sensor signals are downloaded and stored from the server onto a laptop for further processing and analysis (Fig.1c). To survive in the harsh environment of seawater and increase the underwater deployment life-time composite magnets are coated with 2 μm of Parylene C, which provides corrosion resistance, flexibility, and enhanced biocompatibility, while surface passivation of the PCB is achieved with 5μm of Parylene C. The system has successfully implemented for real-time monitoring across a range of animals and motion components, including the head and leg movements of crabs, giant turtles, and sea turtles, indicating its potential for novel and affordable marine monitoring applications.

M3-02. Self-Powered Magneto-Acoustic Tag for Aquatic Animal Tracking. *A. Almansouri*[1], M. Khan[1], H. Al Malki[1], K. Salama[1] and J. Kosel[1] *1. CEMSE, King Abdullah University of Science and Technology (KAUST), Thuwal, Saudi Arabia*

Over the past three decades, passive acoustic telemetry has significantly helped marine scientist to study and understand the spatial ecology, migratory behaviors, and mortality rates of aquatic animals [1][2]. A popular telemetry system consists of two components: an acoustic transmitter tag attached to an aquatic animal and powered by a small battery; and a stationary station that receives the acoustic signals from the tagged animal and determines its location [2][3]. The added weight and increased size of the tag introduced by the battery within the tag limits the implementation of this system to relatively large animals [4][5]. Moreover, these tags have a limited operational time determined by the lifetime of the battery. This work proposes a novel self-powered magneto-acoustic tag for animal tracking. This is achieved by utilizing the low-frequency motions of the animals to excite high frequency acoustic pulses. Figure 1 shows a schematic of the design, which consists of a soft magnetic membrane (amorphous metal) surrounding a cylindrical permanent magnet (NdFeB). The stray field of the magnet produces an attractive force between the membrane and the poles of the magnet. In this bistable system, the soft magnetic membrane will always bend toward one of the two poles. The magnet is attached to a flexible substrate (PDMS-based Si elastomer) that oscillates efficiently at low frequencies that are typically induced by the motion of the tagged animal. Due to the magnet's oscillation, the membrane gets alternatingly attracted to the opposite poles, thereby oscillating at its resonant frequency, which is designed to generate a high-frequency pulse. Figure 2 shows the measurement results of the self-powered magneto-acoustic tag. The test is accomplished by placing a microphone 5 cm away from a tag. Once the device is excited by the motion, the device generates an acoustic pulse with a broad spectrum. The acoustic pulse has a resonant frequency of 3.45 kHz, a peak amplitude of -56.4 dBV, and a 37.6 dB SNR.

M3-03. Comprehensive Model of the ΔE Effect for Sensor Applications. *B. Spetzler*[1], P. Durdaut[2], A. Kittmann[1], R. Knöchel[2], M. Höft[2], E. Quandt[1] and F. Faupel[1] *1. Materials Science, Christian-Albrechts-University Kiel, Kiel, Germany; 2. Institute of Electrical Engineering and Information Technology, Christian-Albrechts-University Kiel, Kiel, Germany*

Investigations into the ΔE effect of magnetoelastic materials have recently revealed the exciting promise of detecting low frequency and small amplitude magnetic fields [1]. Typical approaches are based on electrically exciting a resonator via application of a voltage to a magnetoelectric composite structure with soft magnetic properties [2]. In these structures, the sensor properties and performance result from a complex interplay of magnetic, mechanical and electrical properties. In this work, we close the gap between application and theory currently found in the literature. A comprehensive magneto-electromechanical model is to be presented that considers the interaction of magnetic, mechanical and electrical properties. The model is completely anisotropic and permits the choice of different magnetic configuration, any type of sensor deformation and device geometry. With the model, we discuss the ΔE effect in general and its application in diverse types of electrically excited sensors, including the most common types such as cantilevers or bulk resonators, but also surface acoustic wave devices [3]. The model provides detailed understanding of the general limits of the sensitivity which arise from using the ΔE effect as the sensing principle. The discussion includes the influence of global magnetic energy contributions, especially the magnetostrictive self-energy. Realistic detection limits are predicted in combination with a noise equivalent model. The simulations are validated with experimental data using different sensor designs and magnetic layers including exchange biased multilayers. All in all, new insights are gained on the ΔE effect and its use in magnetic field sensing. Finally, adapted sensor designs are presented, which could make measurements of biomagnetic fields of the human heart possible.

M3-04. Josephson Parametric Amplification of Circuit Quantum Electrodynamic Signals. *N.J. Stevenson*[1,2], K.P. O'Brien[1,2] and I. Siddiqi[1,2] *1. Quantum Nanoelectronics Laboratory, Department of Physics, University of California, Berkeley, Berkeley, CA, United States; 2. Center for Quantum Coherent Science, University of California, Berkeley, Berkeley, CA, United States*

The development of quantum-coherent systems using superconducting circuits has been driven by potential high-impact applications in cryptanalysis, data processing, chemical and biological simulations, and fundamental research into quantum mechanics. Accurate measurement of the circuit quantum electrodynamic signals of qubits is imperative to realizing scalable quantum architectures and reliably transferring quantum information. Previous work develops the Lumped Josephson Parametric Amplifier (LJPA), a nonlinear microwave resonator consisting of two Josephson junctions in a a superconducting quantum interference device (SQUID) loop shunted by a capacitance, achieving quantum-limited noise and signal gains in excess of 30 dB. In this work, it is shown that the application of a bias current to vary the magnetic flux through the SQUID changes the LJPA resonance frequency between 4 and 8 GHz through a magnetic flux quantum, and resonance modes of photons in the printed circuit board and chip casing are demonstrated to be dependent on chip and casing design. The phase diagram of the LJPA as a function of frequency is obtained, displaying the nonlinear dynamics of the system. Signal gain is measured at the amplification mode for varying signal powers, exploring the region of input signal over which the device is useful. Noise power is measured as a function of frequency with strong improvement at the amplification frequency. These results contribute to improving the accuracy of quantum measurements of qubits, providing improved knowledge of physical parameters and opening the door to implementation of more complex quantum algorithms. With ongoing experimental progress extending qubit lifetimes, improving readout, and implementing increasingly complex algorithms, and theoretical work suggesting applications in information processing, simulations, and fundamental research, it is hoped that the presented results may be of widespread value.

M3-05. Ferromagnetic resonance in a low damping ferrimagnet probed with circularly and linearly polarized soft X-rays. *C. Klewe*[2], S. Emori[1], P. Shafer[2], B.A. Gray[4], H. Jeon[4,3], B.M. Howe[4] and E. Arenholz[2] *1. Department of Physics, Virginia Tech, Blacksburg, VA, United States; 2. Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA, United States; 3. Wright State University, Dayton, OH, United States; 4. Materials and Manufacturing Directorate, Air Force Research Lab, Wright Patterson Air Force Base, OH, United States*

Advances of high frequency devices as tunable elements for communications, filters, and magnetic sensors, have prompted the search for high performance magnetic oscillator materials. In particular the generation and control of spin currents from resonant RF excitations of magnetic moments in these structures offers huge potential for progress in these fields. Yet, to enable the detailed investigation of spin excitations in complex material systems and multilayer structures sensitivity to individual resonators is imperative. Ferromagnetic resonance detected with cicularly polarized X-rays, i.e. X-ray detected ferromagnetic resonace (XFMR), is a powerful tool to study the magnetodynamic properties of complex ferromagnetic materials and multilayers by combining the element specificity and the sensitivity to both lattice sites and valence states of X-ray magnetic circular dichroism (XMCD) with the capabilities of ferromagnetic resonance (FMR). This technique has proven to enable new experimental opportunities, e.g. resolving the precessions in different layers in multilayer structures [1], directly observing spin currents [2], and disentangling the precession of different elements and valence states in complex materials [3]. Yet, FMR using dynamic XMCD is limited to the observation of magnetic precessions in ferromagnetically ordered systems and does not allow to access the intensively studied field of antiferromagnet based structures. Here, we present the first experimental studies towards using x-ray magnetic linear dichroism (XMLD) (see Fig.1) to study dynamics in magnetic systems starting with low damping $Ni_{0.65}Zn_{0.3}{}_5Al_{0.8}Fe_{1.2}O_4$ (NZAFO) [4]. By utilizing the sensitivity of XMLD to the spin *axis* rather than the spin *direction*, it is possible to expand the capabilities of conventional X-ray detected magnetic resonance towards the study of antiferromagnetic systems. Our results conceptually prove the feasibility of technique on a ferrimagnetic system and illustrate the potential of dynamic XMLD studies for a wide range of systems.

M3-06. Novel Ultra-wide Band (10 MHz- 26 GHz) Permeability Measurements System for Magnetic Films. *Y. Chen*[1], X. Wang[2], H. Chen[2], Y. Gao[1] and N. Sun[2] *1. Winchester Technologies, Burlington, MA, United States; 2. Electrical and Computer Engineering, Northeastern University, Boston, MA, United States*

Magnetic materials are the necessary parts of the modern rf components. The demand for higher communication speed, such as in the upcoming 5G network, requires higher operation frequency [1]. Permeability measurements provide a basis for the design and characterization of magnetic materials and the development of RF devices. Conventional broadband permeameters use a vector network analyzer (VNA), and a pick-up coil or an electric short [2,3] or a broadband transmission line [4,6] for magnetically exciting the materials under test. The bandwidth of pick-up coil is limited to several hundred MHz. Transmission-lines [4-6] are widely used for broadband permeameters. However, the transmission-line type permeameters are noisy in the frequency range below 100MHz due to the low inductance. Permeability measurements have been limited to 9GHz or below [2-7]. In addition, all these permeameters based on VNA are expensive, and not reliable in measuring thin films or materials with low permeability because of the low signal to noise ratio (SNR). In this article, we demonstrate a new type of permeameter for ultra-wideband permeability measurements with significantly enhanced SNR without using a VNA. The measurement system employs a field-modulation technology consisting of a microwave source, diode detector, lock-in amplifier, and electromagnet. As shown in Fig.1, we measured the complex permeability of a 50nm FeGaB film up to 22GHz and an ultra-thin 2nm NiFe film. This permeameter enables the characterization of the complex permeability between 10MHz-26GHz, as well as many other typical magnetic parameters including linewidth, saturation magnetization, effective anisotropy field, Gilbert damping, and inhomogeneous linewidth broadening. In addition, the new permeability measurement system shows 40 ~ 50dB higher SNR over other reported methods, as illustrated in Table I.

INVITED PAPER

8:30

M4-01. Resolving the Three-Dimensional Magnetic Configuration of Nanowire Arrays using Neutron Techniques. *A.J. Grutter*[1], K.L. Krycka[1], E. Tartakovskaya[2], J. Borchers[1], K. Reddy[4], E. Ortega[3], A. Ponce[3] and B. Stadler[4] *1. NIST Center for Neutron Research, National Institute of Standards and Technology, Gaithersburg, MD, United States; 2. Institute of Magnetism NAS Ukraine, Kiev, Ukraine; 3. Physics and Astronomy, University of Texas at San Antonio, San Antonio, TX, United States; 4. University of Minnesota, Minneapolis, MN, United States*

High density arrays of ferromagnetic nanowires are critical to realizing next-generation 3D spintronic technologies, such as spin transfer torque-based racetrack memory.[1-4] In particular, segmented or thickness modulated nanowires have emerged very recently as exciting routes towards magnetic memory.[5,6] To attain the anticipated densities, nanowires within the array must be in close proximity to each other. However, the effect of long range ordering interactions in closely packed nanowire arrays remains largely untested, and most theoretical treatments of 3D domain structures are based on non-interacting wires or continuum approximations. Neither of these assumptions are fully appropriate for close-packed segmented nanowire arrays in which the combination of intersegment and interwire coupling may result in the formation of long-range magnetic correlations. To address these challenges, we have recently used the unique capabilities of polarization analyzed small angle neutron scattering (PASANS)[7] to probe these Fe_xGa_{1-x}/Cu nanowire arrays, and here we present an exceptional three-dimensional picture of long-range magnetic ordering in these structures.[8] We studied hexagonal arrays of segmented magnetic nanowires with 35 nm diameter, 100 nm wire separation, and Fe_xGa_{1-x}/Cu thicknesses of 12 nm/5 nm. In these wires, competing interactions induce complex, long-range magnetic order including antiferromagnetic interwire stripe patterns, in-plane interwire ferromagnetism, and intrawire fan structures. The magnetic ordering was readily tunable through either the external field or the segment aspect ratio. Through modeling and theoretical calculations, we develop a framework for more accurately treating interwire magnetic interactions in high-density nanowire arrays. The theoretical work and PASANS observations suggest that large, well-aligned arrays of segmented nanowires possess a complex and highly-tunable, long-range magnetic domain structure which must be carefully considered in the design of nanowire-based devices.

M4-02. Magnetization Reversal in Individual Multisegmented [FeCo/Cu]$_n$ Nanowires as determined by Local Magnetooptic Kerr Effect Magnetometry. C. Bran[1], E.M. Palmero[1,2], J. Meier[1], J. Fernandez-Roldan[1], O. Chubykalo-Fesenko[1], R. Perez del Real[1] and *M. Vázquez*[1] *1. Instituto de Ciencia de Materiales de Madrid (CSIC), Madrid, Spain; 2. IMDEA, Madrid, Spain*

Multisegmented cylindrical magnetic nanowires, NW, are being proposed in nanotechnology applications as magnetoresistive reading heads, barcode units for security systems, specific tactile sensors, magnetoplasmonics, markers for Magnetic Resonance Imaging or biochemical selective functionalization of segments [1]. These applications require full understanding of the magnetization process which depend on the crystalline nature of magnetic segments and the shape characteristics (i.e. demagnetizing plus magnetostatic intersegments coupling) [2]. The objective has been to report on the magnetization process in individual multisegmented nanowires and particularly, on the influence of their segmented character through very sensitive Kerr effect magnetometry [3] and micromagnetic modeling. We address the particular case of individual [FeCo/Cu]$_n$ (FM/NM) nanowires electrochemically grown inside the pores of alumina templates with 130 nm diameter and 20 micron total length where the length of FeCo segments goes from 200 to 700 nm while that of Cu ones stays at 30 nm. Experimental studies on individual nanowires released from the templates were performed by magneto-optic longitudinal Kerr effect magnetometer (NanoMOKE^{TM}2) under maximum magnetic field of ±500 Oe applied from parallel to perpendicular to the nanowire axis every 15 degrees allowing us to determine the angular dependence of coercivity and remanence. The profile of the magnetic response along the nanowires was quantified through local MOKE hysteresis loops taken at different positions in steps of 1 micron along the nanowires length. Loops with few clear Barkhausen jumps can be identified at given applied fields at which the amplitude of reversed magnetization increases/decreases with the distance to the nanowire's end (see the figure) denoting the propagation of the remagnetization process. Micromagnetic simulations indicate that complex vortex structures form at the ends of magnetic segments to determine the switching mode in each segment, and reversal process propagates under inter-segments magnetostatic interaction.

M4-03. Micromagnetic evaluation of the dissipated heat in cylindrical magnetic nanowires. *O. Chubykalo-Fesenko*[1], J. Fernandez-Roldan[2], D. Serantes[3], R. Perez del Real[1] and M. Vázquez[4] *1. Insituto de Ciencia de Materiales de Madrid, Madrid, Spain; 2. Institute of Materials Science of Madrid (ICMM-CSIC), Madrid, Spain; 3. Universidade de Santiago de Compostela, Santiago de Compostela, Spain; 4. Instituto de Ciencia de Materiales de Madrid (CSIC), Madrid, Spain*

The ability of nanowires to heat under ac-field is an emerging application. In this respect cylindrical magnetic nanowires (NWs) have been suggested for hyperthermia applications in cancer treatment [1]. Similarly, the heat produced by magnetic nanowires can be used for water purification treatment or in catalysis [2]. The most important advantage for the use of NWs for the heat release with respect to more traditional heating by magnetic nanoparticles comes from their large shape anisotropy which is almost insensitive to their length. At the same time, the use of magnetic NWs for these applications requires understanding of heating mechanisms and optimization of material properties. In the present work, we theoretically evaluate the heat dissipated by a single magnetic NW, originated from the domain wall dynamics under the action of an AC-field. Particularly, our studies indicate that NWs with different types of domain walls (transverse o vortex) heat in different ac-field frequency intervals due to different domain wall mobility. We compare the Permalloy NWs (which demagnetize via the transverse wall propagation) with the Co fcc NWs whose reversal mode is via a vortex domain wall. The average hysteresis loop areas –which are proportional to the Specific Absorption Rate (SAR)– as a function of the field frequency have a pronounced maximum in the range 200MHz-1GHz. This heating frequency range corresponds to smaller values in Permalloy than in Co and the maximum heating frequency depends on the nanowire length. A simple model related to the nucleation and propagation time and domain wall velocity (higher for the vortex than for the transverse domain wall) is proposed to explain the non-monotonic SAR dependence on the frequency. Our results open the possibility of engineering the nanowire material and geometry in relation to the heating capability.

M4-04. Magnetization configurations and reversal of individual ferromagnetic nanotubes. *M. Poggio*[1] *1. Department of Physics, University of Basel, Basel, Switzerland*

Due to their high surface-to-volume ratio, equilibrium magnetization configurations and reversal processes in magnetic nanostructures are often dominated by the influence of surface and edge domains. As a result, surface imperfections and roughness can determine configurations and impede a controllable, reproducible, and fast reversal process. Nanomagnets in flux-closure magnetization configurations, however, are less sensitive to the shape of boundaries, since these configurations close magnetic flux lines within the magnet. Ferromagnetic nanotubes (FNTs), because of their core-free geometry, should favor equilibrium flux-closure configurations with magnetization curling around their hollow axial core. In addition, reversal of a uniform axial magnetization in these structures has been predicted to nucleate and propagate through vortex domains. Here, we use a series of techniques to study the equilibrium magnetization configurations and reversal processes in individual FNTs. We show evidence for different types of remnant flux-closure configurations. We also observe the signatures of vortex-nucleated magnetization reversal in individual FNTs, as predicted by theory. These developments may have practical consequences in the design of nanomagnetic elements required for future high-density magnetic storage devices. Using x-ray magnetic circular dichroism photo-emission electron microscopy (XMCD-PEEM) we image the remnant configurations of FNTs[1]. The images provide direct evidence for flux-closure configurations, including a global vortex state. Furthermore, micromagnetic simulations predict and measurements confirm that vortex states can be programmed as the equilibrium remnant magnetization configurations by reducing the ratio of the NT's length and diameter. We then use scanning nanometer-scale superconducting quantum interference device (SQUID) to map the stray magnetic field produced by individual FNTs[2]. Using a SQUID-on-tip (SOT) sensor, we make images at a series of applied magnetic fields as the FNTs are led through magnetic reversal. Near zero field, sufficiently short FNTs show the signatures of equilibrium vortex states, including opposing and global vortex states. The global vortex state's non-zero stray field reveals a slight distortion in configuration, which simulations show is related to geometrical asymmetries. Finally, we use dynamic cantilever magnetometry (DCM) to observe the reversal of a uniform axial magnetization in individual FNTs[3]. This process has been predicted to nucleate and propagate through end vortices, whose distinctive signatures can be identified in our measurements. We show that these signatures depend on sample geometry as expected from numerical simulations. Control of the appearance and circu-

lation of these vortices is promising for the production of FNTs with both tailored and favorable reversal properties.

M5-01. Permanent Magnets Beyond Nd-Dy-Fe-B. *S. Hirosawa*[1]
1. Elements Strategy Initiative Center for Magnetic Materials, National Institute for Materials Science, Tsukuba, Japan

Permanent magnets beyond Nd-Dy-Fe-B are sought for because of the rapid growth of the market for highly efficient motors and generators, for which stronger permanent magnets are required. To realize such materials, materials science specifically developed for this end is required to clearly understand underlining physics ranging from atomistic coercivity theory to thermodynamics in multi-component permanent magnet alloys. Materials that can be chosen as a base compound for this aim are rare when compounds with smaller magnetization than Nd-Dy-Fe-B and insufficient anisotropy fields are ruled out, leaving only a few Fe-rich light rare earth compounds. Furthermore, sizable coercivity is yet to be developed in those materials including the $ThMn_{12}$-type $Sm(Fe\text{-}Co)_{12}$ compounds [1]. Recent progresses in the material science of permanent magnets as said above are profound in two fields; one is development of atomistic understanding of coercivity [2] and the other is thermodynamics of Nd-Fe-B permanent magnet materials [3]. Current advancements in these fields and recent progresses in materials developments toward permanent magnets beyond Nd-Dy-Fe-B basing upon those bases will be reported in this talk. M5-02. Effects of GaF_3/Ag co-doping on the magnetic properties and Nd-rich grain boundary structure of Nd-Fe-B sintered magnet. *K. Bae*[1], S. Lee[1], H. Kim[2], M. Lee[3] and T. Jang[3] *1. Dept. of Materials Science and Engineering, Korea University, Seoul, The Republic of Korea; 2. R&D Center of Jahwa Electronics Co. Ltd., Cheongwon, The Republic of Korea; 3. Dept. of Advanced Materials Engineering, Sunmoon University, Asan, The Republic of Korea*

The formation of a continuous and uniform non-magnetic Nd-rich grain boundary phases (GBPs) in Nd-Fe-B sintered magnets are the most important microstructural design factor to improve the coercivity (H_c) without reducing the remanence (B_r) [1-4]. Ag which dissolves only in the Nd-rich GBP promotes the continuity of the GBP and therefore the grain growth was properly inhibited [2, 3]. Although Ag promotes uniformity of the GBP microstructure undoubtedly, but there is a limit of the H_c enhancement because the ferromagnetic (FM) GBP having a high Fe content is formed [3]. Ga is known to able to suppress the formation of the FM GBP [4]. When the Ga is added as the GaF_3 powder, it can be easily distributed in the Nd-rich GBP. In this study, we reported that the effect of GaF_3/Ag co-doping on the GBP microstructure to solve the problems of the Ag-doped magnets and to improve the magnetic properties. The $Nd_{13.5}$-$Dy_{0.8}$-$Fe_{bal.}$-$B_{6.0}$-$M_{2.4}$ (at.%) powders were mixed with Ag (0.1 at.%) and GaF_3 (0.3 at.%) powders and sintered at 1070°C for 4hrs. The as-sintered magnets were annealed at 850 °C for 2h and then annealed at 530 °C and 500 °C for 2h, respectively. In the Ag-doped magnet, the FM amorphous-$Nd_{24.1}Fe_{55.8}Ag_{2.1}Cu_{1.8}O_{16.2}$ GBP was formed and it reduces the magnetic decoupling of the main phase. As a result, the H_c and B_r of the Ag-doped magnet were lower than those of the un-doped magnet as shown in Fig. 1. In contrast, in the GaF_3/Ag co-doped magnet, the H_c was increased (15.6 → 18.2 kOe) and the B_r was recovered (13.8 kG) (Fig. 1) because Ga suppressed the FM GBP and the Fe content (~70 at.%) of the main phase was restored due to the dissolution of Ga in the Ag-rich GBP. The average grain size of the GaF_3/Ag co-doped magnet (~7.13 μm) was smaller than those of the un-doped (~7.56 μm) and Ag-doped (~7.3 μm) magnets. In summary, the highest H_c was obtained without reducing the B_r in the GaF_3/Ag co-doped magnet because the Fe content of the main phase was restored, the FM GBPs were effectively suppressed, and the grain size was properly reduced. The effect of Ga on the structure and phase transformation of the GBPs will be discussed.

M5-03. Enhancing the Magnetic Properties of Pr-Co-B Melt-spun Ribbons via Microstructural Refinement. *C.I. Nlebedim*[1], M. Huang[2], L. Zhou[3] and M.J. Kramer[2] *1. Critical Materials Institute, Ames Laboratory, US Department of Energy, Ames, IA, United States; 2. Ames Laboratory, Iowa State University, Ames, IA, United States; 3. Ames Lab, Ames, IA, United States*

The focus of this talk is on improving magnetic properties of $Pr_2Co_{14}B$ by microstructural refinement. There is a need to improve the high temperature magnetic properties of Nd-Fe-B magnet, widely used in many technological

applications. A typical approach is to add Dy to the material which often results in improved high temperature performance. However, the forecasted long term criticality and high cost of Dy can become a major obstacle to the production of such Dy-enhanced $Nd_2Fe_{14}B$ magnets. Another approach is substitution of Co for Fe in $Nd_2Fe_{14}B$ which results in monotonic increase in Curie temperature (~310 C for $Nd_2Fe_{14}B$ and 720 C for $Nd_2Co_{14}B$) but $Nd_2Co_{14}B$ has low saturation magnetization and low anisotropy field. However by replacing Nd in $Nd_2Co_{14}B$ with Pr to form $Pr_2Co_{14}B$, anisotropy field can be significantly enhanced; 75 T at 4.2 K and 16 T at 300 K. Nevertheless $Pr_2Co_{14}B$ has a spin-reorientation temperature at 395 C which makes it impossible to take advantage of its high Curie temperature (720 C). Substituting some Fe for Co helps to suppress the spin-reorientation although at the expense of coercivity. This talk focuses on microstructural refinement approach for improving the coercivity of $Pr_2Co_{14}B$ with TiC. As a result, the decrease in coercivity due to Fe substitution can be limited while still avoiding the existence of the limiting spin-reorientation temperature. Acknowledgement This work was supported by the Critical Materials Institute, an Energy Innovation Hub funded by the U.S. Department of Energy, Office of Energy Efficiency and Renewable Energy, Advanced Manufacturing Office.

M5-04. Machine learning-based prediction of magnetization process in magnetic materials. *K. Ono*[1], H. Tsukahara[2], H. Hino[3], T. Ishikawa[1], K. Iwano[4] and C. Mitsumata[5] *1. KEK, Tsukuba, Japan; 2. High Energy Accelertaor Research Organization, Tsukuba, Japan; 3. University of Tsukuba, Tsukuba, Japan; 4. IMSS, KEK, Tsukuba, Japan; 5. NIMS, Tsukuba, Japan*

The magnetization process of magnetic materials has primal importance in the realization of high-performance magnetic materials for automotive application, since the magnetic properties, such as coercivity and remanent magnetization, are determined by the magnetization process. We have developed the large-scale micromagnetic simulation system for [1]. However, it is not realistic to use the large-scale simulation for material design, due to the long computational time and a large number of materials parameters to be optimized, such as a composition of the main phase, grain size, grain boundary phase, the tilt angle of the easy axis, the shape of grains, etc.. In this study, we established the machine learning-based efficient prediction method for the magnetization process in magnetic materials. We apply the method to the rare-earth permanent magnet. First, the magnetization process of a rare-earth permanent magnet is calculated by the large-scale micromagnetic simulator on IBM Blue Gene/Q supercomputer [1]. The $Nd_2Fe_{14}B$ hot-deformed magnet model with the size of 2048 nm × 2048 nm × 512 nm containing more than 3,000 disc-shaped grains with an average diameter and thickness of 160 nm and 32 nm, respectively were used. About 300 million calculation cells are used in the simulation. We applied a state-of-the-art database management system capable of high-speed data access, for the analysis of big dataset with 50 billion records from large-scale micromagnetic simulation to extract the information and using machine learning technique to establish the predictive model describing the magnetization process. We successfully predicted the magnetization curve of the magnet with more than 3,000 grains with an accuracy of 97% and also predict the material parameters which agree very well with the real magnet. The prediction takes less than 100 msec with a laptop computer. This machine learning-based prediction will accelerate the materials design and materials discovery.

M5-05. Using FORC to Understand the Microstructure-Micromagnetism Relationship in Supermagnets. *S.E. Ilse*[1], F. Groß[1], J. Gräfe[1] and E.J. Goering[1] *1. Modern Magnetic Systems, Max Planck Institute for Intelligent Systems, Stuttgart, Germany*

First-order-reversal-curve (FORC) diagrams yield a great variety of magnetic information such as coercive and interaction field distributions. We have recently shown that FORC diagrams can provide detailed information, as being just a magnetic fingerprint [1,2,3]. Muralidhar *et al.* demonstrated that FORC on MnBi can provide deep insight in the relationship between magnetism and microstructural properties, as grain size distributions and grain shapes. Hence, a more detailed understanding of micromagnetic mechanisms in hard magnets has been provided. Following these studies we investigated commercial bulk neodymium based permanent magnets and their FORC density relationship to microstructural properties. We systematically manipulated the microstructure of the samples by consecutive annealing (at different temperatures and intervals), and correlated their grain size distributions with FORC diagrams. All magnetic measurements as well as the annealing cycles were performed using a Quantum Design MPMS 3 VSM SQUID magnetometer. Microstructural information were obtained by SEM and Kerr microscope images. Our analysis of the grain size distributions showed that the grain sizes shift to higher diameters and the distribution broadens for longer annealing times, as expected due to Ostwald ripening of the grains. The room temperature FORC diagrams revealed that the coercive field distribution moves to slightly lower coercive fields for longer annealing durations and the width of this field distribution increases. Correlating the widths of grain size- and coercive field-distributions reveals a linear dependence, which enables us to draw conclusions about grain sizes directly from FORC measurements. The results agree with micromagnetic theory which states a dependence of the coercive field on the grain size, more precisely a decreasing of coercivity with increasing diameters [4]. Our results demonstrate the versatility of FORC investigations providing rich additional information, beyond magnetic fingerprints, enabling detailed understanding of coercive and interaction field distributions related to microstructure and grain size distributions.

Institute for Chemical Research, Kyoto University, Uji, Japan*

Antiferromagnetic spintronics is an emerging research field which aims to utilize antiferromagnets as core elements in spintronic devices. A central motivation toward this direction is that antiferromagnetic spin dynamics is expected to be much faster than ferromagnetic counterpart because antiferromagnets have higher resonance frequencies than ferromagnets. Recent theories indeed predicted faster dynamics of antiferromagnetic domain walls (DWs) than ferromagnetic DWs. However, experimental investigations of antiferromagnetic spin dynamics have remained unexplored mainly because of the immunity of antiferromagnets to magnetic fields. Furthermore, this immunity makes field-driven antiferromagnetic DW motion impossible despite rich physics of field-driven DW dynamics as proven in ferromagnetic DW studies. Here we show that fast field-driven antiferromagnetic spin dynamics is realized in ferrimagnets at the angular momentum compensation point T_A. Using rare-earth–3d-transition metal ferrimagnetic compounds where net magnetic moment is nonzero at T_A, the field-driven DW mobility remarkably enhances up to 20 km $s^{-1}T^{-1}$. The collective coordinate approach generalized for ferrimagnets and atomistic spin model simulations show that this remarkable enhancement is a consequence of antiferromagnetic spin dynamics at T_A. Our finding allows us to investigate the physics of antiferromagnetic spin dynamics and highlights the importance of tuning of the angular momentum compensation point of ferrimagnets, which could be a key towards ferrimagnetic spintronics [1].

Antiferromagnets have come into the spotlight [1, 2] as a promising material for spintronic devices because they exhibit the fast magnetic dynamics and the low susceptibility to magnetic field. Recently, it has been demonstrated that fast field-driven antiferromagnetic spin dynamics can be realized in ferrimagnets at the angular momentum compensation temperature T_A[3]. The peak of field-driven domain-wall (DW) speed at T_A naturally invokes curiosity about the effect of current on the DW motion across T_A. For this study, we prepared an amorphous ferrimagnetic GdFeCo film, where the detailed structure is 5 nm SiN/30 nm $Gd_{23.5}Fe_{66.9}Co_{9.6}$/100 nm SiN on the intrinsic Si substrate. Since this film lacks nonmagnetic heavy metal as a spin current source, the effect of current can be considered as spin transfer torques (STT), which arise from the exchange interaction between conduction electrons and localized electrons. The field-driven DW speed was measured under positive and negative bias current at various temperatures T. The DW speed difference Δv induced by a current density J is defined as $\Delta v=[v(+J)-v(-J)]/2$. Figure 1 shows $\Delta v/J$ as a function of T under several J. It shows that the effect of current gradually changes its sign across T_A and the asymmetry of $\Delta v/J$ with respect to T_A occurs. To explain such an intriguing observation, we developed a generalized model based on the collective coordinate approach including STT terms [3]. From the theory, the nonadiabatic and adiabatic STT as a function of T respectively constitutes the symmetric and the antisymmetric contribution with respect to T_A. The good agreement between theory and experiment supports that STT-driven DW dynamics is clarified in ferrimagnets at T_A. Details will be discussed in the presentation.

M6-03. Ultrafast and Ultrasmall: Domain Walls and Skyrmions in Compensated Ferrimagnetic Thin Films. *L.M. Caretta*[1], M. Mann[1], F. Buettner[1], K. Ueda[1], B. Pfau[2], C. Guenther[2], P. Hessing[2], A. Churikova[1], M. Schneider[2], D. Engel[2], C. Marcus[1], D. Bono[1], K. Bagschick[3], S. Eisebitt[2] and G. Beach[1] *1. Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, MA, United States; 2. Max-Born Institut, Berlin, Germany; 3. Deutsches Elektronen-Synchrotron (DESY), Hamburg, Germany*

Spintronics is a research field geared toward understanding and controlling spins on the nanoscale, enabling next generation data storage and manipulation. The technological and scientific challenge is to stabilize ultrasmall spin textures and to move them efficiently with ultrahigh velocities. Inspired by hard disk materials, research so far has focused on ferromagnetic materials, but these materials show fundamental limits for speed[1] and size[2], calling for radically different ideas. Here, we demonstrate by direct imaging that compensated ferrimagnets are not affected by these limits. Near angular momentum compensation (T_A), the spins align with the magnetic field without any precession and a driving force immediately leads to acceleration in the direction of force[3,4]. This makes all presently known forms of spin texture motion (DWs and skyrmions) extremely efficient near T_A. While the dynamics depend on T_A,the magnetization compensation (T_M) is important for the statics of spin textures. Near T_M stray fields become negligible and spin textures are stabilized by the competition of exchange, anisotropy, and Dzyaloshinskii-Moriya interaction DMI, i.e., the very strong and short range interactions. Thus, materials with reduced stray fields can sustain zero field skyrmions with less than 10 nm in diameter at room temperature[2]. Using ferrimagnetic Pt/GdCo/Ta with sizable DMI, we realize a record-high current-driven domain wall velocity of 1.3 km/s and room-temperature stable ~10 nm diameter skyrmions near T_A and T_M, respectively. Theoretically, we explain that our observations are universal and that high speed, high density spintronics devices can only be realized using materials where T_A and T_M are close together.

M6-04. Observation of Domains During Spin-Orbit Torque Induced Memristive Switching in Antiferromagnet/Ferromagnet Heterostructures. *A. Kurenkov*[1], M. Baumgartner[2], G. Sala[2], G. Krishnaswamy[2], F. Maccherozzi[3], S. Fukami[1,4] and H. Ohno[1,4] *1. RIEC, Tohoku University, Sendai, Japan; 2. ETH Zurich, Zurich, Switzerland; 3. Diamond Light Source Ltd, Didcot, United Kingdom; 4. Center for Spintronics Integrated Systems, Tohoku University, Sendai, Japan*

Efficient field-free spin-orbit torque (SOT) magnetization switching has been achieved by use of antiferromagnet (AFM)/ferromagnet (FM) structures [1]. In addition, use of AFM leads to analogue-like (memristive) switching with multiple nonvolatile states, allowing proof-of-concept demonstration of an artificial neural network [2]. Additional electrical measurements suggested that memristivity originates from separate switching of domains of 200 nm scale [3], which is nonsimultaneous due to EB variation. The described picture is different from conventional SOT switching in nonmagnet (NM)/FM heterostructures and its deeper understanding is important for fundamental research of SOT and EB as well as applications. Here we use X-ray magnetic circular dichroism which has proven to be insightful for SOT switching [4] and couple it to photoemission electron microscopy to image ferromagnetic domains of AFM/FM structure in intermediate memristive states. Stacks of Ta/ Pt/ PtMn/ $[Co/Ni]_2$/ Co/ MgO/ Ru were sputter-deposited and processed into 10-mm wide channels by photolithography and Ar ion milling. EB was induced by annealing at 300°C for 2 hr in the presence of 1.2 T magnetic field, collinear to the channel. The measurements allowed us to obtain domain patterns corresponding to different points of the hysteresis loop. In accordance with electrical estimations, the observed domain

structure is distinctly different from NM/FM cases and its feature size is of the order of 100 nm. We found that domains reproduce themselves in repetitive switching sequences and do not evolve between applications of switching pulses. Trains of pulses induce gradual switching by extending the domains. This is the first imagining of field-free SOT switching and it opens new avenue for achieving memristors and binary cells of desired properties. A portion of this work was supported by the ImPACT Program of CSTI and JST-OPERA and Grant 200020_172775 of Swiss National Science Foundation.

M6-05. Controlled current-driven bidirectional motion of trains of domain walls along a ferromagnetic strip. *L. Sánchez-Tejerina*[1], E. Martinez[2], V. Raposo[2] and Ó. Alejos[1] *1. Electricidad y Electrónica, Universidad de Valladolid, Valladolid, Spain; 2. Fisica Aplicada, Universidad de Salamanca, Salamanca, Spain*

Domain wall (DW) based magnetic memories, where each bit is represented by a single magnetic domain, have been repeatedly proposed as a way to implement faster and denser memory devices.[1] Multilayer systems where an ultrathin ferromagnetic layer is sandwiched between a heavy metal and an oxide constitute a solid base for their development, as these systems allow particularly fast and syncronous current-driven DW dynamics.[2-4] However, an essential prerequisite for their feasibility is the efficient and precise control of DW positions. The use of ferromagnetic layers with tailored magnetocrystalline anisotropy K_u favours the precise positioning of DWs by establishing a well-defined set of energy minima, where DWs are pinned in the absence of external stimuli.[5-7] Such tailored anisotropies have been achieved experimentally by ion-irradiation,[8] although the dinamics of trains of DWs in these systems by means of spin-currents has not been addressed yet, neither theoretically nor numerically. A particular case, here proposed, is the use of a triangular anisotropy profile defined by two extremal values, K_u^- and K_u^+ ($K_u^- < K_u^+$), as shown in Fig. 1(a). Our numerical study demostrates the feasibility of these current-driven devices and its bidirectional features. Figure 1(b) depicts the snapshots obtained by means of micromagnetic simulations of the precise displacement forth and back of two DWs, due to the application of two current pulses with opposite polarities. Simulations are carried out considering realistic conditions. A one-dimensional model (1DM), updated to take into account the anisotropy profile, was also developed. This 1DM, able to accurately reproduce the micromagnetic results, constitutes a helpful tool for a fine-tuning of the device perfomance.

M7-01. Probing spin-wave dynamics using single-spin magnetometry.
T. Van der Sar[1,2] 1. Quantum Nanoscience, Delft University of Technology, Delft, Netherlands; 2. Faculty of Applied Sciences, Harvard University, Cambridge, MA, United States

Spin waves are the elementary spin excitations of magnetic materials. They provide fundamental insight into magnetic order and may play a key role in future information processing. Spin waves can be probed via the magnetic fields they generate, but this requires a technique with high sensitivity and nanometer sensor-sample distances. I will present the use of the excellent magnetic-field sensitivity of nitrogen-vacancy sensor spins in diamond to explore spin-wave physics in ferromagnets. I will describe the nanoscale characterization of spin-wave resonances, thermally excited spin waves, and spin-wave chemical potentials [1,2,3]. These techniques open up exciting possibilities for imaging and control of spin transport in mesoscopic spin systems.

M7-02. Spin Seebeck Voltage Enhancement by Inserting Mn System Metals into Interface between Magnetic and Nonmagnetic Layers.
H. Yuasa[1,2], F. Nakata[1], T. Niimura[1], H. Li[1] and Y. Kurokawa[1] 1. Graduate School and Faculty of Information Science and Electrnical Engineering, Kyushu University, Fukuoka, Japan; 2. JST-PRESTO, Kawaguchi, Japan

Spin Seebeck effect and inverse spin Hall effect generate voltage by temperature gradient in the ferrimagnetic oxide and nonmagnetic metal systems, which has high potential of thermoelectric generation by a uniform film [1, 2], but the voltage is too small to use for application. We have found that the spin mixing conductance was improved by inserting thin layers, Ru and ferromagnetic metals, into the interface between ferrimagnetic oxide, YIG, and nonmagnetic metals, Pt and TaW alloy, and consequently the spin Seebeck voltage was increased [3,4]. The role of Ru insertion is to restrain the oxidation of the nonmagnetic metals, and that of ferromagnetic metals insertion is enhancement of the magnon scattering, that is, spin current. On the other hand, it was reported the magnon scattering was enhanced by using the antiferromagnetic oxides [5]. In this report, Mn and IrMn were inserted into the YIG/TaW interface since Mn system metals is expected to have the large magnitude of magnon scattering without the oxidation of nonmagnetic metals. It is noted that TaW has the high spin Hall angle with negative sign and the low spin mixing conductance [4]. Figure 1 shows the negative spin Seebeck coefficient -S of bulk-YIG (1 mm)/M (x nm)/TaW (5-x nm) where M denotes Ru, Mn and IrMn. The magnitude of S obtained by IrMn and Mn insertion achieved over twice of that by Ru insertion, which indicates that Mn system metals enhanced the magnon scattering as expected. By increasing Ru and IrMn thickness, |S| was decreased and changed the sign at x=4 nm because Ru and IrMn have the opposite signs of spin Hall angle to TaW. On the contrary, by increasing Mn thickness, |S| keeps the maximum value till the thickness is 2 nm and the sign of S did not change. It suggests that Mn has the negative sign of the spin Hall angle like TaW. Mn system metals are promising materials with high spin mixing conductance owing to the magnon scattering and the spin Hall angle with the same sign as TaW. M7-03. Experimental verification of the Onsager-Thomson reciprocity for spin thermoelectric effects in a ferrimagnetic insulator. *A. Sola*[1], M. Kuepferling[1], V. Basso[1] and M. Pasquale[1] *1. INRIM, Torino, Italy*

Recently, the research on spin caloritronics has been benefited by the experimental observation of the spin Peltier effect (SPE), which is the reciprocal of the spin Seebeck effect (SSE). Up to now, the SPE has been observed by means of micro-fabricated thermopile sensors, thermal imaging and thermocouples. In the present work, we designed a measurement setup that is able to detect heat currents and to resolve the contribution from SPE, of the order of magnitude of 10^{-6} W, over the Joule heating whose respective magnitude is 10^{-1} W for a given YIG-Pt bilayer sample. This is possible by means of two calibrated heat current sensors (thermoelectric elements) that are attached to the top and the bottom surfaces, respectively, and measure differentially heat currents across the sample. It is therefore possible to measure SSE coefficient and SPE coefficient with the same setup and without unmounting the sample. In order to relate the experimentally determined coefficients, we derive the reciprocity of the spin Seebeck coefficient and the spin Peltier coefficient in a ferrimagnetic insulator by means of non-equilibrium thermodynamics. As a spin analogous to the classical thermoelectric effects, the SSE and the SPE refer to the interaction between spin or magnetization currents and the heat currents. In the classical effects the generalized fluxes are related linearly to the generalized forces and as proofed by Onsager the Seebeck and Peltier coefficients are related by $ST = \Pi$, where S is the Seebeck coefficient, Π the Peltier coefficient and T the absolute temperature. We derive, contextually to an experiment performed on a YIG-Pt bilayer, an analogous relation for the spin Seebeck coefficient and the spin Peltier coefficient. The relation is verified within a quantitative agreement of 95%.

M7-04. Magneto-Seebeck Tunneling Across a Vacuum Barrier. *C. Friesen*[1], H. Osterhage[1], J. Friedlein[1], A. Schlenhoff[1] and S. Krause[1] *1. Department of Physics, University of Hamburg, Hamburg, Germany*

Combining magneto- and thermoelectric effects is a prerequisite for the design of energy-efficient spintronic devices that turn waste heat into functionality [1]. The tunneling of spin-polarized electrons across a magnetic tunnel junction driven by a temperature gradient is a fundamental process for the thermal control of electron spin transport. We experimentally investigated the atomic-scale details of this magneto-Seebeck tunneling by approaching a magnetic probe tip to a magnetic sample at cryogenic temperatures, with vacuum serving as the tunneling barrier. By heating the tip and measuring the thermopower of the junction while scanning across the spin texture of the sample, spin-resolved Seebeck coefficients are determined with atomic-scale lateral resolution. The experiments were performed at low temperatures (T = 50 K) and in UHV conditions, on the Fe/W(110) multilayer system [2], using a laser-heated bulk Cr tip and active bias compensation [3]. The non-collinear spin structures present in this sample system, and the atomic-scale lateral resolution of spin-polarized scanning tunneling microscopy, allowed for the imaging of a continuous range of relative tip-sample magnetization orientations. The experiments will be presented and discussed in terms of spin-averaged (including spin-orbit coupling effects) and magneto-Seebeck tunneling.

M7-05. Data-Intensive Spatial Mapping of the Longitudinal Spin Seebeck Effect in Normal Metal/Magnetic Insulator Devices. *M.J. Grossnickle*[1], M.H. Aldosary[2], J. Li[1], M. Lohmann[1], J. Shi[1] and N. Gabor[1] *1. Physics, University of California, Riverside, Riverside, CA, United States; 2. Physics, University of California - Riverside, Riverside, CA, United States*

The rapidly emerging field of spincaloritronics demands new approaches that access the subtle relationship between spins and heat. As a key benchmark, we demonstrate a data-intensive method for spatially mapping the longitudinal spin Seebeck effect (LSSE) in a ferrimagnetic insulator film (YIG) with a thin metal layer (platinum). By spatially scanning a femtosecond pulsed laser (with a large field of view of up to 2mm) over the Pt/YIG device, we use the mobile thermal gradient of the laser pulse to spatially resolve the photovoltage generated by the inverse spin Hall effect. Rotating the applied magnetic field direction over 360 degrees in both in- and out-of-plane directions allows us to remove contributions of the Seebeck effect and measure only the LSSE signal. We find LSSE decay lengths on the order of 100 microns as well as deviations from expected sinusoidal behavior, even at magnetic fields far in excess (0.5 T) of saturation levels. The rich visualization afforded by our technique will have important implications for the next-generation of spincaloritronic devices utilizing magnetic insulators.

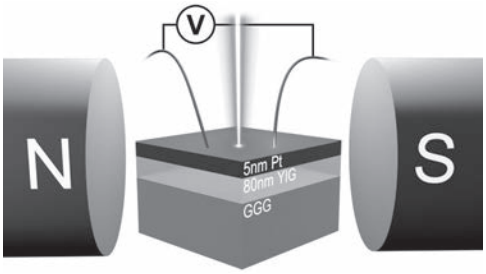

Fig 1. A schematic of our measurement setup, in which we use a spatially scanned laser as a mobile thermal gradient in a Pt-YIG system. The thermal gradient generates Seebeck and Spin Seebeck voltages which are measured using a differential voltage measurement. Permanent magnets apply a 500mT field that can be rotated arbitrarily in-plane.

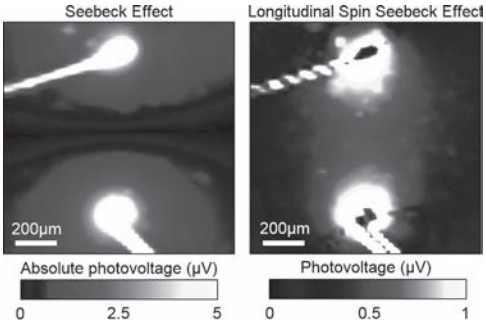

Fig 2. Spatial maps of the Seebeck effect (left) and Longitudinal Spin Seebeck effect (right) voltages generated by the scanning laser beam. Separating the contributions of these two effects allows us to measure the in-plane temperature gradient at every point in space (~50 mK/um far from the contacts) and lets us extract a LSSE decay length of 110um.

HH Wills Laboratory, University of Bristol, Bristol, United Kingdom; 5. Jeremiah Horrocks Institute, University of Central Lancashire, Preston, United Kingdom*

The Mott metal-to-insulator transition continues to be an active topic of investigation; although various mechanisms have been proposed, the precise nature of the transition remains an open question. In many such systems under study, filling (via chemical doping) is used as a tuning parameter, but the resultant disorder hinders the use of sensitive quantum oscillation techniques to study Fermi surface properties. In the Mott insulator NiS_2, one can instead use pressure to tune the ratio of onsite Coulomb repulsion to kinetic energy. By establishing a radio-frequency tank circuit technique in miniature high pressure anvil cells, we have been able to record quantum oscillations in NiS_2 over a wide range of hydrostatic pressures, from near the Mott transition at ~30 kbar up to 115 kbar, allowing for the first time a close investigation of the metallic state on the edge of Mott localization in an inorganic 3D system by quantum oscillatory techniques. We find that the Fermi surface remains nearly unchanged on approaching Mott localization, whereas the effective mass is strongly renormalized – in qualitative agreement with the Brinkman-Rice picture. The successful introduction of quantum oscillation techniques to such high pressures opens exciting opportunities to access the electronic structure, and in particular the carrier mass renormalization, in other correlated materials of current interest near pressure-induced quantum phase transitions.

Preliminary pressure dependence data of effective mass and *(inset)* QO frequency of the central cube-like Fermi surface sheet in NiS_2. The effective mass increases rapidly upon approaching the Mott metal-to-insulator transition, while the Fermi surface volume shows little change.

M8-02. Electronic Structure Change of $NiS_{2-x}Se_x$ in the Metal-Insulator Transition Probed by X-ray Absorption Spectroscopy. *H. Noh*[1], J. Jeong[1], E. Cho[1], S. Kim[2] and H. Kim[3] *1. Physics, Chonnam National University, Gwangju, The Republic of Korea; 2. The College of Liberal Arts, Konyang University, Chungnam, The Republic of Korea; 3. Pohang Accelerator Laboratory, POSTECH, Pohang, The Republic of Korea*

The electronic structure change of $NiS_{2-x}Se_x$ as a function of Se concentration x has been studied by Ni *L*-edge X-ray absorption spectroscopy (XAS). The XAS spectra show distinct features in Ni *L*3 edge, indicating whether the system is insulating or metallic. These features can be semi-quantitatively explained within the framework of the configurational interaction cluster model (CICM). In the S-rich region, relatively large charge-transfer energy (Δ~5 eV) from ligand p to Ni 3*d* states and a little small *p-d* hybridization strength ($V_{pd\sigma}$~1.1 eV) can reproduce the experimental spectra in the CICM calculation, and vice versa in the Se-rich region. Our analysis result is consistent with the Zaanen-Sawatzky-Allen scheme that the systems in S-rich side (x≤ 0.5) are a charge transfer insulator. However, it also requires that the Δ value must change abruptly in spite of the small change of x near x=0.5. As a possible microscopic origin, we propose a percolation scenario where a long range connection of $Ni[(S,Se)_2]^6$ octahedra with Se-Se dimers plays a key role to gap closure.

M8-03. Coulomb localization in orbital degenerate, doped Mott insulators. *A. Avella*[1,2], A.M. Oles[3,4] and P. Horsch[3] *1. Dipartimento di Fisica "E.R. Caianiello", Università degli Studi di Salerno, Fisciano, Italy; 2. UoS di Salerno, CNR-SPIN, Fisciano, Italy; 3. Max-Planck-Institut fuer Festkoerperforschung, Stuttgart, Germany; 4. Marian Smoluchowski Institute of Physics, Jagiellonian University, Krakow, Poland*

We study the localization induced by Coulomb interactions (electron-electron correlations and random defect potentials) in orbital degenerate, doped Mott insulator, modelling doped transition-metal oxides such as the perovskite vanadate systems $R_{1-x}Ca_xVO3$ (R = Y, La) [1-3], through the analysis of the inverse participation ratio of the electronic states of the system. The analysis is performed varying the doping, in order to contrast the degree of localization induced by the random defect potential of the charged defects to that driven by the electron-electron (e-e) correlations in the parent compound, as well as the ratio between the e-e interaction strength and that of the defect potential, both long-range. In this latter case, we explore all relevant cases going from the realistic charge-neutral dipolar case (hole-defect) to the toy model where the e-e interaction is kept local and the overall random potential has a monopolar nature. The results can be rationalized in terms of the formation of spin-orbital polarons [3] whose size and degree of binding to the defect ions depends strongly on all interaction parameters besides on the defect concentration.

Department of Quantum Matter Physics, University of Geneva, Geneva, Switzerland; 5. ESRF, Grenoble, France; 6. Swiss Light Source, Paul Scherrer Institut, Villigen, Switzerland*

Exotic phases induced by doping Mott insulators (MIs) have been a central thread of solid state physics since the discovery of high-temperature superconductivity in the layered cuprate compounds. The doping evolution of the magnetic ground state of the parent insulator is extremely diverse: while in perovskite manganites the parent antiferromagnetic (AFM) order develops into a ferromagnetic (FM) phase[1], doping suppresses the AFM ground state of S=1/2 cuprates[1] and J_{eff}=1/2 iridates[2] and results in a paramagnetic (PM) metal. Great attention has been recently attracted by d^4 MIs, where the moderate spin-orbit coupling (SOC) is expected to stabilize a non-magnetic J_{eff} =0 singlet. In this case, Van-Vleck-type magnetic order can result from the condensation of magnetic excited states driven by intersite interactions[3] and is expected to produce a rich phase diagram (hosting both AFM and FM phases) as a function of electron doping[4] (Fig.1a). Ca_2RuO_4 (Ru^{4+}, $4d^4$) is a prominent candidate for the realization of Van-Vleck type magnetism[3,4]. The parent compound was found to order at low temperature in a canted AFM structure[5]. However, experimental studies on the magnetic order of electron-doped samples have been limited to bulk magnetization measurements (Fig. 1b) and have led to contrasting conclusions [6,7]. With the present work, we report on a combined REXS and absorption study of the Ru^{4+} ground state in $Ca_{2-x}La_xRuO_4$ at the Ru L_3 and L_2 absorption edges[8]. Bandwidth and filling control is achieved by substitution of trivalent La for divalent Ca. Our measurements, which represent the first microscopic study of the electronic and magnetic properties of $Ca_{2-x}La_xRuO_4$, show that the AFM structure of the parent compound is retained in the doped samples up to x=0.07(1) (Fig. 2). Beyond this value, long-range order is suppressed and the system turns PM. Our findings are interpreted in light of the calculated phase diagram for d^4 MIs and used to assess the role of SOC in the low-energy Hamiltonian.

M8-05. Orbital Selective Mott Transition in Thin Film VO_2. T. Eustance[1] and *W. Lee*[1] *1. Physics, Binghamton University - SUNY, Binghamton, NY, United States*

We investigate the electronic structure of the epitaxial VO2 films in the rutile phase using the density functional theory combined with the slave spin method (DFT+SS). In DFT-SS, the multiorbital Hubbard interactions are added to a DFT-fit tight-binding model, and we employ the slave-spin method to treat the electron correlation. We find that while stretching the system along the rutile c-axis results in a band structure leading to an anisotropic orbital fillings, the electron correlation favors an equal electron filling among t2g orbitals. These two distinct effects cooperatively induce interesting orbital-dependent redistributions of the electron occupations and the spectral weights, which pushes the strained VO2 toward an orbital selective Mott transition (OSMT), as observed in recent experiments. Our results indicates that the electron correlation in VO2 is important and can be modulated even in the rutile phase before the Peierls instability sets in. This work is supported by the Air Force Office of Scientific Research under award number FA9550-18-10024.

M9-01. Möbius Topological Superconductivity in UPt_3 and UCoGe.
Y. Yanase[1], A. Daido[1], T. Yoshida[1] and K. Shiozaki[2] *1. Department of Physics, Kyoto University, Kyoto, Japan; 2. Condensed Matter Theory Laboratory, RIKEN, Wako, Japan*

Unconventional superconductivity in strongly correlated electron systems is attracting renewed interest from the viewpoint of topological superconductivity. Although topological phases using proximity-induced s-wave superconductivity were proposed and some of them have been realized, intrinsic topological superconductivity hardly realizes in conventional s-wave superconductors. On the other hand, spin-triplet superconductors or chiral superconductors may be a platform of the natural topological superconductivity. Indeed, most of candidate materials for such exotic superconductivity have been found in heavy fermion systems. In the talk, I present our recent works which clarify the topologically nontrivial superconducting phases in UPt_3 and UCoGe. These heavy fermion superconductors unambiguously exhibit exotic Cooper pairing. The spin-triplet superconductivity has been evidenced by observations of multiple superconducting phases in UPt_3 [1] and ferromagnetic superconductivity in UCoGe [2]. Furthermore, crystal structures of UPt_3 and UCoGe have an intriguing feature; the symmetry is represented by nonsymmorphic space group $P6_3mmc$ and Pnma, respectively. By our work, time-reversal invariant superconducting phases of UPt_3 at high temperatures (A-phase in Fig.1) [3] and UCoGe at high pressures [4] are identified as Z_2 and Z_4 Möbius topological superconductivity, respectively. The Möbius topological superconductivity is protected by nonsymmorphic crystal symmetry, and it cannot exist in continuum systems. Combining the band structures obtained by first principles calculations, order parameter based on the space group symmetry and topological classification by K-theory, we show the nontrivial Z_2 and Z_4 invariant of three-dimensional DIII class. Corresponding topological surface states are demonstrated (Fig.2). Thus, UPt_3 and UCoGe are the first candidate materials of Möbius topological superconductivity which has not been proposed so far.

M9-02. Unconventional gap structure depending on angular momentum.
S. Sumita[1] and Y. Yanase[1] *1. Department of Physics, Kyoto University, Kyoto, Japan*

Classification of a superconducting gap is one of the central subjects in the research field of unconventional superconductivity. Momentum dependence of the superconducting gap is closely related to symmetry of the superconductivity and the pairing mechanism. Since the superconducting gap structure can be identified by various experiments, combined studies of superconducting gap by theory and experiment may clarify the characteristics of superconductivity. Most of the theoretical studies have been based on the classification of order parameter by the crystal point group, which is summarized by Sigrist and Ueda (called Sigrist-Ueda method) [1]. However, their classification may not provide an exact classification of the superconducting gap. For example, several studies have shown that the space group symmetry ensures the unconventional gap structures beyond

the results of the Sigrist-Ueda method [2-5]. These theories classify not the order parameter, but the superconducting gap itself. Therefore, rigorous results are obtained for gap structures. Especially regarding point nodes, many studies have discussed Weyl nodes in superconductors, namely point nodes protected by a nontrivial topological number [6-8]. However, there are only a few and less-known results about point nodes connected with crystal symmetry [2, 3]. In this study, we classify unconventional point nodes beyond the results of the Sigrist-Ueda method, by the group-theoretical analysis of the superconducting gap. We consider the gap structures on high-symmetry n-fold (n = 2, 3, 4, and 6) axes in the Brillouin zone, as examples of the symmetry-protected point nodes. Surprisingly, the analysis shows the existence of point nodes depending on the Bloch-state angular momentum j_z on a 3- or 6-fold axis. Furthermore, we suggest that such "j_z-dependent point nodes" are realized in a heavy fermion superconductor UPt_3. We also discuss superconducting gap structures in MoS_2, SrPtAs, UBe_{13}, and $PrOs_4Sb_{12}$.

M9-03. Unconventional Superconductivity in Single Crystal YFe_2Ge_2. *J. Chen*[1], K.J. Murphy[1], M. Gamza[2], K. Semeniuk[1] and M. Grosche[1] *1. Cavendish Laboratory, University of Cambridge, Cambridge, United Kingdom; 2. Jeremiah Horrocks Institute for Mathematics, Physics and Astrophysics, University of Central Lancashire, Preston, United Kingdom*

The intermetallic d-electron compound YFe_2Ge_2 exhibits an unusually high Sommerfeld coefficient of ~ 100 mJ/(molK^2), indicating strong electronic correlations. Superconductivity with varying transition temperatures below ~ 1.9 K has been widely reported in resistivity measurements for both poly- and single-crystalline samples [1, 2], but an associated heat capacity anomaly suggestive of bulk superconductivity could only be observed in high quality polycrystalline YFe_2Ge_2 [3]. The extreme sensitivity of superconductivity to disorder hints at an unconventional pairing mechanism. In order to enable more detailed studies of the nature of the superconducting state in YFe_2Ge_2, we have grown a new generation of high purity single crystals using a modified Sn-flux method. These crystals reach residual resistivity ratios (RRR) in excess of 150, about twice the highest values previously reported [2], and they display a sharp superconducting heat capacity anomaly around 1 K, the first such observation in single crystalline YFe_2Ge_2. We discuss key conclusions from our YFe_2Ge_2 growth optimisation program and present thermodynamic and transport data arising from the newly obtained bulk superconducting crystals.

M9-04. Phase transitions and topological states in odd-parity superconductors interfaced with antiferromagnets. *M. Mercaldo*[1], P. Kotetes[2] and M. Cuoco[3,1] *1. Dipartimento di Fisica, University of Salerno, Fisciano, Italy; 2. Center for Quantum Devices, Niels Bohr Institute, University of Copenhagen, Copenhagen, Denmark; 3. CNR-SPIN Salerno, Fisciano, Italy*

Understanding unconventional superconductivity remains a challenge in condensed matter physics [1]. Substantial experimental investigations have provided evidence for spin-triplet pairing in diverse classes of materials [2]. One of the most relevant perspective and motivation of this search is to have at hands materials which are employable for topological quantum computing based on Majorana fermions [3]. In actual materials an important issue relates to the role of the order parameter, which generally constitutes a vector in spin-space and its structure can be crucial in controlling the topological properties of the system. In this work, we focus on the behavior of the spin-triplet d-vector and, in turn, of the ensuing topological features by interfacing the superconductor with a chain of magnetically ordered spins. We investigate the role of different type of antiferromagnetic ordering and short-length alternating magnetic domains in relation to the appearance of Majorana edge modes. In this context, by studying the free energy minima, we explore the possibility of having a reorganization of either the magnetic or superconducting order parameters in amplitude and orientation. Taking into account the remarkable effects of a uniform magnetization in a p-wave superconductor [4,5], we explore how the internal degrees of the magnetic subsystem can drive different types of topological phase transitions, including the occurrence of emergent symmetries protecting the Majorana modes. Finally, we investigate the electron spin polarization induced by the Majorana modes and discuss the role of realistic inhomogeneous patterns of the magnetization at the boundary in driving a spatial change of the d-vector at the boundary and in the bulk.

M9-05. Pairing Mechanism of the FeSe monolayer and related Systems: Dynamical Tuning of Pairing Cutoff Energy. *Y. Bang*[1]
1. Dept of Physics, POSTECH, Pohang, The Republic of Korea

There are a group of FeSe systems: FeSe/SrTiO3 monolayer system (Tc~60-100K) and other heavily electron-doped iron selenide (HEDIS) compounds such as $A_xFe_{2-y}Se_2$ (A=K, Rb, Cs, Tl, etc.) (Tc~30-40K), $(Li_{1-x}Fe_xOH)FeSe$ (Tc~40K), etc. These systems have all very high Tc (30K -100K) despite having only the electron Fermi surfaces (FSs) but no hole FS. Here we propose a unifying pairing mechanism [1] based on a new concept: dynamical tuning of pairing cutoff energy. With this mechanism, I show how the incipient band without a Fermi surface can participate pairing interaction through RG process and the system forms the s^{++} wave state only with the electron pockets. In this way, the HEDIS system can achieve the maximum T_c , stored in the system, and yet avoid the detrimental impurity pair breaking scattering. Our theory not only provides a unifying pairing mechanism for all HEDIS system, but also naturally explains the puzzling double dome structure of the phase diagram of T_c *versus* tuning parameter (doping, pressure, etc) [2, 3].

M10-01. Testing laws of thermodynamics with meta magnets.
B. Canals[1], N. Rougemaille[2], Y. Perrin[2] and I. Chioar[3] *1. CNRS - Institut NEEL, Grenoble, France; 2. CNRS - Institut NEEL, Grenoble, France; 3. Departement of Physics and Astronomy, Uppsala University, Uppsala, Sweden*

Complex architectures of nanostructures are routinely elaborated using bottom-up or nanofabrication processes, allowing scientists to engineer frustrated arrays that do not exist in nature, wether it is a question of geometry, or scale. These systems have been the subject of intense research in the last few years and have allowed the investigation of fascinating phenomena, such as the observation of pseudo-excitations involving classical analogues of magnetic charges moving on top of a so called Coulomb phase, or the fragmentation of the local degree of freedom. This talk aims at providing two examples of two-dimensional artificial magnets which allow to probe the low energy manifolds of two exotic Ising systems. The first one is related to the seminal square ice model and shows that it is possible to perform a scan through the 6-vertex model phase diagram with an appropriately designed artificial magnet [1]. The second one refers to a recent proposal, the fragmentation of magnetization [2], in an Ising kagomé model, which corresponds to the effective splitting of the local degree of freedom into two independent channels [3]. These examples provide a way to test the third law of thermodynamics and we shall conclude this talk by pointing to another exotic test of the second law.

M10-02. Spin dynamics in pyrochlore iridates $Ho_2Ir_2O_7$ and $Dy_2Ir_2O_7$.
V. Cathelin[1,2], E. Lefrancois[3,4], E. Lhotel[1], J. Robert[1], P. Lejay[1], F. Damay[5], L. Chapon[6], R. Ballou[1] and V. Simonet[1] *1. Institut Néel CNRS, Grenoble, France; 2. Univ. Grenoble Alpes, Grenoble, France; 3. Max Planck Institute, Stuttgart, Germany; 4. Institut Laue Langevin, Grenoble, France; 5. Laboratoire Léon Brillouin, Saclay, France; 6. Diamond Light Source Ltd, Didcot, United Kingdom*

Pyrochlore iridate oxides are materials of formula $R_2Ir_2O_7$. In these compounds, the iridium and rare-earth (R) ions lie on two interpenetrated pyrochlore lattices. For most of the rare-earth ions, the iridium sublattice orders in an all-in all-out magnetic arrangement at about 100 K, and generates a molecular field oriented along the local <111> directions on the rare-earth sublattice [1]. When R=Ho or Dy, this staggered magnetic field competes at very low temperature with the R-R ferromagnetic interactions. We have shown that $Ho_2Ir_2O_7$ this competition results in magnetic fragmentation, a recently discovered phase in which the magnetic moments fragment, leading to the superposition of a magnetically ordered phase and a persistently fluctuating one [2]. It manifests as the coexistence of spin-ice diffuse scattering with an all-in all-out ordering, whose ordered magnetic moment is half of the total moment. From this phase are emerging excitations, magnetic monopoles, which evolve in a periodic potential, induced by the iridium sublattice. It gives rise to unconventional dynamics that differ from canonical spin ice. In my talk, I will show that $Dy_2Ir_2O_7$ also stabilizes a fragmented phase. I will focus on the slow dynamics at very low temperature measured by ac susceptibility between 50 mK and 4 K. Indeed, relaxation times can be described with an Arrhenius law in both systems but with different time scales and energy barriers. I will eventually compare these results with the dynamics of classical spin ices.

M10-03. Quantum features in the spin dynamics of the frustrated pyrochlore $Er_2Ti_2O_7$.
R. Coldea[1], P.A. McClarty[2], J. Rau[2], D. Prabhakaran[1] and D. Voneshen[3] *1. Department of Physics, University of Oxford, Oxford, United Kingdom; 2. Max Planck Institute for the Physics of Complex Systems, Dresden, Germany; 3. ISIS Facility, Rutherford Appleton Laboratory, Didcot, United Kingdom*

The antiferromagnetic order in the frustrated pyrochlore magnet Er2Ti2O7 has been proposed to be selected by quantum fluctuations from a degenerate classical manifold [1-4]. Here we report high-resolution inelastic neutron scattering measurements of the spin dynamics in applied magnetic field to reveal, in addition to dominant one-magnon excitations, also significant multi-particle continuum excitations and magnon damping effects at high energies.

M10-04. Strong Quantum Character of the Magnetic Phase Diagram of $Yb_2Ti_2O_7$. *S. Säubert*[1], C. Duvinage[1], A. Scheie[2], J. Kindervater[2], H. Changlani[2], S. Zhang[2], S. Koohpayeh[2], O. Tchernyshyov[2], C.L. Broholm[2] and C. Pfleiderer[1] *1. Physics Department, Technical University of Munich, Garching-Forschungszentrum, Germany; 2. Institute for Quantum Matter and Department of Physics and Astronomy, Johns Hopkins University, Baltimore, MD, United States*

At zero magnetic field and milli-Kelvin temperatures high-quality single crystals of $Yb_2Ti_2O_7$ display ferrimagnetic order, with the spins slightly splayed away from one of the six⟨100⟩directions. We report the orientation dependence of the magnetic phase diagram of $Yb_2Ti_2O_7$ as inferred from magnetization measurements down to milli-Kelvin temperatures, corroborated by extensive neutron scattering data. The magnetic phase diagram under applied magnetic field shows an unusual field dependence of a first-order phase boundary, notably an applied field initially increases the ordering temperature when applied parallel to the crystalline ⟨111⟩ or ⟨110⟩ axes. This magnetic field dependence is absent for field along ⟨100⟩. Our key findings may be described qualitatively in a ($q=3$)-Potts model, taking into account a cubic anisotropy and the Zeeman field. However, the critical field for the field-driven phase transition may only be explained quantitatively when including strong quantum effects. This establishes a strong quantum character of the magnetic phase diagram of $Yb_2Ti_2O_7$.

M10-05. Creating a large density of monopoles at 200 mK in the spin ice $Ho_2Ti_2O_7$, and watching them disappear. *C. Paulsen*[1,5], E. Lhotel[1,5], S.R. Giblin[2], S.T. Bramwell[3] and K. Matsuhira[4] *1. Institut Néel CNRS, Grenoble, France; 2. School of Physics and Astronomy, Cardiff Univeristy, Cardiff, United Kingdom; 3. Physics & Astronomy, Universitty College London, London, United Kingdom; 4. Department of Electronics, Faculty of Engineering, Kyushu Institute of Technology, Kitakyushu, Japan; 5. Université Grenoble Alps, Grenoble, France*

Below 200 mK the dynamics of spin ice are dominated by monopoles. By thermally quenching spin ice to millikelvin temperatures using the avalanche quench protocol[1], we have shown how to prepare a large, far from equilibrium density of metastable magnetic monopoles. We use this approach to study Ho2Ti2O7 and have measured the monopole [2] current as well as the field at which avalanches occur while ramping up the field. Emphasis was put on the waiting time after the quench and before the measurements begin, showing rapid recombination of monopoles even at 200 mK. Comparison of the results with Dy2Ti2O7 gives insights to the tunneling mechanism governing the hopping of monopoles on the lattice. The non-standard techniques used to make these measurements will be presented, as well as new results.

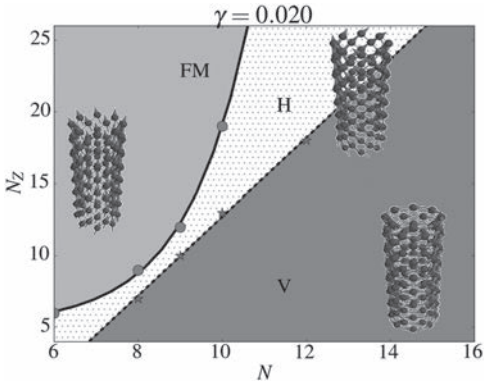
Session N1
CYLINDRICAL NANOSTRUCTURES: PROPERTIES AND APPLICATIONS (Poster Session)

Martino Poggio, Chair
University of Basel, Basel, Switzerland

N1-01. Magnetic groundstate of curved nanotubes. *V.L. Carvalho-Santos*[1], J.M. Fonseca[1] and D. Altbir[2] *1. Physics, Universidade Federal de Viçosa, Viçosa, Brazil; 2. Physics, Universidad de Santiago de Chile, Santiago, Chile*



The potential applications of nanomagnets in random access memory, data storage, spintronic and magnonic devices demand the understanding on the properties of magnetic nanoparticles. In this context, recent advances in experimental techniques to fabricate nanoparticles made it possible the production of nanomagnets with unusual geometries such as rolled-up magnetic membranes [1], paraboloidal magnetic caps [2], modulated nanomagnets and cylindrical nanowires and nanotubes [3]. The production of magnetic nanoparticles with different shapes promotes the description on how geometry influences their properties in an important issue. The influence of the curvature on the properties of nanosized ferromagnetic systems is a prominent research area. Among main theoretical results on this issue, one can cite the appearing of curvature-induced chiral effects [4]. Such chiral effects are responsible for a symmetry breaking of a domain wall motion in magnetic helices [5], for the nucleation of a vortex-antivortex pair in nanomagnets with variable curvature [6] and for an asymmetry in the sign of the wave vector in the dispersion relation of spin-wave propagation in ferromagnetic nanotubes [7]. Ferromagnetic nanotubes are particularly interesting because this geometry can make flux-closure magnetization configurations more favorable than single-domain states for a large range of geometrical parameters [8]. On the other hand, once the magnetic energy related to different magnetization configurations depends on the geometry, the magnetic ground state of a curved nanotube must present differences when compared with a straight tube with same geometrical parameters. The magnetic energies of four different magnetization configurations in a curved magnetic nanotube are obtained. The chosen magnetization states are direct analogies with that obtained in straight cylindrical nanotubes [14], that is: 1) in-plane single domain state; 2) out-of-plane single domain state; 3) in-surface state; and 4) vortex state. The magnetostatic and exchange energy were obtained for each magnetic state. We have then obtained a diagram state in function of the height, external and internal radii of the nanotube.

N1-02. Effect of Dipolar Interactions on the Magnetic Properties of Tubular Nanostructures. *O. Iglesias*[1,2], H.D. Salinas[3] and J. Restrepo[3] *1. Dpt. Condensed Matter Physics, University of Barcelona, Barcelona, Spain; 2. Institut de Nanociencia i Nanotecnologia de la UB, Barcelona, Spain; 3. Instituto de Física, Universidad de Antioquia, Medellín, Colombia*

Tubular magnetic nanostructures have gained recent interest because the increased functionality arising from their inner and outer surfaces may contribute to improve existing applications [1]. Hollow nature of nanotubes favors the formation of closed flux, core free configurations that are more advantageous than those formed in nanowires, when considering the reversal behavior [2]. In order to gain insight into this point, we have studied the low temperature magnetic equilibrium configurations and hysteretic properties of magnetic nanotubes. The main focus is on the low temperature magnetic order and the thermal-driven transition involved between different magnetic states. The results have been obtained by atomistic Monte Carlo simulations of Heisenberg spins residing on the cylindrical lattice of single-wall zigzag nanotubes which interact via competing short-range exchange (J) and long-range dipolar interactions (D) [3]. In order to ensure that the low temperature magnetic states correspond to the true ground states, a modified simulated annealing protocol with dynamic adaptation of the cone aperture of trial angles was followed. Results reveal the occurrence of different low-temperature magnetic states depending on the competition between the exchange and dipolar energies given by the parameter γ =D/J: collinear FM states at low γ, vortex states above a certain threshold γ*, and peculiar non-collinear helical states for a range of intermediate values of γ that depends on the radius and length of the nanotube. These obtained helical states compare favorably with recent direct experimental observations [4]. Introducing a vorticity order parameter, we find the pseudo-critical transition temperatures and we establish the phase diagrams as a function of aspect ratio for a range of values of γ. Comparison of the energies of the states obtained by simulation with those of simpler theoretical structures that interpolate continuously between them, reveals a high degree of metastability of helical states that might be relevant for their reversal modes.

N1-03. Effect of Segment Length on Domain Wall Pinning in Multisegmented Co/Ni nanowires for 3D Memory Applications. *H. Mohammed*[1], J.A. Moreno[2] and J. Kosel[1] *1. Computer, Electrical and Mathematical Sciences & Engineering Division, King Abdullah University of Science and Technology, Thuwal - Jeddah, Saudi Arabia; 2. Physical Science and Engineering Division, King Abdullah University of Science and Technology, Thuwal - Jeddah, Saudi Arabia*

The quest for next generation devices is pushing the boundaries of various technologies such as logic and data storage devices. The racetrack-memory concept [1] based on cylindrical nanowires [2,3] shows considerable potential. Multiple bits or domains can be incorporated in a single nanowire by tuning various parameters such as diameter size and chemical composition. Studies have shown the pinning of domain walls near the interfaces of multisegmented cobalt/nickel nanowires, due to the larger stray field emanating from Co segments[3]. For the design of such a device, a large number of bits per nanowire as well as optimal values of pinning and depinning field are crucial. Here, we simulate the switching field as well as depinning strength of Co/Ni nanowires (80 nm diameter) with various segment lengths. The depinning strength is the magnetic field required to depin a domain wall from a pinning site. Simulations were performed using the Magpar package[4] within the Virtual Micromagnetics environment[5] with average finite element discretization around 4.5 nm for both segments. We find that domain wall pinning is observed in 200 nm, 300 nm as well as 700 nm long nanowire segments. Pinning is also exhibited in a three-segmented nanowire with 700 nm long segments. Since the stray field from the Co segment determines the domain wall pinning, the position of the pinned domain wall is influenced by this stray field. Experimental studies reveal a 150 nm displacement of the domain wall from the interface[3], which is in agreement with our findings. In addition to this, we find that the smaller segment length namely 200 nm and 300 nm segments allow the domain wall to be pinned at the interface itself. These findings are crucial towards determining the minimum segment length to achieve a higher bit density that displays optimal pinning and depinning fields.

Nowadays, magnetic nanowires have received considerable attention due to their potential application in developing advanced spintronic devices. To use this structures in high density magnetic recording media it is necessary to control the magnetic domain state and magnetization reversal process. In particular, future magnetic storage technology might rely on the movement of magnetic domain walls using spin polarized currents [1]. When not in motion, the magnetic domain walls should be pinned in artificially created notches along magnetic wires [2]. It has been shown recently that the depinning of a domain wall from geometrical notches has an intrinsic stochastic component which complicates the application of the proposed scheme in real devices [3]. New types of notches are needed to overcome those limits and to explore new magnetization textures. In this work we have introduced local changes in composition along permalloy nanowires, that may act as local pinning sites (chemical notches). To study the behaviour of magnetic domain walls in these nanowires, it is mandatory to use a technique that combines magnetic and chemical information at submicrometer spatial resolution. The LEEM-PEEM microscope fulfils all these requirements. The LEEM microscope has enough resolution to search for the individual nanowires in the substrate. We have used XAS-PEEM to obtain images with chemical contrast (see Fig. 1a) and XMCD-PEEM to get magnetic contrast (Fig 1b). From these figures we correlate composition and magnetic properties of the nanowires. We have proven that chemical notches act as pinning sites for the domain walls. After applying a magnetic field, the domain walls move and pin to a different notch (see Fig 1c). These results open the possibility of using these chemically modulated nanowires as storage elements in racetrack memories. Once we have checked that domain walls are pinned in chemical notches, we have used magneto-optical Kerr effect to have a deeper knowledge of the magnetic behavior of these nanowires when changing the distance between notches as well as the pinning force of each notch.

N1-05. The effect of magnetization on the capacitance of capacitor structures based on nanoporous alumina with electrodeposited Ni nanowires. *G.M. Oliveira*[1], E. Padrón Hernandez[2], A.A. Quivy[1] and D.R. Cornejo[1] *1. DFMT, Physics Institute Of São Paulo University, São Paulo, Brazil; 2. Physics Department, Universidade Federal de Pernambuco, Recife, Brazil*

The search for devices that allow efficient energy storage and the fast exchange of that energy with other components in a microcircuit is a relevant topic of research in our days. Recently, the possibility of developing high performance capacitive nanostructures using nanoporous alumina membranes (NAM) as a dielectric material, has led to promising results [1]. In this work, we have developed a capacitive heterostructure consisting of two metal electrodes (Al at the base and Ag at the top) with nanoporous Al2O3 as the dielectric separator. The NAM was obtained starting from a high-purity Al sheet, using the two-step anodization process. This technique allows naturally one of the planes of the original sheet to remain unaltered, preserving a thin layer of Al. Before coating the opposite plane with Ag (via sputtering), Ni nanowires (NNW) were electrodeposited in the hexagonal pore array (pores of approximately 50 nm of diameter and 5 um of length). The heterostructure was characterized by X-ray diffraction and lateral SEM. Measurements of capacitance versus voltage for frequencies between 103 and 106 Hz were performed using a Cascade Microtech probe station controlled by a B1500A Analyzer. Capacitances per unit planar area of around 50 nF/cm2 were obtained for this nanostructure. The presence of NNW in the capacitor allows studying the behavior of the capacitance as a function of the magnetization of the NNW. The capacitance tests were performed leaving the NNW in well-defined magnetic states (Figure 1). First, the wires were in the demagnetized state, and the capacitance versus voltage curve corresponds to the black points in the aforementioned figure. The red points correspond to the capacitance measured when the NNW were in a remanent state after the in-plane magnetic saturation. Finally, the curve in blue corresponds to the capacitance when the wires are in the remanent state after the magnetic saturation along the axis of the NNW. We can see clearly the increase in capacitance when the magnetization of the NNW increases. This magnetoelectric effect is an experimental evidence of the interface coupling between a dielectric and a spin-polarized metal [2].

The huge market of permanent market is mostly supplied by rare earth-based magnets, which exhibit the best performances. However, the resource of rare- earth is limited. This challenge motivates scientists for a new generation of magnets. A possible approach consists of assembling single domain nanoparticles with a high anisotropy into dense materials and to take advantage of the nano-structuration. This bottom-up method has the advantage to keep the high coercivity of single nanowire inside the bulk structure. In the case of cobalt-based nanowires, thanks to a good magneto-crystalline anisotropy and a high shape one, they may show the desired magnetic properties. By controlling the hexagonal crystal structure of these cobalt nanowires, it is possible to maximize their magnetic properties and thus to open the way for their application into permanent magnet [1]. In this frame, we studied the magnetic static properties of *hcp*-cobalt nanowires, which show a high shape anisotropy and magneto-crystalline anisotropy by using a standard MPMS magnetometer. The magnetic energy (namely BH_{max}) of these nanowires has been studied as a function of the shape [2,3] as well as of the stacking fault [1,4]. Our results show that the BH_{max} of the Co nanowires is strongly affected by the shape ratio (L/d) as well as by the stacking fault density (δ). When the aspect ratio is optimized (L/d>10), the stacking fault density is the key parameter to control the BH_{max} (see Figure 1 a and b). A huge loss in the magnetic energy is discussed as function of the changing interactions between nanowires. We also present our first results on sintered samples obtained by co-based nanowires assemblies [5]. These latter have shown optimized magnetic properties at room temperature as well as very sensitive reversal magnetic mechanism as function of their nano-structuration (*i.e.* of the nanowires organization). We discuss here future issues and solutions for the elaboration of new free-rare earth nanostructured permanent magnet.

N1-07. Synthesis and Characterization of γ'-Fe_4N Nanowire for Biomedical Application. *Y. Jiang[1] 1. Jiangnan University, Wuxi, China*

In the past few years, various methods for the synthesis of different types of inorganic nanowires have been developed[1,2]. Magnetic nanowires in particular are attractive for a variety of technological applications ranging from flow sensors over bioinspired tactile sensors to cancer treatment[3,4]. Ferromagnetic γ'-Fe_4N has many attractive properties, such as high saturation magnetization and electrical resistivity, making it an ideal candidate to replace current magnetic materials. A novel kind of magnetic nanowire, which main magnetic part is γ'-Fe_4N phase, is developed here by a facile low-cost fabrication process. The facile fabrication process consists of γ'-Fe_4N NW electrodeposition onto aluminum oxide templates, the release of the prepared nanowires and the subsequent passivation in a post-annealing step. By controlling the deposition conditions, nanowires with different lengths and widths can be prepared. Figure 1 shows the TEM images of the prepared γ'-Fe_4N nanowires. The fabricated nanowire has a high magnetic moment, and due to their single domain structure with large shape anisotropy, it exhibit relatively high coercivity and remanence magnetization values. The high remanence value can generate large force to be helpful for the cell separation. Hence, the synthesized γ'-Fe_4N nanowire present an attractive opportunity toward achieving long-term stability and high degree of biocompatibility.

N1-08. Magnetic entropy change and thermomagnetic behavior in $La_{0.7}Ca_{0.23}Sr_{0.07}MnO_3$ nanofibers obtained by electrospinning.
L.A. Burrola Gándara[1], L. Vazquez Zubiate[1], D.M. Carrillo Flores[2] and J.T. Elizalde Galindo[3] *1. Instituto de Ingeniería y Tecnología, Universidad Autónoma de Ciudad Juárez, Juárez, Mexico; 2. Physicis and Mathematics, Universidad Autonoma de Ciudad Juarez, Juarez, Mexico; 3. Physics and Matemathics, Universidad Autonoma de Ciudad Juarez, Ciudad Juarez, Mexico*

This work contributes with the development of new nanostructured manganites and to a better understanding of their physical properties at 1D level. Nanofibers of $La_{0.7}Ca_{0.23}Sr_{0.07}MnO_3$ manganite were fabricated using electrospinning technique aiming to recognize how the nanostructure and heat treatment influence both magnetic entropy change and thermomagnetic behavior. The nanofibers were obtained from the stoichiometric dissolution of La, Ca, Sr and Mn acetates in water at a 0.1 molar concentration. A 22-gauge needle made of stainless steel, a separation of 15 cm between the needle and the Al deposition plate, a 0.1 ml/h fluid flow and a voltage of 15 kV were set as the electrospinning conditions. The heat treatments were applied at a calcination ramp of 1 °C/min followed for an isotherm of 700, 800 and 900 °C applied for 1.5 hours. According to X ray diffraction technique, a single phase orthorhombic structure was identified for each sample with crystallite sizes of 46.94, 49.47 and 58.04 nm respectively using Scherrer equation. ZFC-FC Thermomagnetic curves measured at 2, 5, 10 and 15 mT for each sample shows a ferromagnetic to paramagnetic transition with Curie temperatures of 297, 305 and 311 K for 700, 800 and 900 °C heat treatments respectively. Also, blocking and irreversible temperatures diminishes as the magnetic field increases for all samples and a highly anisotropic ferromagnetic state is evidenced. Magnetic isotherms were measured in a temperature range of 180 K to 380 K under an applied magnetic field from 1 to 3 T. Maximum ΔS_M increases as heat treatment rises for magnetic field changes from 1 to 3 T in each sample. The maximum ΔS_M obtained for 3 T display maximum values of 0.73, 1.64 and 2.05 J/kgK for 700, 800 and 900 °C nanofibers heat treatments respectively. Magnetic behavior in manganites shows to be influenced by one dimensional structure as compared with the bulk form.

N1-10. Magnetic Behavior of Ultra-Short 1D Ferromagnetic Chains Based on Metallo-Phthalocyanine Superlattices. *N.M. Vargas*[1], C. Monton[2] and I.K. Schuller[1] *1. Physics, University of California, San Diego, San Diego, CA, United States; 2. Physics and Astronomy, University of Texas at San Antonio, San Antonio, TX, United States*

The magnetic properties of 1D Fe and varying composition Fe/Co chains are studied as a function of chain length, and temperature. Ultra-short chains (3 to 50 nm) are grown by organic molecular beam epitaxy using Metallo-Phthalocyanine (MPc) superlattices (SLs) as shown in Fig.1. The chain's orientation can be controlled by the appropriate choice of substrate to be parallel (sapphire) or almost perpendicular (Au) to the sample surface, and their composition can be tuned alternating different MPc species in a SL structure. Interestingly, by increasing the numbers of periods of the SL, the magnetic signal of ultra-short chains can be amplified. This enables the use of conventional magnetometer techniques, such as VSM and SQUID, to perform a complete magnetic characterization. In this work, we have fabricated Fe and Fe/Co chains using MPc SLs. We have found that the coercive field of the Fe chains decreases when their length is reduced from 160 to 15 atoms in a SL structure. We correlate this behavior with the structural properties of the chains obtained by x-ray diffraction and x-ray absorption spectroscopy. Work supported by the Office of Basic Energy Science, U.S. Department of Energy, BES-DMS funded by the Department of Energy's Office of Basic Energy Science, DMR under grant DE FG02 87ER-45332, and the US DoD Vannevar Bush Fellowship.

N1-11. Magnetic nanowires as permanent magnets: modeling strategies to increase the coercive field. *H.D. Salinas*[1], J. Fernandez-Roldan[2], J. Restrepo[1] and O. Chubykalo-Fesenko[3] *1. Antioquia, Universidad de Antioquia, Medellin, Colombia; 2. Institute of Materials Science of Madrid (ICMM-CSIC), Madrid, Spain; 3. Insituto de Ciencia de Materiales de Madrid, Madrid, Spain*

Magnetic nanowires are of interest for applications such as high-performance permanent magnets due to their high shape anisotropy and coercive field [1] among others. In this work, we have theoretically investigated different possibilities to increase the coercive force and internal product in FeCo magnetic nanowires with high magnetization saturation. For this purpose, we perform micromagnetic modeling using the oommf package. First, we perform an analysis of the reversal mechanisms of the magnetization as a function of diameter, the aspect ratio and the type of wire edge. Results reveal the conditions under which an increase in the coercive field can be achieved, including the different modes of propagation via transverse or vortices domain walls [2]. In particular, an increase in the size of the domain wall as a function of diameter is evidenced. One of the strategies to increase the coercive field is based on different curvatures at the nanowire ends which may impede the domain wall nucleation. For this case we investigated the magnetization reversal mechanisms as a function of the curvature of the ends of the wire, finding an increase in the coercive field. Our next strategy is based on the superferrimagnetic effect as suggested in [3] where the hard ferromagnetic phase (nanowire) is antiferromagnetically coupled to a soft ferrimagnetic phase (e.g. $GdFe_2$). We explore two scenarios (i) through couplings at the nanowire wire taps and (i) embedding in a ferromagnetic matrix (see figure 1a and 1b). The results reveal a moderate increase in magnetic energy in both cases.

N1-12. Magnetization reversal modes of single-wall zig-zag ferromagnetic nanotubes with Dipolar Interactions. *H.D. Salinas*[1], J. Restrepo[1] and O. Iglesias[2] *1. Antioquia, Universidad de Antioquia, Medellin, Colombia; 2. Dpt. Condensed Matter Physics, University of Barcelona, Barcelona, Spain*

When the size of a material is reduced at atomistic scale, the surface to volume ratio becomes increasingly important, but if in addition, a curved surface is present, the degree of curvature is also more pronounced, making the magnetic properties dependent of such a topologic features [1,2]. To do so, we have conducted standard single-spin movement Metropolis Monte Carlo simulations in the framework of a three-dimensional Heisenberg classical model. In this work we analyze the effect of the competition between long-range magnetic dipolar interactions (D) and short-range exchange interactions (J) through a parameter $\gamma = D/J$ [3] upon the field-driven magnetization reversal modes of single-wall zig-zag ferromagnetic nanotubes at low temperature and for different aspect ratios. The results found suggest different nucleation modes strongly dependent both on γ, the aspect ratio and the orientation (perpendicular to or oriented along the length of the tube) of the external applied magnetic field [see figure 1]. It is interesting also to remark that for high enough values of γ, intermediate vortex states in the edges appear during the switching process from a saturated state as can be observed in figure 2.

N2-01. A comprehensive Study of Sign Change in Electric Field Control Perpendicular Magnetic Anisotropy Energy at Fe/MgO Interface: First-Principles Calculation. *I. Pardede*[1], T. Kanagawa[1], N. Ikhsan[1], M. Obata[1,2] and T. Oda[1,2] *1. Graduate School of Natural Science and Technology, Kanazawa University, Kakuma-machi, Japan; 2. Institute of Science and Engineering, Kanazawa University, Kakuma-machi, Japan*

Electric field (EF) control of magnetic anisotropy energy (MAE) at Fe/MgO interface with a Cr buffer layer has been performed by means of first-principles electronic structure calculation. Buffer layer engineering has been introduced by an intermixing between Fe and Cr as possibly occur as an annealing treatment effect during the deposition process [1,2], namely $[Fe/Cr]_n$ (n=1 and 2). This intermixing leads to a substantial rearrangement in the electronic structure due to proximity effect Fe and Cr. Interestingly, as a proximity effect, we found an opposite sign of the EF control MAE coefficient (γ) as EF dependence. Under electron depletion, the MAE increases and decreases with the absolute values of 89 fJ/Vm and 92 fJ/Vm for n=1 and n=2 respectively. In addition, due to an intermixing effect, a systematic strain engineering was performed which produces a different behavior from the analysis of the 3*d*-orbital states with the magnetic quantum number $|m|$=1 and $|m|$=2 near the Fermi level (E_F). In the case of n=1, it is monotonically shifted down by decreasing the lattice constant while in n=2, the behavior is shifted up (shifted down) by increasing (decreasing) lattice constant with a crossing point in Fe lattice constant. For the latter one, the enhancement of MAE and γ can be achieved with the maximum absolute value 2.43 mJ/m^2 and 170 fJ/Vm respectively. This result shows that the tetragonal distortion can effectively tune the pairs of 3*d*-orbital states ($|m|$=1 and $|m|$=2) around E_F and hence can affect both MAE and γ values. The possible origin will be discussed in terms of the electronic structure which changes the relative occupancy of 3*d*-orbital states in the vicinity of the Fermi level. This result provides a new possible degree of freedom for the EF control in MAE as buffer layer configuration.

N2-02. Effect of metallic Mg insertion on the Voltage-Controlled Magnetic Anisotropy Effect in MgO/CoFeB-Based Magnetic Tunnel Junctions. *J. Ko*[1] and J. Hong[1] *1. Materials Science and Engineering, Yonsei University, Seoul, The Republic of Korea*

Engineering of interfacial structures has become important more than ever before to find new scientific observations and to create novel applications. Here, we show that the interface reconstructed by Mg insertion improved the magneto-electrical properties of perpendicular magnetic tunnel junctions essential for modern spintronic applications. The 0.2–0.4 nm-thick Mg inserted between the MgO tunnel barrier and CoFeB ferromagnet restructured the interface in such ways as to protect the CoFeB from overoxidation, to strengthen the texture, to make the interfacial roughness smooth, and to relax the mechanical stress. Observed were great increases in the perpendicular magnetic moment and perpendicular magnetic anisotropy of the CoFeB by 2.1 and 1.8 times, respectively, which can be ascribed to the optimum interfacial condition because of the least possible chemical damage. The strong enhancement of (010) in-plane and (001) out-of-plane texture and of interfacial roughness led to a significant increase in the tunnel magnetoresistance by 4.4 times from 13.2 to 57.6% by the insertion. Most importantly, such optimum chemical and physical structures at the interface could modulate the perpendicular magnetic properties by an electric field. The electric field-controlled magnetic anisotropy coefficients became symmetrically bipolar to the electric field and were increased over 100 fJ/V●m, which is 6 times larger than one found before the Mg insertion. As a result, we could successfully demonstrate the voltage-induced magnetization switching of the perpendicular magnetic tunnel junctions with the help of an external magnetic field. Our findings will ignite further study on the new way of electrical control over magnetic switching and provide an essential ingredient to realize electric field-driven energy-effective magneto-electronic devices.

Schematics of effects of interface engineering by using the Mg insertion and change of magneto-electrical properties such as voltage controlled magnetic anisotropy and voltage-assisted magnetization switching in MgO/CoFeB-based magnetic tunnel junctions.

N2-03. Electrically Programmable Magnetoresistive Switching in AlO_x Magnetic Tunnel Junctions. C. Hung[1], J. Hong[2], K. Ou Yang[1], *K. Chiu*[1] and M. Lin[1,3] *1. Physics, National Taiwan University, Taipei, Taiwan; 2. Physics, Tamkang University, New Taipei City, Taiwan; 3. Institute of Atomic and Molecular Sciences, Academia Sinica, Taipei, Taiwan*

We report spin-dependent transport properties and I-V hysteresis characteristics in AlO_x magnetic tunnel junctions prepared with different oxidation condition. The bipolar resistive switching and electrically programmable tunneling magnetoresistance measured at high resistance state and low resistance state demonstrate four resistance states in a single device. The R-T curves at low resistance state suggest that the resistive switching is not triggered by metal filament inside the AlO_x layer. The fitting analysis of R-T curves also gives hint that higher-order inelastic hopping within the AlO_x barrier may contribute significantly to the conductivity of the sample, in addition to the tunneling conductivity. Our study reveals the possibility of controlling multiple resistance states in an AlO_x magnetic tunnel junction using both magnetic field and electric stimulus, providing potential application for the multibit memory.

N2-04. Electric-Field Induced Control of Magnetization in Thicker CoPd Multi-layered Films. *A. Siddique*[1], C. Nwokoye[2], A. Aslani[3], L.H. Bennett[1] and E. Della Torre[1] *1. Electrical and Computer Engineering, The George Washington University, Ashburn, VA, United States; 2. Naval Surface Warfare Center, Carderock Division, West Bethesda, MD, United States; 3. Electrical and Computer Engineering, The George Washington University, Washington, DC, United States*

The electric field induced variations in the magnetic properties of thinner films shown previously [1,2] suggest that their thickness is a critical factor alongside other causes like applied field, composition and morphology of the system. Here we present the phenomenon in a much thicker system (~ 35 nm) with a different composition. A CoPd multi-layered film prepared by molecular beam epitaxy (MBE) using e-beam evaporation was used. The sample composition was [Si (100)/SiO_2/22nm W/ 10nm Pd/ (0.3nm Co/ 1nm Pd)$_{15}$ 10 nm Pd/ 1.5nm Fe] and annealed for an hour at 523 K showing strong perpendicular magnetic anisotropy. The electrochemical double layer is formed at the surface of sample placed inside an electrolyte (1 M $LiClO_4$ in Ethyl Acetate). We set the gate voltage to a non-zero value of interest within the electrochemical potential window and measured the hysteresis loop using a MOKE magnetometer. We calculated and analyzed the percentage variation of critical magnetic parameters, e.g. coercivity with the application of gate voltage. The results in Figs. 1 and 2, show that there is a significant change in coercivity from 1.77% to 3.26 % when the biased voltages are increased from -0.5 V to -1.5 V.

N2-05. Electrochemical Manipulation of Magnetism and Magnetization Reorientation in $LiFePO_4$ by Li-ion Intercalation. *T. Tumurbaatar*[1], D. Odkhuu[2] and S. Hong[3] *1. Department of Physics, University of Ulsan, Ulsan, The Republic of Korea; 2. Department of Physics, Incheon National University, Incheon, The Republic of Korea; 3. Physics, University of Ulsan, Ulsan, The Republic of Korea*

Employing first-principles electronic structure calculations, we demonstrate that the magnetic anisotropy of an olivine Li_xFePO_4 ($0 \le x \le 1$) can undergo a transition from magnetization along the [010] for $FePO_4$ to the [001] for $LiFePO_4$. Further calculations show that the local magnetic moment of Fe atoms is reduced from 4.29 μ_B for $FePO_4$ to 3.77 μ_B for $LiFePO_4$, in good agreement with experiments [1]. These findings can be elucidated by means of crystal field theory through the unpaired electron spin counts of Fe^{3+} and Fe^{2+} in high spin state. Moreover, we provide physical insights on an experimental observation of Neel temperature reduction from 125 K in $FePO_4$ to 50 K for $LiFeO_4$ [1] in terms of magnetic energy. While the lowest energy magnetic structure is an antiferromagnetic phase regardless of x in Li_xFePO_4, the difference in total energy between ferromagnetic and antiferromagnetic phases decreases as x increases.

N2-07. Magnetic domain writing defined by electrical gating in Pt/Co film. *F. Ando*[1], M. Ishibashi[1], T. Koyama[2], Y. Shiota[1], T. Moriyama[1], D. Chiba[2] and T. Ono[1] *1. Institute for Chemical Research, Kyoto University, Kyoto, Japan; 2. Department of Applied Physics, The University of Tokyo, Tokyo, Japan*

The energetically efficient control of magnetic domains in ferromagnet is a crucial technique for the realization of magnetic domain wall logic circuit. So far, the control of magnetic domain structure has been accomplished by means of local Oersted field, circularly polarized light [1], or electrochemical-reaction-induced modulation of magnetic property [2]. Recently, an electrical formation of ferromagnetic nanodots was suggested using ferromagnetic semiconductor with a solid-state field effect transistor structure [3]. Here, we directly observed the magnetic domain writing defined by electrical gating in a Pt/Co film using magneto-optical Kerr effect. Because the change of carrier density mediates the modulation of magnetic property in the Pt/Co, this method provides the more controllable, downscaled, and power-efficient way to write the magnetic domain structure. We prepared a capacitor structure to apply a gate voltage V_G, consisting of a perpendicularly magnetized Pt (2.0 nm)/Co (0.25 nm) bottom electrode, a MgO (2.0 nm)/HfO_2 (40 nm) dielectric insulator layer, and a Cr (3.0 nm)/Au (5.0 nm) meshed top gate electrode [3]. Here, the application of positive V_G was defined as the electron accumulation at the top surface of the Co layer. As shown in Fig. 1, the magnetic domain structure was directly observed using a MOKE microscope under the application of V_G. The magnetization direction was selectively switched by sweeping an out-of-plane magnetic field due to the electric-field-induced modulation of the magnetic coercivity.

N2-08. Observation of reversal process of perpendicular exchange bias during magnetoelectric field cooling. *Y. Shiratsuchi*[1], S. Watanabe[1] and R. Nakatani[1] *1. Osaka University, Osaka, Japan*

Exchange bias refers the magnetic bias field caused by the interfacial exchange coupling between ferromagnetic and antiferromagnetic spins and manifest itself as a shift of the magnetization curve along a magnetic field axis. When the exchange bias field exceeds the coercivity, the magnetization direction at the remanent state can fix to the certain direction independent of the magnetic field hysteresis, and the fixed direction is determined by the exchange bias polarity. Although the conventional the exchange bias was defined by the field cooling process and the subsequent control of the polarity was difficult, the recent progress enabled us to control the exchange bias polarity based on the magnetoelectric (ME) control of the antiferromagnetic domain state. Up to date, there are some reports demonstrating the ME-induced switching of the exchange bias polarity[1-6] but the direct observation of the reversal process is lacked. In this work, we observed the change in the magnetic domain pattern after the ME field cooling (MEFC)[1,3,4], one of two typical ME switching protcols. Sample was Pt(1.5 nm)/Co(0.8 nm)/Au(1.0 nm)/Cr_2O_3(150 nm)/Pt(20 nm) stacked film on the α-Al_2O_3(0001) substrate which exhibited both perpendicular magnetic anisotropy and perpendicular exchange bias. Magnetic domains were observed by magneto-optic Kerr microscope. The MEFC process is denoted as follows; (1) the sample was heated above the Néel temperature of our Cr_2O_3 film, ~290 K, (2) the magnetic field, H (+15 kOe) and the electric field, E (0 - +9 V, varied) were applied, and then (3) the sample was cooled to 275 K in maintaining H and E. H and E were applied to the direction perpendicular to the film. With increasing E, the exchange bias polarity changes from negative to positive, agreeing with the previous reports[1,3,4]. Magnetic domain pattern at the remanent state changes accompanying with the switching of the exchange bias polarity. The nucleated domain size is at the order of several μm. With increasing E, the size of the nucleated domain does not highly change but the number of the nucleated domain increases. At the presentation, details of the training effect, the difference with the H-induced switching are also discussed.

N2-09. Reversible electrical field control of magnetization and anomalous Hall effect in Co/PMN-PT hybrid heterostructures. *Y. Tian*[1] and Y. Chen[1] *1. School of Physics, Shandong University, Jinan, China*

Various studies have been focused on electrical field control of magnetic effects in recent years, including magnetic phase transitions, magnetic anisotropy, magnetic domain wall propagation, exchange bias and spin polarization. Electric field control of magnetic properties would hopefully open up new prospects for the realization of high-density magnetic storage and logical technologies with ultralow energy consumption. In spite of intense research efforts and considerable success in recent years, it is still of substantial interest in reversible electrical field induced modification of novel functionalities, which are realized through the combination or competition of multiple manipulation mechanisms in the hybrid multiferroic devices at room temperature. In this work, reversible room temperature electric field control of magnetization and anomalous Hall effect is reported in the Co/Pb($Mg_{1/3}Nb_{2/3}$)O_3-$PbTiO_3$ (PMN-PT) based hybrid multiferroic hetetojunctions. It is demonstrated that in the ZnO/Co/PMN-PT junctions electric field induced strain and oxygen ion migration effect have an opposite influence on the magnetic properties of Co sublayer, and their competition determines the final magnitude of magnetization. The concept of optimize and enhance the effect of electric field on the magnetism by integrating more than one manipulation mechanisms together can be adapted to other hybrid heterojunctions, which hold promising technological application prospects.

N2-10. Electric-field-induced ultra-fast switching of antiferromagnets. *V. Lopez Dominguez*[1], H. Almasi[1] and P. Khalili Amiri[1] *1. Electrical Engineering and Computer Science, Northwestern University, Evanston, IL, United States*

Spintronic devices based on antiferromagnetic (AFM) materials are of increasing interest in computing and communication applications, due to attractive features such as picosecond switching in magnetic memories [1] (~100x faster than the best ferromagnetic memories reported to date [2-4]), immunity to external magnetic fields, high density device arrays without inter-bit dipole interaction, and generation of Terahertz signals at the nanoscale [5,6]. Analogous to the case of their ferromagnetic counterparts, AFM spintronic devices must meet two main requirements: 1) A reliable and scalable electrical method for reading of the magnetic state of the AFM [7,8], and 2) a low-power-consumption method to manipulate the magnetic state of the AFM. This work addresses the second requirement by proposing the use of Voltage-Controlled Magnetic Anisotropy (VCMA) in a metallic AFM film in proximity to a gate oxide. It has been recently reported, based on first-principles calculations, that AFM/oxide interfacessuch as FeRh grown on MgO may exhibit a sizeable VCMA effect [9] (which to date has only been observed in ferromagnetic thin films). We developed a micromagnetic model incorporating the VCMA effect and current-induced spin torques in a uniaxial AFM film. To simulate the spin dynamics, we numerically solved two coupled Landau-Lifshitz-Gilbert equations for two opposite macrospins coupled by an exchange field. The simulation results show that for sufficiently large applied electric fields which overcome the uniaxial anisotropy, a high-frequency resonance is excited. This VCMA-induced antiferromagnetic resonance can be timed to switch the Neel vector by 180 degrees for voltage pulses shorter than 10 ps. In addition, we study the variation of switching behavior and optimum pulse width by application of applied voltage, external magnetic fields, and exchange interaction. These results open a new route for voltage control of AFM materials for ultra-low-energy THz-frequency spintronic devices.

N2-11. Asymmetric Electron-Hole Decoherence in Epitaxial Graphene.
K. Min[2,1], J. Park[1], W. Kim[1] and D. Chae[1,2] *1. Center for electromagnetic metrology, KRISS, Daejeon, The Republic of Korea; 2. University of Science and Technology, Daejeon, The Republic of Korea*

We report the asymmetric quantum interference in ion-gated epitaxial graphene. The ionic liquid gating technique was employed instead of dielectric field effect geometry to overcome the limitation on carrier tenability. The negative magnetoresistance has been observed in low magnetic field region. The decoherence rate extracted from a weak localization analysis exhibits asymmetric electron-hole decoherence; the hole decoherence rate prominently increases with increasing carrier density while the electron decoherence rate does not exhibit any pronounced density dependence. The hole decoherence rate is nearly two times as large as the electron decoherence rate. This observation is markedly distinct from the almost carrier-density independent dephasing in epitaxial graphene with limited density modulation or the symmetric electron-hole decoherence of exfoliated graphene gated in the dielectric field effect geometry. Potential microscopic origins was discussed with our experimental observations.

N3-01. Magnetic order, Kondo effect and crystalline electric field effect in Semiconducting CeSbTe. *B. Lv*[1] *1. Physics Department, Zhejiang University, Hangzhou, China*

Single crystals of CeSbTe were synthesized using iodine transport method. This compound crystallizes in a structure of ZrSiS type with the space group P4/nmm(No.129), and the refined lattice parameters are a=4.39792 Å and c=9.40027 Å. We present the results of magnetic-susceptibility, electrical-resistivity and specific heat measurements. It behaves like a semiconductor and displays a coexistence of magnetic ordering, Kondo effect and crystalline electric field effect. A field-induced metamagnetic transition is observed below the magnetic ordering of 2.7K. The measured Sommerfeld coefficient is moderate, indicating that CeSbTe is a moderately AFM Kondo system. Therefore, we propose that it is a Kondo semiconductor.

N3-02. Electronic Structure of CeNiSn: is it a Kondo Insulator or not?. *T. Nam*[1], B. Cédric[2], C. Kang[1], D. Ryu[1], K. Kim[1] and B. Min[1] *1. POSTECH, Pohang, The Republic of Korea; 2. The University of Tokyo, Tokyo, Japan*

Topological Kondo insulators draw a great deal of recent attention, and so research on conventional Kondo insulators is actively revived. SmB6 is a typical example. Recently, CeNiSn has also been investigated as a promising candidate of Kondo insulator. But it is controversial whether it is a Kondo insulator or semimetal. Recent magnetothermoelectric measurement on CeNiSn [1] suggested that CeNiSn is a nodal metal arising from anisotropic hybridization. Specific heat and thermal conductivity measurements [2], however, indicate that CeNiSn has an anisotropic pseudo-gap. To explore the Kondo nature in CeNiSn, we have investigated the electronic structure of CeNiSn, utilizing the density functional theory and the dynamical mean field theory. We compared our result with ARPES (Angle-resolved photoemission spectroscopy) and found that band structure matches well with each other, especially the kink where the shape of band suddenly bent over, indicating the f-d hybridization below Kondo temperature. Also, our Fermi surface calculation manifests the remnant of f-band. CeNiSn hosts Kondo effect but the gap opens only partially, namely not in the whole Brillouin zone, possibly related to the crystal structure. Temperature-dependent band structures and densities of states are also examined. To search for topological Kondo insulators, we continue to perform band calculations on other materials, which share the same space group as CeNiSn.

Determining the crystal-electric field (CEF) potential is part of the fundamental characterization of any new material in the field of heavy fermion and Kondo physics. Here we present a new method, resonant inelastic soft X-ray scattering (RIXS) at the rare earths M-edge[1], as a promising tool complementary to inelastic neutron scattering (INS) for characterizing the low energy 4*f* electronic states of the rare earth (RE). State-of-the-art RIXS beamlines have now a resolution comparable to the size of RE CEF splitting. RIXS covers a much wider energy range than INS and additional information is provided by probing the excited multiplets. Furthermore, RIXS is element and even configuration specific. Heavy fermion/Kondo physics is driven by the hybridization of the localized 4*f* electrons with the conduction bands. This hybridization can lead to effects like unconventional superconductivity, quantum criticality, or the opening of a hybridization gap. The materials showing these hybridization gaps (Kondo insulators) experienced a revival due to the exciting prediction of non-trivial topological surface states. SmB_6 and non-centrosymmetric $CeRu_4Sn_6$[2,3] fall into this class of materials and have been discussed in terms of strongly correlated topological insulators[4] or heavy Weyl fermions.[5] We will show RIXS data of $CeRu_4Sn_6$ and SmB_6. RIXS directly probes the 4*f* CEF splitting of both the ground $^2F_{5/2}$ and excited $^2F_{7/2}$ spin-orbit multiplets of Ce^{3+} ($4f^1$) so that a full-multiplet analysis[6] provides the full determination of the CEF scheme of $CeRu_4Sn_6$, as well as the ground and excited wavefunctions, and the orbital orientation with respect to the crystal lattice. RIXS and INS give consistent results.[6] SmB_6 is strongly intermediate valent (Sm^{2+} and Sm^{3+}). Although SmB_6 is a long known compound, INS could not solve the CEF because of the superposition of signals from both configurations[7]. Thanks to the configuration selectivity of RIXS and the accessibility of the higher multiplets we can give an upper limit of the CEF splitting, consolidating a recent study showing that the Sm^{3+} CEF-split ground state is a Γ_8 quartet.[8] This information is important for proving the validity of band structure calculation.

N3-04. Divalent ion substitution effect on Yb-site in Kondo Insulator YbB_{12}. *W. Matsuhra*[1], K. Yokomichi[1], W. Hirano[1], S. Kikuchi[1], N. Uematsu[1], H. Nakayama[2], A. Kondo[3], K. Kindo[3] and F. Iga[1,2] *1. Graduate School and Engineering, Ibaraki University, Mito-shi, Japan; 2. College of science, Ibaraki University, Mito-shi, Japan; 3. ISSP, The University of Tokyo, Tokyo, Japan*

Hybridization effect between the 4f electrons of Yb and conduction electrons is very important for the formation of an energy gap in Kondo insulator YbB_{12}. We have investigated the relationship between density of states(DOS) near Fermi level ε_F and c-f hybridization by transport and magnetic properties in $Yb_{1-x}R_xB_{12}$ (R = non-magnetic trivalent ions[1] or tetravalent ions). We have recently succeeded in Ca substitution for Yb by high - pressure synthesis. Decreasing of DOS near ε_F is expected by Ca^{2+} substitution. Thermal activation energy estimated from resistivity (Fig.1) in $Yb_{1-x}Ca_xB_{12}$ shows almost no x-dependence different from the cases in $Yb_{1-x}R_xB_{12}$(R=Lu,Sc) (Fig.2). In this presentation, we will discuss Ca-substitution effects for physical properties in $Yb_{1-x}R_xB_{12}$.

N3-05. Kondo effect at carbon vacancies in graphene sheets: A Numerical Renormalization Group study. *D. May*[1] and F. Anders[2] *1. Theoretical Physics, Technical University Dortmund, Dortmund, Germany; 2. Theoretical Physics, Technical University Dortmund, Dortmund, Germany*

Graphene in its pristine form has transformed our understanding of 2D electron systems leading to fundamental discoveries. In the last decades, graphene has been the centre of attention due to its possible use for spintronic applications. Irradiation experiments turned out to be one proven way to introduce stable magnetic moments into graphene sheets via the creation of carbon point-defects [1]. Recently its has been experimentally shown by Mao et al [2] that these vacancies exhibit Kondo physics. The scanning tunneling spectra are different for different vacancies and show non-trivial dependence on a gate voltage induced chemical potential. These vacancies disrupt the perfect honeycomb lattice and yield a local Jahn-Teller deformation. As a result, one of the three broken in-plane σ bonds remains unpaired and acts as a localized orbital. Furthermore, the removal of a carbon atom causes the formation of the so-called zero-mode bound state with a characteristic long-range decaying wave function. The local curvature in the vicinity of the defect generate a hybridization of the unpaired orbital with the otherwise orthogonal pi-orbitals. The itinerant π band is characterized by a pseudogap density of states (DOS) of graphene that vanishes at the Dirac point. We employ Wilson's Numerical Renormalization Group technique [3] and study an effective two-orbital single impurity model comprising the unbound σ orbital and the vacancy induced bound state coupled to pseudogap DOS of graphene. The interplay of chemical potential and hybridization strength leads to a rich diagram for the different regimes at finite temperature (cf. Fig. 1). We calculate the local spectral functions and examine the underlying microscopic picture. We present three different scenarios for our impurity model and discuss the dependence of the Kondo effect on chemical potential and hybridization in each case.

N3-06. Observation of a resonant-type ground state in graphene intercalated with cerium. *C. Hwang*[1] *1. Physics, Pusan National University, Busan, The Republic of Korea*

The interaction between a magnetic impurity and metallic background provides a key to understand many-body interaction and its effect on the physical properties of a material. Such an interaction leads to the formation of a resonant-type many-body ground state, so-called Kondo resonance, that is enhanced at low temperatures. Using an angle-resolved photomission technique, we investigate temperature-dependent electron band structure of graphene intercalated with cerium, which provides metallic electrons and localized 4*f* electrons, respectively. Cerium intercalation induces new spectral weight in graphene band structure that becomes stronger at low temperature, which is attributed to the formation and development of the new many-body ground state.

N3-08. Abnormal mixed-valent behavior in $Sm_{1-x}Y_xS$. *D.G. Mazzone*[1], J. Hancock[2], K. Imura[3], J. Rueff[4], J. Ablett[4], H. Yamaoka[5], N. Hiraoka[6], K. Tsuei[6] and I. Jarrige[1] *1. National Synchrotron Light Source II, Brookhaven National Laboratory, Upton, NY, United States; 2. Department of Physics, University of Connecticut, Storrs, CT, United States; 3. Department of Physics, Graduate School of Science, Nagoya University, Nagoya, Japan; 4. Synchrotron SOLEIL, Gif-sur-Yvette Cedex, France; 5. RIKEN SPring-8 Center, Hyogo, Japan; 6. National Synchrotron Radiation Research Center, Hsinchu, Taiwan*

SmS is a divalent semiconductor which can be tuned through a first-order isostructural transition into a metallic mixed-valence state, either by external pressure or substitution of Sm with Y [1, 2]. Discovered in the early 1970s, this so-called black-to-golden phase transition has recently regained the spotlight as the low-temperature golden phase of SmS was suggested to either host topological protected surface states [3] or undergo a Lifshitz transition of the Fermi surface topology [4]. We here report on measurements of the *4f*-electron occupancy and local spin configuration in $Sm_{1-x}Y_xS$ across this phase transition, using respectively X-ray absorption spectroscopy in the partial fluorescence yield mode (PFY-XAS) and X-ray emission spectroscopy (XES). Our results show that while a sharp decrease in the *4f* occupancy and local moment occurs across the phase transition at room temperature, an unexpected strong increase of the occupancy gradually takes place in the golden phase upon cooling while the moment remains unchanged. These paradoxical observations shed new light on the low-temperature golden phase, which reverts back to a nearly divalent state albeit with delocalized *4f* moments typical of a strongly mixed-valence state. This experimental evidence of the localized / delocalized dual nature of the Sm *4f* electrons will be discussed in light of the recent debates on the topological properties of golden SmS.

IMR, Tohoku University, Sendai, Japan*

Strong couplings between photons and spins, atoms and superconducting qubits lie at the heart of realizing the quantum manipulation in quantum dots, nitrogenvacancy centers and mechanical oscillators [1-5]. Cavity magnon polaritons [6-8], i.e. the hybrid state of a cavity photon and a spin wave excitation in a magnet in the cavity, have been evidence of such coupling at both ultralow and room temperatures. Strong couplings have been observed in sub-millimeter-sized YIG spheres [8]. Here, we observe strong interlayer magnon-magnon coupling in an on-chip nanomagnonic device at room temperature. Ferromagnetic nanowire arrays are integrated on a 20-nm-thick yttrium iron garnet (YIG) thin film strip. Large anticrossing gaps up to 1.58 GHz are observed between the ferromagnetic resonance of the nanowires and the in-plane standing spin waves of the YIG film. Control experiments and simulations reveal that the interface exchange coupling is the dominating mechanism. The coupling strength is tunable by switching between different magnetic configurations. The coherent control of spin waves by surface induced strong coupling is of interest for magnonic devices.

We study collective spin waves in transversally magnetized chains of thin elliptical dots initially arranged into an antiferromagnetic (AF) configuration. The dispersion relations of the SW as well as the corresponding magnetization precession profiles (eigenvectors) are computed with the dynamical matrix method [1]. We report the peculiar features of AF optical and acoustical spin modes within the effective wavevector model [2], which has been adapted to the present geometry. We investigate the effects of the application of a transverse external field, leading the system from a perfect AF configuration to the ferromagnetic (FM) state, at a specific transition field. We discuss the mode localization and symmetry, and in particular, we focus on the AF soft mode, its symmetry and its relationship with the instability leading to AF-to-FM transition. We discuss the importance and potential application of the SW propagative properties suddenly changed at the switching from AF to FM. Finally, we present the calculations of spin dynamics concerning a FM-to-AF transition in a chain of ellipses with different width: in this case, the different shape anisotropy of the two ellipses results in different switching fields and hence in a field interval where the AF state is spontaneously attained. We show how this AF field interval can also be tuned by an effective uniaxial anisotropy of one out of two ellipses: this is indicative of any other source of anisotropy (like inverse-magnetostriction, particularly promising for voltage driven magnetic transitions in multiferroics): in this way, we investigate the AF-to-FM transition spin dynamics by varying the effective anisotropy constant of the material. Finally, we show and comment on the peculiar and remarkable change of slope of the mode dispersion across the AF-to-FM transition, with its implications in the field of magnon-spintronics devices.

Topological noncollinear magnetic phases of matter are at the heart of many proposals for future information nanotechnology, with novel device concepts based on ultrathin films and nanowires. Their operation requires understanding and control of the underlying dynamics, including excitations such as spin waves. So far, no experimental technique has attempted to probe large wave-vector spin waves in noncollinear low-dimensional systems. In this work, we explain how inelastic electron scattering, being suitable for investigations of surfaces and thin films, can detect the collective spin-excitation spectra of noncollinear magnets [1]. To reveal the particularities of spin waves in such noncollinear samples, we propose the usage of spin-polarized electron-energy-loss spectroscopy augmented with a spin analyzer. With the spin analyzer detecting the polarization of the scattered electrons, four spin-dependent scattering channels are defined. Controlling

the beam polarization, these channels allow us to filter and select specific spin-wave modes. We consider skyrmion, antiskyrmion, and spin-spiral phases on ferro and antiferromagnetic backgrounds. The measured dispersion and lifetime of the excitation modes permit us to fingerprint the magnetic nature of the substrate. Then we demonstrate that, counterintuitively and in contrast to the ferromagnetic case, even non-spin-flip processes can generate spin waves in noncollinear substrates. Furthermore, we discuss the reprociprocal-symmetry breaking in these systems due to Dzyaloshinskii-Moriya interaction in the presence or not of external magnetic fields [2-4].

N4-04. Excitation and propagation of spin wave pulses in a magnonic crystal. *C.L. Ordóñez-Romero*[1], Z. Lazcano-Ortiz[2], N. Qureshi[3] and G. Monsivais[1] *1. Solid State, Physics Institute, UNAM., Mexico City, Mexico; 2. BUAP, Puebla, Mexico; 3. CCADET, UNAM, Mexico City, Mexico*

Magnonic crystals (MCs) have recently demonstrated an outstanding capability to connect fundamental physics with applications at microwave frequencies [1]. Their characteristics have inspired multiple studies where detailed results on the behavior of the frequency-amplitude characteristic as a function of different structural parameters have been demonstrated [2]. However, up to now, all the scientific reports deal exclusively with the resulting spin wave spectrum for the complete MC structure and little has been said about the behavior of the spin wave inside the magnonic crystal. Here, we present a detailed study of the propagation of surface spin waves (MSSW) through a MC, the influence of the pulsed spin wave excitation in the formation and the evolution of frequency bandgaps inside the MC, and the spatial energy distribution as a function of frequency and position. A time and space resolved magneto inductive probing system has been used to map the spin wave propagation in a geometrically structured yttrium iron garnet (YIG) film. The results show that the formation of the bandgaps in the transmitted spin wave spectrum depends not only on the MC structure but also on the duration of the propagating pulse. This work has been supported by UNAM-DGAPA grant 1N103915

Magnetic skyrmions are particle-like, topological stable, nanoscale spin configurations with integer topological numbers which have been recently found in extended lattices of bulk non-centrosymmetric magnetic materials as well as in the ultrathin film with the presence of interfacial Dzyaloshinskii-Moriya interaction (DMI).[1, 2] The static and dynamic properties of magnetic skyrmions show high promise for the future spintronic memory and logic application with the main fundamental limitations of the skyrmion Hall effect. [1] Recently, it has been shown that this issue could be solved by using antiferromagnetic skyrmion [3,4], opening a path for a more competitive skyrmion based racetrack memory. Here, we firstly investigate how to stabilize skyrmions use tunnelling interlayer coupling in synthetic antiferromagnets (SAF) of the Co/Ru/Co trilayer type. To stabilize a SAF skyrmion, the DMI in the top and the bottom ferromagnet should have an opposite sign. By periodical arrangement of these SAF skyrmion, a novel type of magnonic crystal can be realized. We further study the magnonic bandstructure of spin wave in such a kind of antiferromagnetic skyrmion based magnonic crystal. The calculated magnonic spectra exhibit allowed frequency bands and forbidden frequency bandgaps analogous to that of conventional magnonic crystals and ferromagnetic skyrmion based magnonic crystals [6]. Therefore, it is possible to tailor the spin-wave spectra of SAF skyrmion systems into a band-like organization that displays a segregation of allowed and forbidden bands. Our results provide a natural link between two steadily growing fields of antiferromagnetic spintronics: skyrmionics and magnonics.

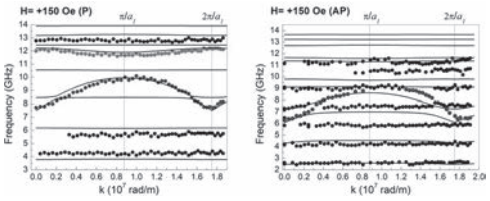
The reconfigurable magnonic band structure in dense arrays of layered Permalloy(10nm)/Cu(10nm)/Permalloy(30nm) nanowires (NWs) has been investigated by means of Brillouin light spectroscopy. The NWs are longitudinally magnetized by a magnetic field H=500 Oe and the wave vector (k) is swept perpendicular to the NW length. The novelty of the proposed trilayer MC structure is due to the fact that interlayer dipolar coupling gives rise to modes whose precession in the ferromagnetic layers is either

in-phase (acoustic mode) or out-of-phase (optic mode). We have found that the overall band structure, as well as the width and the center frequency of the magnonic band of the most dispersive modes, can be tuned by an applied magnetic field which controls the relative orientation of the magnetization in the two NW layers being either parallel (P state) or anti-parallel (AP state). In addition, the dispersive modes are not the lowest frequency ones, as observed in dipolarly coupled single layer NWs. When the system is in the P state two dispersive modes, with positive and negative group velocity, are observed while when the magnetizations are in the AP state, only one dispersive mode, with positive group velocity, is observed. Our findings are successfully compared and interpreted in terms of a microscopic (Hamiltonian-based) theory. Explanation for the observed differences in modes can be attributed to phase relations between the magnetization precession in the two layers. In this respect, acoustic modes, exhibit a dispersive behavior while optic modes, have a dispersionless behaviour, i.e. their frequency is constant vs *k*. This work opens the path to magnetic field-controlled reconfigurable magnonic crystals with multi-modal frequency transmission characteristics.



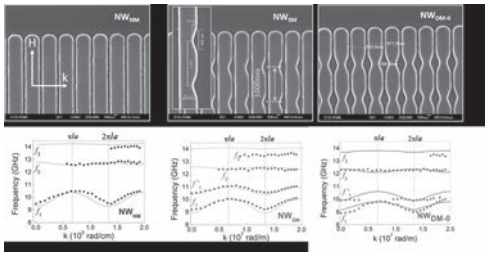


Fig. 1: Comparison between the measured and calculated band structure for the NW array in the parallel (P) and antiparallel (AP) configurations where the layers magnetizations point in the same and opposite directions, respectively. Blue and red point indicate the most dispersive modes.

N4-09. Collective spin waves in arrays of permalloy nanowires with single- and double-side periodical width-modulation. *G. Gubbiotti*[1], L. Xiong[2], F. Montoncello[3], L. Giovannini[3] and A. Adeyeye[4] *1. IOM-CNR, Perugia, Italy; 2. ECE, NUS, Singapore; 3. Physics, University of Ferrara, Ferrara, Italy; 4. Electrical & Computer Engineering, National University of Singapore, Singapore*

Using Brillouin light scattering spectroscopy and dynamical matrix method calculations, we study the propagation of collective spin waves in dense arrays of periodically single-(SM) [1] and double-side (DM) width-modulated nanowires.[2] Width modulation is achieved by creating a sequence of triangular notches on the nanowire edges with periodicity of p=1000 nm. For the double-side width-modulation, both symmetric and asymmetric nanowires, which differ by the relative displacement (D=0, 250 and 500 nm) of the notches sequence on the two lateral edges, were investigated. We found that collective the magnonic band which depend on the type of modulation (SM and DM) and on the relative displacements D. In particular, we found that the lowest two frequency modes (f_1 and f_1`) belong to a doublet of modes, localized in different regions of the nanowires, which origin from the splitting of the modes characteristics of the nanowire with homogeneous width(NW_{NM}). The origin of these doublets is explained in terms of the the inhomogeneity of the internal magnetic field. These results suggest a very efficient way for tuning the magnonic band structure and can be used for the realization of magnonic devices enabling parallel data processing on *multiple frequencies.*

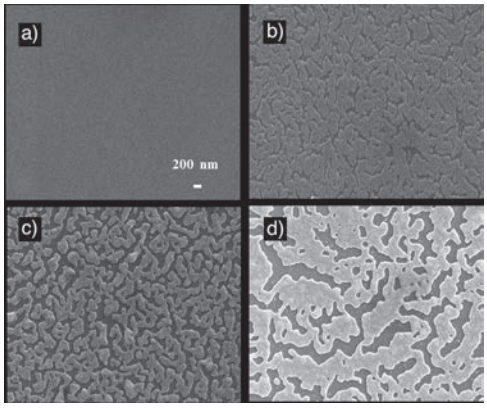
N5-01. Optical and Magneto-optical Studies of Doped Magnetic Shape Memory Ni-Mn-Ga Heusler alloys. *D. Kral*[1], M. Veis[2], P. Cejpek[3], O. Heczko[4], L. Straka[4], L. Beran[1] and M. Zeleny[4] *1. Institute of Physics, Charles University in Prague, Prague, Czechia; 2. Institute of Physics, Charles University, Prague, Czechia; 3. Department of Condensed Matter Physics, Charles University, Praha, Czechia; 4. Department of Functional Materials, Institute of Physics ASCR, Prague, Prague, Czechia*



Ni-Mn-Ga belongs to an extraordinary group of substances called the magnetic shape memory (MSM) alloys. This novel material has been in the center of attention of many research groups for the past decade due to its rather wide application potential [1]. The MSM effect causes the material to strain to up to 12% in moderate magnetic fields (< 1T) which is a feature rather appealing for contactless technology [2]. Its possible utilizations include sensorics and active/passive dumping, as well as a number of new paradigms, such as contactless microfluidic pumps. There are, however, some limitations that need to be overcome beforehand. The MSM effect is a result of the so-called martensitic transformation. Ni-Mn-Ga can only undergo this transformation in a limited scale of temperatures which has to be broadened before the material can be successfully implemented to global market. One of the possible solutions is to modify the material's electronic structure by doping, which influences the transformation via the Jahn-Teller effect. In order to investigate these modifications, we have employed magneto-optical spectroscopy and spectroscopic ellipsometry, which have proven to be the perfect tools for this task [3]. A set of monocrystalline Ni-Mn-Ga samples was produced by arch melting and doped with various amounts of Co and Cu. The samples were annealed and electropolished to obtain surfaces of optical quality. Their optical response was measured with the help of a dual rotating compensator ellipsometer in the photon energy range from 0.7 to 6.5 eV. Magneto-optical spectroscopy was measured using rotating analyzer setup in the same spectral range. The results of the optical and magneto-optical measurements were confronted with ab initio calculations to address the changes in experimental data to the band structure of studied materials. This work was supported by Czech Grant Agency (grant No. 16-00043S) and Ministry of Education of Czech Republic (grant No. OP VVV CZ.02.1.01/0.0/0.0/15_003/0000487).

N5-02. Dewetting Of Ni Thin Films Obtained By Atomic Layer Deposition Due To The Thermal Reduction Process: Variation Of The Thickness. D. Alburquenque[2], M. Del Canto[1], c. arenas[2], F.S. Tejo[2], *A. Pereira*[1] and J. Escrig[2] *1. Centro para el Desarrollo de la Nanociencia y la Nanotecnología CEDENNA, Santiago, Chile; 2. Department of Physics., University of Santiago of Chile, Santiago, Chile*

Nickel oxide thin films with different thicknesses were synthesized by atomic layer deposition. After a thermal reduction process, under a controlled atmosphere of hydrogen, it was possible to convert nickel oxide to metallic nickel. The different thicknesses were obtained for 250 to 2000 cycles of $NiCp_2/O_3$. The Ni thin films were characterized by X-ray diffraction, scanning electron microscopy, and by Magneto-Optical Kerr effect measurements. Micromagnetic simulations have been performed to investigate the mechanism of magnetization reversion of these films. Interestingly, the thermal reduction of films synthesized by ALD allows the generation of both randomly oriented, sized and spaced Ni islands and antidot arrays from thin films.

In this work, the structural properties and the multiferroic function of the challenge $SrMnO_3$ (SMO) oxide are investigated. SMO was chosen as test multiferroic because its low electrical conductivity [1], and *G*-type antiferromagnetic behavior [2]. Theoretical studies have pointed out to the possible ferroelectric ground state of SMO [3 - 5]. Up till now not enough experimental work has been done to analyze the structural instability of SMO upon the application of an electric field. Polycrystalline SMO samples were prepared by standard solid-state reaction. Analysis of the X-ray diffraction patterns indicates that the samples are single phase with 4*H*-hexagonal perovskite--type structure. Magnetic properties of the samples were carefully studied using Vibrating Sample Magnetometry (VSM). SMO exhibits antiferromagnetic (AFM) transition at T_N ~280 K with maximum value of magnetization of ~8×10^{-3} μ_B/Mn at 50 K in an external magnetic field of 30 kOe. These results are found to be in accordance with those found in the literature for polycrystalline SMO samples [6,7] (see inset top of Fig. 1). The isothermal magnetization curve of SMO at 50 K shows an upturn deviation from the linear behavior above 7 kOe (see Fig. 1). Measurements of the electrical polarization as a function of the electric field at room temperature indicate the presence of ferroelectricity in SMO with a maximum remanent polarization value of 0.015 μC/cm^2 at a maximum applied field of 4 kV/cm (see Fig. 2). These findings suggest that SMO could represent a new class of multiferroic material working at temperatures near room temperature.

N5-04. Magnetic Properties of reactive sputtered NiFe-oxide samples. *B. D C*[1], W.J. Geerts[2], A. Oliva[1], A. Ayala[1], S.C. Acharya[1], J. Talbert[1], L. Scolfaro[1] and F. Twagirayezu[1] *1. Physics, Texas State University, San Mrcos, TX, United States; 2. Physics, Texas State University, San Marcos, TX, United States*

NiO thin films and its doped cousins have been extensively studied for a large variety of applications, including solar cells, novel batteries, resistive nonvolatile Random-Access Memory, spintronic electronics, catalyzers, and gas sensors. Its applicability originates from the ability to modify its properties by changing the ratio of oxygen to metal atoms and to modify its crystallinity by doping with other transition metals. Here, we discuss the properties of reactive Radio Frequency sputtered NiO and Fe-doped NiO thin films sputtered at different oxygen flow rate. The films were deposited in an AJA Orion sputtering system from Ni or NiFe targets. The deposition rate was monitored before and after deposition using a Quartz Crystal Monitor. The amount of O_2 and Ar in the sputter gas was varied with MKS mass flow controllers. NiO (NiFeO) films sputtered with O_2 flows below 0.6 (0.9) sccm are metallic to the eye but still transmit in the near infrared part of spectrum. For higher flows the samples become transparent in the visible. In a separate experiment, the deposition rate at the sample location was determined as a function of O_2 flow. The rate of NiFeO increases 24% if the O_2 flow is increased from 0.8 to 1.25 sccm. Between 1.25 and 5 sccm O_2 flow the rate is constant, and then decreases sharply above 5 sccm. Above 5 sccm O_2 flow the sputtering of material of the target can no longer keep up with its oxidation. The formation of a permanent oxide layer on the targets is confirmed by a change of the gun's DC voltage. NiO films sputtered for those high O_2 flows are highly conductive and transparent. The rate change

at O_2 flows below 1.25 sccm is caused by the oxidation of the deposited metal film. This conclusion is supported by X-ray measurements which show the appearance of a metallic peak in the XRD data for lower O_2 flows. Additional proof is provided by vibrating sample magnetometer measurements that show an increase of the magnetic moment for films sputtered at lower O_2 flows. We acknowledge financial support from DOD (HBCU/MI grant W911NF-15-1-0394).

This work reports the low power (0.1 mW) Ferromagnetic Resonance (FMR) study of the magnetic anisotropy of Ni ferrites ($NiFe_2O_4$) produced by the sol-gel protein technique, annealed at high temperatures in the range from 873 to 1373 K. The FMR experiments were done at room temperature using a commercial spectrometer, standard resonant cavity, swept static magnetic field and the usual modulation and phase sensitive detection techniques, at microwave frequency of 9.76 GHz. The FMR lineshape fitting (Fig. 1) were done by considering a four-fold simmetry model for polycrystalline or randomically dispersed monocrystalline samples. The FMR results, also confirmed by X-ray crystallography, show that: (i) the crystallinity of ferrite particles, as shown in Fig. 2, increases proportionally with the annealing temperature; (ii) the cubic anisotropy field ($H_1=2K_1/M_s$) is proportional to the annealing temperature (T_A) and varies from positive to negative, as from +860 Oe, for T_A = 873 K, to -1110 Oe, for T_A = 1173 K and -1470 Oe, for T_A = 1373 K, for instance. Our FMR lineshape fitting model, an improved model descript in the reference [1], considers anisotropies larger an smaller from those defineted by the cristallographyc directions. These anisotropies were creditated to irregularities in the crystalline structure.

N5-07. Magnetic phase diagrams of $TbFe_2Al_{10}$ single crystal.
T. Mizushima[1], Y. Kamide[1], T. Kuwai[1] and Y. Isikawa[1] *1. Department of Physics, University of Toyama, Toyama, 930-8555, Japan*

We prepared single crystals of $TbFe_2Al_{10}$ compound by the Al-flux method. Crystal structure of the orthorhombic $YbFe_2Al_{10}$-type was confirmed by the X-ray powder diffraction pattern and crystal axes were determined by Laue pictures. We carried out the magnetization measurements and the specific heat measurements under various magnetic fields. The effective magnetic moments were obtained to be 10.03, 10.58 and 10.03μ_B for the *a*-, *b*- and *c*-axes by the temperature dependences of the inverse magnetic susceptibilities. These values are slightly larger than the value 9.72μ_B of the free Tb^{3+} ion. The origin may be considered to be the itinerant magnetism of Fe 3d band. Figure 1 shows the magnetization curves along the *a*-, *b*- and *c*-axes in magnetic fields up to 7 T at T = 2 K. Metamagnetic transitions occur at 0.97 and 1.88 T for the *a*-axis and 3.0, 4.0 and 5.0 T for the *c*-axis. A small hysteresis was observed in the magnetization process of the *a*-axis in the magnetic field range between 1 and 2.2 T. The metamagnetic transitions also were observed in the magnetization curve with polycrystalline samples. (1 - 3) Those metamagnetic transition fields are in good agreement with those of the *a*-axis at 0.97, 1.88 T and the *c*-axis at 3.0 T of our results. The magnetization curve of the *b*-axis is a nearly straight line. We determined the magnetic phase diagrams for the *a*-, *b*- and *c*-axes of $TbFe_2Al_{10}$ single crystal. Figure 2 shows the magnetic phase diagram along the *c*-axis. The magnetic phase diagrams have been made using the results of the magnetization measurements and the specific heat measurements under several magnetic fields.

N5-08. Enhanced magnetic anisotropy in Mn_3Ga thin films grown on LSAT. J. Karel[2], *F. Casoli*[1], L. Nasi[1], P. Lupo[1], R. Sahoo[3], E. Benedikt[3], A. Markou[4], A. Kalache[3], R. Cabassi[1], F. Albertini[5] and C. Felser[4] *1. CNR - IMEM, Parma, Italy; 2. Materials Science and Engineering, Monash University, Clayton, VIC, Australia; 3. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 4. Solid State Chemistry, Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 5. IMEM-CNR, Parma, Italy*

Tetragonal $D0_{22}$ Mn_3Ga films show exceptional magnetic and electronic properties, i.e., a unique combination of low magnetization, high uniaxial anisotropy, high Curie temperature, high spin polarization and low Gilbert damping, which make them very promising as ferromagnetic electrodes in Spin-Transfer-Torque Magnetic RAMs. A few recent works have demonstrated epitaxial growth of this phase on MgO, $SrTiO_3$ (STO) or Cr, Pt underlayers [1,2]. We have grown 40 nm $Mn_{3-x}Ga$ ($0<x<1$) films by RF sputtering. We have fully characterized the films by structural and magnetometric techniques (X-Ray Diffraction; High Resolution Transmission Electron Microscopy; Atomic and Magnetic Force Microscopy; SQUID Magnetometry). At 300 °C the $D0_{22}$ tetragonal phase of Mn-Ga grows epitaxially with easy magnetization c-axis oriented perpendicular to the substrate plane. Our previous work on STO substrates showed evidence for the tetragonal c-axis being oriented in the plane of the film for a small fraction of the film. This feature was markedly reduced by decreasing thickness and Mn content [3]. Moreover, Mn-Ga nanodots were fabricated from these films grown on STO and they similarly exhibited perpendicular magnetic anisotropy and large coercivity [4]. In this contribution, an alternative substrate is investigated - $(LaAlO_3)_{0.3}(Sr_2TaAlO_6)_{0.7}$ (referred to herein as LSAT). Growth on LSAT at 300 °C produces epitaxial films with perpendicular magnetic anisotropy and an enhanced magnetic anisotropy and saturation magnetization compared to films with the same composition grown on STO at the same temperature. Due to its smaller lattice parameter (0.387 nm versus 0.390 nm), the LSAT substrate drives a larger compressive strain at the film/substrate interface compared to STO. This strain, which is only partially relieved by the formation of dislocations at the film/substrate interface, leads to an increased c-axis parameter of the tetragonal $D0_{22}$ phase of Mn-Ga. The resulting increase in the distortion of the tetragonal lattice promotes the enhanced magnetocrystalline anisotropy and also determines an increased saturation magnetization [5]. The enhancement in magnetocrystalline anisotropy drives a slight increase in coercivity.

Department of Physics, Vardhaman College, Bijnor, India; 4. School of Natural Sciences, Shiv Nadar University, Gautam Buddha Nagar, India*

Spintronics is the new branch of physics and technology of electronics devices which utilizes not only the charge of the electrons but also their spins and hence offer many advantages such as non-volatility, increased data processing speed, lower power consumption, etc., over the conventional electronics [1]. For driving the spintronics devices, fully-polarized spin current is essential, which can be generated using the special type of magnetic materials, e.g., half-metallic ferromagnets (HMF) [2], spin-gapless semiconductors (SGS) [3, 4], spin-filter (SF) [5] materials, etc. Among such type of materials, SF material is superior and simpler over HMF and SGS materials for spin current generation because it does not require any spin-polarized (magnetic) electrodes. SF materials are magnetic semiconductors in which the band gaps for spin-up and spin-down channels are finite but unequal. Very recently, CrVTiAl (CVTA) Heusler alloy has gained a lot of attention as a potential SF material due to its cubic crystal structure as well as the fully-compensated ferrimagnetic (FCF) semiconducting behavior with a very high Curie temperature ($T_C > 700$ K) [6, 7]. CVTA alloy is predicted theoretically to have a direct band gap of 0.32 eV for the spin-up channel and an indirect band gap of 0.64 eV for the spin-down channel [8]. The epitaxial thin films of CVTA alloy were grown on single crystal MgO (001) substrates using pulsed laser deposition system. The absence of (111) diffraction plane of films in the phi-scan measurement suggests the presence of antisite disorder (B2-type). The magnetic property measurement indicates the ferrimagnetic nature of the films with a T_C of well above 400 K. The observed moment is close to the experimentally reported bulk value (~10^{-3} Bohr magneton/formula unit) [7]. The temperature dependence of electrical resistivity indicated that films are semiconducting in nature with a negative temperature coefficient of resistivity (TCR) values of the order of 10^{-9} - 10^{-7} Ohm-m/K. The magnetic semiconducting nature with a high T_C makes these films as promising material for fabricating the practical spintronics devices.

N5-10. Temperature evolution of unconventional magnetic domains in multiferroic $Sr_3Co_2Fe_{24}O_{41}$. *S. Mori*[1] *1. Materials Sceince, Osaka Prefecture University, Osaka, Japan*

Magnetoelectric (ME) materials have been the subject of intensive studies from both scientific and technological viewpoints because their ferroelectricity (magnetism) can be controlled with the application of a magnetic (electric) field [1]. In the multiferroic hexaferrite $Sr_3Co_2Fe_{24}O_{41}$, ferroelectricity is induced by applying a magnetic field at room temperature, which is due to a transverse helical spin structure [2]. Here we report temperature evolution of the magnetic domain structures in the helical and ferrimagnetic phases by *in-situ* Lorentz microscopy. Stripy domains (~ 20 nm in width) elongating perpendicular to the *c* axis was found to be formed in the transverse helical phase. On heating from the helical to ferrimagnetic phases, the stripy domains started to disappear and the 180° magnetic domains were formed although macroscopic magnetic domains existed in the helical phase remained unchanged. These suggest that the stripy magnetic domains originate from the helical spin structure and have no long-ranged coherence along the *c* axis. Furthermore, upon applying an external magnetic field, the striped magnetic domain walls transformed into magnetic bubbles in another ferrimagnetic phase. Our results suggest that the magnetic anisotropy in the helical and ferrimagnetic phases may play an important role in the formation of the magnetic domain structures [3].

N5-11. Spinel Ferrite Bulk and Surface Cation and Defect Contribution to the Ferrimagnetic Response. *V. Zviagin*[1], P. Huth[2], C. Sturm[1], J. Lenzner[1], A. Setzer[1], R. Denecke[2], P. Esquinazi[1], M. Grundmann[1] and R. Schmidt-Grund[1] *1. Felix Bloch Institute for Solid State Physics, University of Leipzig, Leipzig, Germany; 2. Wilhelm-Ostwald-Institute for Physical and Theoretical Chemistry, University of Leipzig, Leipzig, Germany*

We relate the bulk and surface cationic site occupancy to the overall ferrimagnetic order of inverse, disordered and normal spinel type $Zn_xFe_{3-x}O_4$ ($0 \le x \le 1.26$) thin films fabricated by pulsed laser deposition. We estimate the bulk concentration of octahedral [Fe^{2+}], [Fe^{3+}] and tetrahedral (Fe^{3+}) cations based on the electronic transitions between O 2p and Fe 3d and 4s orbitals, assigned to the model dielectric function (MDF) in a wide spectral range (0.5 – 8.5) eV. A direct correlation is found between the increase of the tetrahedral (Fe^{3+}) occupation and the ferrimagnetic response with a decrease of the $ZnFe_2O_4$ (ZFO) deposition temperature [1]. Analysis of the Fe 2p and 3p XPS core levels allows the determination of the surface cation contribution. The deviation of the surface [Fe^{2+}] : ((Fe^{3+}) + [Fe^{3+}]) cation ratio from the bulk is attributed to the presence of octahedral [Fe^{3+}] cations on the surface (see Fig. 1). Independent of the Zn concentration, the octahedral [Fe^{3+}] would contribute strongly to the competing anti-ferromagnetic and ferromagnetic interactions. Annealing of disordered ZFO films at temperature below the deposition temperature, in argon and oxygen atmospheres, induces a modification of the surface layer without causing a significant change in magnetic response. Upon annealing at temperatures above the deposition temperature, the bulk cationic structure tends to relax toward the stable phase of normal spinel.

N5-12. Nanoporous Amorphous Alumina Membranes — A Model System for d^0 Magnetism. *M. Coey*[1], A. Esmaeily[1], M. Venkatesan[1] and S. Sen[1] *1. Trinity College, Dublin, Dublin, Ireland*

Nanoporous alumina membranes produced by mild or hard anodisation have a controllable pore surface area up to 200 times that of the membrane itself. They exhibit a temperature-independent and almost anhysteretic saturating response to a magnetic field up to temperatures of 300 K or more. The magnetism, which cannot be explained by the ~1 ppm of transition-metal impurities present in the membranes, increases with the area of the open nanopores, reaching values of 0.6 Bohr magnetons per square nanometer for mild anodisation and 8 $\mu_B nm^{-2}$ for the faster hard anodisation, process. Crystallization of the membrane or treatment with salicylic acid can destroy 90 % of the magnetism. The effect is therefore associated with the open pore surfaces of the amorphous Al_2O_3, a system which contains no *d* electrons. Possible explanations in terms of electrons associated with oxygen vacancies (F or F^+ centres) are considered, and it is concluded that the phenomenon involved is likely to be giant saturating orbital paramagnetism (GOP) rather than any sort of collective ferromagnetic spin order. GOP can arise at 2-dimensional conducting surfaces and cavities, here the membrane pores, where the electrons can form a coherent state that responds collectively to zero-point fluctuations of the vacuum electromagnetic field [1, 2]. It is a magnetic analogue of the chemical effects recently detected in resonant optical cavities in the dark [3]. The nonlinear orbital paramagnetic response as a function of applied field *B* varies as $M = M_s\sqrt{[x/(1 + x^3)]}$, where $x = CB$, and the constant $C \approx 8\ T^{-1}$. The characteristic wavelength of the 'orbital cavitronics' is deduced from the fit to the magnetization curves.

The panel at the bottom left shows the magnetization reduction on crystallization; the panel at the bottom right shows a similar drastic reduction of the magnetization produced by treatment of the membrane in salicylic acid.

N5-13. X-ray Nanobeam Irradiation Induced Structural Relaxation for the Control of the Domain Walls Displacement in Amorphous $Fe_{80}B_{20}$ Strips. *U. Urdiroz*[1,2], E. Navarro[1], M. Alonso[1], A. Ruiz[1], M. Sánchez-Agudo[2], F. Palomares[1], F. Cebollada[2], G. Martínez-Criado[1] and J.M. González[1] *1. Nanostructures and Surfaces, ICMM - CSIC, Madrid, Spain; 2. POEM-MA-CEMDATIC, ETSI de Telecomunicación - UPM, Madrid, Spain*

The control of domain walls (DW) propagating in microstrips is required in different applications including the sensing and magnonic ones. We have explored, in order to gain such a control, the X-ray nanobeam irradiation [1] of the easily modifiable anisotropy amorphous $Fe_{80}B_{20}$ alloy [2]. $F_{80}B_{20}$ stripes (16 μm wide) were prepared using UV lithography from films grown onto single-crystal MgO substrates by using pulsed laser ablation deposition. The strips hysteretic properties were measured using a magneto-optic Kerr effect setup (15 μm spot). Irradiation at ESRF - ID16B was performed by using a beam with 56 nm x 56 nm spot size, and energy maximum at E = 17.5 keV with $\Delta E/E = 10^{-2}$. To get information about the interaction between head-to-head DWs propagating along the strip (field parallel to the strip axis) and irradiated regions (IRs) having different widths, we irradiated a strip in five different points separated 100 μm along the strip axis using a flux of 2.21 x 10^{11} photons/s. The IRs had nominal widths ranging from 60 nm up to 1440 nm (widths varied by performing contiguous 60 nm scans). Figure 1 shows our results for the local coercivities obtained at points situated between two consecutive IRs as a function of the width of the IR having the smaller of the pair. From these results we conclude that 1) the irradiation originates a coercivity increase from the non-irradiated strip value (linked to DW nucleation) that we associate to the occurrence at the IRs of DW energy decreases originated by the induction of structural relaxation and anisotropy decrease [3], 2) the coercivity significantly increases with the IR width in the range from 60 nm up to 360 nm, at which the IR widths are larger than the DW width (estimated from micromagnetic calculations on 400 nm for the non-irradiated strip), and 3) the smaller coercivity increase ratio observed for the wider IRs is related to the fact that the DW width is smaller than the width of the latter IRs, which implies that the local coercivity is not related to the IR/DW width ratio but to the difference between the local anisotropies in and out the IR.

N5-14. Magnetic anisotropy and martensitic transformation in thin films of Ni-Mn-Ga and Ni-Fe(Co)-Ga ferromagnetic shape memory alloys. *I. Rodriguez Aseguinolaza*[1], V. Chernenko[1,2], V. Golub[3] and J. Barandiaran[1,4] *1. University of the Basque Country (UPV/EHU), Leioa, Spain; 2. Ikerbasque, Bilbao, Spain; 3. Institute of Magnetism, NASU and MESYSU, Kyiv, Ukraine; 4. BCMaterials, Leioa, Spain*

Thin films of ferromagnetic shape memory alloys (FSMAs) undergo a thermoelastic martensitic transformation of great interest for micro-electro-mechanical systems [1]. In the preparation process, such as sputter-deposition, remarkable macroscopic stresses and conjugate strains arise in the film, modifying its transformation behavior and giving rise to an elastically induced magnetic anisotropy [2]. The study of these properties gets great significance in order to clarify the mechanisms of the magneto-structural interaction and its influence on the functional features. In this work, magnetic measurements have been carried out on Ni-Mn-Ga and Ni-Fe(Co)-Ga FSMA thin films deposited on MgO (001), NaCl and Si/SiO_2 substrates. In Ni-Mn-Ga, the results show an easy-plane magnetic anisotropy in martensitic state for NaCl, in contrast to the films deposited on Si/SiO_2, which present an out-of-plane oblique anisotropy. Compressive or tensile stresses up to about 1 GPa, that appear in these films at room temperature due to the thermal expansion mismatch between them and the substrate, can explain the preferential martensitic variant selection and the corresponding magnetic anisotropy of the films. The Ni–Fe(Co)–Ga film deposited on MgO (001) is polycrystalline consisting of grains with the Heusler structure where the grain boundaries are surrounded by precipitates of the fcc γ-phase. The presence of the γ-phase results in the appearance of an additional resonance line in the FMR spectra and, due to the difference in its Curie temperature with respect to that of the main phase, leads to a particular temperature dependence of the magnetization. The Heusler-type phase exhibits a martensitic transformation into a tetragonal phase between 160–240 K, where two FMR peaks corresponding to the austenite and martensite are observed simultaneously. In this film, the lack of crystal texture leads to an absence of macroscopic magnetocrystalline anisotropy. Contrary to other Heusler alloys, Ni–Fe(Co)–Ga films show a very narrow magnetic resonance line in a broad temperature range, which makes them attractive for magnonic applications. These results can be used to tailor the magnetic properties of FSMA thin films on different substrates.

N6-01. Singlet Ground State in the Spin-1/2 Weakly Coupled Dimer Compound $NH_4[(V_2O_3)_2(4,4'\text{-}bpy)_2(H_2PO_4)(PO_4)_2]_{0.5}H_2O$. *A. Unnikrishnan*[1], V. Kumar[2], P. Anjana[3], A. Thirumurugan[3], J. Sichelschmidt[4], A. Mahajan[2] and R. Nath[1] *1. School of Physics, Indian Institute of Science Education and Research Thiruvananthapuram, Thiruvananthapuram, India; 2. Department of Physics, Indian Institute of Technology Bombay, Mumbai, India; 3. School of Chemistry, Indian Institute of Science Education and Research Thiruvananthapuram, Thiruvananthapuram, India; 4. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany*

We present the synthesis and a detailed investigation of structural and magnetic properties of polycrystalline $NH_4[(V_2O_3)_2(4,4'\text{-}bpy)_2(H_2PO_4(PO_4)_2]$ $0.5H_2O$ by means of x-ray diffraction, magnetic susceptibility, electron spin resonance, and ^{31}P nuclear magnetic resonance measurements. Temperature dependent magnetic susceptibility could be described well using a weakly coupled spin-1/2 dimer model with an excitation gap $\Delta/k_B \approx 26.1$ K between the singlet ground state and triplet excited states and a weak inter-dimer exchange coupling $J'/k_B \approx 4.6$ K. A gapped one dimensional (1D) chain model also described the data well with a gap of about 20 K. The ESR intensity as a function of temperature traces the bulk susceptibility nicely. The isotropic Landé g-factor is estimated to be about $g \approx 1.97$, at room temperature. We are able to resolve the ^{31}P NMR signal as coming from two inequivalent P-sites in the crystal structure. The hyperfine coupling constant between ^{31}P nucleus and V^{4+} spins is calculated to be $A_{hf}(1) \approx 2963$ Oe/ μ_B and $A_{hf}(2) \approx 1466$ Oe/μ_B for the P(1) and P(2) sites, respectively. Our NMR shift and spin-lattice relaxation rate for both the ^{31}P sites show an activated behaviour at low temperatures further confirming the singlet ground state. The estimated value of the spin gap from the NMR data measured in an applied field of $H = 9.394$ T is consistent with the gap obtained from the magnetic susceptibility analysis using the dimer model and gapped 1D chain model. Because of a relatively small spin gap, $NH_4[(V_2O_3)_2(4,4'\text{-}bpy)_2(H_2PO_4)(PO_4)_2]$ $0.5H_2O$ is a promising compound for further experimental studies under high magnetic fields.

Laboratory for Quantum Magnetism, EPFL, Lausanne, Switzerland*

The magnetic interaction in most systems is through a complex process involving the electron hopping between atoms. Purely dipolar-coupled magnets are rather rare due to the low-energy scales involved. In $LiErF_4$ and $LiYbF_4$ we demonstrate the rare realisations of dipolar antiferromagnetic order [1,2,3]. Intriguingly in these systems, despite the dipolar interactions being three-dimensional and long-range in nature, the critical exponents place these materials in the 2D XY/h_4 universality class. Exploiting large perfect crystals, negligible incoherent scattering, the large rare earth moment, and the existence of isotopes with and without the nuclear spins (therefore, demonstrating the effect of switching off the spin bath [4,5]), $LiErF_4$ and $LiYbF_4$, represent an ideal model, where criticality and scaling relations can be explored in great detail.

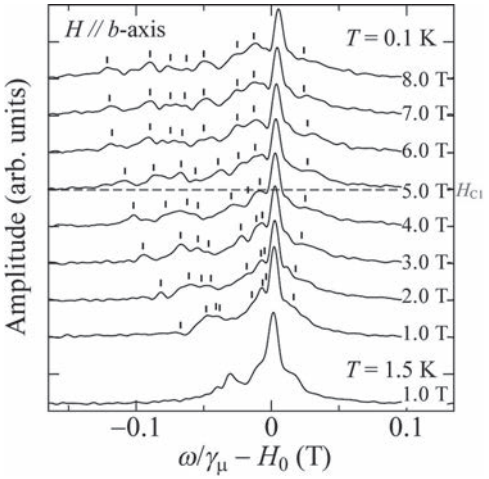
N6-03. Critical Behavior of Quasi-one Dimensional Ferromagnetic $CrTe_{1-x}Sb_x$. *K.A. Ziq*[1] and M.K. Hamad[1] *1. Physics, King Fahad University of Petroleum and Minerals, Dhahran, Saudi Arabia*

We investigate the effect of Sb substitution in quasi-one ferromagnetic $CrTe_{1-x}Sb_x$ system. Magnetic susceptibility revealed transition temperature a linear reduction in the ferromagnetic transition with increasing Sb-substitution. The modified Arrott plots and Kouvel-Fisher plots were used to analyze the initial magnetization isotherms around near Tc. Over the studied range of Sb-substitutions ($0 \leq x \leq 0.5$); the magnetic transition is found to be a second-order phase transition, and the estimated critical exponents do not follow the behavior predicted by simple mean field nor 3-D-Hiesenberg behavior. The values of these critical exponents for x=0.4 are. These critical exponent values may and indicate a crossover behavior between mean field and 3-D-Hiesenberg behavior.



N6-04. High-field TF-μSR study on the ground state of the quantum spin dimer system NH_4CuCl_3 around the 1/4 plateau. *K. Matsui*[1,2], I. Watanabe[4], T. Suzuki[6], M. Fujisawa[3], H. Tanaka[3], T. Goko[5], R. Scheuermann[5] and T. Goto[1] *1. Physics Division, Sophia University, Tokyo, Japan; 2. Research Fellow of Japan Society for the Promotion of Science, Tokyo, Japan; 3. Department of Physics, Tokyo Institute of Technology, Tokyo, Japan; 4. Advanced Meson Science Laboratory, RIKEN, Saitama, Japan; 5. Paul Scherrer Institut, Villigen, Switzerland; 6. Faculty of Engineering, Shibaura Institute of Technology, Saitama, Japan*

NH_4CuCl_3 is a quantum spin dimer system, in which dimers have three dimensional exchange interactions. Its magnetization curve shows two stepped plateaus at 1/4 and 3/4 of saturation magnetization. The plateaus appear for any field directions, indicating that its mechanism roots in the quantum effect. The 1/4 plateau is between H_{C1} = 5.0 T and H_{C2} = 12.8 T, and the 3/4 plateau, between H_{C3} = 17.9 T and H_{C4} = 24.7 T [1]. As applying high magnetic field, the spin gap opens up in 1/4 plateau, and then closes and opens again in 3/4 plateau [2]. In the plateau region, there is no phase transition. The zero-field ground state is gapless, and the system shows a long range order at T_N = 1.25 K [3], shown in Fig. 1. To explain the plateaus, the magnetically inequivalent three-dimer model was proposed by Matsumoto [4]. In order to investigate the spin structure in and out of the 1/4 plateau, we have measured a distribution of an internal field by TF-μSR under high-field at HAL-9500 (PSI). Under the transverse field between 0.49 and 8.0 T at 0.1 K and 1.5 K, TF time spectra with data of 409600 bins for time span of 9.5 μsec were measured. We have obtained frequency spectra by FFT on the extended data of 933888 points with the zero-filling technique, as shown in Fig. 2. With increasing field, the width of the whole spectrum increased, and stopped further increasing in the 1/4 plateau region. This behavior of the width simply traces the uniform magnetization. No drastic change in the spectral profile was observed at H_{C1}. There are nine peaks in field region for 1/4 plateau. The peaks with large shift are considered to be the signals of the muons stopping around triplet dimer. The peaks around zero shift are considered to be the signals of the muons stopping around singlet dimer. These peaks indicate that there are magnetically inequivalent dimers. At $H < H_{C1}$, the spectral profiles are different between 1.5 K and 0.3 K, which is considered to come from existence of ordered moments perpendicular to applied field below T_N.

N6-05. Universality of magnetic-field-induced Bose-Einstein condensation of magnons in the singlet ground state magnet $CsFeBr_3$. *K. Shirasawa*[1], N. Kurita[1] and H. Tanaka[1] *1. Tokyo Institute of Technology, Meguro-ku, Japan*

In the hexagonal antiferromagnet $CsFeBr_3$, magnetic Fe^{2+} ions form one dimensional chains along the *c*-axis and triangular lattices in the *c*-plane. The magnetic properties at low temperatures are described by the $S = 1$ XXZ model with the large single ion anisotropy of the easy-plane type. $CsFeBr_3$ has a singlet ground state and shows no long-range magnetic ordering even at zero temperature because the easy-plane single-ion anisotropy is predominantly over the exchange interactions. When magnetic field is applied along the *c*-axis, the energy gap between the $S^z = 0$ ground states and $S^z = +1$ excited states closes at the critical field H_c and a quantum phase transition to the XY-type antiferromagnetically ordered state occurs. The critical behavior of the field-induced phase transition for a magnetic field parallel to the *c*-axis can be described by the Bose-Einstein condensation (BEC) of dilute magnons under the $U(1)$ symmetry. It was predicted that the phase boundary can be expressed by the power-law $H_c(T) - H_c \propto T^{\phi}$ with the critical exponent $\phi_{BEC} = 3/2$ for the three-dimensional magnon BEC theory. $CsFeBr_3$ is advantageous for investigating the critical behavior because the hexagonal symmetry of crystal lattice is conserved below and above the critical field, so that the in-plane anisotropy that breaks the $U(1)$ symmetry must be negligible even in the ordered phase. In this study, we investigated precisely the critical behavior of the phase boundary for $H \parallel c$ in $CsFeBr_3$, measuring the magnetization down to 0.5 K in magnetic fields up to 7 T and specific heat

down to 0.1 K in magnetic fields up to 9 T. For the specific heat measurement, we have developed a method of effectively suppressing the torque acting on a sample with strong anisotropy that uses the spin dimer compound $Ba_2CoSi_2O_6Cl_2$ with large and anisotropic Van Vleck paramagnetism. The temperature dependence of the transition field H_c (T) was found to follow the power-law $H_c(T) - H_c \propto T^{\phi}$ with a critical exponent of $\phi = 1.50 \pm 0.02$ and critical field of $H_c = 2.60$ T. This result verifies the universality of the three-dimensional BEC of magnons described by $\phi_{BEC} = 3/2$.

N6-06. Quantum Phases of the S=1 Triangular Bilinear-Biquadratic Model in a Magnetic Field. *C. Suzuki*[1], D. Yamamoto[1] and N. Furukawa[1] *1. Department of Physics and Mathematics, Aoyama-Gakuin University, Kanagawa, Japan*

"Order-by-disorder" is an intriguing phenomenon given rise to by the interplay of strong frustration and quantum fluctuations. If a frustrated model possesses an accidental continuous degeneracy in the classical ground state manifold at some highly symmetric points, novel quantum states could emerge as a result of the lifting of the degeneracy by quantum fluctuations. Here we study quantum phases of the S=1 bilinear-biquadratic model on the triangular lattice. The Hamiltonian of the model has the two terms that describe the exchange interactions between dipole moments (J) and between quadrupole moments (K). The mean-field analysis has predicted that four different phases, namely ferromagnetic (FM), antiferromagnetic (AFM), ferroquadrupoler (FQ), and antiferroquadrupoler (AFQ) phases, are formed depending on the ratio of J and K [1]. The case of the zero magnetic field has been well studied also by numerical calculations, including exact diagonalizations [1] and density matrix renormalization group [2]. On the other hand, for finite magnetic fields, although the ground-state phase diagram is obtained within the single-site mean-field approximation, the order-by-disorder selection from the accidental continuous degeneracy has not been discussed. In this work, we study the quantum effects on the mean-field ground-state by means of a numerical cluster mean-field method [3]. As a result, the quantum phase diagram in the plane of $\theta = \tan^{-1}(K/J)$ and magnetic field strength is determined by a cluster-size scaling analysis. We also discuss the details of the quantum lifting of the classical degeneracy and the emerging new quantum phases.

The physical properties of quasi-one-dimensional (Q1D) compounds have attracted considerable interest in condensed matter physics since decades. In Q1D metals, the electron system normally described as a Fermi-liquid in higher dimensional lattices (2D, 3D), starts to behave like a Luttinger-liquid. This is a system near a quantum critical point where the magnetic ground state is dominated by quantum mechanical effects. Consequently, the low-temperature properties are found to be exotic and without counterpart in higher dimensional systems. In this work we present results from a pressure-dependent study on the Q1D zigzag chain compound Ca(1-x) NaxCr2O4 with x = 0, 0.5, 1. Here, the magnetic order is determined not only by the spin density of the chain (i.e. x) but also by the competition between the nearest-neighbor (J1) and the next-nearest-neighbor (J2) correlations. Such geometrical frustration of the magnetic interactions can be tuned by chemical or externally applied pressure. In the current study we have carried out muon spin rotation/relaxation (μ^+SR) and neutron scattering studies [1,2] of the two parent compounds [x = 1 and x = 0] NaCr2O4 and CaCr2O4, respectively. The former displays a unique spin structure where the Cr moments are ordered intra-chain (c-axis) ferromagnetically and inter-chain (a-axis) antiferromagnetically. For x = 0 (Ca), a complex incommensurate AF (IC-AF) order forms below TN. Initially, investigations of the intermediate compound Ca(1−x)NaxCr2O4, was expected to show a magnetic lock-in transition where the IC-AF for a certain x would coordinate itself with the atomic lattice, hereby forming the C-AF order. However, the μ^+SR spectra only show a fast-relaxing component, possibly indicating a spin-glass state. Finally, the magnetic order was shown to impervious to external pressure [3], hereby revealing that the effect from the tuning of the spin density of the chains is clearly dominant. This research is fully funded by the Swedish Foundation for Strategic Research (SSF) within the Swedish national graduate school in neutron scattering (SwedNess).

N6-08. Stabilized Higgs Mode in Anisotropic Quantum Magnets near the Quantum Critical Point. *Y. Su*[1], W. Zhu[1], J. Zhu[1] and S. Lin[1] *1. T4 group, Los Alamos National Laboratory, Los Alamos, NM, United States*

Low-energy excitations in condensed matters can mimic the Higgs boson, an elementary particle in the standard model, and are dubbed Higgs mode. Identifying such kind of excitations is challenging because the Higgs mode is easily decayed into other low-energy bosonic modes that renders the Higgs mode invisible. Therefore, finding ways to stabilize the Higgs mode is desirable and can provide insights of the Higgs mode behavior in condensed matter physics. In this work, we study the Higgs mode in anisotropic quantum magnets near the critical point of the spontaneous symmetry-breaking quantum phase transition between the dimerized phase and the magnetic ordered phase. We find the anisotropy can stabilize the Higgs mode by preventing the decay process and profound Higgs mode peaks are identified in a wide range of anisotropy strength. The anisotropic quantum magnets thus provide ideal platforms to explore the Higgs physics in condensed matters.

N6-09. Magnetic Phase Diagram of Quantum Spin-Dimer Antiferromagnets on the Square and Triangular Lattices. *T. Kanesaka*[1], D. Yamamoto[1] and N. Furukawa[1] *1. Department of Physics and Mathematics, Aoyama-Gakuin University, Sagamihara-Shi, Japan*

In quantum spin-dimer antiferromagnets, ground states are in a nonmagnetic singlet phase due to strong intra-dimer interactions. The nontrivial quantum phenomena induced by the frustration in the exchange interactions, as well as by magnetic field and pressure effects, have currently attracted great attention of many researchers. Recently, quantum spin-dimer compounds that exhibit novel properties, that is, the S=1/2 square-lattice compound $Ba_2CoSi_2O_6Cl_2$[1] and the S=3/2 hexagonal-lattice compound $Ba_3ZnRu_2O_9$[2], have been newly synthesized. The former exhibits a sharp stepwise magnetization curve and dispersionless triplet excitations, while the latter shows spin-liquid-like behavior in spite of the large quantum number. In both cases, it is speculated that the strong frustrations in intra- and inter-dimer exchange interactions are essential for the nontrivial behaviors. In this work, we carry out theoretical analyses of quantum spin-dimer antiferromagnets on square and triangular lattices. It is shown that the many-body dimer model can be effectively reduced to an isolated single dimer when the frustration between the direct and crossed inter-dimer interactions is strong. This explains the stepwise magnetization curve of $Ba_2CoSi_2O_6Cl_2$[1]. In addition, the lattice geometry induces further frustration in the case of triangular lattice. We discuss various magnetic phases induced by the interplay of strong frustration, quantum fluctuations, and magnetic field effects.

N6-11. An Alternate Journey Towards A Quantum Chiral Magnet Family. *L. Testa*[1], P. Babkevich[1], H.M. Ronnow[1], G.S. Tucker[1,2] and K. Kimura[3] *1. LQM, EPFL, Lausanne, Switzerland; 2. Paul Scherrer Institut, Villigen, Switzerland; 3. The University of Tokyo, Tokyo, Japan*

Low-dimensional quantum magnets are of great fundamental importance due to strong quantum fluctuations which can produce novel quantum excitations and ground states. The 2D quantum (S = 1/2) Heisenberg antiferromagnet on a square lattice (2DQHAFSL) is one of the canonical interacting quantum systems. The chiral quantum magnet family $A(b\mathrm{O})\mathrm{CU}_4(\mathrm{PO}_4)_4$ shows great promise to be a very exciting system to study novel quantum magnetism, where A-b = Ba-Ti, Pb-Ti, Sr-Ti and Ba-V. Indeed, ubstitution of A^{2+} cation controls the strength of the structural chirality in this family and shows a dramatic change in the magnetic interactions. This defines a family of chiral magnets with a tunable crystal structure. These compounds crystallises in layers of $\mathrm{Cu}_4\mathrm{O}_{16}$ cupolas that stack along the (00L) direction. Our hope is that it is a good approximation of the square lattice, depending on the chirality of the system. In this presentation, I will show the results of our neutron scattering measurements on several members of this family. An hamiltonian has been derived based on a Multi Bosonic Wave Theory. I will then include our compounds in the frame of the analysis of the J1-J2 Heisenberg model on the square lattice phase diagram.

By manipulating the lattice of incipient ferroelectric $SrTiO_3$ we are able to directly control the quantum criticality in this system. Pressure is the applied external field that couples directly to the lattice and its excitations - phonons. We use pressure to tune the strength of quantum critical fluctuations in this material, as well as the quantum paraelectric state and observe the evolution of a novel phase emergent from the quantum critical point. The quantum paraelectric $SrTiO_3$ exists on the border of ferroelectricity in the vicinity of a quantum critical point. It is this proximity to a quantum critical point and the fluctuations associated with it which are responsible for $SrTiO_3$'s strikingly non-classical dielectric susceptibility. The lack of itinerant electrons and the simplicity of $SrTiO_3$ make it an attractive model system for investigation of the underlying physics of quantum criticality. We present measurements of the dielectric susceptibility of $SrTiO_3$ under applied hydrostatic pressures up to 2 GPa, allowing the full pressure-temperature phase diagram to be mapped out over the observed quantum paraelectric, quantum critical and classical regimes. A quadratic temperature dependence of the inverse dielectric susceptibility, a signature of quantum critical effects, is observed to dominate over a larger temperature range as pressure is decreased towards the quantum critical point. The low temperature minimum in the inverse susceptibility is observed to move up in temperature and increase in magnitude as pressure is applied, consistent with the theoretical description of a coupling of the ferroelectric to an acoustic phonon mode. These coupled modes are argued to form a new 'quantum polar-acoustic state', which follows precisely theoretical predictions of such an interaction. Its apparent emergence from the quantum critical point on our newly-mapped-out phase diagram suggest this new state to be a direct product of the system's quantum critical nature.

Engineering emergent ground states at the interfaces of nanoscale thin films remains one of the strongest strategies to generate new material platforms for electronic and magnetic applications. Strongly correlated materials, such as complex transition metal oxides, are particularly well suited to such studies because tight competition between their various energy scales (e.g. strain, electronic bandwidth, magnetic exchange) often leads to multiple proximate ground states. Here we have studied thin film heterostructures containing quantum wells of the band insulator $SrTiO_3$ embedded

within a Mott insulating rare earth titanate RTiO$_3$ (R = Gd, Sm) matrix. At the RTiO$_3$/SrTiO$_3$ interface, electrostatic doping creates a high-density two-dimensional electron liquid (2DEL) that resides within the SrTiO$_3$ layers near the interface, and hosts a metal-to-insulator transition or quantum criticality depending on the choice of neighboring Mott layer. We used a combination of polarized neutron reflectometry and low-energy muon spin rotation to accurately probe magnetism in the buried layers of these heterostructures. Our results show that there is a critical well thickness of ~2 nm, below which the 2DEL electrons within these thin SrTiO$_3$ layers exhibit robust, magnetic correlations. SrTiO$_3$ wells embedded within ferrimagnetic GdTiO$_3$ displayed ferromagnetic behavior, but SrTiO$_3$ wells embedded within antiferromagnetic SmTiO$_3$ showed evidence of antiferromagnetic correlations. In other words, while the critical thickness for SrTiO$_3$ magnetism was independent of the sign of the neighboring Mott material's magnetic exchange interaction, the magnetic correlations observed in the SrTiO$_3$ matched it. Finally, in the case of a SmTiO$_3$ matrix, the onset of antiferromagnetic correlations in the SrTiO$_3$ well was connected to the opening of a pseudogap in the tunneling spectra that is highly reminiscent of pseudogap formation in doped bulk transition metal oxides. Together, these studies add to our collective understanding of electron-electron correlations in complex oxides with high-density 2D electron systems.

Metal to Insulator Transition (MIT) materials means a transition from metallic state with high electrical conductivity to the insulating state where electrical conductivity is quickly suppressed. Characteristics of transition can be achieved by tuning various ambient parameters such as pressure, temperature, light, or applied field. With the significant change in electrical conductivity, MIT materials can find many exciting applications in emerging nanoelectronic devices such as switching device, thermal sensors, current limiters, surface acoustic wave and superconductor tape spacer. V_2O_3 which is one of the MIT materials which exhibits transformation from corundum structure at room temperature to monoclinic structure below 150K accompanied with 6 orders of magnitude jump in electrical resistivity. (Magnetic property also changes from paramagnetic to antiferromagnetic state.) This phenomenon of MIT exhibits strong dependence on the crystalline quality of V_2O_3, thereby the growth conditions can affect the MIT behavior with high sensitivity. For the practical applications of MIT films, growth maintaining high magnitude resistivity change at critical temperature is a technically important issue. Hence, in the present work, we focus on the control of MIT in V_2O_3 thin films of various thicknesses prepared at a low temperature of 200 Celsius. V_2O_3 films of single layer are fabricated on SiO_2 substrate by reactive magnetron DC sputtering from a metallic V target. From X-ray diffraction (XRD) measurements, all V_2O_3 films are confirmed to grow along a preferred texture of (00l), and are compressed along the c-axis direction compared to the bulk V_2O_3. As the thicknesses increase, lattice spacing along the c-axis approaches that for the bulk V_2O_3. Physical property measurement system (PPMS) was employed to measure the resistivity changes of V_2O_3 films as functions of temperature, and MIT temperature was correlated with lattice parameter to establish the relationship between the lattice parameter and MIT temperature.

N7-05. Metal-insulator Transition in $CaVO_3$ Thin Films: Interplay between Epitaxial Strain, Dimensional Confinement, and Surface Effects. S. Beck[1] and *C. Ederer*[1] *1. Materials Theory, ETH Zurich, Zurich, Switzerland*

The wide variety of interesting emerging phenomena and functionalities in complex oxide thin films and heterostructures is generally determined by different factors, such as substrate-induced epitaxial strain, dimensional confinement, interface effects, or defects. Here, we use density functional theory plus dynamical mean-field theory (DFT+DMFT) to study multiple control parameters for tuning the metal-insulator transition (MIT) in $CaVO_3$ thin films [1,2]. We focus on separating the effects resulting from epitaxial strain from those related to the reduced thickness of the film. We show that tensile epitaxial strain of around 3%–4% is sufficient to induce a transition to a paramagnetic Mott-insulating phase. This level of strain can be achieved using $SrTiO_3$ substrates. Using free-standing slab models, we then demonstrate that reduced film thickness can also cause a MIT in $CaVO_3$, however, only for thicknesses of less than 4 perovskite units. Our calculations indicate that the MIT in such ultrathin films results mainly from a surface-induced crystal-field splitting between the t_{2g} orbitals, favoring the formation of an orbitally polarized Mott insulator. This surface-induced crystal-field splitting is of the same type as the one resulting from tensile epitaxial strain, and thus the two effects can also cooperate. Furthermore, our calculations confirm an enhancement of correlation effects at the film surface, resulting in a reduced quasiparticle spectral weight in the outermost layer, whereas bulk-like properties are recovered within only a few layers away from the surface. Finally, we also investigate how the presence of typical substrate materials, such as $SrTiO_3$ or $LaAlO_3$, alter these effects compared to the free surface. In particular, we investigate the evolution of octahedral rotations across interfaces between two materials with different rotation angles and/or tilt systems, and how this affects the range of electronic reconstruction in the interfacial region. Our study demonstrates the power of modern first-principles-based calculations for correlated electron materials for understanding and predicting emerging properties of complex oxide thin films and heterostructures.

European Synchrotron Radiation Facility, Grenoble, France*

There has been a surge in interest in the *5d* transition-metal oxides in recent years due to the novel physics predicted to arise from the delicate interplay of electric correlations, spin-orbit coupling and crystal fields. The layered Ruddlesden-Popper iridates $Sr_{n+1}Ir_nO_{3n+1}$ have attracted particular interest due to the realisation of a J_{eff} = 1/2 Mott insulating state in the n = 1,2 members. While the magnetic excitations of monolayer Sr_2IrO_4 can be well described by a linear spin-wave solution of a Hamiltonian displaying weakly anisotropic interactions [1], there have been two contrasting models proposed to explain the magnon spectrum of bilayer $Sr_3Ir_2O_7$. In their study, Kim *et al.* [2] saw a single dispersive magnetic feature in their resonant inelastic x-ray scattering (RIXS) spectra, which they interpreted as being the unresolved sum of two magnon modes. Using linear spin-wave theory they explained the small splitting between modes and a large magnon gap by including strong anisotropic couplings within and between otherwise weakly coupled IrO_2 layers. Moretti Sala *et al.* [3], by contrast, found two distinct gapped modes which they explained as quantum dimer excitations using a bond-operator mean field theory. There is still some debate as to which model provides a better description of the in-plane dispersion. Notably the two models exhibit contrasting dependences of the magnon energy and RIXS intensity on the out-of-plane momentum, which has not been studied in detail experimentally. We have therefore conducted comprehensive and systematic measurements of this dependence for multiple in-plane momenta and sample

orientations, in order to settle the nature of the magnetic excitations in $Sr_3Ir_2O_7$ once and for all.

N7-07. Putative magnetic quantum critical point in $(Sr_{1-x}La_x)_3Ir_2O_7$. *J.G. Vale*[1] *1. London Centre for Nanotechnology, University College London (UCL), London, United Kingdom*

$(Sr_{1-x}La_x)_3Ir_2O_7$ undergoes a first-order insulator-to-metal transition (IMT) at x=0.04, which appears concomitant with the loss of long-ranged antiferromagnetic order [1-3]. Meanwhile optical reflectivity data [4] suggests that charge density wave (CDW) order may exist below the structural phase transition, which has not yet been observed experimentally. A detailed analysis of previously published resistivity and resonant (in)elastic X-ray scattering measurements has been performed by the author. Resistivity data suggest a broad crossover regime between Fermi liquid and non-Fermi liquid behaviour above the IMT. This seems to be correlated with an apparent crossover between quantum paramagnetic and quantum critical phenomenology observed by resonant X-ray scattering techniques. This shall be discussed in context with regards to other experimental results, and a possible unified picture for the electronic and magnetic interactions in $(Sr_{1-x}La_x)_3Ir_2O_7$.

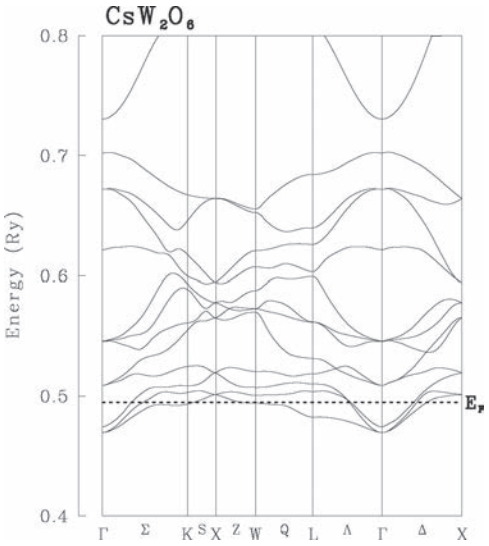
N7-08. Mott Transition in the Pyrochlore Oxides. *N. Swain*[1] and P. Majumdar[2] *1. School of Physical and Mathematical Sciences, Nanyang Technological University, Jurong West, Singapore; 2. Harish-Chandra Research Institute, Allahabad, India*



We study the interplay of electron correlation and geometric frustration in the context of the Mott transition in the pyrochlore lattice. We formulate the single band Hubbard model on this lattice in terms of electrons coupled to auxiliary local magnetic moments, and treat the resulting 'fermion-spin' problem through a real space Monte Carlo technique. While the ground states we obtain are equivalent to unrestricted Hartree-Fock, the presence of the crucial low energy fluctuations in our approach, and their coupling to the electrons, allows us to establish the temperature dependence of transport and spectral features across the Mott transition. Our study shows the pyrochlore lattice has no long-range ordered state. In the vicinity of the Mott transition the local moments become small and the coupling of electrons to these leads to an anomalous resistive state. We further attempted to model the more complex and experimentally relevant pyrochlore molybdates and iridates by including Hund's and spin-orbit coupling respectively. We have thoroughly studied the model problems and have obtained the overall phase diagrams capturing the details of the Mott transition observed in the pyrochlore molybdates and iridates.

N7-09. The origin of the metal insulator phase transition of β-type pyrochlore oxide CsW_2O_6. *H. Harima*[1] *1. Physics, Kobe University, Kobe, Japan*

The β-type pyrochlore oxide CsW_2O_6 was first synthesized in 1993 [1], then reported to show metal insulator transition at 210 K. The transition is accompanied by clear structural phase transition and not magnetic. The low temperature structure was reported as tetragonal [2], but recently it was reported to be cubic #198 ($P2_13$: T^4), breaking the space inversion symmetry [3]. The unit cell becomes quadrupled at low temperature since it is face-centered cubic #227 ($Fd3m$: O_h^7) at high temperatures. To investigate the origin of the phase transition, the band structure calculations both for the high temperature and low temperature cubic phase are carried out. The accurate calculation in the low temperature phase has not yet finished, because it is very time consuming. In the preliminary calculated results, the overlapping of bands remains, and no insulator is obtained. However, looking at the Fermi surface in the high temperature phase as shown in Figure, there are two closed electron Fermi surfaces centered at the Gamma point and the closed hole Fermi surface centered at the X point. The three kind of Fermi surfaces cross the Fermi level at the (1/4, 1/4, 1/4). Then, it is simply expected that the nesting property causes disappearing of the Fermi surface, although the level changes at the Gamma point is necessary to get a clear band gap. Why this structural phase transition loses spatial inversion symmetry is also discussed.

The calculated band structure for CsW_2O_6. The Fermi level is denoted by E_F. The band consisting mainly of W-*5d* is shown. Since there are four Ws in the unit cell, the Fermi level is located at the position filled by two electrons from the bottom.

N7-10. Quantum Monte Carlo Study of Phase Transitions in the ionic Honeycomb Lattice. *T. Ma*[1] *1. Physics, Beijing Normal University, Beijing, China*

We study the transitions from band insulator to semi-metal to Mott insulator in the ionic Hubbard model on a two-dimensional honeycomb lattice by using the determinant quantum Monte Carlo. Evaluation of the temperature dependence of the conductivity demonstrates that the semi-metallic region extends for a finite range of interaction values. The Mott phase at strong coupling is accompanied by antiferromagnetic order. Inclusion of these intersite correlations changes the phase diagram qualitatively compared to dynamical mean field theory.

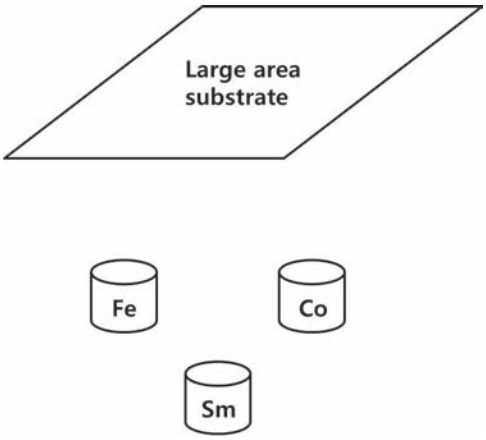
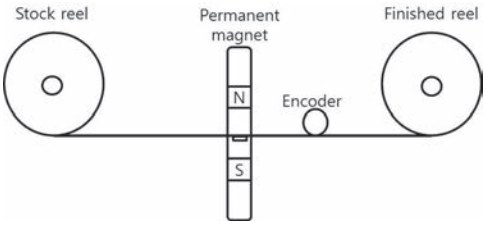
N8-01. High Throughput Experimental Technologies for Hard Magnetic Materials. *A. Huang*[1], X. Jiang[1] and P. Liu[1] *1. R&D, MTI Corporation, Richmond, CA, United States*

Next generation hard magnetic materials with higher energy devices, low cost, long lifetime, and reduced rare earth content require the investigation of unknown alloy systems and a vast amount of experiments. High Throughput and combinatorial experimental technologies are finding their applications in novel hard magnetic material research. In this work, MTI Corporation's effort on developing a high throughput bulk materials production line for novel hard magnetic material research are reviewed and discussed. The high throughput bulk materials production line is designed for novel hard magnetic alloy research with 32 samples up to 10 g in one automatic run. The first step is automatic dispensing of solid powders. Four or more powder dispensing heads and balances, with one dispensing head for each material component, is integrated with a carousel-type sample changer for automatic powder dispensing with varying ratios between different material components. The second step is high throughput ball milling of the as-dispensed powder samples. With 4 sets of 4 cavity milling jars, totally 16 parallel ball milling experiments of 10 g samples can be carried out in a planetary ball mill machine. The mixed powder samples are then high throughput pellet pressed by a 10-ton electric hydraulic press with a carrousel type sample changer. Next, the pellet samples are loaded onto the 32-cavity copper crucible of an automatic high throughput arc melting system integrated with a glove box for preparing the bulk magnetic alloy samples. Then, a compact 16-channel tube furnace up to 1100 °C is employed for sintering, annealing, or quenching operations. Finally, the elemental compositions of bulk samples are high throughput analyzed by an X-ray fluorescence (XRF) scanning system for providing instant feedback to the synthesis/processing steps. High Throughput experimental solutions increase productivity by 16 times. Existing experimental techniques are modified for high throughput application. Novel Cryogenic V-Shaped Mixing and Rotor ball milling are designed for high entropy permanent alloy research. All of the processing steps would be linked by the robot arms in order to build up the AI material discovery pilot line.





N8-02. The study of composition effect of FeCoSm material system using combinatorial method. *H. Kim*[1], D. Ha[1], K. Chung[2] and K.P. Shinde[3] *1. Korea Electrotechnology Research Institute, Changwon, The Republic of Korea; 2. Functional nano-materials research, Korea Institute of Materials Science, Changwon, The Republic of Korea; 3. Nano Functional Materials Department, Korea Institute of Materials Science (KIMS), Changwon, Changwon, The Republic of Korea*

Combinatorial method of synthesis and analysis of magnetic materials was developed to search for new permanent magnets [1, 2]. This method was applied to the FeCoSm material system. Combinatorial synthesis of thin films was carried out in the vacuum chamber with the components of Quartz Crystal Microbalance (QCM) to measure the deposition rate of each source, heating assembly to increase the temperature of large area substrate, and thermal evaporators. We could obtain the continuous composition spread of Fe, Co, and Sm elements on the substrate by means of the specific disposition of evaporation boats and the distances between substrate and boats. Samples with the composition spread were used to investigate the effect of composition ratios of materials on magnetic properties, microstructure, and preferred crystallographic orientation. High-throughput analysis system is also devised and composed mainly of the permanent magnets with surface magnetic intensity of 1.5 Tesla, continuous reel-to-reel tape moving device, and a three-axis Hall sensor. This system can measure the hysteresis loop in each position of tape while the tape moves at regular intervals. The advantages that can be obtained in this combinatorial experiment using long tape form are as follows. 1) We can obtain magnetic compounds having different composition ratios and their intrinsic magnetic properties can be quickly determined through the reel-to-reel continuous measurement results. 2) The reliability of results with the composition ratio dependency is very high and proved with the short samples cut from long tape separately checked by VSM measurement later. By virtue of this process, we could obtain the distribution of magnetization, coercivity, energy product, etc affected by the different composition of FeCoSm magnetic material system with quickness and high reliability. High-throughput methodology can offer the rapid and efficient screening, optimization and discovery of new magnetic materials.

N8-03. The comparison of magnetic properties at room temperature in RCo_5 (R = Y, Sm, Gd) nanoflakes synthesized via time-staged HEBM.
A. Bajorek[1,2], P. Lopadczak[1,2], K. Prusik[2,3], M. Zubko[2,3] and G. Chelkowska[1,2] *1. A. Chelkowski Institute of Physics, University of Silesia in Katowice, Poland, Chorzów, Poland; 2. Silesian Center for Education and Interdisciplinary Research, University of Silesia in Katowice, Chorzów, Poland; 3. Institute of Materials Science, University of Silesia in Katowice, Chorzów, Poland*

More than ten years ago an top-down approach based on high energy ball – milling (HEBM) method was applied for production of nanocomposite magnets [1-3]. So far a variety of R-T (R - rare earth, T – transition metal) nanostructured materials, mainly Sm-Co with enhanced magnetic properties were studied over years due to their possible applications as hard/soft exchange coupled magnets [1]. Here, the aim of the presented study was focused on the effect of time-staged HEBM on the morphology and magnetic properties of RCo_5 (R=Y, Sm, Gd) intermetallic compounds in order to improve their applicable magnetic parameters. The powders were fabricated based on the bulk parent compounds via wet milling [4, 5] at room temperature in dimethylformamide (DMF) using ZrO_2 balls with a diameter of 2 mm and balls to powder ratio of about 10:1. As we have shown, the increase in the milling time leads to the reduction in the average crystallites size to approximately 4 nm and simulatneous increase of microstrain. Additionally, the formation of nanoflakes with thickness even less than 100 nm was evidenced. The analysis of magnetic properties points to the enhancement of coercivity (H_C) for shorter-staged HEBM process with the distinct maximum of 1.4 T for $GdCo_5$ powder milled for 1h. The prolonged milling is reflected in the gradual decrease of H_C. The magnetocrystalline anisotropy constants K_u deduced from hysteresis loops are slightly reduced over milling process, probably due to the influence of shape anisotropy. Furthermore, the increase in milling time results in the slight variation of the *remanent-to-saturation* ratio (M_r/M_S) mainly caused by the variation of M_r and M_S dependent on the type of R element. The shape of the hysteresis loops varies across pulverization exhibiting a characteristic kink for lower milling time, especially well visible for $GdCo_5$. Such a behaviour may be caused by the mixture of coarse and ultrafine particles. The highest value of the maximum energy product $(BH)_{max}$ = 129 kJ/m^3 was noticed for $SmCo_5$ powder after 1h of milling. Further pulverization leads to gradual decrease of $(BH)_{max}$.

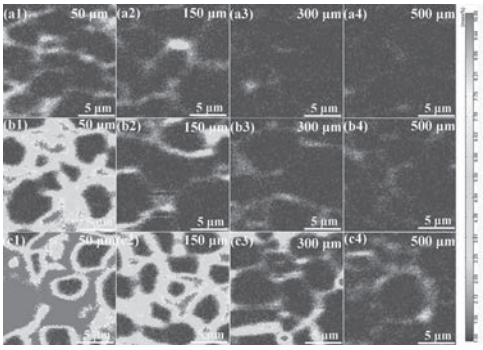
N8-04. Coercivity enhancement of Nd-Fe-B sintered magnet by grain boundary diffusion process with $Pr_{70-x}Tb_xCu_{15}Al_{15}$ alloys.
K. Lu[1], X. Bao[1], G. Chen[1], X. Mu[1], J. Li[1] and X. Gao[1] *1. University of Science and Technology Beijing, Beijing, China*



Core-shell structure and diffusing length of Dy or Tb are crucial to prepare high magnetic performance Nd-Fe-B sintered magnet through grain boundary diffusion (GBD) process [1-3]. In the present work, we investigated the effect of Tb content of diffusion sources on the distribution of Tb-rich core-shell structure and magnetic performance of the starting N50 commercial magnet by diffusing Pr-Tb-Cu-Al alloys. Fig.1 shows room-temperature demagnetization curves of the starting sample and diffusing samples with $Pr_{70-x}Tb_xCu_{15}Al_{15}$ (x=5, 10, 15, 20 at.%), in which the inset shows the dependence of magnetic properties on the Tb content. Compared to the starting sample, coercivity of the diffusing sample with 5 at.% Tb in the Pr-Tb-Cu-Al alloy increases substantially to from 11.9 kOe to 22.4 kOe with consuming only 0.14 wt.% Tb (testing by ICP). However, when Tb content in the Pr-Tb-Cu-Al alloy further increases to 20 at.%, Br of the diffusing sample deteriorates dramatically from 14.21 kGs of the starting magnet to 13.66 kGs, with coercivity increasing to 24.1 kOe. Fig. 2 shows Tb mappings images of the diffused samples by $Pr_{70-x}Tb_xCu_{15}Al_{15}$ alloys, with x=5 at.% (a1-a4), 15 at.% (b1-b4) and 20 at.% (c1-c4), respectively, at various depths from the magnet surface. It can be clearly seen that the thickness and Tb content of Tb-rich shells at the same depth increase obviously with the Tb content of

Pr-Tb-Cu-Al alloys from 5 at.% to 20 at.%. Therefore, in order to obtain the Nd-Fe-B sintered magnet with high comprehensive magnetic performance, Tb content of the Pr-Tb-Cu-Al alloys used for the GBD processed magnet should be limited to a reasonable composition window.

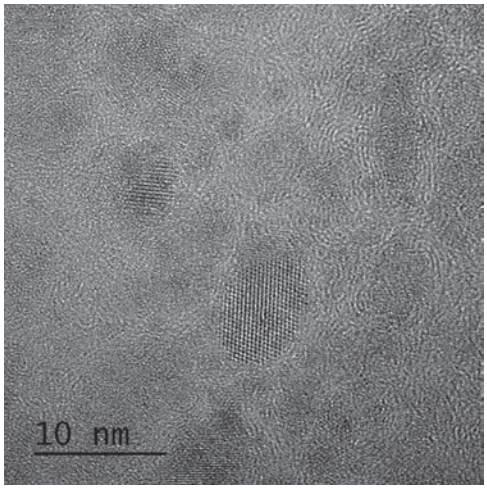
The room-temperature demagnetization curves of the starting sample and diffused samples with $Pr_{70-x}Tb_xCu_{15}Al_{15}$ (x=5, 10, 15, 20 at.%), in which the inset shows the dependence of coercivity and remanence on the Tb content.



EPMA Tb mappings images of the diffused samples by $Pr_{70-x}Tb_{x-}Cu_{15}Al_{15}$ alloys, with x=5 at.% (a1-a4), 15 at.% (b1-b4) and 20 at.% (c1-c4), respectively, at various depths from the magnet surface.

N8-05. Synthesis of NdFeB Nanoparticles and Nano-Flakes by One Step Surfactant-Assisted Planetary Ball Milling. *N. Gunduz Akdogan*[1,2] and O. Akdogan[3,2] *1. Piri Reis University, Istanbul, Turkey; 2. Nanotechnology Research and Application Center, Sabanci University, Istanbul, Turkey; 3. Engineering and Natural Sciences, Bahcesehir University, Istanbul, Turkey*

Nano thin flakes with lateral size below one micrometer have been successfully synthesized by one step surfactant assisted planetary ball milling.(fig.1) Nanoparticles with different size have been obtained by varying the milling time. Crystalline nanoparticles which are below 10 nm is observed in TEM. (fig.2) Compared to the previous works, one step surfactant assisted planetary ball milling is enough to produce nano-sizes due to the nanocrystalline nature of the starting alloy; Nd rich (%20) NdFeB. Nd rich phase wets the grain boundaries, facilitating the breakage of the grains along the grain boundaries. Hence, flakes with narrow lateral size distribution are obtained. For a surfactant assisted milling of 1 to 8 hr, anisotropic Nd2Fe14B nanoparticles have been found with a size ranges from 50 to 5 nm. Room temperature coercivities up to 4 kOe have been observed in flakes. The evolution of magnetic, structural and microstructural properties of the particles will be reported. The successful fabrication of Nd2Fe14B anisotropic nanoparticles and nanoflakes provides hope for the development of nanocomposite permanent magnets with enhanced energy products. Work was supported by Tübitak project: 116C080

N8-06. Changes in the Magnetic Domain Structure of Nd-Fe-B Sintered Magnets by Applying Compressive Stress and Heat. *M. Takezawa*[1], K. Fukushima[1], Y. Morimoto[1] and N. Matsumoto[2] *1. Faculty of Engineering, Kyusyu Institute of Technology, Kitakyushu, Japan; 2. Mitsubishi Electric Corporation, Amagasaki, Japan*

Nd–Fe–B sintered magnets in the rotors of electric-vehicle motors are regularly subjected to severe compressive stresses of several hundred MPa and temperatures of up to 200 °C. In our previous study, we reported that applying a compressive stress of 100 MPa to Nd–Fe–B sintered magnets affected the magnetic domain structure [1]. In this study, we used a Kerr microscope to investigate the changes brought about in the domain structure of the Nd–Fe–B magnet when compressive stress and heat were applied. In this study, a sintered magnet with a coercivity of 1.28 MA/m and a residual flux density of 1.41–1.47 T was used, and this magnet was cut into a 3 mm cube. We achieved magnetization using a pulse field of 5 T along the easy axis. When a compressive stress of 70 MPa was applied to the magnet along the easy axis direction, we observed certain changes in the domain (see Fig. 1). Changes were also observed when the magnet was heated to 80 °C without applying any compressive stress (see Fig. 2). In Figs. 1 and 2, changes can be seen in the domain configurations of the grains encircled in red. All the grains that underwent a domain change had multidomain configuration at the demagnetized state before the magnetization using a pulse field. In Figs. 1 and 2, the grains in the multidomain configuration at the demagnetized state are marked in yellow. From Figs. 1 and 2, we can see that the domain changes due to compressive stress were equivalent to those due to the thermal demagnetization in the mechanism. This paper is based on the results obtained from the Future Pioneering Program “Development

of magnetic material technology for high-efficiency motors" commissioned by the New Energy and Industrial Technology Development Organization (NEDO).

N8-07. Magnetic domain observation of ferrite sintered magnets using MFM images observed from multiple distances and image processing.
G. Obara[1], *T. Sakurai*[1] and O. Ono[1] *1. School of Science and Technology, Meiji University, Kawasaki, Japan*

In order to improve the coercivity of hard magnets, it is required to clarify its mechanism. In the Nd-Fe-B sintered magnets, studies on the coercivity mechanism are advanced by using precise analysis methods of magnetic domain structure [1, 2]. On the other hand, in ferrite sintered magnets, research has not been progressed yet as precise analysis method of magnetic domain structure has not been found. Therefore, in this study, we propose a new method of obtaining magnetic domain pattern of ferrite sintered magnets using MFM images with multiple observation distances. In the proposed method, a plurality of MFM images with each different distance between a cantilever and a sample surface are acquired and the MFM image on the sample surface is estimated from the transition of the magnetic force according to the distance from sample surface, thereby refining the MFM image. Furthermore, magnetic walls are detected from the refined MFM image by image processing. Fig.1 shows the drawn magnetic domain patterns superimposed on the refined MFM image. It can be confirmed that the magnetic domain pattern is matched the MFM image well. In order to evaluate the proposed method, comparison with the Bitter method was conducted. Fig.2 shows the effects of the average particle sizes on the domain widths of ferrite sintered magnets. The domain widths of the samples over 1.4 um are same value. However, the domain widths obtained by using the proposed method are lower than the widths obtained by using Bitter method under 1.0 um of average particle sizes. The average domain widths under 1.0 um of particle sizes, which are single domain sizes, are comparable in size to average particle sizes (dashed line), and it is known that small domains are precisely unobservable using Bitter method. Therefore, this result suggests that magnetic domain patterns can be precisely observed by the proposed method and it is useful as observation of domain structure of ferrite sintered magnets.

N8-08. Comparative Magnetic Force Microscopy Study on the Sintered Nd-Fe-B Permanent Magnet Prepared by Mechanically Polishing Technique and Focused Ion Beam Technique.
H. Chen[1], Y. Yao[2], z. ye[3], F. Yun[1], J. Qu[1] and R. Zheng[1] *1. The University of Sydney, Sydney, NSW, Australia; 2. University of New South Wales, Sydney, NSW, Australia; 3. Hengdian Group DMEGC Magnetics Co. Ltd, Hengdian, China*

As one of the largest applications of RE elements, Nd-Fe-B permanent magnets have been broadly integrated with advanced electric motor technologies such as in direct-drive generators for wind turbines.[1] However, the intrinsic coercivity (H_{ci}) is only ~20-30% of the theoretical value (Brown's paradox), owing to the lack of the detailed knowledge and full understanding of the magnetic structures of Nd-Fe-B magnets. Therefore, fully understanding the microstructure-magnetic structure-magnetic properties is indispensable to unveil the Brown's paradox [2]. Magnetic force microscopy (MFM) is one of most effective approaches to investigate the surface magnetic domain of the magnets. However, the poor resolution limits the sharpness of the results. Here, in order to obtain the better contrast of MFM images, the effects of experimental parameters on the atomic force microscopy (AFM) and MFM images, such as the tip, setpoint amplitude, lift height, and sample preparation methods are fully investigated. It can

be concluded that: 1. the higher setpoint amplitude is helpful in tracking the sample surface for the authenticity of the AFM image; 2. SEM-based focused ion beam (FIB) technique is more suitable for preparing the sample for MFM due to the lower roughness value; 3. Lowering the lift height will enhance the magnetic signal so that a better contrast MFM image will be obtained, with an increasing possibility of hitting the sample. Figure 1 shows the influence of lift-height on the AFM and MFM images of the SEM-FIB sample on two different locations, marked by Square X_1Y_1 and Square X_2Y_2 in Figure 1(a), where MESP-V2 probes and PPP-MFMR probes were used respectively. With increasing lift-height from 40 nm to 100 nm, the magnetic domains still become blurred and the range of MFM signal response shrinks considerably from -23°~-40° to -17°~-25°. Note that high-resolution AFM and MFM images were obtained on the SEM-FIB sample using MESP-V2 probes. When the lift-height is reduced from 100nm to 40 nm, the magnetic nanodomains are present, caused by a weaker averaging effect of the magnetic field, as illustrated in Figure 1(d).

N8-09. Magnetic performance and electrical resistivity of ceramics-bonded Nd-Fe-B-type magnet. *M. Kang*[1], H. Kwon[1], D. Kim[2], J. Lee[3] and J. Yu[3] *1. Pukyong National University, Busan, The Republic of Korea; 2. Star-Group Ind. Co., Daegu, The Republic of Korea; 3. Korea Institute of Materials Science, Changwon, The Republic of Korea*

Nd-Fe-B-type permanent magnet is almost exclusively used in traction motor of EV and HEV. As operating temperature of the magnet in the traction motor is overly high (> 150 °C), large temperature coefficient of coercivity of the magnet (β) still remains as technological barrier to be overcome. Common approach for solving this problem is further enhancing coercivity. As the overly high operating temperature of the magnet is due mainly to eddy current induced in the magnet during operation, enhancing electrical resistivity of the magnet could suppress the induction of eddy current. High electrical resistivity of the magnet would, therefore, create added synergy when combined with enhanced coercivity. We made attempt to prepare ceramics-bonded Nd-Fe-B-type magnet with high electrical resistivity using dielectric oxide binder with low melting point. Isotropic and anisotropic ceramics-bonded Nd-Fe-B-type magnets were fabricated by hot-pressing or die-upsetting mixture of magnetic particles (Nd-Fe-B-type melt-spun and HDDR materials) and multi-component oxide ceramics particles with low melting point (280 °C – 550 °C). Fabrication of isotropic or anisotropic ceramics-bonded Nd-Fe-B-type magnets with good magnetic performance and high electrical resistivity was feasible by the hot-pressing or die-upsetting. Electrical resistivity of the ceramics-bonded Nd-Fe-B-type magnets was remarkably high (>1300 μΩ.cm) with respect to that (< 200 μΩ.cm) of the magnets without the ceramics-binder (Fig. 1). Added dielectric binder played a key role in electrical isolation of the magnetic particles, hence leading to high electrical resistivity. Coercivity of the ceramics-bonded magnet was heavily dependent upon the pressing temperature and the melting point of binder. The isotropic and anisotropic ceramics-bonded magnets pressed at lower temperature using oxide binder with lower melting point could retain high coercivity comparable to that in the initial magnetic powder. In this article, magnetic performance and electrical resistivity of isotropic or anisotropic ceramics-bonded Nd-Fe-B-type magnet are to be discussed.

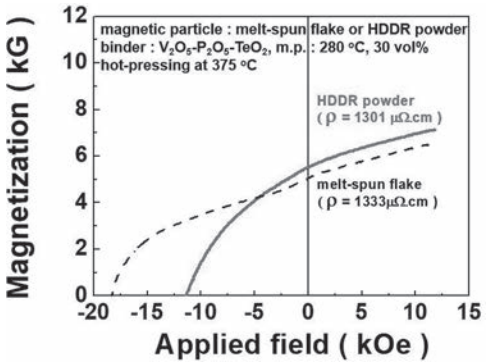

Fig. 1. Electrical resistivity and demagnetization curves of the isotropic ceramics-bonded magnets.

N8-10. The Effect of Nd_8Cu_2 Alloy on the Microstructure and Magnetic Properties of (Nd, MM) FeB Sintered Magnets. Q. Ma[1,2], Z. Zhang[2], Z. Hu[2], Y. Liu[1,2], *X. Zhang*[1,2], F. Liu[2], X. Ju[2] and Y. Li[1,2] *1. Inner Mongolia Key Laboratory for Utilization of Bayan Obo Multi Metallic Resources: Elected State Key Laboratory, Inner Mongolia University of Science and Technology, Baotou 014010, China; 2. School of Science, Inner Mongolia University of Science and Technology, Baotou 014010, China*

Using Misch-Metal(MM) partial substitution of Nd in NdFeB has become a hot topic in the study of rare earth permanent magnet in recent years[1-3]. However, the magnetic properties of MMFeB magnets are far inferior to those of $Nd_2Fe_{14}B$. Especially for the intrinsic coercivity[4]. The mechanism of the coercivity enhancement in (MM/Nd)FeB sintered magnets with the low-melting point intergranular additive was discussed in details. In the present study, Nd_8Cu_2 (at.%) alloy powders were added in the (MM/Nd)FeB double main phases sintered magnets. The powders of $MM_{31.6}Fe_{66.65}Co_{0.15}Ho_{0.25}Cu_{0.1}Al_{0.06}Zr_{0.05}Ga_{0.04}$ $Nb_{0.1}B_1$ (wt.%) alloy were prepared and mixed with commercial $(Nd,Pr)_{30}Fe_{bal}B_1$ (wt.%) powders at a mass fraction of 0.3. Then the mixed powders were aligned and compacted under a magnetic field of 1.5 T and a pressure of ~ 5 MPa in an N_2-filled glove box, followed by an isostatic pressing at ~200MPa. In order to improve the microstructure and coercivity of the $(Nd_{0.7}, MM_{0.3})_2Fe_{14}B$ magnets, Nd_8Cu_2 (at.%) powders were added into the magnets in this work. Consequently the green compacts were sintered at the temperatures ranging from 1060-1080 °C for 2h to make sure the density of the magnets and then the as-sintered magnets were annealed at the temperatures ranging from 500 - 520 °C for 2h. When added with 5 wt.% Nd_8Cu_2 powders, the

coercivity of the magnets could be enhanced from 7.01 kOe to 10.99 kOe, with a slight decline in remanence. The microstructures of the magnets were further characterized by SEM, which results show that Nd_8Cu_2 alloy could optimize grain boundary and promote Nd element diffusing into 2:14:1 main phase during the process of sintering. The Nd-rich shell grains, which with higher anisotropic field were surrounded by the restructured RE-rich phases result in obvious enhancement of coercivity. The micro-components and their in-situ magnetic domains have been investigated with SEM and Kerr microscopy, respectively. On a plane parallel to the easy axis, the NdFeB phases exhibit stripe domains while the MMFeB phases containing a large amount of La/Ce exhibit maze domains. This indicated that MMFeB phases are less susceptible to magnetic field orientation than NdFeB phases.

N8-11. Origin of crystaline magnetic anisotropy of $Sm_2Fe_{17}N_3$ permanent magnet material. *H. Akai*[1] *1. Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan*

Electronic structure and magnetic properties of $Sm_2Fe_{17}N_x$ are studies on the basis of the first-principles electronic structure calculation in the framework of the den- sity functional theory within the local density and coherent potential approximations. The magnetic anisotropy of the system as a function of nitrogen concentration x is discussed by taking account not only of the crystal field effects but also of the effects of the hybridization of f-states of Sm with the neighboring N p-states[1]. Without N atoms, the hybridization of Sm-f states with surrounding atoms is rather small and the f states keep a feature of narrow atomic-like state irrespective of the relative angle between the magnetization and crystal axes. In this situation, the rotation of crystal axes has little effect on the Sm-f states and causes no significant magnetic anisotropy. When N atoms are introduced, the hybridization between Sm-4f and N-2p states occurs. When the magnetization lies along the c-axis, the strongest hybridization occurs between N-2p and Sm-4f with magnetic quantum number m = ±3 states. On the other hand, for the in-plane magnetization, the strongest hybridization is between the Sm m = 0 state and N-2p states. Comparing these two cases, we may say that an energy gain is expected only when the hybridization occurs between m = –3 and the N-2p states. This is because the spin-orbit douping pushes up only the m = –3 state above the Fermi level and thus causes the energy gain due to the lowering of the occupied state energy levels[2]. The importance of hybridization is also proven by the fact that, if the open-core scheme for Sm-f states be adopted, where no hybridization occurs between Sm-f and N-2p states, the uniaxial magnetic anisotropy does not occur.

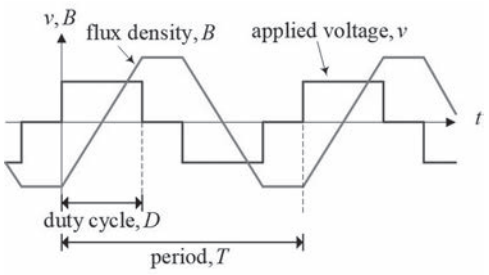
N9-01. Effect of Stress Annealing on Domain Structures and noise performance of METGLAS 2714AZ for Fluxgate sensing applications. *P. Sarkar*[1], C. Lu[1], J. Jeng[2], F. Yuan[3], M. Lai[3], P. Ripka[4], K. Zaveta[5] and C. Chang[6] *1. Department of Mechanical Engineering, National Taipei University of Technology, Taipei, Taiwan; 2. Mechanical Engineering, National Kaohsiung University of Applied Sciences, Kaohsiung, Taiwan; 3. iSentek Inc., Taipei, Taiwan; 4. Faculty of Electrical Engineering, Czech Technical University, Prague, Czechia; 5. Institute of Physics, Prague, Czechia; 6. Department of Physics, National Taiwan University, Taipei, Taiwan*



METGLAS 2714 with nearly zero magnetostriction has been widely used in switching mode power supplies, high-frequency transformers, ultrasensitive current transformers, magnetic shielding [1], and magnetic field measuring sensors [2]. Thermal annealing of glassy metals has received considerable attention for understanding the amorphous-crystalline transition and thermal stability as well as for its influence on Structural, mechanical and magnetic properties. The heating can be realized using isothermal annealing, radio frequency heat treatment, flash annealing etc. in addition of externally applied magnetic field and/or under mechanical stress. The domain structure of as-cast and stress-annealed 2.5mm wide Metglas 2714AZ was studied by means of type II magnetic contrast in SEM. The material was stress-annealed without magnetic field to obtain magnetic properties suitable for low-noise fluxgate sensor core. Various types of domain structures were observed on the shiny surface of ribbons with variations of annealing temperature (350°C and 390°C), stress (50-200 MPa) and time (5-30 minutes). The observed domain structures were compared with the processes of magnetization. During the annealing well above the Curie temperature of 250°C and below the crystallization temperature of 558°C we observed a change of the magnetic easy axis from the original longitudinal to the required transverse one, but for short annealing times the process was more complicated. The observed stripe structure with magnetization in the domain essentially transverse to ribbon direction and parallel to the easy direction leads to the demanded shape of the magnetization curve with low coercivity and remanence and linear between the saturation states. For annealing above T_C the effect of ribbon cooling on the ribbon properties is decisive and we found distinct differences for annealing and cooling in the static regime or when the ribbon was moved continuously through the furnace. The latter procedure gave apparently the best properties for the intended use in fluxgate sensors. At the optimized temperature, stress and time, noise spectrums were measured and obtained around 1 nT/√Hz make it a suitable candidate to use as fluxgate sensing cores.

N9-02. A Steinmetz Equation as a Function of Duty Cycle for Transformer Applications. *S.R. Moon*[1,2], K. Byerly[1,3] and P. Ohodnicki[1] *1. National Energy Technology Laboratory, Pittsburgh, PA, United States; 2. US Department of Energy, Oak Ridge Institute for Science and Education, Oak Ridge, TN, United States; 3. Contractor to the US Department of Energy, AECOM, Pittsburgh, PA, United States*

The power equation (a.k.a. Steinmetz equation, $P=kf^{\alpha}B^{\beta}$, where P is the power loss per unit volume or weight, B is the peak induction of sinusoidal excitation with frequency f, and k, α, and β are coefficients) are often used to estimate the core losses of transformers, but it is only valid for sinusoidal flux shape. Therefore, it is inadequate for power electronics applications, in which its flux waveforms are non-sinusoidal, and an example of non-sinusoidal flux waveform is shown in the first figure. Variations of the Steinmetz equation, such as MSE, GSE, iGSE, etc., are presented in the literature to overcome the inadequacy. However, these variations are not only much more difficult to utilize than the Steinmetz equation, but also its estimations may not be accurate. We propose that the coefficients of the Steinmetz equation (i.e. k, α, and β) be functions of the duty cycle D of the voltage across transformers in power electronics applications. The original form of the Steinmetz equation is maintained, and the coefficient functions are derived based on the loss measurements at different operating points, such as peak induction levels, frequencies, and duty cycles. Since the proposed method for the coefficient is purely based on measurements, it is potentially more accurate than the assumption-based modifications of the Steinmetz equation as long as operating points are within and near the measurement space. Additionally, this approach allows direct core material comparisons for PWM based power electronics applications. In the full manuscript submission, the loss measurement method, a review of various flux waveforms in power electronics applications, detailed analysis of coefficient trends, an application example of the proposed method, etc., will be presented based on various core materials, such as nanocomposite and ferrite. The trend lines of coefficients are presented in the second figure based on preliminary measurements, and the observed trends will be discussed in light of physical mechanisms such as hysteretic and eddy current based losses.

N9-03. Study on Vibration of Iron Core of Transformer and Reactor based on Maxwell Stress and Anisotropic Magnetostriction. *P. Zhang*[1], L. Li[1], Z. Cheng[2] and C. Tian[1] *1. North China Electric Power University, Beijing, China; 2. Baoding Tianwei Group Co. Ltd, Baoding, China*

The vibration and noise generated by electrical equipment not only pollute people's daily life and work environment, but also endanger human health, the life of the equipment. How to effectively calculate the vibration has been a very important research topic. The silicon steel sheet has a large magnetostrictive strain in the transverse direction (TD), which is many times the magnetostriction in rolling direction [1-2]. The main reason for the vibration of the transformer is the magnetostrictive effect of the silicon steel sheet [3], and the vibration of the shunt reactor core is associated with the magnetostrictive and Maxwell force related in the air gap[4]. But there is no direct understanding of the influence of Maxwell force on the vibration of shunt reactor or transformer core. The RD magnetostriction butterfly curves under 50Hz excitations are shown in Fig. 1(a). The RD and TD magnetostriction λ_{pp} of different magnetization is interpolated as shown in Fig.1(b). Considering anisotropic permeability and magnetostriction of silicon steel sheet by using Jiles-Atherton hysteresis model, the magneto-mechanical coupling model of transformer is established. In order to quantitatively calculate the specific values of the Maxwell force and magnetostrictive force and their contribution to vibration, a reactor with a 2mm air gap in the middle iron core is produced in the same size as the transformer. The distribution of magnetic field, Maxwell stress and displacement in the core is calculated. The results show that the vibration of core corner and T-joint is larger if considering the magnetostriction in the transverse direction. The magnetostriction is the main cause of vibration of transformer model, and the Maxwell force is the main vibration reason of reactor without air gap pad. The simulation result of the shunt reactor under the excitation voltage of 136V are compared with the experiment, is as shown in Figure 2. It can be seen that the simulation result of the reactor is in good agreement with the experiment, which verifies the correctness of the simulation.

N9-04. Measurement Research on magnetostriction influence of Electrical Sheet Steel under Different DC Bias. *D. Chen*[1], Z. Feng[1] and B. Bai[1] *1. School of Electrical Engineering, Shenyang University of Technology, Shenyang, China*

Abstract: This paper presents the performance of vibration and the noise in the transformer core considering the different magnetostriction influence of electrical steel sheet in the lamination rolling direction and perpendicular to this direction. Experiment are supplied to obtain the magnetostrictive curves, which are required for the accurate FEM simulation setup. Finally, the simulation results of a single phase power transformer are verified by the experimental results under the DC bias. I. Introduction One significant phenomenon of DC bias happened in the power transformer is the aggravation of core vibration and noise, which are mainly caused by the DC power system or geomagnetic storm. The main reason of vibration and noise production in transformer is the magnetostriction of electrical steel. Thus, it is necessary to analyze the transformer vibration and noise considering magnetostriction effect [1].[2] has built the mathematical models for the electromagnetic and magnetostriction force analysis by measuring the magnetostriction displacement, without further analyzing the noise around the core based on the vibration displacement. II. Principles, results and discussions Fig.1 shows the testing device of steel sheet magnetostriction. Fig.2 shows the butterfly curve of magnetostriction in rolling direction and the other vertical to which. Fig.3 shows the single-value curve obtained through interpolation fitting based on the butterfly curve of magnetostriction. Fig.4 shows the transformer vibration displacement and stress distribution when the DC bias is 0A and 2.3A respectively. Fig.5 shows the noise sound pressure level distribution under different DC bias. III. Conclusion This paper investigates the magnetostriction effect on the electrical steel by theory analysis and experiment verification. Experiment are conducted to obtain the magnetostrictive curves, which the FEM model considering magnetostriction curves is completed to evaluate the vibration and noise and modified for better performance. Moreover the test setup and experimental result of noise in a single phase power transformer are also presented to verify the simulation result.

N9-05. Analytical study of magnetic properties of Fe-(6, 6.5, 7) mass% Si alloys prepared by high purity metallurgy. *I. Sasaki*[1], K. Matsuyama[1], X. Ren[1], Z. LEI[2], M. Takezawa[1], H. Era[1], C. Kaido[3] and T. Ogawa[4]
1. Kyushu Institute of Technology, Kitakyushu, Japan; 2. Nippon Koshuha Steel, Imizu, Japan; 3. Kitakyushu National College of Technology, Kitakyushu, Japan; 4. Fukuoka Industrial Technology Center, Kitakyushu, Japan

Introduction To improve magnetic properties of electromagnetic steel sheets, the study of Fe-Si alloys prepared by high purity metallurgy is important. Kaido et al. proposed the effectiveness of purification by high-purity Fe-3.1 mass% Si alloy [1] and Lei et. al cleared the effect of carbon addition on magnetic properties by Fe-4 mass% Si alloy [2]. Further, Lei et al. fabricated high-purity Fe-(5, 6) mass% Si alloys and analyzed magnetic properties in detail [3]. To investigate more Si- rich- content areas, Matsuyama et al. fabricated high-purity Fe-(6.5, 7) mass% Si alloys and measured fundamental properties [4], but detailed analysis of magnetic properties on the alloys has not been obtained. The purpose of this study is to analyze the magnetic properties of high-purity Fe-(6.5, 7) mass% Si alloys and to discuss magnetic properties of high-purity Fe-(3-7) mass% Si alloys. Experimental High-purity Fe-(6, 6.5, 7) mass% Si alloy ingots were made of 99.99 mass% electrolytic iron and 99.999 mass% silicon in a CCLM (Cold Crucible Levitation Melting) furnace in a high vacuum atmosphere under 10^{-3} Pa. Ring samples were cut out from the alloy ingots, and measurement was performed under a maximum applied magnetic field of 5000 A/m by using an Automatic DC Magnetization Analyzer. Results Fig. 1 shows half hysteresis loops of high-purity Fe-(6, 6.5, 7) mass% Si alloys at a magnetic flux density of 1.5 T. The coercivity of high-purity Fe-6.5 mass% Si alloy, Hc = 7.64 A/m, is the smallest of all samples. Hysteresis losses of high-purity Fe-7 mass% Si alloy are of relatively small value. This shows the effect of high purity. Fig. 2 shows permeabilities of high-purity Fe-(6, 6.5, 7) mass% Si alloys. The permeability and coercivity show the best values for high-purity Fe-6.5 mass% Si alloy. Additionally, we discuss the magnetic properties, the relationships between maximum magnetization and hysteresis loss, coercivity and residual magnetization at the corresponding maximum magnetization, and the relationships between maximum magnetization and the half width of loops.

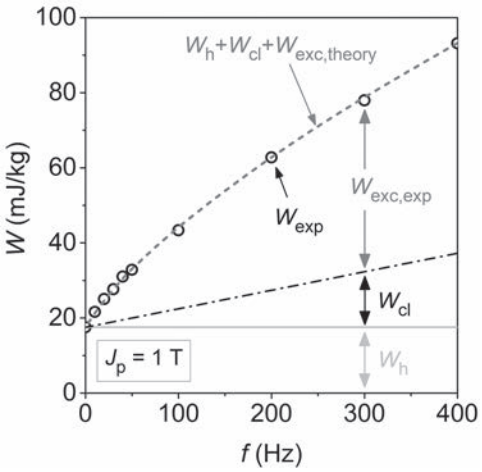
N9-06. Magnetic Loss Decomposition in Non-Oriented Steels after Loss-Reducing Dynamic/Continuous Heat Processing. *S. Dobak*[1], J. Fuzer[1], P. Kollar[1], F. Kovac[2] and I. Petryshynets[2] *1. Institute of Physics, Faculty of Science, P.J. Safarik University, Kosice, Slovakia; 2. Division of Metals Systems, Institute of Materials Research, Slovak Academy of Sciences, Kosice, Slovakia*



The laminated cores made of non-oriented (NO) electrical steels are vastly preferred materials employed in transformers and electrical machines. An inevitable prerequisite for the optimal design of electromagnetic devices, considering the importance of their global environmental impact, is the accurate prediction of their magnetic losses. Projection of new processing methods allows for further efficiency improvements. We studied the influence of novel heat processing of the vacuum degassed NO Fe-Si steels of M530-50A grade (EN 10126) in the form of 500 μm thick sheets. Effects of dynamic/continuous heat treatment were investigated on two sets of samples taken from industrial line: (i) before and (ii) after temper rolling reduction of ~ 8% in sheet thickness. The samples were thermally treated either under dynamic or continuous regime according to patent [1]. Magnetic losses were measured by a digital hysteresisgraph under sinusoidal polarization upon conditions of application interest (frequency DC ≤ f ≤ 400 Hz, peak polarization 1 T ≤ J_p ≤ 1.5 T). Different treatment resulted in a various behavior of normal magnetization curves (Fig. 1). Dynamic treatment in non-rolled sample caused the loss decrease of ~ 20% at 400 Hz while in rolled steel of ~ 25%. The most efficient overall behavior combining the lowest losses with

the highest permeability was obtained after dynamic treatment of temper rolled steel. By applying the solidly justified Statistical Theory of Losses [2], we decomposed the energy losses into a sum of hysteresis W_h, classical W_{cl} and excess W_{exc} parts (Fig. 2). Analysis of correlation regions (domain walls) led to the calculation of W_{exc} by its complete formulation [3]. The sum of W_h, predicted W_{cl} and so-calculated $W_{exc,\,theory}$ (Fig. 2, dashed line) confidently fits measured losses. A sound knowledge of loss mechanisms permits to find out the correlations between steel structure and so-obtained loss components applicable in industry. *Financial support by the Slovak Research and Development Agency [APVV-15-0259] is acknowledged.*

N9-07. Effect of Cut-Edge Residual Stress on Magnetic Properties in Non-oriented Electrical Steel. *H. Lee*[1] and J. Park[1] *1. POSCO, Pohang, The Republic of Korea*

The non-oriented electrical steels are widely used as motor core materials after punching process. During the punching process residual stress is inevitablly generated at cut-edge, therefore magnetic properties are deteriorated. In this study, the effect of cut-edge residual stress on magnetic properties was investigated. The samples were cut by various methods to induce different amounts of residual stresses at cut-edges. The residual stress was analyzed by optical microscopy, micro Vickers hardness tester and Electron Backscatter Diffraction (EBSD). The magnetic properties in low field strength were closely realted to residual stress because the magnetic domain wall motion is inhibited by crystal lattice defects.

N9-08. The dependence of magnetic properties on the areal fraction of Goss orientation in Fe-2% Si steel. *H. Ko*[1], K. Han[1] and J. Park[1] *1. POSCO, Pohang, The Republic of Korea*

Over the past few decades, the grain-oriented electrical steel (GOES) has been made by the unique manufacturing process adopting the novel phenomenon of the abnormal grain growth discovered by N. P. Goss in 1934. The efforts to improve the manufacturing process for the better magnetic properties of GOES have been done based on the abnormal grain growth. However, the large grains formed by the abnormal grain growth increase the eddy current loss due to the large size of magnetic domains. In the present work, Fe-2% Si steel have been prepared and the areal fraction of Goss orientation was controlled to have 30 to 85% with deviation of 15degree. The grain size was limited below 150um to reveal the effect of small grain size on the magnetic properties compared to the Fe-3% Si steel. The areal fraction of Goss orientation and the grain size were investigated by means of Electron Backscatter Diffraction (EBSD) technique. The relation between the areal fraction of Goss orientation and the value of magnetization at applied magnetic field of 1000A/m has been investigated as shown in Fig. 1. In the figure, the measured magnetization ($B10_N$) of Fe-2% Si steel divided by the magnetization ($B10_A$) of Fe-3% Si steel was depicted in y-axis. It could be stated that the value of magnetization is highly dependent on the areal fraction of Goss orientation. The variation of core loss has been studied by analyzing the amount of hysteresis loss and eddy current loss, respectively. To explain the core loss in Fe-2% Si steel having small grain size, the magnetic domain patterns were investigated with magneto-optical Kerr microscope. It was observed the stripe domain patterns located across grain boundaries, which is contrary to the magnetic domains spaced inside of the large grains in Fe-3% Si steel. Despite of the small grain size and narrow domain width, the reduction rate of core loss at the applied tensile stress of 6MPa reached to the average value of 8.2%, which means that it could be possible to reduce the core loss with proper tension coating on the surface.

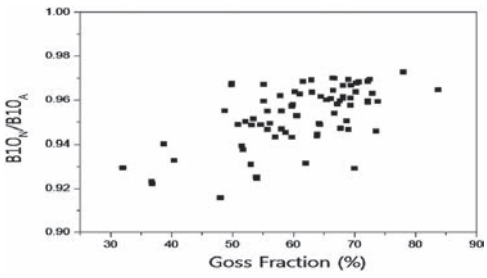

Figure 1. The variation of $B10_N/B10_A$ as a function of the areal fraction of Goss orientation (B10 means the measured magnetization with applying the magnetic field of 1000A/m)

N9-09. Magnetic characterization of ARMCO Pure Iron for the HL-LHC magnets. *A. Parrella*[1], P. Arpaia[2], M. Buzio[1], A. Liccardo[2], M. Pentella[2], R. Principe[1] and P. Ramos[3] *1. TE, CERN, St Genis Pouilly, France; 2. DIETI, University of Naples, Naples, Italy; 3. Institute of telecomunication, Instituto Superior Tecnico, University of Lisbon, Lisbon, Portugal*

The construction of the superconducting magnets for the High-Luminosity upgrade of the LHC accelerator at CERN has resulted in demands for new ferromagnetic laminations for the magnet iron yokes. Among other alternatives, ARMCO Pure Iron (Grade 4) has been considered for the yokes, because of its purity and low carbon content. An in-depth characterization of its magnetic properties has been conducted during the last 3 years to define the production requirements. This paper illustrates in detail this magnetic

characterization procedure, which mainly address the effect of the annealing on the material magnetization; its dependence on temperature and applied strain. Moreover, the material behavior at flux densities well above the saturation has been studied. It will be shown that the annealing improves the magnetic performance of the material, if it is kept at room temperature, but this improvement disappears after the cool down of the material to the operation conditions at 4 K. The dependency on temperature will be shown by testing the material at cryogenic temperature, namely at 4 K and 77 K, and also at room temperature. The results show a decrease of the magnetic performances at low temperatures. Nevertheless, the obtained results are still acceptable in comparison to the properties the alternative materials. Tests performed before and after the application of a mechanical stress has also been studied. Finally, the behavior of the material for much higher magnetic fields (8.6 to 11 T according to the field distribution in HL-LHC magnets) has been studied. This was achieved with a customized measurement system with a ring sample at cryogenic temperatures and superconducting excitation coil. The effect of the permeability variations on the performance of the magnets has been studied with numerical field simulations.

N10-01. Experimental study of the spin Hall effect in platinum films by using scanning tunneling microscopy. *T. Xie*[1], M. Dreyer[2], D. Bowen[3], D. Hinkel[3], R. Butera[3], C. Krafft[3] and I. Mayergoyz[1] *1. ECE, University of Maryland, College Park, MD, United States; 2. Physics, University of Maryland, College Park, MD, United States; 3. LPS, College Park, MD, United States*

Previously, we have developed a scanning tunneling microscopy (STM) based technique for the sensing of the SHE in tungsten films [1-4]. The main advantage of this technique is the nanoscale sensing of the surface accumulated spin-polarized electrons in current-carrying samples. In this presentation, we shall report new results on the STM based nanoscale sensing of the SHE in platinum films, which were prepared by DC magnetron sputtering under UHV conditions. The experiments were carried out with tungsten tips and iron-coated tungsten tips. In both cases, we have detected the sample-current dependent asymmetry in tunneling currents, which can be naturally attributed to the SHE. The tunneling current asymmetry detected by using tungsten tips is caused by the tunneling voltage polarity reversal in the presence of identical sample currents (see Fig. 1). We argue that this sample-current dependent asymmetry is a result of the appearance of the spin-polarized electrons at the surface of the sample. In the case of iron-coated tips, an additional asymmetry in tunneling currents was observed by switching the direction of the sample current while maintaining the same tunneling voltage across the tunneling gap. This asymmetry can be attributed to the opposite spin polarization of electrons at the film surface corresponding to opposite sample current directions as well as to the spin-dependent density of states of iron-coated tips. The obtained results demonstrate that the asymmetry measured with tungsten tips in platinum samples is similar to one observed from tungsten samples, except that the observation of this asymmetry requires higher bias currents in platinum than in tungsten. Furthermore, the opposite signs of the spin Hall angle in platinum and tungsten samples can be clearly revealed by the tunneling asymmetry detected with iron-coated tips. Finally, the STM technique provides the unique opportunity for mapping the strength of the SHE at the nanoscale as illustrated in the Fig. 2.

N10-02. Low current modifications in anomalous Hall Effect signals in perpendicularly magnetized system. *R. Guerrero*[3], A. Anadon[3], A. Gudin[3], J. Diez[3], F. Ajejas[3], J. Camarero[1], R. Miranda[2] and P. Perna[3] *1. Universidad Autonoma de Madrid & IMDEA Nanoscience, Madrid, Spain; 2. IMDEA Nanociencia, Madrid, Spain; 3. IMDEA NANOSCIENCE, Madrid, Spain*

In magnetic multilayers, the interplay between the perpendicular magnetic anisotropy, the interfacial Dzyaloshinskii-Moriya interaction (DMI) and the dipolar coupling may result in the appearance of a variety of chiral magnetic textures, such as skyrmions, even at room temperature[1–5]. A strong DMI usually allows the stabilization of such topological textures which can be nucleated and manipulated via spin-orbit torque (SOT) and/or thermal effects by applying external current pulses. We have studied a Ta(5nm)/Co(0.8nm)/Pt(5nm)/Ta(5nm) trilayer deposited on SiO_2 and patterned by optical lithography and Ar milling in 10 μm wide Hall bars. The interest of this structure lies in: *i)* the different spin Hall angle signs in Ta and Ptenhances the SOT, *ii)* large DMI has demonstrated in [4,6] of the order of 1.3 mJm^{-2} *iii)* and the possibility to neglect the interlayer coupling contribution (potentially large

in systems with several repetition) that may be play a fundamental role on the effect of SOT on the magnetic behavior.. We have investigated the anomalous Hall effect (AHE) that is, generally, proportional to the out of plane component of the magnetization, as function of the magnetic field applied along the z direction. We have disclosed the effect of the SOT by detecting simultaneously the Hall resistance curve and the polar Kerr hysteresis as described in reference [7]. The results are shown in figure 1a. We observe a clear discrepancy at current densities as low as $6x10^{8}Am^{-2}$. The difference between both curves is depicted in Fig. 1b, where large peaks corresponding to the annihilation and creation of magnetic domains. We have moreover investigated these features as function as the current density and in-plane magnetic fields in order to discriminate the role of the antidamping and field like torques.

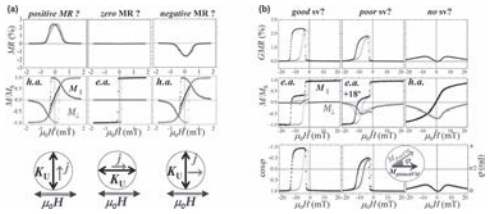
Department of Physics, University of Ulsan, Uji, Japan*



Unidirectional spin Hall magnetoresistance (USMR) is a new member of the magnetoresistance family arising from the spin current generation in ferromagnet(FM)/non-magnetic heavy metal (HM) bilayers. Because the USMR shows asymmetric behavior with respect to the current or external magnetic field directions, it allows us not only to quantify amount of charge-to-spin conversion in a system, but also to recognize a sign of spin current. Though it is well known that spin current generation gives rise to the USMR, its mechanism is still debating. C. Ovci et al. firstly report the USMR and explain the mechanism using spin accumulation concept [1], while electron-magnon scattering has been also reported as a considerable mechanism of the USMR [2,3]. In this study, we find that magnitude of the USMR strongly depends on a sort of FM in a FM/W bilayer. Results of the 2nd harmonic voltage measurement with two bilayer systems, Co/W and Py/W, shows that the USMR of the Py/W is much larger than Co/W when the thicknesses (t) of FM layers becomes thinner than 2 nm. In case of the damping enhancement ($\Delta\alpha$), we find opposite trend; $\Delta\alpha$ of Co/W is much larger than the Py/W when t is under 2 nm, which reflects that the spin angular momentum dissipation in the Co/W is larger than the case of Py/W. Therefore, our observation indicates that the USMR and the spin orbit torque may have different mechanisms though both arise from spin current generation. Details about our observations will be discussed in this presentation.

Despite the enormous market moving around the spintronic technologies, the microscopic understanding of magnetoresistive effects in low dimensional structures has not been fully addressed experimentally so far. Here we demonstrate that anisotropic magnetoresistance (AMR) effects are generic notion and that only detailed angular-dependent studies combining magnetoresistive and vectorial-resolved magnetic hysteresis loops provide the origin of AMR in magnetic nanostructures [1]. For instance, the top graphs of the Figure show selected MR hysteresis curves of a single ferromagnetic (FM) film with well-defined uniaxial anisotropy (a) and GMR hysteresis curves of an exchange-biased spin valve structure (b). As a first glance, very different behaviours are found. For the single FM, from left to right, positive, negligible, and negative MR field-dependent evolutions can be observed [2]. For the multilayered structure (sv), from left to right, squared and smothered irreversible GMR transitions and almost reversible GMR transitions can be found and, in addition, they present very different GMR values at zero field [1]. Vectorial-resolved magnetic measurements acquired simultaneously demonstrate that the different magnetoresistive responses originate from the intrinsic anisotropic angular dependence of the magnetization reversal. For the sv, the angle between the magnetization of the free and pinned layers (ϕ) is the key parameter controlling the GMR response [1], whereas for the single FM is the relative orientation of the magnetization vector with respect to the current direction (j) which control the MR response [1,3]. Our results show unambiguously that the widely different field-dependent transport behaviours originate from extrinsic parameters, such as magnetic field orientations, and/or intrinsic magnetic anisotropies.

N10-05. Electron-phonon and magnetic impurity scatterings in copper oxides. *Y. Tazaki*[1], Y. Kageyama[1] and K. Ando[1] *1. Applied Physics and Physico-Informatics, Keio University, Kanagawa, Japan*

The conversion between an electric current and a spin current through spin-orbit coupling(SOC) is fundamental to realize spintronic devices. The Elucidation of the mechanism that causes an electric current to spin current conversion is crucial to develop efficient spintronic devices. Conventionally, the efficient conversion from an electric current to a spin current has been achieved using heavy metals with strong spin-orbit coupling, such as Pt. However, recently it was discovered that the conversion efficiency of Cu with weak spin-orbit coupling is found to be significantly enhanced through natural oxidation. The conversion efficiency from an electric current into a spin current of naturally-oxidized Cu is comparable to that of Pt. Although the efficient conversion using Cu promises a way to realize efficient spin-orbit devices without using heavy metals, the mechanism of the enhancement of the conversion efficiency through the oxidation remains elusive. In this study, We investigated the weak anti-localization effect for CuOx films with various oxidation levels. We found that the strength of the spin-orbit coupling decreases with increasing the oxidation level in the CuOx film, showing that the recently-discovered enhancement of the spin Hall effect in Cu induced by natural oxidation is irrelevant to a possible enhancement of the extrinsic SHE due to nonmagnetic impurities. Figure 1 shows the monotonic decrease of SOC. The weak anti-localization also indicates that the oxidation triggers electron-phonon and magnetic impurity scatterings. Figure 2 shows the monotonic decrease of phase coherence length which include the magnetic scattering and inelastic scattering mechanisms. These results suggest a possibility that the enhanced spin Hall effect in naturally-oxidized Cu is associated with the extrinsic spin Hall effect originating from the phonon and/or magnetic impurity skew scatterings.

N10-06. Crystalline-direction dependent spin transport in single crystal Fe/GaAs(110) films. *F. Zeng*[1], C. Zhou[1], M. Jia[1], Y. Huo[1] and Y. Wu[1] *1. Physics Department, Fudan University, Shanghai, China*

Anisotropic magnetoresistance (AMR) which originates from s-d electron scattering related to spin orbit coupling, is the basic transport property of ferromagnetic materials. Based on phenomenological analysis, Mcguire and Potter firstly derived the single crystalline AMR equation with respect to arbitrary magnetization and current directions. Until recently, there are little researches on current-direction dependence in single crystalline metals, e.g., Fe, Co and Ni. In the bcc Fe(110) film, early AMR experiments observed a evident asymmetric curve with the current direction along high symmetric [001] crystalline axis. Unfortunately, there is a lack of knowledge about that asymmetry yet and previous studies may be more reasonable if they had concentrated on all the rest of the current directions. Therefore, we investigate systematically the current-direction dependence of AMR in single crystalline Fe(10nm)/GaAs(110) films, and find longitudinal resistivity $\rho_{xx}(\phi_M)$ and transverse resistivity $\rho_{xy}(\phi_M)$ deviate clearly from conventional polycrystalline (co)sinusoidal equations. In addition, the amplitude of ρ_{xx}

has a dominating two-fold symmetry and the amplitude of ρ_{xy} has a pure four-fold symmetry with respect to current direction. Taking account of the magnetization direction up to fourth order based on phenomenological theory, we derive expressions of magnetoresistance that are consistent with our results perfectly. The thickness dependent anisotropic magnetoresistance is also explored with current direction along three high symmetric directions respectively. AMR ratio for the same thickness always behaves the relationship: J‖[111]> J‖[110] > J‖[001] varying temperature from 300K to 6K. Anomalous Hall effect (AHE) is another basic transport property of ferromagnetic. The AHE in four-fold symmetry Co(001) thin film proved to be isotropic with respect to current direction. To further break crystalline symmetry, we found anomalous Hall resistivity is isotropic and intrinsic contribution b is anisotropic due to anisotropic longitudinal resistivity in two-fold symmetry Fe(110) film. Our results reveal more complex and abundant phenomena than polycrystal so that it deserves we conduct further studies in single crystal.

Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan*

The heavy-fermion superconductor $CeCoIn_5$ shows clear signatures of quantum critical fluctuations near the superconducting upper critical field H_{c2}, but their origin is still unresolved because relevant magnetic order has not yet been identified in this compound. Recently, we have revealed in the mixed alloys $CeCo(In_{1-x}Zn_x)_5$ that the doping of Zn into $CeCoIn_5$ suppresses the superconducting transition temperature T_c from 2.3 K (x=0) to 1.3 K (x=0.07), and then generates the antiferromagnetic (low-field AFM) order above x~0.05 [1]. This experimental finding, along with the prior and progressive researches for the Cd- and Hg-doped alloys [2], indicates the presence of the antiferromagnetic instability in $CeCoIn_5$. Here, we demonstrate an emergence of another new field-induced antiferromagnetic (high-field AFM) order coupled with quantum critical fluctuations in Zn7%-doped $CeCoIn_5$ [3]. Applying magnetic field B along the c axis suppresses the low-field AFM phase at 5 T (=B_{M1}), and then induces the high-field AFM phase between 5 T and 10 T (=B_{M2}). The specific heat divided by temperature, C/T, shows non-Fermi-liquid characteristic corresponding to the -log$T$ dependence at B_{M2}, strongly suggesting a presence of quantum critical point at this field. Furthermore, the scaling analysis for the specific heat data above B_{M2} suggests that the quantum critical fluctuations seen in pure and Zn-doped $CeCoIn_5$ have almost the same origin; the quantum critical fluctuations enhanced near H_{c2} in pure $CeCoIn_5$ originate from the "hidden" order parameter of the high-field AFM phase observed in Zn7%-doped $CeCoIn_5$.

N11-02. Non-linear Meissner response in unconventional superconductors: $CeCoIn_5$ and KFe_2As_2. *J.A. Wilcox*[1], D. Kaczorowski[2] and A. Carrington[1] *1. Physics, University of Bristol, Bristol, United Kingdom; 2. Institute of Low Temperature and Structure Research, Polish Academy of Sciences, Wroclaw, Poland*

One of the key predictions of the theory of unconventional superconductors is that the Meissner response should be non-linear in the applied field; that is, the effective magnetic penetration depth λ should be field dependent in sharp contrast to the field-independent behaviour observed in conventional superconductors with isotropic gaps. This effect was searched for extensively in cuprates but was not clearly observed, possibly because of other competing effects such as the formation of Andreev bound states. Here we have measured the field dependence of λ in two other putative nodal superconductors: $CeCoIn_5$ and $KFe2As_2$. Measurements were made down to 50mK in fields up to and slightly exceeding the lower critical field. For $CeCoIn_5$ the field dependence of λ displays many of the hallmarks of the theoretical predictions for a d-wave superconductor thus confirming for the first time the validity of the theory. Some aspects are however unexplained by existing theory and may require extensions to include the possible multi-band-multigap nature of superconductivity in this material. For KFe_2As_2 a quite different response was found, which, together with the ease with which gapped behaviour may be induced in the temperature dependence of λ, suggests that any nodes in the gap function of this material are not symmetry protected and negative parts of the gap function are shallow and easily lifted by disorder.

N11-03. Thermal Conductivity of Heavy-Fermion Superconductor $CeCo(In_{1-x}Zn_x)_5$. *A. Osawa*[1], Y. Oshima[1], K. Suzuki[1], K. Tenya[2] and M. Yokoyama[1] *1. Physics Department, Ibaraki University, Mito, Japan; 2. Shinshu University, Nagano, Japan*

The heavy-fermion superconductor CeCoIn5 (T_c=2.3 K) has magnetic instability such that the quantum critical fluctuations give rise to non-Fermi-liquid behaviors in various bulk quantities. Indeed, we have recently observed that the 7% doping of Zn into $CeCoIn_5$ induces two different antiferromagnetic phases at low- and high-magnetic field regions in connection with a reduction of T_c down to 1.3 K [1,2]. From this experimental result we have suggested the close connection between high-field antiferromagnetic order in Zn7%-doped CeCoIn5 and the quantum critical fluctuations in pure $CeCoIn_5$ [2]. However, the role of low-field antiferromagnetic order in the quantum critical fluctuations is still unclear at present. We thus investigate the emergence of low-field antiferromagnetic order at lower Zn concentration range of $CeCo(In_{1-x}Zn_x)_5$ by performing thermal conductivity measurements at zero magnetic field. We have observed that the thermal conductivity of pure $CeCoIn_5$ shows an unusual upturn below T_c, consistent with the previous report [3]. This upturn anomaly becomes rapidly weak by doping Zn, though the superconducting transition is still clearly observed by the other measurements such as ac susceptibility, resistivity, and specific heat. At x=0.07, on the other hand, thermal conductivity exhibits a clear kink associated with the antiferromagnetic transition at 2.2 K (=T_N), which is distinguished from an anomaly with the superconducting transition (1.3 K). The kink moves toward lower temperature with decreasing x, and then overlaps with the anomaly associated with the superconducting transition at x~0.05. Eventually, it disappears for x ≤0.035 at least within the measured temperature range (> 1 K). This trend is also seen in specific heat [1]. These experimental results suggest that low-field antiferromagnetic order is strongly suppressed at zero field when the condition $T_N<T_c$ holds, and this suppression may generate the antiferromagnetic fluctuation at zero field for x~0, as argued previously [4,5].

N11-05. Pressure Effect on the Antiferromagnetic Compound $Ce_2Ni_3Ge_5$.
J. Gouchi[1], Y. Nakamura[2], M. Nakashima[3], Y. Amako[3] and Y. Uwatoko[1]
1. Institute for Solid State Physics, University of Tokyo, Kashiwa, Japan;
2. Graduate School of Science, Shinshu University, Matsumoto, Japan;
3. Faculty of Science, Shinshu University, Matsumoto, Japan

The Ce-compound $Ce_2Ni_3Ge_5$ shows the orthorhombic structure and has two antiferromagnetic transitions at = 4.8 K and = 4.1 K. The value measured by specific heat amounts to 90 mJ/K^{2}mol Ce and the effective magnetic moment is = 2.51/Ce for H || [100], which is close to free-Ce^{3+} ion value(2.54/Ce).[1] In earlier investigation, Nakashima *et al.* have measured the electrical resistivity under pressure using by polycrystalline sample and observed the pressure-induced superconductivity at 0.26 K, suggesting that it is originated from antiferromagnetic fluctuation. The upper critical field in superconductivity is approximately 0.7T. Although the superconducting transition temperature 0.26 K is low, a value is large, indicating a heavy fermion state[2]. Recently, single crystal of $Ce_2Ni_3Ge_5$ were prepared by Bi-flux method. In this study, we have measured the electrical resistivity in single crystal $Ce_2Ni_3Ge_5$ under pressure using by palm cubic anvil apparatus in order to investigate the superconducting properties. Figure 1 shows the temperature dependence of electrical resistivity under several pressures. We observed the antiferromagnetic transition at = 4.8 K and = 4.4 K similarly to polycrystalline sample at ambient pressure. The antiferromagnetic transition temperature decreased with applying pressure, while the disappeared above 1.5 GPa. The disappeared above 4 GPa. The coefficient A, which is term in the and the residual resistivity possess maximum around 4GPa, suggesting that the critical pressure of $Ce_2Ni_3Ge_5$ is around 4 GPa, which substantiate the previous result.

Temperature dependence of electrical resistivity in $Ce_2Ni_3Ge_5$ under several pressures.

N11-06. Electronic correlations within Fermi-liquid regime of the *T-P* phase diagram of quantum critical heavy Fermion superconductors.
P.B. Castro[1], J.L. Ferreira[1], M.B. Neto[1] and *M. ElMassalami*[1] *1. Fisica dos Solidos, Instituto de Física, Rio de Janeiro, Brazil*

It is remarkable that the *T-P* phase diagram of most quantum critical heavy Fermion superconductors (QCHFS) often manifests a Fermi-liquid regime: a regime wherein the normal-state properties can be described within a Fermi-liquid scenario in spite of the expected non-Fermi-liquid-inducing influence of the neighboring quantum critical fluctuations (QCF). A best illustration is the pressure range $P_{xo} < P < 40$ GPa within the phase diagram of $CeCoIn_5$ [1] (P_{xo} is a crossover point above which the transport and thermodynamic properties switch from a non-Fermi-liquid into a Fermi-liquid-like behavior-crossover from a strongly correlated system to a weakly correlated one). Within this range, the additional inelastic electronic contribution to the resistivity follows a AT^2 behavior while the superconductivity is most probably of a d-wave, BCS-type character [1]. It is then interesting to investigate, within this Fermi-liquid regime of QCHFS, whether the baric evolution of T_c (as a hallmark of the superconductivity) and A (as a hallmark of Fermi-liquid normal state) can be correlated and whether the manifestation of this correlation is indicative of a common Fermi-liquid scenario [2,3]. We searched for such a correlation within the above-mentioned range of *T-P* phase diagram of various QCHFS. Our analysis indicated that, within that Fermi-liquid region which is situated far away from the influence of the QCFs, $\ln(T_c)$ is lineally related with $A^{-1/2}$ [3]. Invoking the Kadowaki-Woods relation $A \propto \gamma^2 \propto [N_{Ef}]^2$ (all terms have their usual meanings), then this relation can be transformed into the conventional BCS-like limit $T_c = \Theta\exp(-1/(VN_{Ef}))$. We discuss why in some pressure ranges, such a relation (consequently the common Fermi liquid scenario) is not manifested. Finally, we discuss whether the AT^2 contribution is related to inelastic scattering from conventional electron-electron process or to electron-impurity (Koshino-Taylor) process.

N12-01. Electro-Magnetic Modeling of the Light Interactions with Nano-Gain-Medium. *Y. Yu*[1] *1. College of Electronic & Control Engineering, Chang'an University, Xi'an, China*

The electro-magnetic interaction of light with nano-gain-material is of great interest especially in the context of active nano-magnetic and nano-lasing devices. To understand the microscopic details of lasing action in order to optimise the device designs, accurate simulation of the interaction between the electro-magnetic fields and the active gain medium are required. Thus, we here develop and report an auxiliary differential equation Finite-Difference Time-Domain (ADE-FDTD) computational model using a semi-classical quantum system of 6 discrete energy-levels for understanding the underlying dynamics of population densities in gain medium. Electron transitions between these quantized energy levels are governed by coupled differential rate equations and the Pauli Exclusion Principle. Each level-pair is simulated in this model by defining a macroscopic polarization vector and solving the quantum-mechanics-corrected polarization equation along with the classical Maxwell's equations. Such a semi-classical approach allows efficient simulations without the need of a full quantum-mechanics calculation. By advancing into a more sophisticated 6-level quantum system, more realistic and physically meaningful simulations can thus be expected in comparison with the previously-reported 4-level algorithm [1]. The model proposed here is capable of integrating the overall electron dynamics of the gain system into arbitrary electromagnetic confinement geometries efficient enough to be applied for simulations of active magnetic devices. This work is supported by the Fundamental Research Funds for the Central Universities of China (Grant #: 310832173601 & 300102328301). The technical details and numerical results are to be covered and discussed during the presentation.

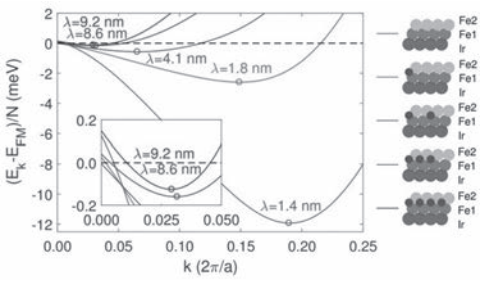
N12-02. Transverse-field-induced magnetization dynamics of two-body Stoner particles. *Z. Sun*[1], Y. Yang[1] and F. Li[1] *1. College of Physics, Optoelectronics and Energy, Soochow University, Suzhou, China*



The magnetization dynamics of magnetic materials in nanometer scale has recently drawn extensive attention for its academic interests and industrial applications, such as harddisk technology, magnetic memory, and logic devices [1, 2]. Nowadays the fabrication of single-domain magnetic nanoparticles (usually referred to as Stoner particles) can be implemented and has inspired numerously researches [3, 4]. The dipolar interaction between two Stoner particles plays an important role in their magnetization switching processes [5, 6]. In this work, we have investigated the influence of magnetic dipolar interaction on the processes of magnetization dynamics for two-body Stoner particles both controlled by a transverse magnetic field. We observed an interesting nonzero net magnetization along the easy axes in the parallel configuration where the connecting line between the centers of two particles are parallel to the easy axes, while only zero net magnetization occurred along the easy axes direction in the perpendicular configuration where the center connecting line are perpendicular to the easy axis. We have also shown that a critical synchronized switching field exists in the parallel configuration, beyond which the magnetization vectors of two particles will synchronize to a precession state, which does not exist in the perpendicular configuration. Moreover, in the parallel configuration, the critical synchronized switching field diminishes and finally disappears with the dipolar interaction strength increasing. The findings could provide possibilities for new magnetic sensor and magnetic information storage applications.

Noncollinear spin structures such as domain walls, spin spirals and magnetic skyrmions have attracted significant research interest lately due to their projected applications in memory and logic devices [1]. In order to influence the microscopic interactions responsible for the stabilization of noncollinear structures in ultrathin films and magnetic multilayers, various combinations of magnetic elements and heavy metals with strong spin-orbit interactions have been proposed [2]. Here we demonstrate that the adsorption of atomic hydrogen is also capable of drastically influencing noncollinear spin order in surface magnetic systems [3]. *Ab initio* calculations performed for two-atomic-layer-thick Fe films on Ir(111) surface indicate that the period of the spin spiral ground state can be enhanced by hydrogen adsorption, see Figure 1. Microscopically this effect is attributed to the weakening of the Dzyaloshinsky-Moriya interactions and the decreased frustration between ferromagnetic nearest-neighbour and antiferromagnetic next-nearest-neighbour Heisenberg exchange interactions. It is shown via spin dynamics simulations that in the hydrogenated system magnetic skyrmions emerge when an external field of the strength of around 3 T is applied perpendicularly to the surface, while the pristine Fe double layer remains in the spin spiral state even for very high field values [4]. The theoretical calculations are shown to be in agreement with spin-polarized scanning tunneling microscopy experiments performed on the system, see Figure 2. Based on these results, it is expected that the adsorption of hydrogen and other nonmagnetic light elements on magnetic ultrathin films opens further avenues for engineering skyrmions and other noncollinear spin configurations.

N12-04. Nanoparticles of Anti-Ferromagnetic Chromium Oxide.
H. Gokturk[1] 1. Ecoken, San Francisco, CA, United States

Ferromagnetic materials like gadolinium and its silicon/germanium alloys which have Curie temperatures close to room temperature are being considered for applications in magnetic refrigeration. Anti-ferromagnetic materials can also exhibit magneto-caloric properties due to orderly alignment of spins. In this research properties of chromium oxide nanoparticles are investigated. Neel temperature (Tn) of chromium oxide in bulk form is about 47°C. The research is carried out with quantum mechanical calculations using DFT method with B3LYP functional and Pople type basis sets. Atomic models consist of nanoparticles carved out of the bulk crystal of chromium oxide maintaining symmetry as much as possible. Optimal geometry of each nanoparticle is calculated in two ways which correspond to the its state above and below Tn: (a) total spin, as well as spin densities of individual atoms are zero; (b) total spin is zero, but spin densities of individual atoms are non-zero. Results of the calculations indicate that quantum mechanical energy in case b is lower than that of case a, as expected. Difference in energy is 3.7 eV for the smallest nanoparticle, Cr2O3 which consist of only 5 atoms. Cr atoms exhibit more magnetism, having spin density values +/-0.12, whereas those of oxygen atoms are nearly zero. Atomic model is expanded by increasing size of the nanoparticle or by increasing the number of Cr2O3 particles to create a multi-particle model. Results indicate that energy difference between magnetic and non-magnetic states becomes smaller with increasing size. For example for Cr4O6, the difference is only 1.2 eV although the mass is doubled. As for the multi-particle case, energy difference varies with inter-particle distance (D). For example, energy difference per particle is 0.8 eV for D=0.3 nm and 2.2 eV for D=0.6 nm. Results suggest that energy of small nanoparticles of chromium oxide can change several eV per particle due to magnetic phase transition, if inter-particle interaction is minimized.

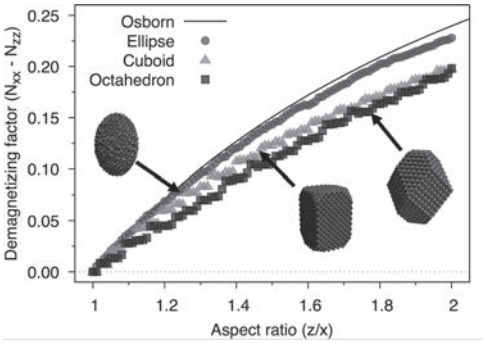
N12-05. Insight into Magnetism of Graphene and Graphene-derivatives from Experiment and Electronic-structure Calculations.
P.S. Blonski[1], J. Tucek[1], Z. Sofer[2], M. Pumera[3], M. Otyepka[1] and R. Zboril[1] 1. Department of Physical Chemistry, Regional Centre of Advanced Technologies and Materials, Palacky University Olomouc, Olomouc, Czechia; 2. Department of Inorganic Chemistry, University of Chemistry and Technology Prague, Prague, Czechia; 3. Division of Chemistry & Biological Chemistry, School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore

Since the isolation of graphene in 2004, imprinting magnetic features into graphene has been challenging for physicists, chemists, and materials scientists [1]. The strategies include sp^3 chemical functionalization of graphene sheets, giving rise to various graphene derivatives [2, 3] when some of them show a magnetic ordering self-sustainable up to high temperatures [3]. Development of room temperature organic magnets prepared by a simple and controllable route based on the substitution of fluorine atoms in fluorographene with hydroxyl groups will be discussed. The theoretical model addresses the origin of the room temperature magnetism in terms of sp^2-conjugated diradical motifs embedded in an sp^3 matrix and superexchange interactions via –OH functionalization. The doping of foreign atoms of non *d*- and *f*-block origin into the crystal lattice of graphene offers an alternative strategy to induce magnetism in graphene. The magnetic properties of doped graphene are governed by the chemical nature of the doping element, *p*- or *n*-type character of the doping element, doping concentration, and structural motifs in the host lattice as proved by our recent works [4, 5]. Electronic-structure calculations further proved the existence of exchange coupling among the paramagnetic centers mediated by the conduction electrons.



Another strategy to induce magnetism in graphene involves spatial confinement with edge engineering. An effective and scalable experimental route based on oxidative scissoring of graphene nanofibers leading to graphene nanoplatelets of various morphologies bearing exceptional magnetic properties will be presented [6]. The as-synthesized graphene nanoplateletes show magnetic features with a temperature sustainability much higher than graphene nanoribbons experimentally prepared so far. Theoretical calculations indicates on synergistic effects of the size, geometry of nanographenes, edge terminations, and angle between adjacent edges in this sort of morphology driven magnetism of graphene nanoplateletes. In addition, a new way for preparing magnetically ordered nanoplateles with even higher transition temperature based on theoretical calculations will be presented.

N12-06. The role of faceting and shape on the effective magnetic anisotropy of magnetite nanocrystals. S. Poyser[1], *R. Moreno Ortega*[1], A. Meo[1], G. Vallejo-Fernandez[4], S. Majetich[3], V. Lazarov[1] and R.F. Evans[2] *1. Physics, University of York, York, United Kingdom; 2. Department of Physics, University of York, York, United Kingdom; 3. Carnegie Mellon University, Pittsburgh, PA, United States; 4. The University of York, York, United Kingdom*

Magnetite nanoparticles are promising for magnetic hyperthermia due to their biocompatibility and heating properties. However the magnetic properties of the particles are complex due to their small size leading to significant finite size and surface effects. In their highly crystalline form the nanoparticles can form well defined facets depending on their method of preparation. Using an atomistic spin model we investigate the effects of size, elongation and faceting on the effective magnetic anisotropy of magnetite nanocrystals using the VAMPIRE code [1]. We find that even small elongations of a few monolayers along one axis lead to a dominant uniaxial contribution to the effective anisotropy energy. In addition differently faceted crystals show different size and shape dependent behaviour leading to different contributions to the effective magnetic anisotropy as a function of the aspect ratio of the particle, as shown in Fig. 1. Finally we determine the effective higher order anisotropy energy surface due to the competing shape and cubic magnetocrystalline anisotropy contributions. We conclude that surface anisotropy is not a requirement for enhanced magnetic anisotropy in nanoparticle systems with even a small amount of shape anisotropy.

Calculated demagnetisation factors as a function of aspect ratio for different particle facetings. The discontinuous nature of the jumps is due to monolayer additions of spins. A visualisation of different surface faceted nanocrystals is shown inset.

N12-07. Toward Two-Dimensional Dirac Half-metallic MnX_3 for Spintronics. *Q. Sun*[1] and N. Kioussis[2] *1. Physics and Astronomy Department, California State University, Northridge, Northridge, CA, United States; 2. Physics, California State University Northridge, Northridge, CA, United States*

The recent discovery of intrinsic ferromagnetism in two-dimensional (2D) van der Waals crystals down to the monolayer limit has sparked intense interest due to their potential applications in spintronics.[1] Here, we predict that the 2D pristine MnX_3 is a family of intrinsic Dirac half metals characterized by a band structure with an unusually large gap in one spin channel and a Dirac cone in the other with carrier mobilities comparable to those in graphene. We demonstrate that the MnX_3 exhibit large magnetic moments, high Curie temperatures and large in-plane magnetic anisotropy energy. In addition, the gap opening induced by the spin-orbit coupling drives the lighter systems into the quantum anomalous Hall state with the Chern number (C = -1). The combination of these unique properties renders this class of 2D ferromagnets a promising platform for high efficiency spintronic applications.

N12-08. MonteCarlo calculation of the magnetic properties of $(S=3/2)_{10}$ rings. *F. Bartolome*[1,2], E. Bartolome[3] and J. Bartolomé[1,2] *1. ICMA, CSIC - Universidad de Zaragoza, Zaragoza, Spain; 2. Física de la Materia Condensada, Universidad de Zaragoza, Zaragoza, Spain; 3. Escola Universitària Salesiana de Sarrià, Barcelona, Spain*

MonteCarlo simulations have been performed on a set of closed rings of 10, S=3/2 Heisenberg spin interacting entities, schematized in Fig. 1, left. The calculation has been performed to quantitatively analyze the magnetization and susceptibility as a function of applied field and temperature of an array of wheel Cr_{10} molecules, aiming to obtain exchange constants and the total spin of the "molecular" ground state. The Hamiltonian includes single-ion terms; namely Zeeman interaction and zero-field splitting; intra-ring interactions, including nearest, next-nearest neighbor and dipolar interactions; and inter-ring interactions, such as substrate mediated exchange and dipolar interactions. Heisenberg 3/2 spins are implemented by fixing the z quantization axis with four (S_z = ±3/2, ±1/2) Potts-model circles simulating $S_{x,y}$. The energy minimization procedure implements the Metropolis algorithm. To delimit the study, only those intra-ring interaction schemes compatible with the centrosymmetric nature of the original molecular structure have been explored. The experimental $M(H)$ and $\chi_{dc}(T)$ curves on the bulk $\{Cr_{10}\}$ powder are properly described in terms of a total molecule spin S=9 ground state (in agreement with EPR data in literature [1]), with overall ferromagnetic coupling (increasing χT for decreasing T). The MonteCarlo simulations describe the overall antiferromagnetic coupling on the 14 ML sample coupling (decreasing χT for decreasing T) by weakening the Cr-Cr intramolecular exchange constants, as shown in Fig. 1, right. The single layer case presents a reduced magnetization, which may be related to antiferromagnetic inter-ring interactions or a decrease of the magnetic moment due to hybridization with the substrate. The Ising $\{Cr_6\}$ ring has been also computed to allow direct comparison with codes performing full diagonalization of the Hamiltonian, such as MAGPACK [2]. A good agreement is found between both computational approaches.

N12-09. Free-Energy Landscapes in Magnetic Systems from Metadynamics. *J. Tobik*[1], R. Martonak[2] and V. Cambel[1] *1. Institute of Electrical Engineering, Slovak Academy of Sciences, Bratislava, Slovakia; 2. Comenius University, Faculty of Mathematics, Physics and Information Technology, Bratislava, Slovakia*

One of the most widely used applications of magnetic materials is information storage. The crucial property of the memory is the stability of the stored information. The key parameter determining the thermal stability is the lowest energy barrier between various magnetic states. Very small energy barrier causes that device will be prone to information loss due to the thermal fluctuations of its state, however very high energy barrier causes energy inefficiency during information write process. The magnetic device is typically composed of large amount of individual magnetic atoms, where each atomic magnetic moment has two degrees of freedom - polar angles defining orientation of the magnetic moment. This huge amount of degrees of freedom makes it difficult to calculate minimum energy paths among states of interest. We attack this problem with the metadynamics algorithm. The crucial prerequisite of this algorithm is the identification of few collective variables which characterise and clearly distinguish magnetic states of interest. Metadynamics is then ordinary dynamics extended by time dependent repulsive potential added for every visited configuration in the collective variable space. This step disfavours re-visiting configurations already visited in the history and rises the energy of the system until a saddle point in energy landscape is reached. System then traverses the saddle point and is pushed to explore another basin of attraction. After sufficiently long time it is possible to reconstruct the free energy profile of the magnetic device. On this free energy map it is possible to identify minimum energy paths and lowest energy barriers. With this tool we study the vortex nucleation process in magnetic nanodots with spatially broken symmetry. With the help of reconstructed free-energy surfaces, we show the origin of symmetry broken vortex nucleation, where one polarity of the nucleated vortex core is preferred, even though only an in-plane magnetic field is present. This work was supported by APVV grant agency, grant number APVV-16-0068 and VEGA agency, grant number VEGA-2/0150/18.

N12-10. Highly efficient energy dissipation in soft magnetic nanoparticles in single-domain state. M. Kim[1], J. Sim[1], J. Lee[1], M. Kim[1] and *S. Kim*[1] *1. Department of Materials Science and Engineering, Seoul National University, Seoul, The Republic of Korea*

Magnetic nanoparticles are of increasing interest due to their unique physical properties such as superparamagnetism, the exchange-bias effect, and particle-size-dependent static and dynamic properties [1-3]. These novel characteristics make magnetic nanoparticles very attractive for bio-applications including magnetic hyperthermia and MRI contrast agents. As an example, soft magnetic nanoparticles in single-domain states exhibit collective Larmor precession of individual spins. In cases where the frequency of time-varying magnetic fields equals the Larmor precession frequency, individual magnetic moments efficiently absorb energies that are transferred from externally applied AC magnetic fields, after which those energies dissipate into other forms due to their intrinsic damping of given materials. Such energy dissipations of magnetic nanoparticles are of crucial importance in hyperthermia bio-applications for high specific loss power (SLP). In the present study, we explored robust non-linear magnetization dynamics and the associated high-efficiency energy-dissipation effect using soft single-domain-state magnetic nanospheres excited by oscillating magnetic fields of different frequencies and amplitudes under given static magnetic fields. We conducted micromagnetic simulations to explore the novel magnetization dynamics of soft magnetic particles and additional analytical derivations of the energy-dissipation rate for the steady-state regime by varying the frequency and strength of rotating magnetic fields for different Gilbert damping constants and static magnetic field strengths. All of the simulation results and analytical calculations agree well quantitatively. The dynamic origin of such a high-efficiency energy-dissipation mechanism is completely different from those of the typical ones used in bio-applications. This work provides further insights into the fundamentals of magnetization dynamics in magnetic particles and the associated energy dissipation effect, and suggests a highly efficient means of magnetic-hyperthermia-applicable energy dissipation.

N13-01. Phase Transitions in the Antiferromagnetic Kagome XY Model with and without Next-Nearest-Neighbor Interactions. *S. Okazaki*[1], D. Yamamoto[1] and N. Furukawa[1] *1. Department of Physics and Mathematics, Aoyama-Gakuin University, Kanagawa, Japan*

Due to the lattice geometry, the ground state of the antiferromagnetic kagome XY model has an infinite degeneracy with respect to the chirality configuration of the 120-degree spin structure in each unit triangle, in addition to the continuous degeneracy regarding the global rotation of all spins. Therefore, the Kosterlitz-Thouless (KT) transition does not take place in the standard sense. However, it has been suggested that the kagome XY model can still exhibit a finite-temperature phase transition associated with the unbinding of pairs of "fractional" vortices [1,2]. The transition temperature has been determined by the Monte-Carlo simulations on finite size clusters of spins. In this work, we revisit the phase transition phenomena of the antiferromagnetic kagome XY model by performing Monte-Carlo simulations on larger-size clusters and using a finite-size scaling analysis. Moreover, we also study the effects of additional next-nearest-neighbor (NNN) interactions at the transitions. The infinite ground-state degeneracy with respect to the chirality configuration is lifted by the presence of the NNN interactions. While the antiferromagnetic NNN interaction favors a uniform chirality pattern over all unit triangles, the ferromagnetic one chooses an alternating chirality pattern. In both cases, the ground state exhibits a O(2)×Z2 symmetry breaking with respect to the global rotation of spins and the sign of the chirality. We discuss the details of the finite-temperature phase transitions in the presence of the NNN interactions, taking into consideration the possible existence of an intermediate phase between the Z2 symmetry-broken KT phase and the paramagnetic phase.

N13-02. A Husimi-cactus Approximation Study on the Diluted Spin Ice. *H. Otsuka*[1], Y. Okabe[1] and K. Nefedev[3,2] *1. Physics, Tokyo Metropolitan University, Hachioji, Japan; 2. Far Eastern Branch, Russian Academy of Science, Vladivostok, Russian Federation; 3. School of Natural Sciences, Far Eastern Federal University, Vladivostok, Russian Federation*

We investigate dilution effects on the classical spin-ice materials such as $Ho_2Ti_2O_7$ and $Dy_2Ti_2O_7$. In particular, we derive a formula of the thermodynamic quantities as functions of the temperature and a nonmagnetic ion concentration based on a Husimi-cactus approximation [1]. We find that it predicts a dilution-induced crossover from the cooperative to the conventional paramagnets in a ground state, and also reproduces the "generalized Pauling's entropy' given by Ke et al. [2]. To verify the formula from a numerical viewpoint, we compare these results with Monte-Carlo simulation calculation data [3], and then find a good agreement for all parameter values.

Facultad de Ciencias Exactas y Naturales, Universidad de Cartagena, Cartagena, Colombia; 4. Facultad de Ciencias Fisico Matematicas, Universidad Michoacana de San Nicolas de Hidalgo, Morelia, Mexico*

The high Curie temperature ($T_C \approx 450$ K), colossal magnetoresistance, and half-metallicity of the double perovskite Sr_2FeMoO_6 (SFMO) make this compound very attractive for magneto-electronic applications. Also, it is known that the SFMO system increases its T_C upon La doping, but its ferromagnetic state is sacrificed in the way. Theoretical calculations to understand the behavior of the SFMO compound with temperature are very complicated due to the sensibility of transition metal oxides involved in this system together with the computational time involved. Robust theoretical models are still lacking to improve our knowledge about the T_C behavior and be able to predict it. In this work, we compute the U and J correlated parameters for different magnetic states, to seek out an extensive approach to the real system and to find the T_C for the above representative compound. Calculations cover the ferro-, para-, and anti-ferromagnetic states using extended DFT+U functionals that include magnetic (exchange) interactions (DFT+U+J). We report relevant differences among the densities of states for these magnetic phases that induce several discrepancies on the band gap.

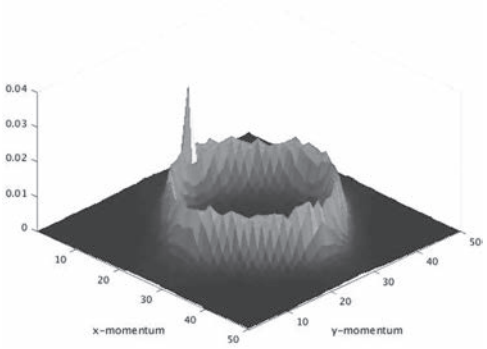
N13-04. Variational Monte Carlo simulations on 2D Rectangular Heisenberg Spin 1/2 Lattices using Gutzwiller projected Staggered flux Ansatz. *N. Shaik*[1], B. Dalla Piazza[1], D. Ivanov[2] and H.M. Ronnow[1] *1. Physics, Ecole Polytechnique Federale De Lausanne, Lausanne, Switzerland; 2. Physics, ETH Zurich, Zurich, Switzerland*

Despite being exactly solvable in 1D, the Heisenberg model for S=1/2 still elludes a analytical solution in 2D. It would be interesting to study the Heisenberg model on a rectangular lattice $J_y/J_x \neq 1$, where we can access the 1D, quasi 1D and 2D regimes by tuning the parameter J_y/J_x. In our current research work we investigate the Heisenberg model on a rectangular lattice, using gutzwiller projected trial wave function Ansatz of a RVB state known as Staggered flux state[1]. A recent study performed on the square lattice spin 1/2 Heisenberg model[2], using this technique, was able to successfully reproduce some anomalies observed in related experiments[3], which were not explained by spin wave theory. Under this model, the observed anomalies were attributed to 2D version of spinon like excitations. Since, spinons are primary type of excitations in case of 1D chains, we were interested in extending the model to a rectangular lattice, to observe the effects of decreasing J_y/J_x on these excitations, as we approach a 1D case. The



gutzwiller projection and calculation of observables is performed using a Variational Monte Carlo technique[4]. We present the evolution of the groundstate properties and relevent variational parameters as a function of J_y/J_x. We will also present the latest results corresponding to the excitation spectrum of this model.

N13-05. Anderson Localization of Spin waves in 2D Ferromagnets: Theory and Numerics. *D. Tay*[1], B. Gremaud[1,2], C. Miniatura[1,2] and C. Ong[1] *1. Science, National University of Singapore, Singapore; 2. Center for Quantum Technologies, Singapore*

Anderson localization refers to the absence of diffusion in a disordered medium [1]. In recent years, Anderson localization has been studied extensively in cold atoms [2] and light waves [3]. Spin waves, which are found extensively in modern spintronic devices [4], can also exhibit Anderson Localization [5]. In the present work, a comprehensive study of Anderson localization spin waves is presented from two perspectives: analytical theory and numerical simulations. Firstly, we show that the nonlinear Landau–Lifshitz–Gilbert (LLG) equation can re-expressed in a linearized form which is directly analogous to the Anderson model. Subsequently, the behaviour of the system can be described using an established theoretical framework [6] which predicts, among other interesting effects, the existence of a Coherent Forward Scattering (CFS) peak which was not observed in [5]. We also discuss how the nonlinearities present in the LLG equation can affect the CBS and CFS peaks. Secondly, whereas the original numerical study [5] used runge-kutta methods to numerically solve the time evolution of spin waves, we show that the same numerical simulations can be more efficiently completed using Suzuki-Trotter Decomposition methods [7] which offer better energy conservation for the same time step used. Furthermore, we show that the linearized form of the LLG equation can be solved using iterative method based on the expansion of the evolution operator in combinations of Chebyshev polynomial of the Hamiltonian [8]. With these modifications, a 2D lattice of up to a million spins (2D 1000 x 1000 array) can be efficiently computed. Lastly, we show that the speed of numerical computations can be further accelerated via parallel computing making use of the High Performance Computing (HPC) facilities available at the National University of Singapore (NUS).

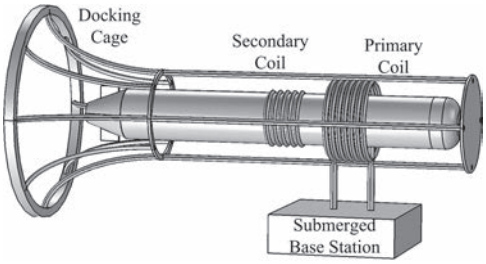
Momentum distribution averaged over 100 configurations, showing the existence of a coherent backscattering (CBS) peak observed against an isotropic scattering background.



Cross-section of the momentum distribution, showing the CBS peak identified in Figure 1. We note that the CBS peak is exactly twice as high as the isotropic background

N13-06. A Novel Concentric Circular Ring Structure Applied in AUV's Inductive Power Transfer System for Resisting the Disturbance of Ocean Current. H. Wen[1], K. Zhang[1], *Z. Yan*[2] and B. Song[3] *1. School of Marine Science and Technology, Northwestern Polytechnical University, Xi'an, China; 2. Northwestern Polytechnical University, Xi'an, China; 3. School of Marine Science and Technology, Northwestern Polytechnical University, Xi'an, China*

Autonomous Underwater Vehicle (AUV) plays an important role in ocean observatory. The traditional wet conductive connectors, which are used to transfer power from the seabed cable and recharge AUVs from submerged base station or energy node in deep sea environments, suffer seal wear, winding problem and are prone to arcing, making frequent maintenance a necessity, resulting in decrease in reliability and increase in cost. Inductive power transmission (IPT) system transfers power by electromagnetic coupling and realizes non-physical contacts between the power energy supplier and load. IPT systems have been widely utilized in various applications such as power supply for electrical vehicles and robots. However, in marine environment, the seawater current vibration could bring disturbances to the axial relative displacements of the primary and secondary coils in IPT system, which might change the primary and secondary parameters all the time. Thus, the coupling coils' parameters are changed, which leads to reduction of the power transmission system's stability. Aiming at this problem, a concentric circular ring structure is proposed. In this novel structure, the primary coil consists of more winding turns than the secondary, also the primary side's dimension is larger compares to the secondary side. Therefore, the new structure have a better tolerance for docking error between the AUV and submerged base station. In this study, the synthetic electric field in various working conditions, whose axial disturbances are caused by seawater current, is calculated theoretically, also finite element analysis simulation method is utilized to verify the calculated results. On

the basis of synthetic electric field calculation, the relevance between the stability of the IPT system against ocean current vibration and the distance L between the primary coil and the secondary coil is obtained. An experimental prototype is implemented, and the test results have confirmed the feasibility and correctness of the novel coupling structure, in comparison to the conventional symmetric inductive coupling coils.

N13-07. Synthetic Electric Field Calculation Method Based on a Three-coils Structure WPT System for Resisting the Seawater Current Vibration. *K. Zhang*[1] and X. Zhang[1] *1. School of Marine Science and Technology, Northwestern Polytechnical University, Xi'an, China*

In the marine environment, the magnetic coupling resonance wireless power transfer (MCR-WPT) technology offers many benefits such as increased flexibility, complete rejection of the winding problem. However, for underwater vehicles, the impact of seawater flow vibration will lead to the axial relative displacements of the primary and secondary coils, which can change the primary and secondary all the time. So the stability of the power transmission is affected by the changing coil coupling parameters. Aiming at the problem, a symmetrical three-coil structure, that two transmitting coils are located symmetrically on both sides of the receiving coil, is proposed. Better to analyze the secondary side power, the method to calculate the synthetic electric field of two transmitting coils is studied on the basis of the three-coil structure. The novel calculation method is that the electric field excited by each single-turn coil is discretized according to the positional relationship and stored in the matrix to calculate the resultant electric field generated by the dual-transmit coil around the receive coil. Then the synthetic electric field of two transmitting coils is simulated by the finite element simulation software COMSOL to verify the calculated results. According to the synthetic electric field, the relationship between the stability of the system power transmission against axial disturbance and the distance L_{12} between the two primary coils is obtained. An experimental prototype is implemented and the experimental results have confirmed the feasibility and correctness of the calculation method that will be used to optimize the system parameter later.

B2-ordered FeRh undergoes a first order phase transition from an antiferromagnet to a ferromagnet (FM) upon heating through the transition temperature ~ 380 K [1]. The transition is accompanied by a change in entropy, and volume, as well as a large change in resistivity [2]. The transition temperature is known to be sensitive to the plethora of external stimuli as well as composition and the use of dopants [2]. The versatility of the transition, alongside the easily achievable transition temperature, makes FeRh an ideal candidate for use in magnetic memory devices [3]. The coexistence of the two magnetic phases leads to magnetic frustration, the relaxation of which could affect the devices' long-term stability. Here we present magnetic relaxation measurements of freestanding B2-ordered FeRh thin films measured using a SQUID-VSM and XPCS. These measurements are fitted to a stretched exponential function to characterize the relaxation using the stretching exponent and the relaxation time. The large difference in these parameters for the two branches measured with the SQUID-VSM is suggestive of two distinct magnetic glass (MG) phases present on the different branches. This is attributed to the presence of supercooled FM domains when cooling and a lack of a complimentary superheated state on the heating arm [4]. The MG state seen in the XPCS measurements is consistent between the two branches, with the heating branch exhibiting a slightly more frustrated behaviour [5]. The two techniques yield different behaviours for the heating arm indicating varying levels of frustration on the length scales, *l*, probed by the different techniques (SQUID-VSM l > 1mm & XPCS l < 20 um). This dependence on the length scale is absent for the dynamics of the cooling branch. This difference is accredited to the asymmetry in nucleation kinetics of the minor phase on each transition branch [6].

N14-02. Ferromagnetic Manganese Based Ultra Thin Films: Structural, Spectroscopic and Magnetic Characterization. *C. Navío*[1], M. Villanueva[1], E. Céspedes[1], F.J. Mompean[2], M. García-Hernández[2], J. Camarero[3,1] and A. Bollero[1] *1. IMDEA Nanoscience, Madrid, Spain; 2. ICMM CSIC, Madrid, Spain; 3. Universidad Autonoma de Madrid & IMDEA Nanoscience, Madrid, Spain*

The scientific community is making a great effort on developing new combinations of materials to overcome the problem on the scarcity of certain elements. For this purpose, the use of the ferromagnetic (FM) Mn-based alloys has been proposed for certain applications as rare earth-free permanent magnets. In particular, the $L1_0$-MnAl and the LTP-MnBi are the only FM phases of their phase diagrams, and in spite of the abundance of studies [1-6] their behavior in thin films is not fully explored. The $L1_0$-MnAl has a high uniaxial magnetocrystalline anisotropy, a Curie temperature T_C~650 K, thus covering the application range of NdFeB-based magnets, and, by contrast, with no spin reorientation effect at low temperatures. The LTP-MnBi has also a large uniaxial magnetocrystalline anisotropy, T_C~711 K, RT coercivities (H_c) over 15 kOe and a positive temperature coefficient, which makes MnBi a good candidate for high temperature applications. In this study, films of MnAl and MnBi have been grown on GaAs (001) and glass, respectively, by Molecular Beam Epitaxy (MBE). Surface characterization was performed *in situ* before carrying out the magnetic and structural measurements *ex situ*. For the $L1_0$-MnAl phase, well-oriented films with H_c over 8 kOe were obtained with the simultaneous formation of a FM interphase, which contribution competes with the MnAl. Thanks to the surface analysis techniques, the signal coming from the interphase compound was discriminated (Fig 1) [7]. Particulate and continuous FM MnBi films were grown by sputtering and MBE, respectively (Fig 2). Coercivities ranging from 4 to 16 kOe were achieved at 300 K [8]. Due to the positive temperature coefficient, H_c reached 29 kOe at 500 K, being among the largest values reported. The strong variations on the morphology play a critical role on magnetic properties [8], which allows a tailor-made growth for a broad number of applications.

The challenge of controlling magnetism using electric fields raises fundamental questions and addresses technological needs such as low-dissipation magnetic memory[1]. The recently reported two-dimensional (2D) magnets provide a new system for studying this problem owing to their unique magnetic properties[2–8]. For instance, bilayer chromium triiodide (CrI_3) behaves as a layered antiferromagnet with a magnetic field-driven metamagnetic transition[2,6]. Here, we demonstrate electrostatic gate control of magnetism in CrI_3 bilayers, probed by magneto-optical Kerr effect (MOKE) microscopy. At fixed magnetic fields near the metamagnetic transition, we realize voltage-controlled switching between antiferromagnetic and ferromagnetic states. At zero magnetic field, we demonstrate a time-reversal pair of layered antiferromagnetic states which exhibit spin-layer locking, leading to a remarkable linear dependence of their MOKE signals on gate voltage with opposite slopes. Our results pave the way for exploring new magnetoelectric phenomena and van der Waals spintronics based on 2D materials.

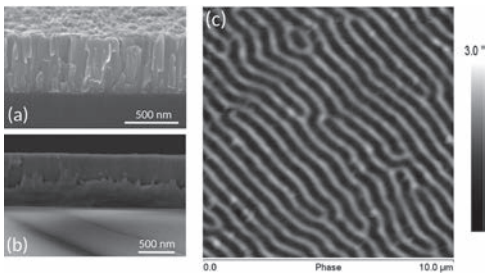
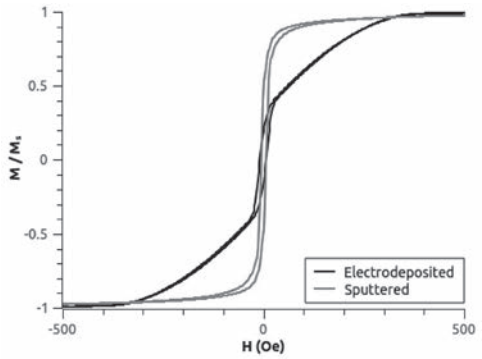
Kerr signal as a function of gate voltage, showing a gate induced transition from layered antiferromagnetic (AFM) to ferromagnetic (FM) states at select magnetic fields: 0.58 T (blue), 0.60 T (grey), 0.62 T (orange). The MOKE signal starts near zero at negative gate voltages, corresponding to AFM ordering. As the voltage increases to a critical value, the MOKE signal quickly rises and reaches a saturated value, undoubtedly demonstrating electrical switching from a layered AFM state to the FM state.



Gate-dependent Kerr signal with no applied magnetic field for a non-encapsulated bilayer CrI_3 device prepared in both layered AFM states, up-down (green) and down-up (black), where the first and second directions denote the out-of-plane magnetizations in the top and bottom layers, respectively. The opposite slopes of the Kerr signal between the two AFM states highlight the spin-layer locking effect with gate-induced MOKE and are unique fingerprints for identifying each AFM state.



N14-04. Influence of deposition techniques on the magnetic properties and microstructure of FePd thin films. *M. Cialone*[1,2], M. Coisson[1], F. Celegato[1], G. Barrera[1], M. Fernandez Barcia[3], M. Uhlemann[3], A. Gebert[3], P. Rizzi[2] and P. Tiberto[1] *1. Nanoscience and Materials, Istituto Nazionale di Ricerca Metrologica, Torino, Italy; 2. Chemistry and NIS, Università degli studi di Torino, Torino, Italy; 3. Chemistry of Functional Materials, Leibniz Institute for Solid State and Materials Research (IFW) Dresden, Dresden, Germany*

FePd alloys possess outstanding magnetic and mechanical properties, which make them suitable for a number of different applications, ranging from magnetic data storage [1] to mechanical actuation [2]. Their properties can be tuned by varying both the alloy stoichiometry and phase. In this work, we analysed the role of the deposition technique on the material properties. FePd thin films containing 30 % at. of Pd were prepared both from radio frequency sputtering and potentiostatic electrodeposition. The sputtered film were deposited on Si/SiO_2 substrates from composite target, electrodeposited films were plated onto Au coated Si/SiO_2 substrates, using a double ammonia-sulfosalicylic acid based aqueous solution[3]. Morphology and crystalline structure were studied via scanning electron microscopy and x-ray diffraction respectively, while the magnetization reversal process was investigated via alternating gradient field magnetometer. The magnetic domain pattern was imaged using magnetic force microscopy. The two different deposition techniques determine differences in the crystalline structure and morphology of the films. The electrodeposition induces an higher roughness on the surface, as compared with the sputtered films. Moreover sputtered film show a columnar growth (Fig. 1 (a)), not observed in the electrodeposited film (Fig. 1(b)). Both show a homogeneous and dense deposit, with absence of cracks. As shown in Fig. 1 (d), different reversal of magnetization are observed in the two films. The electrodeposited film displays the typical transcritical loops indicating the presence of a perpendicular anisotropy. This is confirmed by a stripe domain pattern [4], visible in Fig. 1(c). The perpendicular anisotropy in the electrodeposited films is determined by residual stresses induced by the formation of palladium hydrates. Conversely, sputtered film displays a typical soft magnetic behavior, with the magnetization lying entirely on the film plane. Founding of this work by SELECTA – ETN (grant no. 642642) is acknowledge.

N14-05. Data Mining for New Two- and One-Dimensional Weakly Bonded Solids and Assembly-free Heterostructures. *G. Cheon*[1], K.N. Duerloo[2], A.D. Sendek[1], C. Porter[1], Y. Chen[1] and E.J. Reed[1] *1. Stanford University, Stanford, CA, United States; 2. Boston Consulting Group, Amsterdam, Netherlands*

We employ data-driven methods to discover new two- and one-dimensional materials. Layered materials have attracted interest for technological applications and fundamental physics. But only a few van der Waals solids have been subject to considerable research focus. Through data mining, we identify 1173 two-dimensional layered materials and 487 weakly bonded one-dimensional molecular chains. This is an order of magnitude increase in the number of known materials. Moreover, we discover 98 heterostructures of two-dimensional and one-dimensional subcomponents that are found within bulk materials, opening new possibilities for van der Waals heterostructures. To identify these materials, we present a novel data mining algorithm that determines the dimensionality of weakly bonded subcomponents. Chemical families, band gaps, and point groups and single-layer piezoelectricity of the materials identified with data mining are presented. We also describe our collaborative efforts with NIST to elucidate more properties of these materials, including magnetic properties.

N14-06. Magneto-dielectric behavior of CFO/BTO/CFO composite film. *E. López-Moreno*[1], H. Montiel[1], G. Alvarez[2,3] and A. Conde[2]
1. Instituto de Ciencias Aplicadas y Tecnología, Universidad Nacional Autónoma de México, México City, Mexico; 2. Departamento de Física, CINVESTAV-IPN, México City, Mexico; 3. UACM-Cuautepec, Universidad Autonoma de la Ciudad de Mexico, Mexico City, Mexico

The multiferroic composite films in which piezoelectric and magnetostrictive phases are coupled, via local strain make, these are suitable for multifunctional device applications[1]. $CoFe_2O_4$ (CFO) and $BaTiO_3$ (BTO) heterostructures have shown a coupling between ferroelectric and magnetic order parameter [2]. CFO/BTO/CFO magnetoelectric composite have been deposited on ITO coated electrode employing PLD (pulsed laser deposition) method. Both CFO (spinel) and BTO (hexagonal) phases are confirmed by X-ray diffraction patterns and Raman spectroscopy. In composite, the magnetic hysteresis shows ferromagnetic behavior with in-plane coercivity of 2.9 KOe and saturation magnetization of 40 emu/g. Impedance spectroscopy were carried out as function of frequency (10Khz-100Mhz) and magnetic field (0-0.363T). The impedance plane shows different semicircle arcs under magnetic field and an equivalent electrical circuit has been proposed to fit impedance results. Low frequency Debye-type dielectric behavior with single relaxation time is revealed from experimental data, where the relaxation process is activated similar to magneto-impedance effect (Fig.1). The magneto-dielectric response MD(%)=100*[ε'(H) - ε'(0)]/ε'(0) have changes around 42% at 20 Khz. The frequency capacitance–voltage characterization of composite film also was measured under magnetic field (0-0.363T), where capacitance value decreases with increase in frequency between with values of 3.3 to 1.5 nF at 20 Khz.

N14-07. Stress-induced Nanoscale Magnetic Domain Configurations Imprinted in Ni Thin Films by Proximity to V_2O_3. *A. Fraile Rodríguez*[1,2], I. Valmianski[3], M. García del Muro[1,2], J. Ramirez[4], F. Kronast[5], I.K. Schuller[3], A. Labarta[1,2] and X. Batlle[1,2] *1. Física Matèria Condensada, Universitat de Barcelona, Barcelona, Spain; 2. Institut de Nanociència i Nanotecnologia, Universitat de Barcelona, Barcelona, Spain; 3. Physics, UCSD, La Jolla, CA, United States; 4. Department of Physics, Universidad de los Andes, Bogotá, Colombia; 5. Helmholtz-Zentrum Berlin für Materialien und Energie, Berlin, Germany*

Nanoscale manipulation of magnetic thin films can be achieved through proximity effects in bilayer or multilayer structures. In particular, the proximity of a ferromagnetic (FM) thin film to a vanadium oxide results in a reversible modification of the magnetic properties due to the magnetoelastic anisotropy caused by the interfacial stress [1,2]. However, it remains to be proven if the recently reported nanoscale phase coexistence in V_2O_3 [3] yields a nanoscale magnetic domain pattern in the Ni layer. In this work, we combine photoemission electron microscopy (PEEM) with X-ray magnetic circular dichroism (XMCD) to map the temperature-driven variation of the Ni domain pattern across the SPT of V_2O_3 in Ni (10 nm)/V_2O_3 (100 nm) bilayers. The histograms of the Ni magnetization orientations indicate sharp distributions at two different directions corresponding to the low-T and high-T states, respectively, and a broad distribution of intermediate orientations across the SPT, suggesting that the magnetization rotation is induced by the SPT. Thus, the fraction of the reoriented spins rises monotonically with the predominance of one of the coexisting V_2O_3 structural phases, in agreement with the evolution of the metal-insulator (MI) transition in the V_2O_3 thin film [3]. Furthermore, below the SPT, the Ni domains form stripe patterns with length (100s of nm) and periodicity matching the MI striped pattern in V_2O_3 [3]. More importantly, an in-plane reorientation of the Ni magnetization is observed, likely due to the rotation of the stress anisotropy axis associated with the SPT in V_2O_3 from the monoclinic low-T to the rhombohedral high-T phases. This in agreement with in-plane ferromagnetic resonance experiments [4]. Finally, the spatial-resolved map of the SPT temperatures across the sample obtained from the Ni domain pattern at each temperature is consistent with the nanoscale phase coexistence in V_2O_3 [3]. This work was supported by the Spanish MINECO MAT2015-68772-P project, European Union FEDER funds and the US-DOE DE-FG02-87ER-45332 grant.

N14-08. Electronic and magnetic structure of epitaxial $Y(Mn_{1-x}Fe_x)O_3$ films studied with X-ray absorption spectroscopy. S. Haw[1], J. Lee[1], S. Chen[1], *K. Lu*[1] and J. Chen[1] *1. Scientific Research Division, National Synchrotron Radiation Research Center, Hsinchu, Taiwan*

Perovskite o-$YMn_{1-x}Fe_xO_3$ (x=0.125, 0.25, 0.50) epitaxial thin films were prepared on a $YAlO_3$(010) substrate by pulsed-laser deposition. A single phase was determined from XRD patterns. XRD analysis further indicated a shortened *b*-axis and lengthened *a*- and *c*-axes. From an analysis of the experimental polarization-dependent X-ray absorption spectroscopy (XAS) spectra at the Mn-$L_{2,3}$ and Fe-$L_{2,3}$ edges with full-multiplet calculations, the electronic structures of Mn^{3+} and Fe^{3+} ions in o-$YMn_{1-x}Fe_xO_3$ films were determined. We observed that the polarization anisotropy at the Mn-$L_{2,3}$ and Fe-$L_{2,3}$ absorption spectra was decreased with increasing Fe concentration above x=0.125. The spectral changes between x=0.125 and x=0 for Mn-$L_{2,3}$ edge XAS spectra will be negligible as the polarization-dependent Mn-$L_{2,3}$ edge XAS spectra of o-$YMn_{1-x}Fe_xO_3$ for x=0.125 are very close to those of

pure o-$YMnO_3$, whereas Fe-$L_{2,3}$ edge XAS spectra show a clear polarization dependence with an energy shift for $E//b$ smaller than for $E//a$ and $E//c$ in a similar way to that observed in the Mn-$L_{2,3}$ edge XAS spectra. The observed spectral changes reflect the local Jahn-Teller (JT) distortion of the Mn^{3+} ion that is decreased by the neighboring spherical high-spin Fe^{3+} ion, whereas the local symmetry of the Fe^{3+} ion is distorted by the neighboring JT-active Mn^{3+} ion. Although the Mn-e_g electron predominantly occupies the $d_{3y^2-r^2}$ orbital in o-$YMn_{1-x}Fe_xO_3$ up to 50 % Fe substitution, the JT distortion and $GdFeO_3$-type structure distortion are decreased. The antiferromagnetic easy axis in o-$YMn_{0.5}Fe_{0.5}O_3$ is inclined to align with *b*-axis in Fe sublattice along with the observation of gradual transformation of AFM spin state disorder/order with decreasing temperature in Fe sublattice.

N14-09. Structural, Magnetic, and Optical Characterization of Fe/Ag Continuous Films and Nanodot Arrays. *D. Markó*[1,2], W. Chuang[3], S. Ciou[4], H. Han[4], J. Chen[3], J. Wu[4], B. Alkadour[5], P. Manna[5], J. van Lierop[5], K. Lin[3] and D. Schmool[1,2] *1. GEMaC, CNRS, Versailles, France; 2. Université de Versailles/Saint-Quentin-en-Yvelines, Université Paris-Saclay, Versailles, France; 3. Hybrid nanostructures consisting of ferromagnetic materials and noble metals that combine dual magnetic and plasmonic functionality resulting in enhanced magneto-optical properties have been extensively investigated over the past few years, leading to a dedicated research field known as magneto-plasmonics [1]. In this study, we present the first steps towards the goal of manipulating optical and magnetic properties of such nanostructures via magnetoplasmonic coupling. For this purpose, Fe(50 nm)/Ag(30 nm) bilayers have been prepared on amorphous SiO_2 substrates by using a dual ion-beam sputtering deposition technique [2]. Continuous Fe/Ag thin films exhibit smooth surfaces, consist of polycrystalline fcc Fe and fcc Ag, and show soft magnetic properties including low coercivity. Fe/Ag nanodot arrays (diameter ~ 200 nm, pitch ~ 400 nm) have been successfully fabricated by combining electron beam lithography and Ar-ion etching techniques [3]. The magnetic excitations of the samples have been investigated by vector network analyzer ferromagnetic resonance (VNA-FMR) [4] in both in-plane and out-of-plane geometries. From angle-dependent measurements, linewidths, magnetic anisotropies, and possible magnetic interactions between the magnetic elements have been analyzed. The VNA-FMR spectrum of the reference Fe/Ag bilayers (Fig. 1(a)) is comprised of two modes: the uniform mode as well as a mode with higher frequency. However, the FMR spectrum obtained from the Fe/Ag nanodot arrays (Fig. 1(b)) displays significant modification. While both the uniform mode and the mode with higher frequency are also present in the Fe/Ag nanostructures, indicating that the latter is an interface mode, their frequency spacing is noticeably reduced. Moreover, there is a third dot array mode with frequencies below the uniform mode. In addition to the structural and magnetic characterization, the first optical absorption spectra in the visible light range of both Fe/Ag full films and nanostructures have been recorded. Research was supported by MOST of Taiwan, NSERC and CFI of Canada, as well as CNRS of France.

N14-10. Soft X-Ray XAS, XMLD, and XMCD Study of Self-Organized 1D Transition Metal-Oxide Hybrid Chain Structures. T. Kißlinger[2], L. Hammer[2], M. Ammon[2], P. Gargiani[1], S. Agrestini[1], *E. Pellegrin*[1] and M. Schneider[2] *1. Experiments, ALBA Synchrotron Light Source, Barcelona, Spain; 2. Department of Physics, Friedrich-Alexander University Erlangen-Nürnberg, Erlangen, Germany*

We have carried out soft X-ray XAS, XMLD, and XMCD measurements on transition metal oxide chains with TMO_2 (TM=Mn, Fe, Co, Ni) stoichiometry. These one-dimensional self-organized chains were grown on Ir(100) with extremely high perfection and have been structurally characterized by LEED as well as by prior STM analyses.[1] Also, the magnetic ground states and inter-chain cross-couplings for the different TMO_2 chains were predicted by DFT calculations.[1] Results from the above soft x-ray spectroscopy measurements will be presented in order to provide information on the (local) eletronic and magnetic structure of such a novel and fundamental 1D TM oxide chain system as well as to provide an experimental cross-check for the validity of the theoretical modelling by DFT. To this end, the experimental TM2p spectra will also be compared with advanced crystal field multiplet calculations.

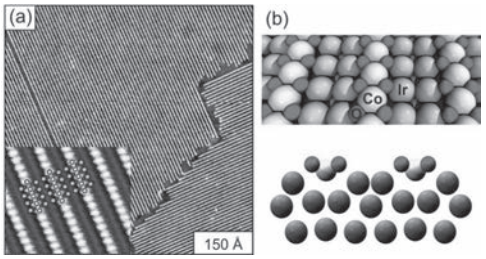

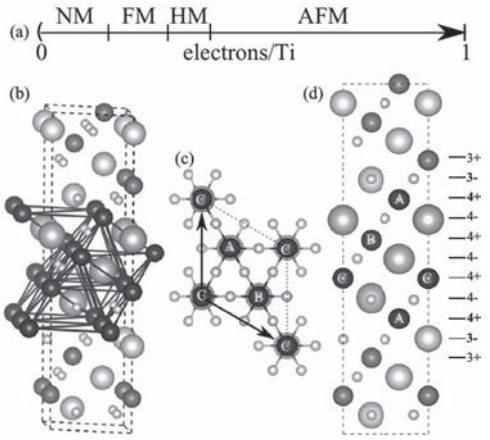

Figure 1: (a) STM image showing the large scale homogeneity of the ferromagnetic CoO_2 chain structure. Inset: atomically resolved image. (b) Crystallographic structure of the CoO_2 chains as derived from quantitative LEED analysis [1] in top and side view. There are no direct bonds between the Co atoms and the Ir atoms of the substrate. Other TMO_2 structures are qualitatively identical to CoO_2.

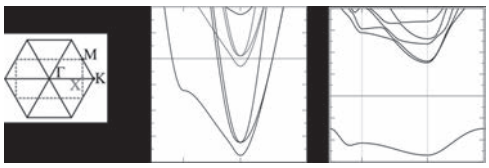
N14-11. Metal-Insulator Transition in (111) $LaAlO_3/SrTiO_3$ Superlattices. J. Beltrán[1] and *C. Muñoz*[2] *1. GFMC, Física de Materiales, Universidad Complutense de Madrid, Madrid, Spain; 2. Instituto de Ciencia de Materiales de Madrid (ICMM), Consejo Superior de Investigaciones Científicas (CSIC), Madrid, Spain*



Complex oxide heterostructures (HSs) offer the possibility of tuning crystal symmetry, strain, spatial confinement, and dimensionality and thereby they allow one to manipulate the charge, spin, and orbital order. We report the occurrence of a metal insulator transition driven by quantum confinement in (111)-oriented $LaAlO_3/SrTiO_3$ (LAO/STO) superlattices (SL). Density functional theory calculations demonstrate that by selecting the STO thickness the ground state of *n*-type (111) LAO/STO symmetric superlattices can be tuned. It ranges from a trivial metal for thick STO slabs to a Mott-type antiferromagnet in the ultrathin limit. Therefore, by changing the SL thickness a quantum metal-insulator transition is induced. This remarkable property is a distinct characteristic of (111) perovskite heterostructures and originates from the combined effect of polar discontinuity at the interface, trigonal lattice symmetry, and quantum confinement. While the polar discontinuity promotes the filling with one electron of the empty Ti *d*-orbitals of the STO independent of the superlattice periods, the trigonal symmetry dictates that the wave function of the occupied SL conduction bands spreads over the entire STO slab. Consequently, the electron density can be chosen by selecting the STO thickness. For high densities, symmetry breaking and on-site Coulomb interaction drive the emergence of a Mott-like antiferromagnetic ground state, while a half-metal, an itinerant ferromagnet and finally to a non-magnetic metal phase develop for decreasing the electronic

density, i.e., increasing STO thickness. Our results show that low dimensionality can lead to unconventional behaviour of oxide heterostructures formed by electronically fairly simple nonmagnetic band insulators, and open new perspectives for the use of LAO/STO SLs grown along the [111] direction to explore quantum phase transitions

N14-12. Giant pseudo-magnetic fields, valley polarization and topological channels by nanoscale strain engineering of monolayer graphene.
J. Wang[1], *C. Hsu*[1], M. Teague[1], M. Jao[2] and N. Yeh[1,3] *1. Caltech, Pasadena, CA, United States; 2. National Taiwan University, Taipei, Taiwan; 3. Kavli Nanoscience Institute, Caltech, Pasadena, CA, United States*

We report the use of nearly strain-free PECVD-grown graphene[1] to induce controllable strain and pseudo-magnetic fields (B_S) by placing graphene on synthesized tetrahedron nanocrystals.[2] The nanocrystals were spin-coated on a Si substrates and then covered by a monolayer of h-BN followed by a monolayer of graphene. In isolated tetrahedrons, giant B_S values up to ~5000 T had been revealed from direct measurements of Landau levels in the scanning tunneling spectroscopic studies, whereas topographic distortion further implied maximum B_S approaching ~ 25000 T along the ridge of the single tetrahedron. In contrast, the maximum B_S value became significantly reduced to ~ 600 T along the ridge of two correlated tetrahedrons as the result of comparable height variations over more extended lateral areas relative to the distortion induced by single tetrahedrons. The effect of pseudo-magnetic field-induced local time-reversal symmetry breaking on valley polarization was confirmed by the alternating presence and absence of zeroth Landau level at two inequivalent sublattice sites.[3] These empirical results were compared with Molecular Dynamics (MD) simulations for the magnitude and spatial distribution of strain-induced pseudo-magnetic fields, and the consistency ensured that properly designed arrays of nanostructures could induce the desirable B_S values and spatial distributions to yield realistic valleytronic devices. Additionally, the boundaries along alternating positive and negative pseudo-magnetic fields are natural topological channels promising for high-fidelity propagation of valley-polarized currents due to as a result of topological protection.

Monolayer van der Waals (vdW) magnets provide an exciting opportunity for exploring two-dimensional (2D) magnetism for scientific and technological advances, but the intrinsic ferromagnetism has only been observed at low temperatures. Here, we report the observation of room temperature ferromagnetism in manganese selenide ($MnSe_x$) films grown by molecular beam epitaxy (MBE). Magnetic and structural characterization provides strong evidence that, in the monolayer limit, the ferromagnetism originates from a vdW manganese diselenide ($MnSe_2$) monolayer, while for thicker films it could originate from a combination of vdW $MnSe_2$ and/or interfacial magnetism of α-MnSe(111). Magnetization measurements of monolayer $MnSe_x$ films on GaSe and $SnSe_2$ epilayers show ferromagnetic ordering with a large saturation magnetization of ~4 Bohr magnetons per Mn, which is consistent with the density functional theory calculations predicting ferromagnetism in monolayer 1T-$MnSe_2$. Growing $MnSe_x$ films on GaSe up to a high thickness (~40 nm) produces α-MnSe(111) and an enhanced magnetic moment (~2×) compared to the monolayer $MnSe_x$ samples. Detailed structural characterization by scanning transmission electron microscopy (STEM), scanning tunneling microscopy (STM), and reflection high energy electron diffraction (RHEED) reveals an abrupt and clean interface between GaSe(0001) and α-MnSe(111). In particular, the structure measured by STEM is consistent with the presence of a $MnSe_2$ monolayer at the interface. These results hold promise for potential applications in energy efficient information storage and processing.

N15-01. Magnetization plateaus in $Tb_2SrFe_2O_7$*. *H. Cao*[1], J. Kim[2], W. Tian[1], Y. Wu[1] and S. Cheong[2] *1. Neutron Scattering Division, Oak Ridge National Laboratory, Oak Ridge, TN, United States; 2. Physics and Astronomy, Rutgers University, Piscataway, NJ, United States*

Geometrically frustrated magnets are highly interesting due to the occurrence of unconventional magnetic states, such as spin glasses, spin liquid, spin ice, and also the discovery of magnetic monopoles [1-3]. We recently studied a magnetization plateau behavior in a layered perovskite $Tb_2SrFe_2O_7$ and discovered an ordered 2-in-2-out Tb-spin structure, similar to the field-induced ordered spin-ice state [4]. $Tb_2SrFe_2O_7$ has a bilayer perovskite structure ($A_3B_2O_7$) with Tb and Sr both at A-sites alternately ordered along the *c*-axis. Different from the multiferroic $Ca_2SrFe_2O_7$ that hosts the polar crystal structure and also the magnetic ordered state with canted Fe moments, $Tb_2SrFe_2O_7$ has the non-polar structure symmetry of *P*42/*mnm* and the collinear antiferromagnetic structure for the Fe-sublattice below 600 K. The magnetization plateaus were observed below the second magnetic transition at 15 K in $Tb_2SrFe_2O_7$. With the field applied along *c*-axis, three plateaus were observed. Single crystal neutron diffraction revealed that the magnetic transition at 15 K is from magnetic order of Tb-sublattice accompanied with the spin reorientation of Fe-sublattice. It was also proved that the order of 2-in-2-out spin structure is due to magnetic coupling with the Fe-sublattice. In this presentation, I will show the evolution of the spin structure with temperature and magnetic field and disclose the nature of the magnetization plateaus in $Tb_2SrFe_2O_7$. *This research used resources at the Spallation Neutron Source and the High Flux Isotope Reactor, a DOE Office of Science User Facility operated by the Oak Ridge National Laboratory.

N15-02. Synthesis and characterization of pyrochlore ruthenate $Gd_2Ru_{2-x}Mo_xO_7$ via a molten salt method. *A. Castro Espinosa*[1], R. Escamilla Guerrero[1], M. Romero Martinez[2] and O. Olicón Hernandez[1] *1. Instituto de Investigaciones en Materiales, Universidad Nacional Autónoma de México, Ciudad de México, Mexico; 2. Facultad de Ciencias, Universidad Nacional Autónoma de México, Ciudad de México, Mexico*

The pyrochlore compounds can be written as $A_2^{3+}B_2^{4+}O_6^{-2}O'^{-2}$ with cubic structure and space group Fd3m (*Z*=8) [1]. The A cations have an eight coordination AO_8 while smaller B cations a six-coordination BO_6 which form infinite interpenetrating networks of tetrahedrons that share the corners and presents geometrically frustrated magnetism. In these materials, the correlation between structure and electric properties has been well established, for example along of the Ru-O-Ru bond angle: between 135° and 140°, and between 129° and 134° it has a metallic and semiconducting response, respectively [2]. The magnetic behavior in the $Gd_2Mo_2O_7$ is ferromagnetic [3] while in the Gd_2Ru_2O7 is antiferromagnetic [4]. In the present study, polycrystalline samples of $Gd_2Ru_{2-x}Mo_xO_7$ with x=0.0, 0.1, 0.2, 0.3, 0.4 were synthesized by the molten salt method and characterized by X-ray diffraction (XRD) and Rietveld refinement. The magnetic properties were measured using a Magnetic Property Measurement System (MPMS®3). We present the temperature dependence of the magnetization in a zero-field-cooling (ZFC) and field-cooling (FC) process in a field of 1000 Oe and 100 Oe.

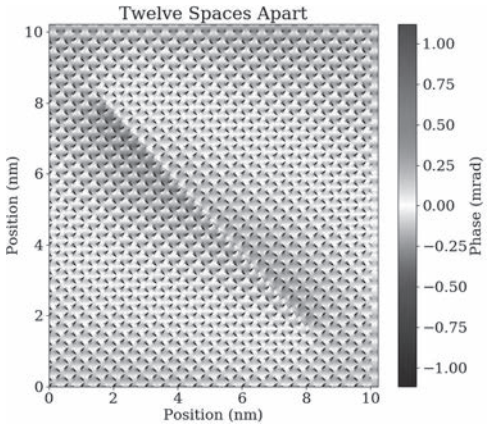
Perimeter Institute for Theoretical Physics, Waterloo, ON, Canada*

The breathing pyrochlore lattice material $Ba_3Yb_2Zn_5O_{11}$ exists in the nearly decoupled limit in contrast to most other breathing pyrochlore lattices studied to date. Here we study the magnetic field dependent behavior of $Ba_3Yb_2Zn_5O_{11}$ at low temperatures to further examine the physics of this model system. Experimentally, we probe the behavior of pollycrystalline samples of $Ba_3Yb_2Zn_5O_{11}$ with a combination inelastic neutron scattering and heat capacity measurements to 0.75 mK and 10 T. Consistent with previous work the inelastic neutron scattering finds a level crossing near 3 T, but no significant dispersion of the spin excitations is detected to 10 T. Refinement of the theoretical model determined at zero field can reproduce much of the inelastic neutron scattering spectra and specific heat data. A notable exception is a low temperature peak in the specific heat at ~0.1 K. This may indicate the scale of interactions between tetrahedra or may reflect undetected disorder in $Ba_3Yb_2Zn_5O_{11}$.

Inelastic neutron scattering data (H=0 and T=0.1 K) and heat capacity data (H=0) compared to model calculations.



Inelastic neutron scattering data (H=6 T and T=0.1 K) and heat capacity data (H=6 T) compared to model calculations.

N15-04. Simulation of Electron Holography of Pyrochlore Spin Ice.
A. Dhar[1], L. Jaubert[2], N. Shannon[1] and T. Shintake[1] *1. Okinawa Institute of Science and Technology, Onna-son, Japan; 2. Laboratoire Ondes et Matière d'Aquitaine (LOMA), Bordeaux, France*

A major topic in frustrated magnetism is emergent magnetic monopoles in spin ice[1]. These low-energy excitations are effective classical analogues of Dirac monopoles[2]. As such, they present a valuable testing ground for the physics of magnetic monopoles which remain elusive as high energy particles. However, signatures of monopoles in spin-ice materials have only been indirect so far, and their direct observation has remained an open challenge since their discovery[2]. Electron holography is suited to probe these properties with its high sensitivity to magnetic fields. This is commonly done in a TEM by taking the electron beam through a field free region, where half of the beam interacts with the sample and the other half remains unperturbed, and interfering it with itself by use of an electron biprism. The resulting hologram is used to reconstruct the magnitude and phase of the electron wave using computational methods[3]. To date, electron holography has achieved 3D spatial imaging of spin phenomena with nanometer resolution[4]. This makes the technique uniquely suited for directly imaging spin ice monopoles. I have developed computational methods to predict how an electron wave would propagate through the spin ice's magnetic structure. The magnetic arrangement of pyrochlore spin ice thin films was either generated by hand or with the help of Monte Carlo simulation[5]. From there my finite element code calculates the magnetic vector potential around the spin ice, and its resulting effect on electron phase. This phase map is then converted into a hologram by using Fresnel propagation about the biprism and interference. Currently the best holographic microscopes reach a spatial resolution of 210 pm and phase resolution of $2\pi/200$ in a sample region, which is being taken into consideration when simulating the experimental conditions necessary to image these monopoles[6]. These simulated results enable us to show for the first time what a monopole would look like if imaged using electron holography.

N15-05. Local susceptibility of frustrated pyrochlores. Polarized Neutrons and Point Charge model.
A. Gukasov[1] *1. CEA-CNRS, Leon Brillouin Laboratory, Gif sur Yvette, France*

Rare earth frustrated pyrochlore magnets are among the materials that exhibit no long range order down to the lowest explored temperatures. In the pyrochlore lattice, selection between Ising, Heisenberg, or XY types of the anisotropy cannot be based on the analysis of the macroscopic properties because of the presence of four equivalent local anisotropy (<111> -type) axes. Then only an average over the four axes can be measured by classical methods. Polarized neutron diffraction based on the 'local susceptibility approach' allows to determine the local susceptibility tensor on the magnetic site [1]. In the mean time the local susceptibility of rare earth pyrochlores can be calculated using crystal field parameters measured by inelastic neutron scattering. Using this method it was found that for rare earth pyrochlores an isotropic exchange model is not suitable to explain their magnetic behavior and that, instead, the exchange interaction appear anisotropic to large extent [2,3]. In a number of cases with low symmetry ligand environment, however, inelastic neutron scattering spectra doesn't allow the determination of crystal field parameters. In these cases the local susceptibilities can be calculated using point charge model taking into account the electrostatic field produced by the charges of the crystal environment of a rare earth atom. We used the McPhase software [3] which allows calculating of the crystal field parameters using crystal structure parameters. In the case of pyrochlores the point charge model constrained by trigonal symmetry resumes in two variable charge parameters, effective valences of O1 in apical (8b) position and O2 in basal (48f) position. Figure 1 shows that the description of the local susceptibility in a Tb and Ho titanates can be easily obtained by adjusting the difference between the O1 and O2 valences by about10-15%. We also have found that this method allows to describe the local susceptibility of multiferroics TbMnO3 and DyMnO3 in which the determination of crystal field parameters from neutron inelastic spectra is impossible.

N15-06. Magnetisation and far infrared study of chromium spinels MCr_2O_4 (M = Co, Ni, Mn) with frustrated exchange interactions.

D. Kamenskyi[1], A. Bush[2], J. Law[4] and A.V. Pronin[3] *1. High Field Magnet Laboratory, Radboud University, Nijmegen, Netherlands; 2. Moscow Technological University, Moscow, Russian Federation; 3. 1. Physikalisches Institut, University of Stuttgart, Stuttgart, Germany; 4. Hochfeld Magnet Labor, Helmholtz Zentrum Dresden-Rossendorf, Dresden, Germany*

The multiferroicity of $CoCr_2O_4$ reported by Yamasaki et al in 2006 [1] has triggered a number of experimental studies of $CoCr_2O_4$ as well as whole family of spinels MCr_2O_4. The interest was triggered not only by technological potential of multiferroics but also by strong frustration of magnetic subsystem which leads to the number of exotic phenomena reach phase diagram of these materials [2]. Here, we report on magnetic and far infrared properties of multiferroics with frustrated spin exchange interactions MCr_2O_4 (M = Co, Ni, Mn) in magnetic fields up to 60 T. Below the ferrimagnetic transition (94 and 75 K for $CoCr_2O_4$ and $NiCr_2O_4$, respectively), the terahertz response of $CoCr_2O_4$ is dominated by a magnon mode with a zero-field gap of 15.8 cm^{-1}. This mode shows a steep linear magnetic field dependence and can be ascribed to an exchange resonance between two magnetic sublattices with different g factors [3]. At zero magnetic field, $NiCr_2O_4$ exhibits similar mode at 13.6 cm^{-1} (mode A in a figure) whereas in $MnCr_2O_4$ such mode is absent. When the magnetic field applied, mode A shifts to the higher energies similarly to $CoCr_2O_4$. However, in higher magnetic fields the second mode appears (mode B) in $NiCr_2O_4$. We discuss the origin of these magnon modes and the microscopic magnetic structure of chromium spinals by compiling the results of far infrared spectroscopy with magnetisation measurements performed in pulsed magnetic fields (up to 60 T). The obtained results provide information about devepolment of the magnetic structure over the broad range of the magnetic field.

N15-07. Discovery of new magnetic orders on pyrochlore spinels.

G. Sim[1] and S. Lee[1] *1. Korea Advanced Institute of Science and Technology (KAIST), Daejeon, The Republic of Korea*

Geometrically frustration, where couplings of localized moments have conflict between each other, arises in many magnetic materials.[1,2] At the same time, spin orbit coupling plays a crucial role by inducing anisotropic spin exchanges and many related issues has been studied recently.[3,4] One might expect to see new types of magnetic phases when these two interplay with each other. We investigate the magnetic properties of spinel compounds (a chemical formula AB2X4) where magnetic ions are occupied in B-site. [5-7] The B-site in spinels form a corner shared tetrahedral structure so called a pyrochlore lattice. When spin orbit coupling comes in, it turns out that complicated superexchange paths make further neighbor anisotropic spin interaction to be relevant. Consequently, we see that intertwined geometric frustration and spin orbit couplings play a central role in determining magnetic orderings. Pyrochlore lattice is well known example where the effect of geometrical frustration is essential.[8,9] However, the importance of further neighbor anisotropic exchanges has been barely pointed out and we stress that it results in unconventional non-coplanar magnetic states, named as 'octagonal (prism)' state and '(distorted) cubic' state described by multiple ordering wavevectors. Related physical phenomena is also argued such as finite orbital current and orbital magnetization even in Mott insulators.[10] We also find several other phases which are already known, but stabilized by anisotropic further neighbor spin interactions; local XY state, all-in all-out state, Palmer-Chlker state etc. Our work suggests new insights of magnetic spinel compounds and understanding of relevant experiments. N15-08. Magnetization curves and low-temperature thermodynamics of two spin-1/2 Heisenberg edge-shared tetrahedrons. *J. Strecka*[1] and K. Karlova[2] *1. P. J. Safarik University, Kosice, Slovakia; 2. Department of theoretical physics and astrophysics, P. J. Safarik University in Kosice, Kosice, Slovakia*

Low-temperature magnetization and magneto-thermodynamics of two spin-1/2 Heisenberg edge-shared tetrahedrons with two different coupling constants are investigated by Kambe projection method providing a full energy spectrum. It is shown that a competition between both coupling constants drives at zero magnetic field the investigated Heisenberg spin cluster either into a singlet or triplet state. The low-temperature magnetization curves accordingly exhibit three different sequences of intermediate magnetization plateaux, more specifically, either 1/3-2/3-1, 0-1/3-2/3-1 or 0-2/3-1. The susceptibility and specific-heat data may display an outstanding temperature dependence with a pronounced Schottky-type maximum located at low enough temperatures. The obtained theoretical results bring insight into the experimental data recently reported for the natural mineral crystal fedotovite K2Cu3(SO4)3 [1].

N15-12. Learning to Discover Loop Algorithm on Spin Ice Model. K. Zhao[1], *W. Kao*[1] and Y. Kao[1] *1. Physics, National Taiwan University, Taipei, Taiwan*

Reinforcement learning (RL) is a fast-growing research branch of artificial intelligence because of its outstanding exploration capability on dynamic environments. Inspired by psychological learning theories, the RL framework contains a software agent with improvable policies that takes actions on the environment and attempts to achieve the goal. A policy is a stochastic rule which governs the decision-making process of the agent and is updated from the response of the environment. In this work, we apply RL framework on the spin ice model. Spin ice is a frustrated magnetic system with strong topological constraints on the low-energy configurations. In the physics community, it is well-known that the loop Monte Carlo algorithm can update the system efficiently without breaking its local constraint. However, from a broader perspective, the global update schemes can be problem-dependent and require customized algorithm design. Therefore, we exploit a reinforcement learning method that parameterize transition operator with neural networks. By promoting the Markov chain into Markov decision process, the algorithm can adaptively search for global update policy through its interactions with the physical model. It may serve as a general framework for the search of update patterns in many-body physics.

N15-13. Magnetic frustration in low dimensional substructures of hulsite $Ni_{5.15}Sn_{0.85}(O_2BO_3)_2$. *E.B. Saitovitch*[1], C.P. Contreras Medrano[1,2], D. Freitas[2], M. Continentino[1], E. Passamani Caetano[3], M. Alzamora[4] and D. Sanchez Candela[2] *1. CONAM, Centro Brasileiro de Pesquisas Fisicas, Rio de Janeiro, Brazil; 2. Instituto de Física, Universidade Federal Fluminense, Niteroi, Brazil; 3. Departamento de Física, Universidade Federal do Espírito Santo, Vitoria, Brazil; 4. Instituto de Física, Universidade Federal do Rio de Janeiro, Xerém, Brazil*

In the present work, we develop an extensive study on a novel hulsite, a type of oxyborate barely studied. The structural, magnetic, and thermodynamic properties of hulsite $Ni_{5.15}Sn_{0.85}(O_2BO_3)2$, revealed a complex magnetic behavior related to high magnetic frustration and low spin (S= 1). The structure of the hulsite is formed by two planar substructures, one with a rectangular structure for the metal ions and the other with a triangular metallic arrangement. This system literally adds a new dimension to the study of oxyborates. Our results point to a partial magnetic order consistent with the two substructures. The planes with rectangular arrangement show a spin glass behavior below 180 K. On the other hand, the other subsystem, formed by Ni atoms located in a two dimensional triangular lattice, does not order at temperatures as low as 3 K. The experimental results suggest a spin liquid behavior for this subsystem.

N16-01. Impurity dominated weak antilocalization in sputtered polycrystalline topological insulator. *P. Sahu*[1], J. Chen[2], J. Myers[4] and J. Wang[3] *1. Department of Physics and Astronomy, University of Minnesota, Minneapolis, MN, United States; 2. Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States; 3. Electrical and Computer Engineering, School of Physics & Astronomy, Minneapolis, MN, United States; 4. Characterization Facility, University of Minnesota, Minneapolis, MN, United States*

Topological insulator (TI) based materials have generated a lot of interest among device physicists for novel spintronic applications. TIs consist of conducting surface states that are topologically protected by time-reversal symmetry. This symmetry can be broken under the application of perpendicular magnetic field giving rise to the well-known property of weak antilocalization (WAL)[1]. However, material growth remains a major bottleneck for TI applications. Bismuth Selenide based TIs tend to rhombohedral structure when grown on proper substrate to minimize lattice strain. Most TIs are grown by molecular beam epitaxy which suffers from low throughput. We had recently reported high spin Hall angle in sputtered Bi_xSe_{1-x} which suggests the possibility of strong spin-orbit coupling in disordered systems[2]. Polycrystalline films can have multiple defects/impurities that can play an important role in the transport behavior. We characterized the transport property of 20 nm Bi_xSe_{1-x}, deposited by magnetron sputtering. High carrier concentration (10^{20} /cm^3) indicates that the bulk/impurity channels can overwhelm the surface states. Drude model was used to obtain the carrier mobility (~8 cm^2/(Vs)). Low temperature magnetoresistance reveals a strong cusp at zero perpendicular magnetic field signifying WAL, which turns parabolic at higher temperatures. The 2D magnetoconductivity was fitted with Hikami-Larkin-Nagaoka equation which gave us the phase coherence length of the carriers and number of conducting channels[3]. This gave us, higher than usual value of conducting channels (number of channels > 2), suggesting bulk/impurity contributions. Variation of phase coherence length with temperature suggests electron-electron interaction as the major dephasing mechanism[4]. The angle dependent magnetoconductivity shows variation with respect to perpendicular component of magnetic field at different tilt angles. The angular dependence of WAL along with low mobility leads us to infer that the major contribution of WAL comes from the impurity band[5].

N16-03. Gd doping effect in p-type Bi_2Te_3 single crystals. S. Kim[1] and *M. Jung*[1] *1. Department of Physics, Sogang University, Seoul, The Republic of Korea*

Topological insulators (TIs), a new class of quantum materials, have attracted a lot of interest due to the peculiar band structure of gapless surface states inside the insulating band gap. By introducing magnetic order into TIs, different kinds of quantum phenomena can be achieved such as quantum anomalous Hall effect, image magnetic monopoles, and giant magneto optical effects. The simplest way to introduce the magnetic order into TIs is doping of magnetic impurities, as demonstrated in dilute magnetic semiconductors (DMS). Long-range ferromagnetic order has been realized in several Bi_2Se_3 and Bi_2Te_3 series by doping 3*d* transition-metal elements such as Fe and Cr. Recently, we have reported that antiferromagnetic order is induced by 4*f* rare-earth elements such as Ce and Gd in Bi_2Se_3 and Bi_2Te_3 [1,2,3]. If the doping elements are rare-earth metals, we can expect no charge carriers but tune only the magnetic moments. In our previous studies, we reported a magnetic transition to antiferromagnetic phase at $x = 0.09$ in Te-excessive $Gd_xBi_{2-x}Te_3$ system [1], where we obtained n-type charge carriers because the Te excess generated Te_{Bi}-type antisite defects. Then, a simple question arises as to how the magnetic properties are propagated in p-type $Gd_xBi_{2-x}Te_3$ with different type of antisite defects, which is Bi_{Te}-type. In this work,

we fabricated Te-deficient $Gd_xBi_{2-x}Te_3$ ($x = 0.04, 0.06, 0.08, 0.12, 0.15, 0.20$) single crystals. Even though we increased the amount of Gd substitution, the transport and magnetic data did not show any big differences. For example, metallic behavior of electrical resistivity was observed, so that the residual resistivity ratio value was almost the same for all the samples. We estimated the actual Gd composition to be almost the same from the Curie-Weiss fit of magnetic susceptibility data, and we observed no signature of antiferromagnetic order in the measured temperature range down to 2 K. These results suggest that p-type charge carriers are not suitable for introducing the antiferromagnetic order in Te-deficient $Gd_xBi_{2-x}Te_3$, unlike the carrier-induced ferromagnetism in p-type doped DMS.

Dirac topological semimetals are characterized by the presence of doubly degenerate Dirac nodes in the linear electronic spectrum of conduction electrons. Upon alloying with magnetic impurities, it is expected to remove the degeneracy and split the Dirac nodes into two Weyl nodes. We studied the influence of magnetic impurities Eu on the magnetic properties of α-Cd_3As_2. It is found that the small Eu doping changes the character of the dependence on the field and sign from positive on negative of the transverse magnetoresistance. Data on the magnetic susceptibility and saturation magnetization showed the presence of an additional phase of Eu^{2+} ions magnetized opposite to the external field. Measurements of electron spin resonance (ESR), carried out at high temperatures, allow us to conclude that this phase consists of Eu^{2+} ions located in interstices positions - tetrahedral vacancies in fluorite type cell. Whereas the main phase consists of the Eu^{2+} ions in the positions substituting of the Cd^{2+} ions. The ESR data show anomalous large values of the g - factor of the Eu^{2+} ions, which in its turn indicates very large values of the g factor of the conduction electrons ($g \sim 16$-18). Analysis of the role of the RKKY interaction [1, 2] in this situation leads to the conclusion that the RKKY interaction in the classical view can not lead to change of a sign of interaction selectively in dependence on position types in the crystal lattice. Consequently, we are dealing with a new type of indirect interaction [3], whose agents are the local symmetry breakings of the crystal by magnetic ions. This interaction leads to the splitting of twotime degenerate Dirac nodes by anological with splitting of electronic states with different spin directions.

N16-05. Effects of pressure on the Fermi surface of Cd_3As_2. *A. Vasiljković*[1], F. Orbanić[2], M. Novak[2], M. Grosche[1] and I. Kokanovic[2,1] *1. Cavendish Laboratory, University of Cambridge, Cambridge, United Kingdom; 2. Department of Physics, University of Zagreb, Zagreb, Croatia*

Cd_3As_2 is a symmetry-protected three dimensional Dirac semimetal with high carrier mobility [1], motivating detailed investigations of the electronic structure and its evolution with applied pressures. Shubnikov-de Haas oscillations have previously been reported with frequencies of around 55T, corresponding to tiny Fermi surface pockets in a semimetallic band structure [2]. De Haas-van Alphen oscillations have also been observed with slightly smaller frequencies [2]. We have examined the Shubnikov-de Haas oscillations of the magnetoresistance in a high-quality crystal grown under different conditions over a wide range of temperature and pressure. In contrast to previous reports, we observe a significantly lower quantum oscillation frequency of ~27T with corresponding effective mass ~$0.03m_e$ at ambient pressure in a direction perpendicular to the c direction, which decreases significantly with increasing pressure. We also observed a second oscillation frequency of about 35T at ambient pressure for fields along the c direction. As the pressure was increased, an even lower oscillation frequency of ~15T was seen to develop in a direction perpendicular to the c direction. The observed SdH oscillations help characterize the Fermi surface and its evolution with applied pressure.

N16-06. Features of the electronic transport in the 3D topological semimetal Cd_3As_2 doped by magnetic impurity. *Y. Goryunov*[1], A. Nateprov[2] and Y. Proshin[3] *1. E.K.Zavoisky Kazan Physical-Technical Institute, Kazan Federal Research Center of the FASO RF, Kazan, Russian Federation; 2. Institute of Applied Physics of the ASM, Chishenau, Moldova (the Republic of); 3. Institute of Physics, Kazan Federal University, Kazan, Russian Federation*

We studied electronic transport properties of 3D Dirac topological semimetal Cd_3As_2 doped by 0.1 at.% europium. Dirac topological semimetals are characterized by the presence of doubly degenerate Dirac nodes in the linear electronic spectrum of conduction electrons. Upon influence of the Eu magnetic impurities, it is expected split of the Dirac nodes into two Weyl nodes and the appearance of a corresponding gap in the spectrum. We find the electron concentration increases in about 37 times and it become $ne = 2{,}2\times10^{19}$ cm^{-3} for the doped sample and is temperature independent. Magnetic transitions are observed at 6 K and 124 K. The temperature dependence of the resistance of a 3D topological semimetal Cd_3As_2 doped with a small amount of a europium is completely described by an exponential term with a gap of about 30 K and a linear phonon term with a negative residual resistance which indicates on the unusual scattering of current carriers. However, against such background, we found a weak contribution to the resistance which oscillates with temperature and magnetic field. An analogous contribution is also manifested in the field dependence of the magnetization. Similar phenomena were previously observed in magnetic semiconductors [1] and were associated with the temperature dependence of the Fermi level and a change in its position relative to the Landau levels arising in the quantization of electron orbits in a magnetic field. In our case, the appearance of such phenomena can be a consequence of the splitting under the influence of magnetic impurities of Dirac nodes in the electronic spectrum into Weyl nodes, variation of population of levels and the behavior of europium ions due to their non-integral valence.

N16-07. Non-Trivial Phenomena at Low Temperatures on the Trigonal Tellurium under Pressure. J. Ferreira de oliveira[1], C. Enderlein[2], M. Fontes[1] and *E.B. Saitovitch*[1] *1. COMAN, Centro Brasileiro de Pesquisas Fisicas, RIo de Janeiro, Brazil; 2. Universidade Federal do Rio de Janeiro, RIo de Janeiro, Brazil*

Elemental tellurium (Te) is a small band gap semiconductor ($\Delta \sim 340$ meV), which crystallizes in a chiral trigonal lattice. Recently, the material called a lot of attention due to the existence of several Weyl-points above and below the Fermi energy. This leads to the possible emergence of a Weyl-metal or topological insulator phases [1][2] under external modest hydrostatic pressure. Here, we present temperature dependent resistivity and magnetoresistance measurements under hydrostatic pressure. Contrary to recent DFT-calculations, we do not find a gap closing in the predict pressure range. However, we observe an anomaly in the low temperature regime, which is accompanied by weak-antilocalization-like features in the magnetoresistance. Comparison to historical data shows that the feature is unique to ultra-high quality single crystals with a small amount of charge carriers in

the system. The anomaly might be related to the natural doping of the single crystals by tellurium vacancies and the charge accumulation, which occurs naturally on the surface of these crystals.

Electromagnetic terahertz (THz) radiation is a versatile tool for a wide variety of sensing technologies ranging from security systems to medical applications. Commonly THz radiation is generated using semiconducting materials and using their inherent charge dynamics. Recently, it was also demonstrated that optical excitation of fast spin current pulses in magnetic materials may generate strong broadband THz radiation from transverse spin transport phenomena, known as spin Hall effects. These experiments rely on a bulk conversion of spin currents into charge current, which then subsequently generate the THz radiation. Here we investigate whether interfacial spin-orbit coupling phenomena may also be an efficient source for generating THz radiation. For this purpose we combine a bilayer of Ag and Bi, which is known to have strong Rashba-type spin-orbit coupling at its interface with a magnetic CoFeB layer. Upon optical excitation we also observe in this system THz radiation. Additional experiments with individual Ag and Bi layers show that this radiation originates from interfacial spin galvanic effects. Furthermore, we demonstrate that the amplitude of the THz radiation varies with the helicity of the incident optical light pulse. These observations open up new perspectives for the development of ultrafast spintronic devices. This work was supported by the U.S. Department of Energy, Office of Science, Materials Sciences and Engineering Division. N17-02. Pulse laser-induced terahertz emission for Ta/CoFeB/MgO structure. Y. Sasaki[1,2], K. Suzuki[1,3] and *S. Mizukami*[1,3] *1. WPI-AIMR, Tohoku University, Sendai, Japan; 2. Department of Applied Physics, Graduate School of Engineering, Tohoku University, Sendai, Japan; 3. CSRN, Tohoku University, Sendai, Japan*

A spintronic THz emitter has attracted attention because a broad frequency spectrum and relatively strong intensity at low laser power density were demonstrated [1,2]. Although further improvement of THz emission intensity is required, the physical mechanism of the pulse laser-induced THz emission has not been clear yet. In this study, we focus on the annealing effect on THz emission for Ta/CoFeB/MgO structure [3]. Ta(5.0)/$Co_{20}Fe_{60}B_{20}$(t_{CFB}=0~10.0)/MgO(2.0)/Ta(2.0) (thickness in nm) films were deposited on a thermally oxidized Si substrate using an ultrahigh vacuum magnetron sputtering. The films were annealed at various temperatures T_a in vacuum for 1 h. The THz wave emitted from the sample was detected by means of an electro-optic sampling with a 1-mm-thick (110) ZnTe crystal using a Ti: sapphire laser and regenerative amplifier. An in-plane magnetic field of 1.5 T was applied. Figure 1 shows typical waves form of THz wave signal with various annealing temperatures for t_{CFB}=2.0 nm films. The peak value of THz wave signal increased with increasing annealing temperature. The peak value of THz wave signal as a function of annealing temperature T_a with various thickness of CoFeB layer is shown in Fig. 2. The enhancement of THz wave signal was observed in all films. The THz emission intensity was larger by a factor of about 1.5 than that for the as-deposited films. The result demonstrates that the light-THz wave conversion efficiency can be tuned by the annealing. The influence of the crystallization of CoFeB to the THz emission will be discussed [3]. This work was partly supported by KAKENHI (16H03846, 26103004). Y. S. thanks to G. P. spin in Tohoku University.

N17-03. Spin Transfer Torque Generation due to Ultrafast Demagnetization. *K. Carva*[1], P. Baláz[1], P. Maldonado[2] and P.M. Oppeneer[2] *1. Dept. Condensed Matter Physics, Charles University, Prague, Czechia; 2. Dept. of Physics and Astronomy, Uppsala University, Uppsala, Sweden*

Laser-induced ultrafast magnetization dynamics has attracted a lot of interest in recent years. Experimental findings have stimulated new concepts in theory. We discuss here generation of spin currents accompanying ultrafast magnetization quenching. Such spin currents can exert spin transfer torque on an adjacent magnetic layer as suggested in a recent experiment [1], and their femtosecond length could be a significant advantage for possible applications in spintronics. Nonequilibrium hot charge carriers excited to bands with higher mobilities by a laser migrate away from the laser spot and reduce the local magnetic moment, as described by the superdiffusive spin transport model [2]. This model has been employed to study the spin transfer torque and magnetization dynamics induced by a fs laser pulse in spin valves consisting of two perpendicularly oriented magnetic layers, FM1 and FM2, separated by a nonmagnetic one, NM (Fig. 1). In such spin valves it is possible to achieve spin manipulation in at unprecedented speeds and generated spin pulses are also localized on the scale of several nm [3]. We calculate the spin transfer torque acting on the magnetic layers and model the magnetization dynamics described by the Landau-Lifshitz-Gilbert equation. We have shown that a femtosecond laser pulse focused on FM1 can lead to a magnetization precessions in FM2, which can persist for few nanoseconds (Fig. 2). We also find an optimal thickness of the polarizing (FM1) layer that leads to the maximal torque in the spin valve [4].

We used coherent X-ray resonant magnetic scattering at the Linac Coherent Light Source to study the dynamic response of a nanoscale magnetic domain network in a 50 nm thick [Co90Fe10/Ni] multilayer after ultrafast optical pumping. The geometry of our experiment allowed for a simultaneous observation of the 1st and 3rd order magnetic scattering rings. We found surprising differences in the transient behavior of the two orders: Both scattering peaks exhibit a sharp drop in magnitude and a rapid shift in the peak position on short timescales; while at longer times, the magnitude of the 3rd order peak, in contrast to the 1st order peak, continued to decrease after an initial recovery, as shown in the figure. By comparing our experimental results with numerical simulations that include a rigorous treatment of the laser pump absorption by the multilayer film [1], thermal diffusion modelling using the three-temperature model [2], and propagation of the X-rays through a sample of finite thickness, we correlated the differences in the diffraction ring dynamics with both the depth variation of the magnetization and the domain wall thickness. We find that an initial gradient in the absorbed pump laser fluence leads to strong demagnetization of the surface layers of the sample while the deeper layers are relatively unchanged. This results in a strong magnetization gradient through the sample thickness, as well as broadening of domain walls near the top due to the temperature dependence of the anisotropy. On longer time scales, electrons transport the heat through the film and couple it to the lattice thus increasing the lattice temperature in the deeper layers. Through the temperature dependence of the magnetic anisotropy, this leads to broadening of domain walls in the bottom portion of the film. This process is schematically illustrated in the figure. An agreement between our experimental results and the magnetic scattering predicted by the model suggests that there is also a strong gradient in the lattice temperature (8.2 K/nm at 5 ps) that persists at long times (3.7 K/nm at 20 ps).

N17-05. Ultrafast magnetization dynamics in an itinerant ferromagnetic model system with spin-orbit coupling: Elliott-Yafet and exchange scattering. *K. Leckron*[1] and H. Schneider[1] *1. Physics Department and Research Center OPTIMAS, TU Kaiserslautern, Kaiserslautern, Germany*

This contribution presents our recent work on the microscopic electronic dynamics underlying magnetization dynamics on ultrashort timescales in itinerant ferromagnets. In band ferromagnets the excitation by ultrafast pulses leads to demagnetization dynamics, which was originally explained as spin dynamics arising from an Elliott-Yafet mechanism [1]. In derromagnetic alloys with itinerant electrons, recent experiments show that demagnetization and remagnetization dynamics is more complicated and different for the different atomic species [2]. We first present a dynamical study of the Elliott-Yafet demagnetization mechanism [3,4] in a ferromagnetic model system. We determine [5] the full microscopic dynamics of the (momentum-resolved) spin-density matrix for a ferromagnetic Rashba model, which contains ferromagnetism at a mean-field level (Stoner gap) and the spin-orbit coupling – see lower left side of figure 1 for the resulting band and spin structure – and include spin-independent electron-phonon scattering. We show that the "coherent" noncollinear electronic spin dynamics around k-dependent effective spin orbit fields is important and that the spin angular momentum is changed by a dephasing of the precession around these effective internal spin-orbit fields. While the microscopic process seems very different from the usual picture of Elliott-Yafet spin flip transitions, we discuss the conditions under which the resulting magnetization dynamics can be approximated by such incoherent spin-flip scattering. In order to mimic a ferromagnetic system composed of two different elements, which are exchange coupled, we regard the ferromagnetic model system discussed above as one subsystem and couple it to another subsystem of localized electrons via ferromagnetic exchange, as depicted in figure 1. This allows us to study spin dynamics for a variety of system parameters, see e.g. figure 2 for different Stoner mean-field splittings, and explain characteristic features of the remagnetization dynamics.

N17-06. Ultrafast dynamics of the Néel vector in aniferromagnetic Mn_2Au thin films detected with optical pump probe spectroscopy. *V. Grigorev*[1,2], A. Sapozhnik[3,2], M. Jourdan[1,2], S. Bodnar[4], S.Y. Agustsson[1] and J. Demsar[1,2] *1. Institute of Physics, Johannes Gutenberg University, Mainz, Germany; 2. Graduate School of Excellence, Materials Science in Mainz (MAINZ), Mainz, Germany; 3. Institute of Physics, Johannes Gutenberg University, MAINZ, Germany; 4. Physics, Johannes Gutenberg University, Mainz, Germany*

Determination of the Néel vector in an antiferromagnetic (AFM) thin film is not trivial and usually requires large-scale facilities. However, recently a new method was demonstrated where optical pump-probe technique is used to resolve the direction of the Néel vector [1]. Here, symmetry breaking due to AFM ordering gives rise to a weak birefringence of the sample. An intense optical pump pulse can trigger a transient reduction of the order parameter (staggered magnetization) and thus change the birefringence. Recording the polarization plane rotation as a function of angle α between the polarization of the incident probe beam and the crystal axis, the Néel vector can be determined [1]. We applied this method to determine the Néel vector in c-axis oriented Mn_2Au thin films. Figure 1 displays the dependence of the photoinduced polarization rotation as a function of time delay and angle α. From these data we determine the staggered magnetization (Néel vector) to be oriented along <110> crystallographic directions as shown in the insert. This observation agrees with theoretical calculations [2] and recent experimental studies [3][4]. It is worth mentioning that the observed anisotropy in the optical response implies an asymmetric AFM domain distribution in the investigated Mn_2Au thin film. The technique also allows studying Néel vector reorientation, and perform time resolved dynamic experiments. Following time evolution of the angular dependence we can track Neel vector dynamics up to 80 ps. We observed Néel vector rotation with raise time in range of 10 ps and relaxation to initial state within several tens of picoseconds. Time scales of observed dynamics in good agreement with recently observed AFM resonance for this material.

In this contribution, we discuss the opportunities arising from the spectrally dense, narrow band, tunable, high repetition rate THz source; TELBE [1,2,3]; which recently started user operation. The user facility includes an endstation for transient Faraday/MOKE and THz emission spectroscopy and is also equipped with a superconducting splitcoil cryomagnet. Thereby the dynamics of selectively driven resonances in the frequency range between 0.1 and 1.2 THz can be followed with a femtosecond sub THz-cycle time resolution at temperatures between 3 and 300 K and in magnetic fields up to 10T. Future prospects such as the implementation of novel duty-cycle hungry ultra-fast probe techniques like TR SNIM and TR ARPES are also presented

We report on tuneable narrow band THz emission from $Mn_{3-x}Ga$ ferrimagnetic nanofilms, which recently has attracted a lot of interest because of their low saturation magnetization and high spin polarization [1,2]. The THz emission is emitted from coherently excited spin precession after pulsed laser-induced heating. The central frequency of emission is determined by magnetic anisotropy and the bandwidth is related to Gilbert damping [3]. The central frequency of the emission is shown to be continuously tunable by Mn content, temperature and magnetic field in a frequency range between 0.15 THz to 0. 52 THz. In combination with the ideas to drive the THz emission by spin-polarized currents, these films are promising candidates for unique THz emitter devices. [4]. Furthermore, we show the importance of THz emission spectroscopy to study the dynamical properties of magnetic thin films with high precision. Acknowledgment: This project has received funding from the European Commission's Horizon 2020 research and innovation programme, under grant agreement No DLV-737038 (TRANSPIRE).

O1-01. Antiferromagnetic spintronics. *T. Jungwirth[1,2] 1. Spintronics and Nanoelectronics, Institute of Physics, Academy of Sciences of the Czech Republic, Praha 6, Czechia; 2. School of Physics and Astronomy, University of Nottingham, Nottingham, United Kingdom*

Louis Néel pointed out in his Nobel lecture that while interesting from theoretical viewpoint, antiferromagnets did not seem to have any applications. Indeed, the alternating directions of magnetic moments on individual atoms and the resulting zero net magnetization make antiferromagnets hard to control by tools common in ferromagnets. This has hindered both the research and utility of these abundant magnetic materials. Recent studies have shown, however, that relativistic quantum mechanics can provide staggered current induced fields whose sign alternates within the magnetic unit cell of the antiferromagnet and can be used to efficiently reorient the Néel vector. Combined electrical writing and electrical readout have been experimentally demonstrated in thin-film antiferromagnets CuMnAs or Mn_2Au and a proof-of-concept USB device has been realized showcasing binary and multi-level characteristics of memory cells fabricated in these antiferromagnets. The absence of dipolar fields is favorable for high density integration and makes the memory robust against external magnetic field perturbations. The multi-level switching allows to integrate memory with logic or neuromorphic functionalities within the bit cell. Another unique merit of antiferromagnets is the ultra-fast, THz spin dynamics which has allowed to demonstrate switching by electrical pulses whose length has been scaled down to a picosecond. Despite recent progress, antiferromagnetic spintronics is still at its infancy with the field's full potential yet to be explored. We will conclude the lecture by outlining the rich symmetry and topology landscape that is now emerging by including antiferromagnets in spintronics to stimulate a renewed basic and applied research interest in these historically overlooked Néel's magnets.

Focus on Antiferromagnetic Spintronics, *Nature Physics* 14 (2018).

A memory bit cell fabricated on chip of an antiferromagnet-CuMnAs/Si, placed on a standard printed circuit board and connected to a computer by a USB port. Periodically, three successive writing current pulses along one direction are followed by three successive pulses along an orthogonal direction. Electrical readout after each pulse demonstrates a multi-level bit-cell characteristics.

P1-02. Dynamics of skyrmions in magnetic multilayers at room temperature. *S. Woo[1] 1. Center for Spintronics, Korea Institute of Science and Technology, Seoul, The Republic of Korea*

In spintronics, magnetic skyrmions are the most promising candidate for the next-generation memory-type application due to their nanometer-size, topological stability and efficient current-driven motion. [1] Recent efforts have realized the room-temperature stabilization of magnetic skyrmions and their current pulse-induced displacement on nanotracks in magnetic hetero-structures, [2, 3, 4] where the strong interfacial Dzyaloshinskii-Moriya (DM) interaction leads to the stabilization of such skyrmion structure. However, there still exist many unsolved practical limitations toward the realization of fully functional skyrmionic devices. In this presentation, we show our recent achievements in the field of room-tempearture skyrmionics by using static and dynamic soft X-ray transmission microscopy. We first demonstrate a new type of skyrmion, called *ferrimagnetic skyrmion*. [5] Ferromagnetic skyrmions show undesirable topological effect, the skyrmion Hall effect, which leads to their current-driven motion towards device edges, where skyrmions could easily be annihilated by topographic defects. Recent theoretical studies have predicted enhanced current-driven behaviour for antiferromagnetically exchange-coupled skyrmions with opposite topological charges excited in two sublattices. [6] In this work, we present the stabilization of such skyrmions and their current-driven dynamics in ferrimagnetic GdFeCo films. By utilizing element-specific soft X-ray imaging, we find that the skyrmions in the Gd and FeCo sublayers are antiferromagnetically exchange-coupled. As shown in Fig. 1, we further confirm that ferrimagnetic skyrmions can move at a velocity of ~50 m s^{-1} with significantly reduced skyrmion Hall angle, $\theta_{SkHE} < 20°$. We believe that this finding experimentally highlights the possibility to build more reliable skyrmionic devices using ferrimagnetic and antiferromagnetic materials. [5] We then demonstrate the electrical creation and annihilation of a single magnetic skyrmion at room temperature, which are essential prerequisites for device application but have remained elusive so far. The stroboscopic pump-probe X-ray measurement serves as a key technique to reveal the deterministic and completely reproducible nature of the observation. [7] We experimentally present that an engineered current pulses can efficiently create and annihilate a single skyrmion in ferrimagnetic materials, GdFeCo, in nanosecond time scale. Micromagnetic simulations reveal the microscopic origin behind the observed topological fluctuation with great qualitative and quantitative agreement. Our findings show that the deterministic field-free writing and deleting of a single skyrmion can be easily achieved using electrical methods, which could serve as a key discovery for the realization of fully-functional skyrmion application. P1-02. Resolving Thickness-Dependent Reorientation of Chiral Hybrid Textures in Magnetic Multilayers for Spin-torque Engineering. *W. Legrand[1], J. Chauleau[2,1], D. Maccariello[1], N. Reyren[1], S. Collin[1], K. Bouzehouane[1], N. Jaouen[2], V. Cros[1] and A. Fert[1] 1. Unité Mixte de Physique CNRS/Thales, Palaiseau, France; 2. SEXTANTS, Synchrotron SOLEIL, L'Orme des merisiers, 91192 Gif sur Yvette, France*

Magnetic skyrmions are magnetic textures, topologically different from the uniform ferromagnetic state, holding a lot of promise for applications as well as of fundamental interest [1]. Initially observed at low temperature and under large magnetic fields in a few bulk non-centrosymmetric compounds [2] and ultra-thin Fe films [3], there has been a huge research effort in the last couple of years to stabilize them at room temperature in magnetic multilayers [4,5]. In these systems, a key to stabilize magnetic skyrmions is the Dzyaloshinskii-Moriya interaction, which promotes a unique chirality of the skyrmionic spin textures. Combined with spin-orbit torques generated in heavy-metal layers, this unique chirality allows efficient current-induced motion of skyrmions [6,7]. Here, we show how in such multilayers with a large number of repetitions, the different magnetic interactions between

layers can actually lead to the stabilization of more complex magnetization configurations. We report about our predictions and experimental observations of the existence of a hybrid chirality in skyrmionic systems. After having demonstrated a direct evidence of such hybrid chirality [8] by probing the surface spin ordering of multilayers with circular dichroism in X-ray resonant magnetic scattering [9], we will further discuss the impact of such hybrid chirality in technologically relevant multilayers depending on different parameters such as the number of stacked layers, interfacial anisotropy or interlayer exchange coupling. In the perspective of technological applications of skyrmions, controlling their chirality to match the spin-orbit torques injection geometry of the multilayers is required to achieve efficient current-induced motion, as shown in Fig. 1 [8].

P1-03. Simultaneous stabilization of Skyrmions and Antiskyrmions in rank-1 DMI materials allowing the concept of a Skyrmion-Antiskyrmion Racetrack Memory. *M. Hoffmann*[1], B. Zimmermann[1], G.P. Müller[1,2], N.S. Kiselev[1], C. Melcher[3] and S. Blügel[1] *1. PGI-1/IAS-1, Forschungszentrum Jülich, Jülich, Germany; 2. Science Institute of the University of Iceland, Reykjavík, Iceland; 3. Department of Mathematics I & JARA, RWTH Aachen University, Aachen, Germany*

Recently, we extended the scope of skyrmions and antiskyrmions and introduced a classification scheme of chiral magnets [1]. Typically investigated Bloch-type skyrmions in B20 alloys and Néel-type skyrmions at (111) oriented interfaces belong to isotropic rank-three Dzyaloshinskii-Moriya (DM) bulk and rank-two DM film magnets with a DM interaction described by a single spiralization constant. Within this class, antiskyrmions are stable only for bulk crystals with certain point group symmetries. New are the anisotropic rank-two DMI film magnets where skyrmions and antiskyrmions can coexist while the determinant of the spiralisation tensor determines which of them have lower energy. Finally, zero determinant indicates a rank-one DMI material in which skyrmions and antiskyrmions have the same energy. Here, we discuss the behavior of skyrmions and antiskyrmions in the same magnetic system of rank-one solids. Our focus lies on the analysis of their (common) motion and the orientation dependent interaction between the two skyrmionic objects of opposite topological charge. Based on this, we propose a design of a racetrack memory based on the coexistence of skyrmions and antiskyrmions [2]. Acknowledged is funding from the DARPA TEE program (grant MIPR#HR0011831554) from the DOI and from the Icelandic Research Fund (grant no. 152483-052).

Magnetic skyrmions are swirling spin texture exhibiting large potential as information unit in spin-electronic devices due to their unique topological properties. Recent studies demonstrated that, at room temperature, a train of magnetic skyrmions can be displaced by electric pulse currents[1-3], by taking static images before and after the current pulses. However, for the development of ultrafast skyrmionic devices, it is important to understand their dynamic behaviors such as skyrmion breathing[4], gyration[4,5], or skyrmion Hall effect[4,6,7]. Such observation of ultrafast dynamics of chiral skyrmions in real spaces is still challenging due to the experimental limitations that simultaneously achieve nanosecond time resolution and <100 nm spatial resolution. In this talk, we will demonstrate the nanosecond-dynamics of chiral skyrmions driven by current-induced spin-orbit torques in Pt/CoFeB/MgO multilayers, directly observed by time-resolved X-ray microscopy[8]. Unlike earlier studies, we first show that, in the absence of magnetic field, skyrmion state can be generated by applying electrical bipolar pulses which causes thermal excitations. More importantly, using time-resolved microscopy, we reveal that two distinctive skyrmion excitation states, breathing-like and translational excitation states, can be achieved and readily manipulated by tuning the amplitude of spin-orbit torques. Micromagnetic simulations were performed to understand the physical origin, and the results reveal the massless particle-like nature of magnetic skyrmions at room temperature. In sum, we believe that our findings provide important physical understanding

of room temperature magnetic skyrmions and also offer unique electrical manipulation methods that could realize the development of ultrafast skyrmionic applications in the future.

Forschungszentrum Julich, Julich, Germany; 7. School of Physics and Astronomy, University of Leeds, Leeds, United Kingdom; 8. Max Planck Institute for Intelligent Systems, Stuttgart, Germany*

Despite the numerous predictions from micromagnetic simulations [1], only limited experimental investigations of the dynamical processes of perpendicularly magnetized spin configurations, such as e.g. magnetic skyrmions [2,3] exist. One of the causes behind this is the relatively high Gilbert damping (e.g. for Pt/Co stacks on the order of 0.2 [4]), and to the relatively high density of pinning sites of the typical materials employed for the stabilization of such magnetic states. Such high values of both pinning and Gilbert damping strongly influence the behavior of the perpendicularly magnetized spin configurations both statically [5] and dynamically [3]. In this contribution, we present an alternative solution to the use of multilayer stacks exhibiting perpendicular magnetic anisotropy (PMA) for the time-resolved investigation of the dynamical processes of magnetic skyrmions and the more complex nπ states. This solution relies on the use of a Permalloy-based PMA system exhibiting a weak PMA [6]. By judiciously optimizing the sample design, we were able to stabilize magnetic configurations ranging from magnetic skyrmions to more complex nπ states (see Fig. 1) in nanostructured elements. The nπ states stabilized in the nanostructured elements were excited by RF and pulsed magnetic fields generated through the injection of electrical currents across a tailored antenna fabricated close to the magnetic nanostructures. Thanks to the combination of a low Gilbert damping and a relatively low density of pinning sites of this weakly-PMA system, the gyration dynamics in magnetic states ranging from magnetic skyrmions to the more complex nπ states could be imaged by time-resolved scanning transmission x-ray microscopy, proving the feasibility of this material for the study of the dynamical processes in magnetic skyrmions and in nπ states.

P2-01. Control the magnetization reversal electrically in ferromagnetic devices at room temperature. *K. Wang*[1,2] *1. Institute of Semiconductors, Chinese Academy of Sciences, Beijing, China; 2. Center for Excellence in Topological Quantum Computation and College of Materials Science & Opto-Electronic Technology, University of Chinese Academy of Science, Beijing, China*

Electrically control the spin in solids is the core of spintronics. We investigated the magnetization switching by spin orbit torque in heavy metal/ferromagnet/heavy metal multilayers and also piezo voltages control the magnetization switching of heusler alloy Co_2FeAl. By designed the symmetric device structrue, a strong damping-like torque from the spin Hall effect and unmeasurable field-like torque from Rashba effect were demostrated. The spin-orbit effective fields due to the spin Hall effect were investigated quantitatively and were found to be consistent with the switching effective fields after accounting for the switching current reduction due to thermal fluctuations from the current pulse[1]. The spin-orbit torque switching controllablly in above structures have to have the assistant of the external magnetic field. Two ferromagnetic Co layers, with in-plane and out-of-plane anisotropy respectively, are separated by a spacer Ta layer, which plays a dual role of inducing antiferromagnetic interlayer coupling, and contributing to the current-induced effective magnetic field through the spin Hall effect. The current-induced magnetization switching behavior can be tuned by pre-magnetizing the in-plane Co layer [2]. Without breaking the symmetry of the structure of the thin film, we realized the deterministic magnetization switching in a hybrid ferromagnetic/ferroelectric structure with Pt/Co/Ni/Co/Pt layers on PMN-PT substrate. The effective magnetic field can be reversed by changing the direction of the applied electric field on the PMN-PT substrate, which fully replaces the controllability function of the external magnetic field[3]. Using piezo voltages, the planar Hall resistance in ferromagnetic Co_2FeAl devices can be effectively tuned. The room temperature magnetic NOT and NOR gates have been demonstrated based on the Co_2FeAl planar Hall effect devices without external magnetic field[4].

P2-02. Phase Coexistence in Multiferroic $BiFeO_3$. *D. Ferenc Segedin*[1], J. Mundy[2] and R. Ramesh[3,1] *1. Physics, University of California, Berkeley, Berkeley, CA, United States; 2. Harvard University, Cambridge, MA, United States; 3. Physics / MSE, UCBerkeley, Berkeley, CA, United States*

The robust ferroelectric polarization and direct electric field control of weak ferromagnetic order at room temperature have rendered $BiFeO_3$ the most studied magnetoelectric multiferroic. An electrical polar discontinuity presents an opportunity to stabilize an emergent phase at an interface in such a material. Here, we synthesize thin films and superlattices of dielectric $DyScO_3$ and ferroelectric $BiFeO_3$, i.e. $(BiFeO_3)_m/(DyScO_3)_n$ for various *m,* on (110)-oriented $DyScO_3$ single crystal substrates using pulsed laser deposition. The ferroelectric polarization in contact with the dielectric layer leads to a large interfacial depolarizing electric field in the absence of compensating charge. We report the results of Scanning Transmission Electron Microscopy (STEM), X-Ray Diffraction (XRD) and Atomic-Force Microscopy (AFM) measurements, demonstrating that our films exhibit excellent structural quality. Atomic-scale STEM images of the structure show that, for layer thicknesses of 4 nm (10 unit cells), $BiFeO_3$ adopts an orthorhombic, anti-ferroelectric ground state. This work thus provides the first direct observation of this ground state in un-doped $BiFeO_3$. Additional STEM analysis shows that for layer thicknesses of 7 unit cells, $BiFeO_3$ adopts an orthorhombic, non-polar structural ground state and for layer thicknesses of 14 unit cells, the material adopts the bulk rhombohedral, ferroelectric ground state. The instability between these structural ground states within only a seven unit cell thickness range thus demonstrates the ability of interfacial fields to dramatically alter the structural and electric ground state of an ultra-thin film, which can also alter functional properties, including magnetism, in $BiFeO_3$. This work further suggests that ultra-thin $BiFeO_3$ synthesized between dielectric layers could be used for reversible, low power switching between stable structural ground states in a distinct next-generation memory technology.

Scanning Transmission Electron Microscopy image of a $DyScO_3/BiFeO_3/DyScO_3$(substrate) tri-layer heterostructure, showing high structural quality and sharp interfaces. In this study, we investigate the structural ground state of $BiFeO_3$ as a function of $BiFeO_3$ layer thickness.

P2-03. The Strain and Temperature dependent Phase Diagram of Multiferroic $SrMnO_3$ from First Principles. A. Edström[1] and *C. Ederer*[1]
1. Materials Theory, ETH Zurich, Zurich, Switzerland

While bulk $SrMnO_3$ is a rather common G-type antiferromagnet, a very rich phase diagram involving transitions between different magnetic orders as well as emerging ferroelectricity under strain has been predicted theoretically [1]. Recent experimental observations seem to corroborate these predictions [2,3]. The possibility to alter both magnetic and ferroelectric ordering temperatures by epitaxial strain as well as Ba substitution [4], allows to tune the system into a region where both ordering temperatures coincide and thus very pronounced magneto-electric coupling effects can be expected. Here, we use ab-initio electronic structure calculations in combination with first-principles-derived effective model Hamiltonians to obtain the temperature and strain-dependent ferroelectric/magnetic phase diagram of $SrMnO_3$. We identify a region around 3% tensile strain, where magnetic and ferroelectric ordering temperatures coincide and the corresponding order parameters are strongly coupled. Furthermore, our microscopic model shows how both strain and the ferroelectric displacements affect the magnetic Heisenberg-type couplings and can induce a transition to a ferromagnetic state. We then explore temperature-dependent coupling effects between the polar and magnetic order. A particular focus thereby are possible multi-caloric effects, i.e., adiabatic temperature changes induced by applied electric and/or magnetic fields, that are very promising for future solid state cooling devices [5].

P2-04. Interplay Between Ferroelastic and Ferromagnetic Domain Structures in Magnetic Shape Memory Ni-Mn-Ga Compound. *O. Heczko*[1,2], A. Perevertov[1], V. Kopecký[1], L. Straka[1] and R. Schaefer[3]
1. Department of Magnetic Measurements and Materials, Institute of Physics of CAS, Prague, Czechia; 2. Faculty of Mathematics and Physics, Charles University, Prague, Czechia; 3. IFW Dresden, Dresden, Germany

Anisotropic (ferro-)magnetic properties together with extremely high mobility of twin boundary are basic conditions for magnetically induced reorientation, one of the magnetic shape memory effects providing up to 12% deformation in magnetic field. Inversely, using mechanical stress one can control the magnetic behaviour of the material. Both the giant field-induced strain and specific mechano-magnetic behaviour are direct consequence of the reorientation of ferroelastic domains mediated by twin boundary motion originated from the strong coupling between ferroelastic and ferromagnetic domains structure. Thus it can be considered as a specific kind of multiferroic behaviour. While the ferroelastic domains are well identifiable by optical microscopy and scanning electron microscopy the direct observation of magnetic domains has remained long time elusive. Recently we demonstrated that advanced Kerr microscopy can be used for the domains observation in Ni-Mn-Ga [1]. Together with recent identification of ferroelastic a-b twin laminate using backscattered electrons [2] it opens new venue to study in detail the dynamics of the multiferroic behaviour or interaction between ferroelastic and ferromagnetic domains. Here we present the study of the mutual interaction of these domains under mechanical stress and magnetic field in 10M martensite of Ni-Mn-Ga single crystal exhibiting magnetic shape memory effects. We show how underlining ferroelastic domains affect the magnetic domain structure and discuss the consequence for magnetically induced reorientation. The optical studies using Kerr microscopy will be augmented by magnetic measurements and observation using magnetic force and electron microscopy. Moreover, the previously published results will be critically discussed and reinterpreted in the view of current knowledge.

Hexagonal $HoMnO_3$, a two dimensional triangular lattice Heisenberg antiferromagnet, has been studied via inelastic neutron scattering. A simple Heisenberg model with a single ion anisotropy within the linear spin wave theory (LSWT) describes most features of the spin wave dispersion curves. However, there is shown to be a renormalization of the magnon energies located at around 10 meV. Since both the magnon-magnon interaction and magnon-phonon coupling can affect the renormalization, we have accounted for both of these couplings by using Heisenberg XXZ model with 1/S expansions [1] and the Einstein Site Phonon (ESP) model [2], respectively. Both models describe well the observed spin waves dispersion curves. However, the intensity at B point is in good agreement with the calculated intensity from the ESP model. In addition, the two-magnon continuum state from magnon decay due to magnon-magnon interaction is not seen in the data. Two-ion anisotropy $\Delta=1-J_z/J$ included in the Heisenberg XXZ model is estimated to be 0.1, which is considered to be larger than $LuMnO_3$ case [3]. This quantitative analysis leads to the conclusion that the renormalization effect primarily originates from the magnon-phonon coupling, while the spontaneous magnon decay due to the magnon-magnon interaction is suppressed by the strong two-ion anisotropy.

P3-01. Rhodium substituted ε-iron oxide (ε-$Rh_xFe_{2-x}O_3$) nanomagnets exhibiting high frequency millimeter wave absorption. *A. Namai*[1], M. Yoshikiyo[1] and S. Ohkoshi[1] *1. The University of Tokyo, Tokyo, Japan*

Epsilon iron oxide, ε-Fe_2O_3, is one of the polymorphs of iron oxide. Our research group firstly reported pure ε-Fe_2O_3, and observed a large magnetic coercive field (H_c) over 20 kOe. Due to its large magnetic anisotropy, ε-Fe_2O_3 can be downsized to the single nanometer size region remaining its magnetic ordering. Therefore, this material is expected to be used in the next generation magnetic recording media. We have been investigating metal substitution of ε-Fe_2O_3 to tune its magnetic properteis, and reported vaious metal substituted ε-Fe_2O_3. Among them, we found that rhodium substitution enhances the coercive field. Furthermore, rhodium substituted ε-Fe_2O_3, ε-$Rh_xFe_{2-x}O_3$, shows high frequency millimeter wave absorption due to zero-field ferromagnetic resonance. Herein, we reports the synthesis, crystal structure, magnetic properties, and millimeter wave absorption properties of ε-$Rh_xFe_{2-x}O_3$. A series of ε-$Rh_xFe_{2-x}O_3$ ($0 \le x \le 0.19$) were prepared by a nanoscale synthesis using mesoporous sillica as template, or the sol-gel method. The samples were obtained as spherical nanoparticles with average sizes of ca. 30 nm. The crystallographic structure study using X-ray diffraction shows that ε-$Rh_xFe_{2-x}O_3$ has an orthorhombic crystal structure in the $Pna2_1$ space group. Among the four non-equivalent substitution sites (A–D sites), Rh^{3+} ions mainly substitute into the C sites. The coercive field increases with increasing rhodium concentration. The crystallographically oriented ε-$Rh_{0.14}Fe_{1.86}O_3$ shows the large H_c value of 35 kOe at 300 K. Electromagnetic wave absorption property was measured using using terahertz time domain spectroscopy (THz-TDS). The observed electromagnetic wave absorption characteristics due to natural resonance (zero-field ferromagnetic resonance) reveal that the natural resonance frequency shifts from 182 GHz (ε-Fe_2O_3) to 222 GHz (ε-$Rh_{0.19}Fe_{1.81}O_3$) upon rhodium substitution. This is the highest natural resonance frequency of a magnetic material, and is attributed to the large magnetic anisotropy due to rhodium substitution. In addition, aluminum or galium substitution can largely tunes the absorption frequency, from 182 GHz to 35 GHz. ε-$M_xFe_{2-x}O_3$ is expected as high frequency millimeter wave absorbers since the absorption frequency covers of the window of air.

P3-02. Study of Mossbauer spectroscopy for R-YIG (R=La, Nd, and Gd) derivedby a sol-gel method. *Y. Uhm*[1] and C. Kim[2] *1. Korea Atomic Energy Research Institute, Daejeon, The Republic of Korea; 2. Kookmin University, Seoul, The Republic of Korea*

The magnetic properties of single phase garnet $R_{3-x}R_xFe_5O_{12}$ (R=La, Ns,and Gd) were studied using Mossbauer spectroscopy, and vibrating samples magnetometer (VSM). The Gd^{3+} and Nd^{3+} are magnetic heavy rareearth ion, and light rare earth ion, respevtively. While La^{3+} is non magnetic ion. Adetail investigation of the bond angle of Fe_a-O-Fe_d affected by 24(c) site was carried out using Mossbauer spectroscopy. The Curie temperaturewas slightly increased when substituting rare earth ions such as Gd, Nd, and La with a relatively larger ionic readius than those of Y (yttrium). The magnetic hyperfine fields (H_{hf}) are slightly decreased as rare earth materials are substituted to R-YIG. The ionic radius doped in 24(c) site have more immeiate and vital influence on the magnetization. This implies that the bond angle of Fe_a-O-Fe_d is changed as the 24(c) site is substituted to rare-earth ions with large ionic radius. However, heavy rare earth ion of Gd^{3+} doped YIG show the lowest values of H_{hf} at low temperature. The super-exchage link, Fe_a-O-Ge_d at 13 K is weaken due to Gd^{3+} ions in 24(c)-site.

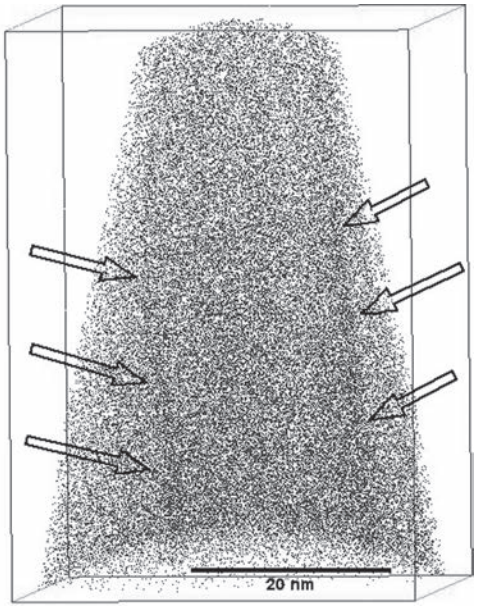
P3-03. Development of new amorphous and nanocrystalline magnetic materials for use in energy-efficient devices. *E. Theisen*[1] *1. R&D, Metglas, Conway, SC, United States*



Fe-based amorphous and nanocrystalline soft magnetic alloys have been intensively researched for many applications, including high efficiency electrical distribution and motor applications. New amorphous foils with a saturation magnetization of 1.64T and new nanocrystalline foils with saturation up to 1.85T have been developed. The increases in operating induction levels combined with higher lamination factors in today's amorphous ribbon allow for a significant size reduction of the transformer core. Here we look at the commercial adoption of these new materials in distribution transformers. We will also look at other applications, such as high efficiency motors, where the soft magnetic material properties are ideal but the challenges in fabrication limit the use of these new alloys.

P3-04. High Resolution Correlative Characterization of Nanocrystalline Soft Magnetic Materials. *T. Clark*[1], N.R. Overman[3], S. Mathaudhu[1] and A. Devaraj[2] *1. Materials Science and Engineering, University of California, Riverside, Riverside, CA, United States; 2. Physical and Computational Science Directorate, Pacific Northwest National Laboratory, Richland, WA, United States; 3. Energy and Environmental Directorate, Pacific Northwest National Laboratory, Richland, WA, United States*

The unique coercivity behavior observed in amorphous and nanocrystalline soft magnetic materials can be understood through the random anisotropy model [1] to be dependent on grain size. However, the model fails to address other structure and scale sensitive properties such as permeability and domain wall motion which can be affected by local anisotropy variations due to compositional variation or crystalline defects. Because of the convolution of magnetic and structural information in transmission electron microscopy, understanding of how magnetic domains interact within complex nanostructured bulk samples with many types of defect interactions has proven difficult to probe. Thus there is a lack of understanding of the fundamental mechanisms behind these interactions. In this work, an amorphous/nanocrystalline Fe based alloy with a rich variety of defects has been synthesized. Mossbauer spectroscopy studies [2] indicate that solute content influences the number of Fe nearest neighbor and next nearest neighbor interactions which effect local magnetic field and crystal structure. These solute effects can be more potent near grain boundaries where some solutes show a propensity to segregate. High resolution chemical mapping and correlated structural information is needed to gain insight on fundamental mechanisms of domain-defect interactions. Aberration-corrected scanning transmission electron microscopy, Lorentz transmission electron microscopy and atom probe tomography analysis methods are used to correlate magnetic domain behavior with specific nanoscale defects and features. The broader implication of this work is to make possible the exploration of fundamental physical interactions between nanoscale defects (such as grain boundaries, solute segregation, dislocations and voids) and the saturation magnetization, permeability and coercivity in novel bulk FeSi nanostructured soft- magnets. This knowledge could be harnessed to enable unprecedented improvements in magnetic properties and performance.

P3-05. Creep induced anisotropy in nanocrystalline Fe-B alloys prepared by ultra-rapid annealing. R.R. Parsons[1], K. Onodera[2], H. Kishimoto[2], T. Shoji[2], A. Kato[2] and *K. Suzuki*[1] *1. Department of Materials Science and Engineering, Monash University, Clayton, VIC, Australia; 2. Toyota Motor Corporation, Susono, Japan*

It has recently been found that a magnetically soft nanostructure with coercivity (H_c) values < 8 A/m can be prepared in Fe-B based alloys with Fe contents greater than 97 wt% [1]. This nanostructure is realized by annealing amorphous precursors ultra-rapidly and the saturation magnetization (J_s) is as high as 1.9 T. Although, these magnetic properties are potentially useful for practical applications, it is desirable to establish the means to control the macroscopic anisotropy for tailoring the hysteresis loop. In the present paper we report the effect of applied tensile stress during ultra-rapid annealing on the induced uniaxial anisotropy (K_u) in the Fe-B based nanocrystalline soft magnetic alloys. Precursor amorphous ribbons were prepared by melt-spinning. The ribbons were annealed at 753 K by a pair of Cu blocks which were preheated. Tensile stress was applied along the ribbon axis during annealing. The *J-H* loops were acquired at room temperature on an Epstein frame. Figure 1 shows the *J-H* loops of nanocrystalline $Fe_{86}B_{13}Cu_1$ after ultra-rapid annealing. Both the permeability and the remanent magnetization (J_r) show a clear tendency to decrease with increasing the applied stress (σ), indicating that K_u is induced with the hard axis along the stress direction. It has been known[2] that the direction of the hard axis depends on the sign of the volume-averaged magnetostriction (λ_s) in the crystalline phase and the hard ribbon axis in nanocrystalline $Fe_{86}B_{13}Cu_1$ is attributable to the negative λ_s of the bcc-Fe phase. Figure 2 shows the changes in H_c and J_r/J_s as a function of σ. The K_u values estimated from the *J-H* curves are also shown in the inset. The remanence ratio is supressed to 0.009 by applying σ = 140 MPa during annealing and the resultant K_u is 475 J/m^3. The effect of the creep-induced K_u on the magnetic core properties including core losses will also be discussed. Our results demonstrate that the hysteresis loop of ultra-rapidly annealed nanocrystalline alloys can be tailored by stress annealing.

P4-01. Spin Current in Quantum Materials. *W. Han*[1] *1. International Center for Quantum Materials, Peking University, Beijing, China*
2016 IUPAP Young Scientist Prize in Magnetism

Spintronics aims to utilize the spin degree freedom of electrons for information storage and computing applications. The key challenges are the generation, detection, transport, and the use of pure spin current. In this talk, I will discuss the spin current in quantum materials and states. The first part of my talk will focus on the pure spin current in graphene as the information carrier. The generation and transport of the pure spin current in graphene is investigated in the nonlocal spin valve geometry, and outstanding spin properties of graphene are revealed [1]. The second part of my talk will discuss the pure spin current for the spin orbit torque as one route for magnetization switching applications. Recent quantum materials, including spin-momentum locked Rashba interfaces and topological insulator surface states, and noncollinear antiferromagnets have exhibited efficient and/or gate-tunable spin and charge conversion [2-4]. The last part of my talk will discuss the pure spin current as a probe for novel quantum states. The experimental signatures of spin superfluid ground state in canted antiferromagnet Cr2O3 will be discussed [5].

P4-02. Inverse Edelstein Effect Induced by Magnon-Phonon Coupling. M. Xu[1], J. Puebla[2], F. Auvray[1], B. Rana[2], K. Kondou[2] and *Y. Otani*[1,2]
1. ISSP, University of Tokyo, Kashiwa, Japan; 2. CEMS, RIKEN, Wakoshi,Saitama, Japan

Methods for generation of spin current and its conversion to electrical charge has been vigorously studied in recent years, particularly based on physical phenomena at the nanoscale [1]. In the presence of magnetic materials, spin currents can be generated by magnon-photon or magnon-phonon coupling. Magnon-phonon coupling can be achieved by passing surface acoustic waves (SAW) across ferromagnetic layers due to magnetoelastic effect [2], driving magnetization dynamics such as ferromagnetic resonance (FMR). This process is known as acoustic FMR(A-FMR), and is analogous to the most common FMR which is driven by electromagnetic wave photons. Both, FMR and A-FMR are used as mechanism for generation of spin current which can be injected into an adjacent nonmagnetic layers, a process better known as spin pumping [3]. Recent reports showed efficient spin to charge current conversion at interfaces with spatial inversion asymmetry between two nonmagnetic materials [4,5], known as inverse Edelstein effect (IEE). In this work, We demonstrate the spin to charge current conversion via magnon-phonon coupling and inverse Edelstein effect at the hybrid device Ni/Cu(Ag)/Bi_2O_3 (see Fig.1). We characterize the magnetic field angle dependence of acoustic spin pumping signals, in transverse and longitudinal detection geometry. We observe four-fold butterfly shape signal, the fingerprint of acoustic spin pumping (A-SP)(see Fig.2). In this study, Rayleigh-type surface acoustic waves in GHz regime is exploited to induce coherent elastic motion, exciting spin currents resonantly at room temperature. The result of our work indicates surface acoustic wave provides an efficient tool to generate spin currents and shows its potential to develop spintronic devices.

P4-03. Topology for Magnetization Control by Spin-Orbit Torques.
J. Hanke[1,2], F. Freimuth[2], C. Niu[2], S. Blügel[2] and Y. Mokrousov[2]
1. Institut für Physik, Johannes Gutenberg University, Mainz, Germany; 2. Peter Grünberg Institut and Institute for Advanced Simulation, Forschungszentrum Jülich, Jülich, Germany

Berry phases facilitate an elegant interpretation of fundamental condensed-matter effects that root in the complex geometry of momentum space, resulting in intrinsic contributions to anomalous transport and orbital magnetism. Only recently, also the phenomenon of current-induced spin-orbit torques was recognized as innately geometrical effect which originates, however, from the global properties of a *mixed* phase space entangling the crystal momentum with the magnetization direction [1]. These spin-orbit torques hold bright promises for the innovative design of novel memory devices that utilize the spin-orbit interaction to control magnetism by electric fields. Here, we promote the use of the universal arguments of topology in order to optimize the performance of magnetization switching in topologically complex materials [2]. Based on theoretical methods, we identify magnetically induced band crossings as microscopic origin for the obtained giant magneto-electric responses in insulating ferromagnets, exceeding by far the magnitude of spin-orbit torques in conventional metallic heterostructures. Thereby, we demonstrate the interplay of non-trivial topologies and spin torques, which lays out fascinating perspectives for the energy-efficient magnetization control of nanomagnets in absence of longitudinal charge currents. We gratefully acknowledge funding from the German Research Foundation (DFG) under Grant No. MO 1731/5-1 as well as from the EU Horizon 2020 research and innovation programme under grant agreement number 665095 (FET-Open project MAGicSky).

Interplay of magnetization (blue arrow), applied electric field (white arrow), and topology in magnetic insulators. If changes of the magnetization direction trigger topological phase transitions, the emergent band crossing constitutes an important microscopic source for spin-orbitronic phenomena. Ultimately, these magnetic monopoles can manifest in strongly enhanced electric-field responses.

9:30

P4-04. Interface-generated spin currents. *M.D. Stiles*[1] and V.P. Amin[2,1]
1. National Institute of Standards and Technology, Gaithersburg, MD, United States; 2. Maryland NanoCenter, University of Maryland, College Park, MD, United States

Transport calculations based on ab-initio band structures reveal large interface-generated spin currents at Co/Pt, Co/Cu, and Pt/Cu interfaces. These spin currents are driven by in-plane electric fields but flow out-of-plane, and can have similar strengths to spin currents generated by the spin Hall effect in bulk Pt. Each interface generates spin currents with polarization along z×E, where z is the interface normal and E denotes the electric field. The Co/Cu and Co/Pt interfaces additionally generate spin currents with polarization along m×(z×E), where m gives the magnetization direction of Co. The latter spin polarization is controlled by - but not aligned with - the magnetization, providing a novel mechanism for generating spin torques in magnetic trilayers.

Interface-generated spin currents, V. Amin and M. D. Stiles (submitted).

9:45

P4-05. Spin pumping at the ferromagnetic/paramagnetic phase transition. *E. Papaioannou*[1], S. Keller[1], A. Inglis[2], J.F. Gregg[2] and B. Hillebrands[1] *1. Physics, TU Kaiserslautern, Kaiserslautern, Germany; 2. Department of Physics, University of Oxford, Oxford, United Kingdom*

The effect of spin pumping close to the magnetic phase transition has been studied so far for bilayer samples composed of a paramagnetic insulating layer/ Pt [1] and of antiferromagnetic layer/Pt [2]. On the contrary here, a metallic ferromagnetic layer is used for the phase transition from a ferromagnet to a paramagnet. This can be achieved by using δ-doped Pd(Fe) layers which have the advantage of a controllable Curie temperature, T_C [3]. Temperature-dependent Inverse spin Hall effect (ISHE) voltage measurements show that the ISHE signal remains persistent over a relatively wide temperature range above the Curie temperature. We discuss our results based on Overhauser spin pumping [4]: The Overhauser spin accumulation is formed even in the paramagnetic Fe layer after it is microwave-irradiated and it can be turned into a simple microwave Spin Battery which generates pure spin currents that are unencumbered by charge transport.

P5-01. Recycling and Valorisation of Rare Earth-based magnets.
J. Denis[1], F. Mandil[1] and *S. Rivoirard*[1] *1. Institut Néel CNRS, Grenoble, France*

The issue of so-called "critical" materials is crucial for the development of new technologies for energy. In particular, rare earth (RE) elements are in the front line in Europe, because they combine both a very high supply risk together with a growing economic importance. For example, access to the Nd, Pr, Dy elements which enter for 30% in the composition of NdFeB magnets is crucial for technologies such as electric vehicles, wind turbines and electronic equipments. This context fosters reflection on the development of alternative RE sources. In Europe, the European Commission has set collection targets for the coming years and supports an important amount of research activities on the recycling processes of RE containing wastes. Even if only 35% of the total amount of WEEE (Waste of Electrical & Electronic Equipment) has been treated in 2015, the collection issue in "urban mines" is increasingly being addressed at WEEE treatment centers across Europe with a collection target of 85% in 2019. Up to date, recycling methods mainly rely on hydrometallurgy methods, which are already in use in the REE ore-processing industry. Since hydrometallurgical methods are mainly based on the introduction of a strong acid, they can be applicable to all sorts of end of life magnet material and scrap. However, these methods result in large and toxic waste generation and important energy consumption. In this work, physical separation methods are proposed as an alternative way to recycle RE sintered magnets. In the RECUP'TR project, the process is divided into two steps: hydrogen processing enables both to extract the magnet from the hard disk drive and to reduce it into powder. Then, the RE elements are extracted from the alloy by magnetic separation. A mixture of several RE elements (mainly Nd, Dy and Pr) is obtained. As a physical separation method, magnetic sorting combines the advantage of being a robust, cost effective and environmentally-friendly technique. For magnetic separation purposes, HGMS devices (High Gradient Magnetic Separator) creating strong magnetic forces are developed. In combination with other processing steps, this technique is also proposed for the treatment and valorisation of NdFeB bonded magnets.

P5-02. Optimizing the recycling process of NdFeB magnets. *O. Tosoni*[1], M. Bailleux[1], C. Rado[1], M. Dalmasso[1], S. Genevrier[1] and S. Luca[1] *1. Univ. Grenoble Alpes, CEA Grenoble, LITEN / DTNM, Grenoble, France*

High performance NdFeB-based magnets are key components of hybrid electric vehicles (HEV) and electric power generation (wind turbines) and are playing a crucial role in the development of electric power generation technologies based on renewable sources such as wind and hydro-power [1]. The rare earths contained at about 30% in this type of magnets are among the critical materials presenting a high risk of supply and large price fluctuations. In this work we report a study on the recycling of NdFeB based permanent magnets, using state of the art pre-industrial equipment used in the conventional powder metallurgy route of the manufacturing of NdFeB sintered magnets. Different types of magnets with known compositions were hydrogenated at different H_2 pressure. The resulting powder was sieved in order to: (i) eliminate the Ni-Cu coating, which remained in the form of chips and (ii) to eliminate the largest particles. This powder was subsequently Jet Milled down to 5 μm, under N_2. It was afterwards mixed in various proportions, from 0% to 50%, with a non-recycled NdFeB powder which contains 31% wt of rare earths (0.5% wt of Dy). The Dy in the recycled magnets was 2% wt. Sintered magnets were afterwards manufactured and magnetic properties were measured at room temperature, and compared to the magnet containing 0% of recycled powder (Figure 1). Magnets containing 50% of recycled powder present low magnetic performances and they are not considered furthermore in the analysis. The sintered magnet containing 30% of recycled powder has a remanence of 1.3T and a coercivity of 950 kA/m. The remanence and coercive field differ slightly from the reference magnet (with 0% recycled powder) due to the difference in the Dy content. Finally, a last test was carried out by mixing the recycled powder with a powder highly enriched in cobalt, known to reduce the sensitivity to oxidation of magnets. Similar properties (Br = 1.30T for Hc = 950 kA / m) could be obtained with a recycling rate reaching this time 50%. The process described here, easily transposable in industry, involves only NdFeB powders, without any addition of Nd in the form of NdH_2 as proposed in [2].

As the raw materials used for permanent magnets production is critical to the low carbon future envisioned by the European Union, the Horizon 2020 project Resource Efficient Production of Magnets (REProMag http://www.repromag-project.eu/) aims to address the issue of sustainability of RE permanent magnets by developing an innovative automated manufacturing route called SDS process (Shaping, Debinding and Sintering). This process will allow economically efficient production of net shape or near net shape magnetic parts with complex structures and geometries, whilst being waste-free through the use of fully recycled raw material and a 100% material efficiency in the consequent processing steps shaping, debinding and sintering. The REProMag SDS processing route is based on the use of powder obtained from end of life rare earth magnets by using the hydrogen processing for magnetic scrap (HPMS) process [1,2]. A proprietary binder system has been developed for producing a mouldable SDS feedstock, having a chemical composition optimised for the processing of the highly reactive magnetic powder. NdFeB magnets were processed in modified injection moulding equipment that were consequently debinded and sintered under tailored conditions. An overview of the project, including the processing steps and their challenges, the influence of debinding and sintering conditions on the microstructure and magnetic properties of isotropic sintered SDS parts with and without Nd-additions are presented and discussed. Special attention is given to temperature control, gas pressure conditions and atmospheres during thermal debinding and sintering.

Efficient use of rare-earth element in permanent magnets used in motors is becoming a serious issue since continuous demands for electric vehicles are expected. The main motivation of our research is to find an origin of the coercivity and to know a function of rare-earth element in permanent magnet [1]. It is widely accepted that the coercivity is determined by not only intrinsic magnetic properties of main phase but also microstructures, which have a strong influence on magnetic domains. However, few methods are capable to analyze magnetic domains and microstructures in bulk quantitatively. Small-angle neutron scattering (SANS), which is supposed to be a powerful tool to analyze them [2], has not been utilized for permanent magnets due to some difficulties in quantitative analysis. Firstly, statistical reliability of SANS signal to capture subtle change in magnetic domain is often not enough due to trade-off with measuring time. Secondly, the mainstream of SANS analysis is based on model fitting with analytical forms of scattering intensity for diluted systems, which is not suitable for complex microstructures and magnetic domains in permanent magnets. The aim of our research is to bring a breakthrough for the imaging of three-dimensional magnetic domain structure as well as for SANS measurements and analysis with help from computational methods. SANS measurements for nano-crystalline Nd-Fe-B based magnets were carried out at SINQ in PSI, Switzerland. The optimum measuring time was determined by the time dependence of signal and noise, and higher quality SANS patterns were estimated by kernel density estimation using measured SANS data. Furthermore, the characteristic three-dimensional micro and magnetic structures can be derived from measured SANS patterns using machine learning techniques. This machine learning based SANS analysis will let us construct a three-dimensional real space image, and has a potential to be a powerful tool for any kinds of materials development.

P5-05. Magnetic domain structures and magnetic properties of lightly Nd doped Sm-Co magnets with high squareness and high heat resistance. *H. Machida*[1], T. Fujiwara[1], C. Fujimoto[1], Y. Kanamori[1], J. Tanaka[2] and M. Takezawa[2] *1. TOKIN Corporation, Sendai, Japan; 2. Faculty of Engineering, Kyusyu Institute of Technology, Kitakyushu, Japan*

Sm-Co magnet is well known for having high heat resistance and used for many applications working under high temperature environments. As a way of enhancing magnetic properties, substitution of Fe for Co has been actively conducted. However, increasing Fe concentration is easy to be low squareness, hard to be homogenization and decrease heat resistance [1]. Here, we focused on substitution of Nd for Sm because Nd contributes to enhance magnetization and need not change the amount of Co playing a key role in heat resistance. To date, although a number of researches with respect to Nd amount dependence of magnetic properties have been conducted, there seems to be no reports discussing relation magnetic domain structures and magnetic properties, showing high squareness. We presumed that this reason is due to inhomogeneous microstructure and producing some low anisotropy phase, *e.g.* $NdCo_5$. In this research, we employed slow cooling between sintering and solution treatment to be homogenization and investigated magnetic properties from the viewpoint of magnetic domain structures and microstructures. Magnetic properties were evaluated with a B-H tracer, then $[BH]_m$ and H_{cb} were 33.8 MGOe and 11.2 kOe at 25°C respectively. Moreover B-H line was linear at 150°C, which means that irreversible demagnetization doesn’t occur even at 150°C (Fig. 1). Temperature coefficient of B_r and H_{cj} calculated from the demagnetization curves shown in Fig. 1 were 0.035 %/K and 0.24 %/K respectively. These values were not different from conventional Sm-Co magnets [2]. Magnetic domain structures were observed with a Kerr effect microscope with a magnetic field applied from 0 to -20 kOe, then reverse magnetic domains were generated evenly from grain boundaries. This magnetization process was almost the same to our previous report about the Sm-Co magnet with a high $[BH]_m$ of 34.0 MGOe [3]. Microstructures were observed by TEM, these were also the same to it as well as magnetic domain structures. Therefore, high squareness and heat resistance of the developed magnet were achieved by the doping of Nd that can control magnetic domain structures and microstructures.

The discovery of exchange bias (EB) switching, from negative to positive sign, in a dipole-induced coupling system where the antiferromagnet (AFM) and the ferromagnet (FM) are separated by a metalic paramagnetic (PM) spacer is presented. The strength and sign of the EB field are determined by the cooling field magnitude and the PM thickness. We report the observation of long range switching, from negative to positive EB in FeF_2/Au/Ni wedge-shaped trilayers, and provide a theoretical model that describes the results. PEB and NEB can be tuned as a function of both the field cooling strength H_{FC}, and the PM thickness. A model is developed that yields quantitative agreement with the experimental results. The model ignores the short range interfacial exchange interactions of the usual EB theories, retaining solely the long range dipole field that allows for the coupling of the FM and AFM across the PM spacer. Therefore, it breaks down for PM spacer thicknesses less than 0.5 nm. The experiments allow for novel switching capabilities of long range EB systems, while the theory adequately describes structures where the FM and AFM are not in atomic contact. The results provide a new approach to design novel interacting heterostructures. Moreover, it has been recently demonstrated that long-range interactions play a key role to stabilize isolated skyrmions and to control localized spin structures at the nanoscale. Thus, a full understanding of the physical mechanism of long-range interactions is essential for designing of layered structures with novel spin textures.

Many magnetic devices in advanced electronics rely on the exchange bias (EB) of a soft ferromagnetic layer coupled to an antiferromagnetic material[1-3]. Setting and optimizing the exchange bias involves a thermal treatment in presence of an external magnetic field, which affects the degree of magnetic order at the interface between both materials[4-5]. In this work we demonstrate an alternative process for the generation of exchange bias[6]. In IrMn/FeCo bilayers, we have found the deposition conditions which leave the IrMn layer in a metastable amorphous/nanocrystalline phase (top inset to fig. 1). During the days after deposition, a structural phase transition in the IrMn layer develops spontaneously at room temperature and spreads according to a two-dimensional nucleation and growth process (fig. 1), leading to a highly crystalline, chemically-disordered γ-phase (bottom inset to fig. 1), which was characterized by XRD and TEM. The magnetic characterization by VSM and MOKE microscopy (fig. 2) reveals that the disordered state of the as-deposited IrMn does not lead to any measurable exchange bias in the adjacent FeCo layer. As the crystalline IrMn phase propagates across the sample, the FeCo gets progressively exchange-biased in the direction of its remanent magnetization. This allows the interesting possibility of controlling the direction of the exchange bias, simply by switching the magnetization of the FeCo layer as the phase transition propagates in the IrMn. The resulting microscopic patterning of the EB direction in a spin valve device is shown in fig. 2. The study of this mechanism for establishing and tailoring the exchange bias in IrMn/FeCo bilayers, can contribute toward the clarification of fundamental aspects of this phenomenon, as well as toward the development of innovative spintronic devices.

P6-03. Exchange bias and domain evolution at 10nm scales. *H.J. Hug*[1,2], X. Zhao[2], A. Mandru[2] and M.A. Marioni[2] *1. Department of Physics, University of Basel, Basel, Switzerland; 2. Empa, Swiss Federal Laboratories for Materials Science and Technology, Dübendorf, Switzerland*

An obstacle to understanding the exchange bias (EB) effect is that only a subset of the pinned uncompensated spins (pinUCS), those pinned and coupled to the ferromagnet (F) are responsible for the EB effect. Experimental methods that measure the pinUCS density distribution with spatial resolution comparable to the materials grain size are needed. Here we use quantitative, high-resolution magnetic force microscopy (MFM) to measure the local areal density of pinned uncompensated spins (pinUCS) and to correlate the F-domain structure in a perpendicular anisotropy Co/Pt multilayer with the pinUCS density in the CoO antiferromagnet [1]. Larger applied fields drive the receding domains to areas of proportionally higher pinUCS aligned antiparallel to F-moments. This confirms our prior results [2] that these antiparallel pinUCS are responsible for the EB effect, while parallel pinUCS coexist. The experimentally observed domain evolution with field could be matched well with a 2D phase-field model that incorporates the 10 nm-resolved measured local biasing characteristics of the antiferromagnet [3]. Frustration limits the exchange bias field in typical ferromagnet/antiferromagnet EB systems. Frustration can be avoided if the antiferromagnet is replaced by a rare-earth ferromagnetic layer and exchange bias fields larger than 1T were observed [4]. Because of the strong coupling between the ferromagnetic and ferrimagnetic thin films, a different magnetization process of the ferromagnetic film is observed [5]: instead of domain nucleation followed by a lateral motion of the domain walls over the landscape of pinUCS, an increasing number of isolated CoPt grains reverse their magnetization and a high-energy in-plane domain wall is formed at the ferromagnet/rare earth ferrimagnet interface.

P6-04. Interfacial coupling induced chiral symmetry-breaking of spin-orbit interaction in exchange biased systems. P. Perna[1], F. Ajejas[1], D. Maccariello[1], R. Guerrero[1], R. Miranda[1] and *J. Camarero*[2] *1. IMDEA Nanoscience, Madrid, Spain; 2. Universidad Autonoma de Madrid & IMDEA Nanoscience, Madrid, Spain*

In many branches of science, chiral asymmetries are often associated to symmetry-breaking effects. In magnetic materials, the handedness of the magnetization vector and the external field result generally in non-chiral magnetization and magnetoresistance hysteresis phenomena [1]. In spintronics, the need of stabilizing and controlling the magnetoresistance (MR) output of device, is satisfied by resorting to ferromagnetic/antiferromagnetic (FM/AFM) structures in which the magnetization direction of the FM layer is pinned. In these systems an added anisotropy comes out from frustrated exchange interactions at FM/AFM interface, introducing a interfacial symmetry-breaking along the field axis determining a spin rearrangement in both layer surfaces [2]. Here, we show that the symmetry-breaking of Spin-Orbit (SO) effects can promote chiral phenomena in the magnetic and transport properties of exchange-biased structures [2,3], namely FM/AFM polycrystalline Co/IrMn bilayer. This is done by performing angular- and field-dependent simultaneous measurements of the magnetoresistance and vectorial-resolved Kerr magnetization hysteresis loops [1-4]. We highlight the role of the exchange-bias induced magnetic anisotropy in determining asymmetric features of the field-driven angular anisotropic magnetoresistance curves, which are directly correlated to the magnetization reversal mechanisms. The experimental field dependent curves, including their asymmetries, gives direct visualization of SO chiral asymmetry which is intrinsic of an exchange-bias system (Figure 1). In addition, although the magnetoresistance in bilayers and exchange biased spin-valves are related to different transport phenomena (i.e., AMR and GMR, respectively), our findings indicate that the chiral asymmetries are intrinsic of systems with unidirectional anisotropy [5].

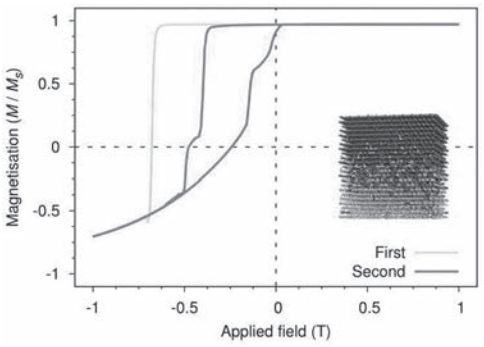
P6-05. Investigation into the Origin of the Athermal Training Effect in Exchange Bias Multilayers. *S. Jenkins*[1], R.F. Evans[1] and R. Chantrell[1] *1. Physics, University of York, York, United Kingdom*



The exchange bias effect occurs when a ferromagnet is coupled to an antiferromagnet, causing a shift of the magnetic hysteresis loop. The shift is caused by pinned interfacial spins, causing a unidirectional field pinning the atomic spins at the interface. The training effect causes a large drop in the

measured exchange bias after the first measured hysteresis loop[1]. This has two main causes: thermal training and athermal training[1]. Thermal training is due to well understood thermal instabilities in the AFM[1]. The origin of athermal training however is still a widely disputed problem due to the difficulty in experimentally probing the rearrangement of AFM spins at the interface. It has been proposed to be due to the degree of order of the AFM at the interface[1]. Here we investigate the origin of training in a CoFe/γ-$IrMn_3$ FM/AFM bilayer using an atomistic spin model[2]. The properties of the disordered γ-$IrMn_3$ AFM are modelled using the Heisenberg form of the exchange interaction and the anisotropy is calculated using the Neel pair anisotropy model. These reproduce key experimental results including the Neel temperature and magnetic ground state. It was found that for a single grain with an atomically flat interface there is no training effect and the exchange biased loops are completely repeatable. As the width of the interface mixing is increased we see an increase in the athermal training effect, as shown in Fig.1. The exchange bias was observed to increase with interface mixing for the initial hysteresis loop, but the training effect also increased causing a larger reduction in the exchange bias. We will present systematic calculations of the exchange bias and training effects as a function of interface mixing and further simulations of the temperature dependence of the exchange bias with thermal training and a statistical study of polygranular exchange biased systems. This work used the ARCHER UK National Supercomputing Service (http://www.archer.ac.uk).

Recently, electrolyte gating techniques using ionic liquids have proven highly effective in tuning large carrier densities at material surfaces. These electrolytes enable electric double layer transistor operation, the large capacitances (10's of μF/cm^2) generating electron/hole densities up to 10^{14} - 10^{15} cm^{-2}, *i.e.*, significant fractions of an electron/hole per unit cell in most materials. Uncertainties remain, however, including the true doping mechanism (*i.e.*, electrostatic *vs*. electrochemical), the challenge of *in operando* characterization, and the need to understand the full potential and universality. In this talk we will focus on the use of ionic *gels* [1,2], in all-solid-state devices enabling gate-control of ferromagnetism. Employing ultrathin epitaxial $La_{1-x}Sr_xCoO_3$ as a model system, our findings first clarify charge carrier *vs*. oxygen defect creation. Dramatic asymmetry with respect to bias polarity is observed both from transport [3] and *in operando* probes based on synchrotron X-ray diffraction and polarized neutron reflectometry (PNR) [4]. In essence we find oxygen vacancy formation at positive bias, but electrostatic hole accumulation at negative bias. This is interpreted in a simple picture where electrostatic *vs*. electrochemical response is dictated by enthalpy of formation of oxygen vacancies, bias polarity, and initial doping [3,4]. Control of ferromagnetism is then demonstrated in both electrochemical and electrostatic modes. Electrochemical control is possible even in thick films, due to the low formation enthalpy and high diffusivity of oxygen vacancies in $La_{1-x}Sr_xCoO_3$ [4]. Most importantly, working at negative bias in electrostatic mode, and guided by theory [5], we demonstrate reversible electrical control of Curie temperature over a 150 K window. This is achieved *via* a gate-induced cluster percolation mechanism, leading to optimized control of ferromagnetism, directly verified by magnetoresistance, anomalous Hall effect, and PNR measurements. Work supported primarily by the MRSEC program of the NSF. Neutron scattering component supported by the DOE under the UMN Center for Quantum Materials.

P7-02. Towards pure spin currents for oxide spintronic devices. *C. Cox*[1], A. Caruana[2], B. Nicholson[3], A. Mora-Hernandez[3], A. Hindmarch[3], C. Kinane[4], T. Charlton[5] and K. Morrison[1] *1. Physics, Loughborough University, Loughborough, United Kingdom; 2. ISIS Neutron and Muon Source, Rutherford Appleton Laboratory, Didcot, United Kingdom; 3. Durham University, Durham, United Kingdom; 4. Rutherford Appleton Laboratory, STFC, Didcot, United Kingdom; 5. Large Scale Structures Group, Oak Ridge National Laboratory, Oak Ridge, TN, United States*

The advent of commercial spintronics is ever approaching and the realisation of such devices is contingent upon calculable manipulation of spin currents across material interfaces. Magnetic proximity effects (MPE) (resulting in the polarization of spins in non-magnetic materials such as Pt due to adjacent magnetic material), have the potential to contaminate and even annihilate spin current injection/production in such devices and render them unreliable. Of particular interest is the use of ferrites, e.g. Fe_3O_4, as the magnetic material. We present the characterisation and investigation of high quality Fe_3O_4/Pt bilayers grown by pulsed laser deposition [1]. In Fe_3O_4, the metal-insulator (Verwey) transition, T_v, provides the opportunity to investigate the MPE in both the metallic and insulating state[2]. Synchrotron techniques, such as X-ray Resonant Magnetic Reflectivity (XRMR)[3], have the ability to tune the incident wavelength to the L_3-edge of Pt providing element specific magnetic contrast. This is in addition to the structural contrast of standard x-ray reflectivity (XRR), as shown in Figure 1. Utilising XRMR, the magnitude and coherence length of the induced magnetic moment in the adjacent Pt has been evaluated (fits shown in Figure 2). Initial results hint at the presence of a 1-2 nm region of magnetised Pt (0.1μ_B/Pt atom) at temperatures above the T_v. Below the T_v, XRMR suggests the magnetisation in Pt is reduced but not eradicated, suggesting [KM1] that the metallic state is correlated to, but not a determining factor for, the MPE.

The control of orbital polarization in transition metal oxides offers the possibility to tailor their properties. In $LaNiO_3$ (LNO) a single hole occupancy at the degenerate e_g states ($3d^7$: t_{2g}^6 e_g^1) induces a metallic character. Breaking the local symmetry around the Ni3+ ions may lift the orbital degeneracy thus leaving an orbital occupation analogous to the HTSC cuprates. This theoretical prediction [1] stimulated a considerable research [2]. Here we explore how strain acting on LNO films breaks orbital degeneracy and produces an orbital polarization. We use LNO thin films epitaxially grown on suitable substrates and take advantage of the associate epitaxial strain that deforms the oxygen polyhedral around the Ni^{3+} ions to break the degeneracy of in-plane e_g (x^2-y^2) and out-of-plane e_g($3z^2$-r^2) orbitals. We have followed two alternative approaches. First, we have grown LNO films of various thicknesses on different single crystalline substrates, which impose a different epitaxial strain. Next, we have grown LNO films on piezoelectric (PMN-PT) substrates which allow continuous modulation of strain by applying a suitable voltage across the substrate. Orbital polarization is determined by using X-absorption at the Ni $L_{2,3}$ edges and determining the linear dichroism (XLD). It turns out that, similarly to what had been found earlier in manganite thin films [3], the XLD signal reveals the presence of two contributing sources of dichroism: one coming from the LNO lattice deformation induced by epitaxial strain superimposed to another arising from the breaking of symmetry at the film surface. When applying a suitable voltage (V) across the PMN-PT substrate to the LNO film a related change of the XLD signal is observed. More precisely, a butterfly-like XLD(V) loop is measured, that clearly illustrates the voltage-controlled change of orbital occupancy [4]. We have compared quantitatively the sensitivity of the orbital occupancy to static and piezo strain and discovered that changes are more subtle and information richer than what can be expected at first sight. Here we shall present these fresh results and discus their relevance in view of the recently reported indication of superconductivity in LNO-based multilayers [5]

P7-04. Extraordinary ferromagnetic coupling and magnetodielectric phenomena in NiO nanoparticles. S. Roy[1], R. Katoch[1] and *A. Subramanian[1] 1. Centre for Nano and Soft Matter Sciences, Bangalore, India*

We intend to understand the ferromagnetism and magnetodielectric phenomena in NiO nanoparticles. The NiO nanoparticles with average diameter ~ 20 nm were synthesized by a chemical route. The magnetization studies in the temperature range from 10 to 300 K revealed that NiO nanoparticles are weakly ferromagnetic. The origin of the observed weak ferromagnetic nature could arise from the uncompensated spins at the surface of the nanoparticles. Notably, the temperature dependent magnetization studies show a bifurcation of the FC-ZFC curves, suggesting a competition between FM and AFM interactions. The ZFC magnetization shows a cusp in the magnetic data corresponding to the blocking temperature (T_B) of the superparamagnetic spins. We observed the exchange bias effect in the nanoparticles with a loop shift of ~100 Oe at 10 K. This behaviour could be explained on the basis of a core-shell structure of nanoparticles, with an outer FM shell and inner AFM core, like bulk NiO.[1] Magneto-dielectric studies revealed that the changes in the dielectric constant and loss induced by the magnetic field are strongly frequency-dependent, which could originate from combined effect of extrinsic Maxwell–Wagner polarisation along with magnetoresistance. It is found that the magnetoimpedance under external magnetic field, changes the sign from negative at low frequencies to positive at higher frequencies of excitation signal. Cole-Cole studies reveal two distinct relaxation processes in the sample; one at the lowest frequencies corresponding to the shell/interface and the other at the highest frequency due to the core/bulk. This suggests that the magnetoimpedance is dominated by the core at higher frequencies and shell at lower frequencies. Since, the magnetoresistance is negative in ferromagnetic coupling and positive for antiferromagnetic case, it gives further credence to the existence of AFM core and FM shell structure in NiO nanoparticles.[2]

Comprehensive neutron and X-ray diffraction, thermodynamic and transport measurements will be reported on a stacked-triangular-lattice metal. The system orders anti-ferromagnetically below a Néel temperature with spatially loclised moments directed perpendicular to the plane of the triangular lattice. The order within the plane has a √3 x √3 unit cell, characteristic of 2D geometrically frustrated triangular lattices [1]. The order is incommensurately modulated along the stacking direction. This magnetic order contains triangular lattice planes in which 1/3 of the magnetic sites have zero moment. This magnetic structure persists down to the lowest temperature measured. At temperatures below the Neel temperature we report that the heat capacity manifests quantum critical behaviour with C/T ~ log(T) for over a decade of temperature down to ~ 200 mK, diverging even more strongly below this temperature. Quantum critical behaviour within an ordered state is highly unusual and indeed we believe our observations are unique for a system with magnetic ions located on only one crystallographic site. We attribute the quantum criticallity to the Kondo screening of the unsaturated moments that remain unsaturated in the magneticaly ordered structure owing to geometric frustration. Theoretically, Kondo screening should result in a charge transfer. We have directly detected this charge transfer. The significance of our findings is that the same moments are both partially Kondo screened and simultaneously magnetically ordered. Such a behavoiur does not fit into the standard Doniach model [2] in which magnetic ordering quenches Kondo screening. The required theoretical description has to accommodate both the bosonic character of the magnetically ordered state and the fermionic character of Kondo screening applied simultaneously to the same electrons.

$Yb_2Fe_{12}P_7$ is a hexagonal compound first described by Jeitschko et al. [1], which shows unusual features of the specific heat $C(T)$: a sharp peak indicative of magnetic ordering at $T_m \sim 0.9$ K is preceded by a broad hump with a maximum of C/T around $T_{max} \sim 0.3$ K [2]. The magnetic susceptibility at low temperatures T indicates that the easy direction is along the c axis. In addition, the compound shows an unconventional magnetic-field – temperature phase diagram with extended ranges of non-Fermi-liquid behavior of the electrical resistivity. – In order to elucidate these features, we have measured the thermal-expansion coefficients a_a and a_c along the a and c axes between 80 mK and 10 K in magnetic fields up to $B = 3$ T. Both $a_a(T)/T$ and $a_c(T)/T$ qualitatively show the features seen in C/T, but exhibit a behavior exactly opposite to each other: a broad maximum (minimum) around 0.3 K and a sharp negative (positive) peak at 0.9 K for the a direction (c direction). The analysis shows that this peak contributes only 10 % of the entropy of the crystal-field ground state R ln 2 while 90 % is due to the broad hump. T_m shifts to higher (lower) T with uniaxial stress along (perpendicular to) c. The converse effect is found for T_{max}. This suggests that the sharp maximum arises from ordering of Yb magnetic moments along the c direction, which is indeed the direction of the nearest Yb neighbors. Elastic neutron scattering did not give any evidence of long-range magnetic ordering, suggesting that the system is highly frustrated. Geometric frustration might also be the cause of the peak at T_m contributing only 10 % to the entropy and for the presence of a broad peak at T_{max} instead of a further anomaly towards lower T. – A magnetic field of 3 T has a pronounced effect on the thermal expansion. For B perpendicular to c, the broad maximum measured in $a_a(T)/T$ turns into a minimum, while the negative peak quickly broadens in field and vanishes around 1 T. For $B \parallel c$, the effect on the broad maximum in $a_a(T)/T$ is weaker, but a sign change is still observed. For this field direction, the sharp anomalies at T_m remain visible above 1 T; they gradually shift to zero for both $a_a(T)/T$ and $a_c(T)/T$, allowing to establish a B-T phase diagram.

National Institute for Materials Science, Tukuba, Japan*

Interplay between Kondo screening and geometrical frustration has been found in CePdAl with the hexagonal ZrNiAl-type structure, which is an example of Ising-spin kagome Kondo lattice [1,2]. Isostructural compounds CeRhSn and CeIrSn are considered to belong to the quasi-kagome Kondo lattice. However, the high Kondo temperatures of 450 K and 900 K, respectively, place them in the valence fluctuation region with nonmagnetic ground states [3]. Below 2 K, however, CeRhSn exhibits non-Fermi liquid behaviors in magnetic susceptibility χ, electrical resistivity ρ, thermal expansion coefficient α, and specific heat C [4,5]. Thereby, highly anisotropic behaviors appear, $\chi_c(T) >> \chi_a(T)$ and $\rho_a(T) > \rho_c(T)$ [4]. Furthermore, the thermal expansion coefficient divided by temperature α /T displays the divergent behavior only along the a axis [5]. The divergent behaviors in C/T and α_a/T are the characteristics of quantum criticality. The metamagnetic anomaly only for $B//a$ at around 3.5 T supports the model that the quantum criticality is driven by the geometrical frustration in the Ising-spin quasi-kagome Kondo lattice [5,6]. Similar quantum criticality is expected to appear in the isostructural and isovalent compound CeIrSn. Therefore, we have prepared a single crystal of CeIrSn by the Czochralski method. The single crystal x-ray diffraction analysis indicated the absence of a doubling of the c axis as found in ZrIrSn [7]. Strongly anisotropic behaviors, $\chi_c(T) >> \chi_a(T)$ and $\rho_a(T) > \rho_c(T)$, are observed as similar with CeRhSn. With decreasing temperature, C/T and $\chi(T)$ of CeIrSn diverge stronger than in CeRhSn despite the higher Kondo scale in CeIrSn. At $T < 1$ K, the isothermal magnetization $M(B//a)$ shows a metamagnetic crossover at around 5.5 T, where the magneto resistance for $B//a$ exhibits a minimum. The metamagnetic crossover along the a axis is attributed to the relaxation of magnetic frustration in magnetic field applied perpendicular to the Ising axis.

P8-04. Antiferromagnetic Ordering Competition in Nd-doped $CeIn_3$. *J.R. Badger*[1,2], P. Klavins[1] and V. Taufour[1] *1. Physics, University of California, Davis, Davis, CA, United States; 2. Chemistry, University of California, Davis, Davis, CA, United States*

Both $CeIn_3$ and $NdIn_3$ crystallize in the same cubic structure (Pm-3m) and show an- tiferromagnetic ordering below 10.1K and 5.9K, respectively. We investigate the magnetic ordering of single crystals of $Ce_{1-x}Nd_xIn_3$ and discover a region of frustrated magnetism near $x \sim 0.3$ where the magnetic order is suppressed to below 1.8K. In this region, the two antiferromagnetic orders appears to be in competition with one another despite that fact that antiferromagnetic interactions are still observed. We present the sample synthesis, and char- acterizations, as well as a discussion of the observed magnetic properties in the context of heavy-fermion behavior, percolation of magnetic ordering, and magnetic anisotropy.

P8-05. Continuous Evolution of Spin Fluctuations Through the Metal-Insulator Transition in $NaOsO_3$. *J.G. Vale*[1], S. Calder[2], K. Yamaura[3], J. van den Brink[4], A. Christianson[2] and D.F. McMorrow[1] *1. London Centre for Nanotechnology, University College London (UCL), London, United Kingdom; 2. Oak Ridge National Laboratory, Oak Ridge, TN, United States; 3. National Institute for Materials Science (NIMS), Tsukuba, Japan; 4. IFW Dresden, Dresden, Germany*

$NaOsO_3$ undergoes a metal-insulator transition (MIT) at 410 K, concomitant with the onset of antiferromagnetic order. Notably the MIT is not associated with any structural distortion, placing it outside the conventional Mott-Hubbard picture. Such behaviour has been previously understood as a rare example of a Slater transition in three dimensions, by which the onset of magnetic order itself drives the formation of the insulating state. There is some debate, however, about the role that spin-orbit coupling plays with regards to the electronic and magnetic behaviour of this system. The excitation spectra have been investigated through the MIT by resonant inelastic x-ray scattering (RIXS) at the Os L_3 edge (10.871 keV). Low resolution (dE ~ 300 meV) measurements over a wide range of energies reveal that local electronic excitations do not change appreciably through the MIT. This is consistent with a picture in which structural distortions do not drive the MIT. In contrast, high resolution (dE ~ 55 meV) measurements show that the well-defined, low energy magnons - which are gapped at all wavevectors - in the insulating state weaken and dampen upon approaching the metallic state. Concomitantly, a broad continuum of excitations develops which is well described by the magnetic fluctuations of a nearly antiferromagnetic Fermi liquid. By revealing the continuous evolution of the magnetic quasiparticle spectrum as it changes its character from itinerant to localized, our results provide unprecedented insight into the nature of the MIT in $NaOsO_3$. In particular, the presence of weak correlations in the paramagnetic phase implies a degree of departure from the ideal Slater limit. Furthermore, it provides an ideal test case for theoretical studies of the RIXS response towards the itinerant limit, without any extrinsic factors such as disorder to consider.

I will discuss the surprising observation of a Fermi surface in various families of Kondo insulators, as revealed by the observation of magnetic quantum oscillations in the measured torque magnetisation. Intriguingly, differences in the observed Fermi surface are manifested across various materials families, from light conduction-electron-like Fermi surfaces observed in SmB_6 to heavy semi-metal-like Fermi surfaces observed in YbB_{12}. A rich spectrum of theoretical models is suggested to explain the origin across different Kondo insulating families of a bulk Fermi surface potentially from novel itinerant quasiparticles that couple to magnetic fields, yet do not couple to weak DC electric fields.

P9-02. Quantum Oscillations in Electrical Resistivity in Kondo Insulators. *L. Li*[1] *1. University of Michigan, Ann Arbor, MI, United States*

In metals, orbital motions of conduction electrons are quantized in magnetic fields, which is manifested by quantum oscillations in electrical resistivity. This Landau quantization is generally absent in insulators, in which all the electrons are localized. Here we report a notable exception in an insulator — ytterbium dodecaboride (YbB_{12}). The resistivity of YbB_{12}, despite much larger than that of usual metals, exhibits profound quantum oscillations under intense magnetic fields. This unconventional oscillation is shown to arise from the insulating bulk, instead of conducting surface states. The large effective masses indicate strong correlation effects between electrons. Our result is the first discovery of quantum oscillations in the electrical resistivity of a strongly correlated insulator, and will bring crucial insight to the understanding of the ground state in gapped Kondo systems.

Topological electronic states and its spin texture realized in the non-conventional bulk insulators such as Kondo insulators whose bandgap opens due to the strong electron correlations is gathering much attention in these days, namely topological Kondo insulator [1,2]. It is because they are regarded as a promising playground to search for new, exotic electronic phenomena driven by concerted effects between strong electron correlation and topological order. On the other hand, recently the low-energy electronic structure around the Fermi level of SmB_6 is extensively studied from another aspect as a strange, carrier-less Fermi surface detected by the de Haas–van Alphen (dHvA) effect [3-5]. While the detailed information about the Fermi surface of SmB_6 is desired from two neighboring research fields, there has not been any good overview for bridging both fields. In this work, we observed the surface electronic structure of the single-crystalline SmB_6 on its well-defined (111) clean surface using angle-resolved photoelectron spectroscopy (ARPES) and spin-resolved ARPES. It clearly showed the spin-polarized 2D metallic surface states on SmB_6 suggesting the non-trivial topological order of SmB_6 [6]. Here we discuss the orientation dependence of Fermi surfaces based on our ARPES results on the (111) surface together with the earlier ARPES works on (001) cleaved surfaces, and also compare with the dHvA results on various crystal orientations.

Physics, University of Edinburgh, Edinburgh, United Kingdom; 5. University of St.Andrews, St.Andrews, United Kingdom*

In the past few decades topology has become a central theme in condensed matter physics, allowing a more complete understanding of concepts such as the quantum Hall effect and of the class of materials termed topological insulators. Topological insulators were first predicted in 1987 and have subsequently been experimentally realised in a host of materials [1,2]. A similar effect has been predicted to occur for $SrCu_2(BO_3)_2$ (SCBO) but with one crucial difference; unlike those materials previously found, it is the spin waves that have a topological character rather than the conduc-

tion bands [3]. SCBO is therefore a bosonic topological material. SCBO is an experimental realisation of the Shastry-Sutherland model; a theoretical 2-dimensional square lattice shown to have an exact dimer ground state. SCBO is therefore something of a rarity in that it is a physical manifestation of an exactly solvable model. The rigorous results that may be derived in such systems are extremely useful in elucidating the mechanisms behind various phenomena. Theoretical predictions from [3] suggest that the topological nature of SCBO should be evident from thermal Hall effect measurements. In order to demonstrate the feasibility of these measurements, we have used our setup to reproduce those results from [4], which show a (magnon) Hall effect signal of a similar magnitude to that predicted for SCBO, and under similar conditions. We then present new thermal Hall data on the material SCBO, for which a positive result would be evidence for one of the first known bosonic topological insulators.

P10-01. Experimental Insights into Ground-State Selection of Quantum XY Pyrochlores. *A. Hallas[1,2] 1. Physics & Astronomy Department, Rice University, Houston, TX, United States; 2. Rice Center for Quantum Materials (RCQM), Rice University, Houston, TX, United States*

Extensive experimental investigations of the magnetic structures and excitations in the XY pyrochlores have been carried out over the past decade. Three families of XY pyrochlores have emerged: $Yb_2B_2O_7$, $Er_2B_2O_7$, and, most recently, $AA'Co_2F_7$. In each case, the magnetic cation (either Yb, Er, or Co) exhibits XY anisotropy within the local pyrochlore coordinates, a consequence of crystal field effects. Materials in these families display rich phase behavior and are candidates for exotic ground states, such as quantum spin ice, and exotic ground-state selection via order-by-disorder mechanisms. In this talk, I will present an experimental summary of the ground-state properties of the XY pyrochlores, including evidence that they are strongly influenced by phase competition [1]. I will empirically demonstrate the signatures for phase competition in a frustrated magnet: multiple heat capacity anomalies, suppressed T_N or T_C, sample- and pressure-dependent ground states [2,3], and unconventional spin dynamics [4-8].

P10-02. Beyond conventional magnetic order in the Shastry-Sutherland frustrated magnet TmB_4. *D. Lançon[1,2]*, V. Scagnoli[1,2], E. Canévet[1], R. Sibille[1], M. Ciomaga Hatnean[3], G. Balakrishnan[3], O. Petrenko[3], U. Staub[1], C. Rüegg[1], L. Heyderman[1,2] and T. Fennell[1] *1. Paul Scherrer Institut, Villigen-PSI, Switzerland; 2. Mesoscopic Systems, ETH Zurich, Zurich, Switzerland; 3. Departement of Physics, University of Warwick, Coventry, United Kingdom*

Geometrically frustrated lattices such as the 2D Shastry-Sutherland lattice are known to induce emergent quantum phenomena such as spin liquids, topologically protected states, and complex magnetic order. The spin liquid $SrCu_2(BO_3)_2$ is a famous example of the physical realisation of the Shastry-Sutherland lattice in an insulator [1], yet there exists a family of rare-earth metal tetraborides that exhibit both lattice-induced geometrical frustration and itinerant behavior [2]. In this context, the magnetic order in the frustrated magnet TmB_4 is of particular interest. The arrangement of the Tm rare-earth moments in each layer are indeed topologically equivalent to the 2D Shastry-Sutherland lattice while the crystal field effects lead to a strong Ising anisotropy. Unlike $SrCu_2(BO_3)_2$, antiferromagnetic order has been shown to exist in TmB_4 below 10 K. Nevertheless, competing interactions lead to a complex magnetic field-temperature phase diagram [3]. Additional interest in TmB_4 is driven by the emergence of fractionalized magnetization plateaus as seen in $SrCu_2(BO_3)_2$ [4]. Through measurements of neutron diffuse magnetic scattering, neutron diffraction experiments and resonant soft X-ray scattering, we have demonstrated the co-existence of magnetic order with Q-dependant short-ranged correlations in all the ordered magnetic phases. Competing long-ranged and short ranged correlations will be linked to the frustrated exchange interactions in TmB_4. In addition, I will discuss the commensurate antiferromagnetic and three incommensurate magnetic phases with strong history-dependent interconversion hosted by the temperature-field magnetic phase diagram. Using a reproducible protocol for single crystal neutron scattering experiments in such a history-dependent system, we have established the evolution of the unconventional magnetic ordering in TmB_4 as a function of temperature and applied field.

P10-03. Breakdown of the helical order in the Dzyaloshinskii-Moriya Antiferromagnet $Ba_2CuGe_2O_7$. *S. Muehlbauer*[1], G. Brandl[2,3], M. Månsson[4] and M. Garst[5] *1. Heinz Maier Leibnitz Zentrum (MLZ), Technical University of Munich, Garching, Germany; 2. Forschungszentrum Jülich GmbH, Jülich Centre for Neutron Science (JCNS) at Heinz Maier-Leibnitz Zentrum (MLZ), Garching, Germany; 3. Physik Department E21, Technische Universität München, Garching, Germany; 4. Materials Physics, KTH Royal Institute of Technology, Kopenhagen, Sweden; 5. TU Dresden, Köln, Germany*

The Dzyaloshinskii-Moriya interaction (DMI) favors incommensurate helical magnetic order in noncentrosymmetric space groups. For weak spin-orbit coupling, the associated wavelength becomes large and magneto-crystalline anisotropies are less effective in fixing the orientation of the helices. Depending on the symmetry, the energies of the helices might then be almost degenerate for orientations of their wave vectors k that belong to manifolds in k-space, e.g., a sphere. Approaching the phase transition from high temperatures, magnons soften on this manifold and the associated large phase space gives rise to large entropy that might drive the phase transition to first order denoted Brazovskii transition [1]. Recently, experimental evidence proved the realization of such a scenario in the cubic helimagnet MnSi [2] and other isostructural compounds [3], with the magnons softening on a sphere in k-space. We have examined if such a scenario is also realized in systems of lower symmetry [4] like the noncentrosymmetric tetragonal AF $Ba_2CuGe_2O_7$. Below $T_N \approx 3.05$K, an incommensurate, AF cycloid is caused by the DMI. Nearest neighbor AF exchange in the *(a,b)*-plane is the dominant magnetic interaction. The coupling between adjacent planes is weak, leading to a system of weakly coupled 2D-layers. The transition between the zero-field paramagnet and the cycloidal order is weakly first-order. Similar to MnSi, the specific heat shows a sharp latent heat that sits on top of a broader peak. We performed neutron diffraction on $Ba_2CuGe_2O_7$ to study the critical magnetic fluctuations. We find that, close to T_N, magnetic intensity indeed accumulates on a manifold in momentum space which corresponds to a ring in the *(a,b)*-plane. This suggests that magneto-crystalline anisotropies are comparatively small. These observations fulfill the preconditions for a Brazovskii type transition. However, the temperature dependence of the inverse correlation length, $\kappa(T)$, is not in agreement with the predictions of the Brazovskii theory: We find that $\kappa(T)$ does not change its curvature, but is always convex in an extended temperature range above T_N, caused by the effective low dimensionality of fluctuations due to the weak coupling between the layers.

P10-04. Light Enhanced Anomalous Hall Effect on Magnetic Topological Insulator Cr-$(Bi,Sb)_2Te_3$. *C. Chen*[1], A.R. Llanos[1], M. Teague[1], N. Yeh[1,2], L. Pan[3], K. Murata[3] and K.L. Wang[3] *1. Physics, Caltech, Pasadena, CA, United States; 2. Kavli Nanoscience Institute, Caltech, Pasadena, CA, United States; 3. Electrical Engineering, UCLA, Los Angeles, CA, United States*

Magnetic topological insulators are expected to show Quantum Anomalous Hall effect (QAHE) due to their intrinsic magnetization and topological structure. However, QAHE could only been achieved in Cr-doped and V-doped TIs $(Bi,Sb)_2Te_3$ at 30mK, a temperature much lower than the 3D Curie Temperature T_c^{3D} (30K) determined from Anomalous Hall effect (AHE). The physical origin for the suppression of QAHE is still not well understood. Strong intrinsic magnetism might break time reversal symmetry (TRS) or even the band structure of the TIs. There, instead of studying magnetic TI directly, we studied the pure TI on magnetic TI bilayer structure, and using proximity effect to break TRS on top pure TI layer. Our previous STM studys have shown that when top pure TI layer is less than 4 Quintuple layers (QL), a spatially inhomogeneous tunneling gap of the surface state (SS) opened up below a 2D Curie Temperature T_c^{2D} (220~260K depending on Cr doping concentration). The surface gap became more uniform at lower temperature and stronger magnetic field. Hence, the inhomogeneous SS gap distribution is likely due to deviation of the Cr magnetic moments from the bilayer c-axis. Such misalignment may be an important factor that suppressed the QAHE except extremely low temperatures. Circularly-polarized light with energy higher than the bulk band gap of the magnetic TIs can preferentially excite one spin channel and therefore produce excess spin polarization in the surface state. The excess photo-induced spin polarization may help align the magnetic moments of Cr and thus influence the magnetism of the sample. Based on this conjecture, we investigate the interplay of circularly polarized light and external magnetic fields on the SS gap homogeneity, the anomalous Hall signals, and the values of T_c^{2D} and T_c^{3D} by both photo-assisted STS and electrical transport measurements. We found that circularly polarized light could indeed enhance the anomalous Hall resistance in ternary magnetic TIs at low temperatures, as exemplified in Figure 1 for a magnetic hystersis loop taken at $T = 2$ K on a bilayer of $(Bi,Sb)_2Te_3$ on Cr-doped $(Bi,Sb)_2Te_3$, where 1700 nm circularly polarized light resulted in ~ 10% increase in the anomalous Hall resistance.

P10-05. Phase Transitions in Skyrmion host Cu_2OSeO_3. H.C. Chauhan[1], J. Tiwari[1] and *S. Ghosh*[1] *1. School of Physical Sciences, Jawaharlal Nehru University, New Delhi, India*

A skyrmion, a stable vortex-like spin-swirling object that can be treated as particle of nanometre size has been observed in MnSi, FeGe, $Fe_{1-x}Co_xSi$ and Cu_2OSeO_3. These kind of chiral helimagnetic materials have attracted a great interest due to their novel properties and potential applications in future memory devices. In these types of multifunctional magnetic materials, the time reversal and spatial-inversion symmetries are broken. Most of the skyrmionic materials are metallic with cubic B20 structure such as, MnSi, FeGe, $Fe_{1-x}Co_xSi$. Cu_2OSeO_3 is the only known insulating multiferroic material[1] with helical spin structure in which skyrmion has been observed. In Cu_2OSeO_3, the inverse Dzyaloshinskii-Moriya (DM) interaction between spins and can induce electrically ordered phase. The interplay between Heisenberg interaction and DM interaction gives rise to different magnetic properties in spin driven multiferroics and allows the switching of the electric polarization by external magnetic field. The structural and magnetic characteristics of the bulk sample of Cu_2OSeO_3 prepared through solid state reaction are presented in the present study. The crystal structure of Cu_2OSeO_3 has been found to be in the space group of (P213) as in MnSi. We have investigated phase transition (Figure 1) and critical phenomenon in Cu_2OSeO_3. The critical exponent is found to be very close to 3D Heisenberg Model. Five phases have been observed depending on temperature and applied magnetic field. From detailed experimetal magnetization (M) vs magnetic data at different temperature with the help of Arrott's plots and scaling analysis, it has been found that first order phase transition occurs around A phase (Skyrmions) and second order phase transitions around rest of the phase curves (Figure 2).

Q1-01. Velocity enhancement by synchronization of magnetic domain walls. *A. Hrabec*[1], V. Krizakova[2], S. Pizzini[2], J. Sampaio[1], A. Thiaville[1], S. Rohart[1] and J. Vogel[2] *1. Lab. Physique des Solides, Universite Paris-Sud, Orsay, France; 2. Institut Néel, CNRS, Grenoble, France*

In the presented work we use the physics of synchronization to enhance the velocities of precessing domain walls (DWs) in thin magnetic bilayers. A DW is not a simple interface described only by its position, as dynamics is directly connected to its internal structure via the magnetization angle inside the DW, and they form a set of conjugated coordinates. We use stacks of Pt/Co/Au/Co/Pt which offer a unique way to constructively combine two chiral interactions [1]: the Dzyaloshinskii--Moriya interaction (DMI), whose sign is set by the interface nature [2], and the dipolar field, whose sense is not adjustable [3]. The two DWs have opposite chiralities and can be coupled through the stray field in a manner illustrated in Fig.1(a). Thererefore, the interaction between two oscillators, represented by a pair of chiral DWs, is mediated by a dipolar field which does not only link the position of the walls but also locks their internal structure. The field-induced DW dynamics is investigated by polar Kerr microscopy which allows to distinguish between the cases of a DW present in the bottom, top or both (coupled) layers, respectively. Fig.1(b) shows that the velocities of decoupled DWs in the bottom and top layer are lower than the velocity of coupled walls. This is a direct consequence of the concept shown in Fig.1(a) holding even at higher fields, i.e. when the DWs oscillate implying their synchronization. This is supported by micromagnetic simulations providing an insight into the synchronization mechanism. We show that the properties of the two oscillators can be tuned by an additional in-plane field enabling a variety of states, from entrainment to complete detuning. The present work represents a first experimental realization of a coupled system whose motion can benefit from synchronization [4].

Q1-02. Tuning domain wall velocity with Dzyaloshinskii-Moriya interaction in epitaxial asymmetric trilayers. *F. Ajejas*[4], A. Gudin[4], R. Guerrero[4], D. de Souza Chaves[1], J. Vogel[1], J. Camarero[2], S. Pizzini[1] and P. Perna[4] *1. Institut Néel, CNRS, Grenoble, France; 2. Universidad Autonoma de Madrid & IMDEA Nanoscience, Madrid, Spain; 4. IMDEA NANOSCIENCE, Madrid, Spain*

Domain wall (DW) dynamics in multilayer films with PMA are attracting a lot of attention as carriers of binary information. We will address the issue of domain wall velocity limitations in ultrathin magnetic films in symmetric and non-symmetric stacks. The DW wall speed is in general limited by the breakdown that occurs at the Walker field Hw, beyond which the DW starts precessing and the domain wall velocity drops. This limitation is overcome in asymmetric trilayer systems in which Co is deposited on a heavy metal: in this case the Dzyaloshinskii-Moriya interaction (DMI) favours chiral Néel walls that are more stable against precession [1] [2]. It can be shown that the presence of DMI does not change the DW mobility but increases the Walker field, so that large DMI can promote large speeds. Experimentally, it has been shown that in asymmetric thin layer systems the domain wall speed saturates above the Walker field, which is in general not the case for symmetric samples [3][4]. Using magneto-optical Kerr magnetometry and microscopy, we measured domain wall velocities driven by magnetic field pulses in several epitaxial symmetric and asymmetric trilayers grown by magnetron sputtering on MgO giving rise to materials with different crystallinity and interface quality. Typical samples are Pt/Co/Pt and Pt/Co/M (M=Al, Cu, Ir,) Typical Co thicknesses is 0.6 nm. The main result is that the saturation velocity of the DWs in the Pt/Co/M trilayers is strongly dependent on the nature of the top interface Fig.(1). Since the total magnetisation is approximately constant in the different trilayers, we attribute this variation to the different contribution of the Co/M interfaces to the total DMI strength. The largest saturation velocities (typically 300m/s) are obtained for the samples covered by Al, Cu, or an oxyde, while much smaller velocities (typicaly 100m/s) are obtained for Ir top layer. This tends to indicate that the M/Co (M= Ir) give a DMI contribution of the same sign to that of the Pt/Co interface [5]. On the other hand, we have determinate the sig of the chirality of the DW motion. The presence of an in plane field breaks the symmetry expansion of the DW. Inverting the interfaces change the sign.

In the last decade, magnetic ratchet effect of domain walls has been proposed by several groups as a working principle for spintronic devices like magnetic diodes or shift registers. Indeed, some of the proposed strategies are promising candidates to be seen in the near future in working devices. As an alternative route, we have succeeded in producing and observing magnetic ratchet effects, as well as crossed-ratchet effects, in a ferromagnetic thin film where we have nanopatterned 2D arrays of asymmetric holes in the submicrometric limit for hole sizes. The combination of Kerr microscopy, X-Ray PhotoEmission Electron Microscopy and micromagnetic simulations has allowed a full magnetic characterisation of the domain wall (DW) propagation processes over the whole array and the local DW morphology and pinning at the holes. It is found that the DW dynamics in the submicrometric size limit are governed by the interplay between DW elasticity and half vortex propagation along hole edges: as hole size becomes comparable to DW width, flat DW propagation modes are favoured over kinked DW propagation due to an enhancement of DW stiffness, and pinned DW segments adopt asymmetric configurations related with Nèel DW chirality. Both ratchet and crossed-ratchet effects have been experimentally found, and we propose a new ratchet/inverted-ratchet effect in the submicrometric range driven by magnetic fields and electrical currents [1].

Q1-05. Current-induced domain-wall motion in pinned magnetic wires. *M. Samiepour*[1], H. Corte-León[2], J. Kim[3], K. O'Grady[1], O. Kazakova[4] and A. Hirohata[1] *1. University of York, York, United Kingdom; 2. TQEM, National Physical Laboratory, Teddington, United Kingdom; 3. Physics, University of York, York, United Kingdom; 4. National Physical Laboratory, Teddington, United Kingdom*

In racetrack memory [1] digital data is stored in a series of magnetic domain walls (DWs) in ferromagnetic nanowires. This memory is a solid state device without moving parts and can operate faster than hard disk drives (HDDs). In our previous work [2], we have fabricated a simple pinning scheme for the DWs in straight wires using exchange bias. We have patterned IrMn antiferromagnetic (AF) wires perpendicularly the CoFe ferromagnetic (F) wires. The AF wires induce exchange bias at AF/F crossing points which act as pinning sites. In the racetrack memory [3] having uniform domain wall pin is essential to control the motion of DWs along the nanowires. A vibrating sample magnetometer (VSM, ADE, Model10) was used to characterise an unpatterned continuous film to estimate the pinning strength which exhibits a loop shift of H_{ex}=46 Oe induced by the exchange bias at the CoFe (10nm) / IrMn (5nm) interface [2]. Focused magneto-optical Kerr effect (MOKE) was used to measure local magnetic properties of the FM wires in different devices. These previous results prove that such a structure is ideal for producing DW pins with controlled strength. In this presentation we designed a L-shaped magnetic wire with a round corner with a diameter of 650μm, in which one end of the wire is connected to a diamond shaped pad (1.5 μm square) to inject DW and the other end is a sharp arrow to prevent the nucleation of DW. The scanning electron microscope (SEM) image of device is shown in Figure 1. We observed that exchange bias gives rise to the domain wall pin therefore we used IrMn bars to pin the DW in our new devices. In this study we fabricated a variety of devices with different AF widths between 200 nm and 500 nm deposited on the 500 nm width F layer. We used magnetic force microscopy (MFM), figure 2, to study details of DWs in different states in our nanoscale devices as well as current-induced domain wall displacement.

Q1-06. Fast current-induced domain wall motion in symmetric ferrimagnetic Tb-Co alloy wires. *T.V. Pham*[1,2], B. Do[2], S. Sumi[1] and H. Awano[1] *1. Toyota Technological Institute, Nagoya, Japan; 2. Institute of Materials Science, Vietnam Academy of Science and Technology, Ha Noi, Vietnam*

Current-induced domain wall motion (CIDWM) in magnetic nanowires has been studied extensively in spintronic field for a past decade due to its promising applications for the future memory or logic devices, especially a novel magnetic memory so-called race track memory, where digital data

are stored in magnetic DWs in nanowires [1]. Previous studies showed that the CIDWM driven by spin orbit torques (SOTs) generated at the interface between the heavy metal layer such as Pt and the magnetic layer is more effective than that driven by the conventional spin transfer torques (STTs) originated from transferring angular momentums of spin-polarized conducting electrons to the DW [2-3]. Unlike the conventional STTs that drive the DW in the electron flow direction, the SOTs can drive the DW opposite or the same as the electron flow direction. Up to now, a maximum DW velocity of up to 750 m/s was observed in Co/Ni/Co/Ru (t)/Co/Ni/Co wires with a synthetic antiferromagnetic structure (SAF). Such a high DW velocity can be observed owing to the SAF structure that gives rise to a novel torque associated with the antiferromagnetic exchange coupling field [4]. However, in order to move the DW with this high velocity, the required current density is quite high (J>3×10^{12} A/m^2) that makes high energy consumption and heat to damage the memory device. Nowadays, researchers have been still looking for optimal material structures for realizing a high-speed and low-power magnetic memory based on the CIDWM. Rare-earth-transitional metals (RE-TMs) materials consist of RE sublattices coupled anti-ferromagnetically with TM sublattices. This coupling can induce a negative exchange interaction between the RE-TM sublattices [5], which may also result in moving the DW faster at low current density. Here, we report a fast CIDWM with DW velocity of over 400 m/s at J < 1×10^{12} A/m^2 in RE-TM-based wires with structure of Pt (3 nm)/Tb-Co alloy (6 nm)/Pt(3 nm). Q1-07. Nanoscale magnetic texture modification in Co/Pd multilayer for effective domain wall pinning. *T. Jin*[1], W. Gan[1], D. Kumar[1], F. Tan[1], M. Ranjbar[1], W. Lew[1] and S. Piramanayagam[1] *1. Nanyang Technological University, Singapore*

Widespread use of social media and computing devices is generating huge data. Hard disk drive technology which has helped to store huge information is slowing down [1]. Domain wall memory, wherein the information is stored in nanowires, is believed to replace hard disk drives in the future [2]. To make these devices possible, a precise control of domain wall displacement in nanowires is essential. Domain wall pinning based on topographical notches fabricated by lithography have been studied extensively. However, scaling the domain wall memory to nanoscale dimensions will require better domain wall pinning strategies [3]. In this work, localized modification of magnetic properties in Co/Pd multilayers nanowires by ion implantation has been investigated as a non-topographical approach to form pinning sites. The films were sputtered with the stack of Si (SiO_2)/underlayer (Ta (5 nm)/Cu (5 nm)/Pd (3 nm))/ [Co (0.3 nm)/Pd (0.8 nm)]$_N$ /Capping layer (Ta (5 nm)). Figure 1 show the out-of-plane (OOP) hysteresis loops with different values of N before and after implantation and domain images after ac demagnetization. All the samples show micro-size domains with a strong contrast at the domain walls before implantation. The domains size decreases with the increasing N for unimplanted samples, as shown in Fig.1 (b, e and h). After B^+ implantation, clear changes were observed form the OOP hysteresis loops, as shown in Fig. 1 (a, d and g). And also the domain texture change was observed from Fig. 1 (c, f and i). Domain wall devices of [Co/Pd]$_{10}$, where B^+ implantation was carried out in selected regions through patterned masks, were fabricated using e-beam lithography. Kerr images of the devices at different applied fields show that the domain walls are pinned at the B^+ ion diffused regions, as shown in figure 2. These results demonstrate that localized compositional modification using ion-implantation can pin domain walls.

Q1-08. Domain propagation controlled by homogeneous external magnetic fields in an ultrathin magnetic layer with the Dzyaloshinskii-Moriya interaction. *P. Kuswik*[1], M. Matczak[1], M. Kowacz[2], K. Szuba-Jablonski[3], B. Anastaziak[1] and F. Stobiecki[1] *1. Institute of Molecular Physics Polish Academy of Sciences, Poznan, Poland; 2. Faculty of Technical Physics, Poznan University of Technology, Poznan, Poland; 3. Department of Physics, College of Science, Swansea University, Swansea, United Kingdom*

The Dzyaloshinskii-Moriya interaction (DMI) is currently widely investigated because it introduces an energy term responsible for the chiral spin configuration of domain walls in a thin film [1]. It was also shown that the DMI plays a significant role in the formation of the Néel type domain walls in magnetic thin films with the perpendicular magnetic anisotropy (PMA), which enables the remote control of the propagation of magnetic domains [2]. Here, we study the Au/Co/NiO/Au layered system with PMA, where we found that the DMI forces the Néel domain walls (NDWs) with the clockwise chirality [3,4]. Using specifically designed external magnetic field sequences we created a magnetic domain surrounded by a NDW and move it in a deterministic manner. Movement of the domain was registered with polar magnetooptical Kerr effect (P-MOKE) microscope. It was shown that using combination of magnetic fields applied perpendicularly H_z and in-plane H_x and/or H_y it is possible to propagate the domain over a distance of hundreds of microns in any direction in the sample plane (Fig. 1). Thus, we have demonstrated that the use of magnetic fields oriented along x, y, z coordinates allow to move domains on any chosen route between desired positions, which open a new way to control the domain movement over the

sample surface. This work was supported by the National Science Centre Poland under the SONATA-BIS project (UMO-2015/18/E/ST3/00557).

Q1-09. Elliptical expansion of magnetic domain walls in samples with tilted anisotropy. *A. K G*[1], V. Parakkat[2] and A. P S[1] *1. Department of Physics, Indian Institute of Science, Bangalore, India; 2. Department of Physics, University of Washington, Seattle, WA, United States*

Perpendicularly magnetized ultrathin films with subtle interfacial interactions have revealed very interesting physics of spin-orbit interactions like DMI and are very valuable systems for high-density perpendicular data storage. In order to utilize these systems to achieve higher density and faster read and write time, we must acquire detailed information about the domain wall dynamics and different means of manipulating it. We studied the effect of angular deposition on the symmetry of domain wall propagation in perpendicularly magnetized Pt(4 nm)/Co(0.45 nm)/Pt(1 nm) ultrathin stack grown on SiO_2 substrates. Here, an in-plane asymmetry in the expansion of the reverse domains with the out-of-plane magnetic field was observed when the Co film or the Pt underlayer was grown without substrate rotation. Interestingly, the domains expanded as an ellipse. The velocity along the major and minor axis of the ellipse was studied as a function of out-of-plane field. A control sample prepared with the sample rotation showed circular domains during magnetization reversal with uniform domain wall velocity along different in-plane directions. The eccentricity of a reference (rotated) film turns out to be ~0.1 whereas Cobalt non-rotated film was as high as ~0.85. This is attributed to the in-plane anisotropy in the Co film when grown at an oblique angle. We also carried out detailed velocity measurements which confirmed that the velocity of the domain wall is following the creep dynamics in both major axes and the minor axis of the domain wall structure with different depinning field. The formula for the velocity is given by $v = v_0\exp[-(T_{dep}/T)(H_{dep}/H)^{\mu}]$ ----(1) Where T_{dep} is the depinning temperature, H_{dep} is the depinning field and μ is auniversal constant with valu 1/4. This suggests that there is a non-uniform distribution of H_{dep} in the films grown without rotation compared to the rotated films.

National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan*

The magnetic anisotropy induced spontaneously through the heterojunction has a significant effect for the artificial ferromagnets on a ferroelectric substrate [1, 2], modifying the characteristics of magnetization reversal and domain structure. We investigate the magnetization reversal and magnetic dynamics in the zebra-stripe domain structure formed by the heterojunction between Ni wires and single crystalline lithium niobate $LiNbO_3$ substrate. We fabricate 30-nm-thick Ni wires onto the $LiNbO_3$ substrate by electron-beam lithography and lift-off processing using magnetron sputtering. Here, we measure the magnetoresistance, ferromagnetic resonance and Kerr microscopy to clarify the magnetization dynamics or domain wall displacement in the Ni wires on $LiNbO_3$ substrate. Figure 1 displays the Kerr images under the application of magnetic field. The zebra-stripe domain structures are formed in the Ni wires aligned perpendicular to the OF direction (along X-axis of $LiNbO_3$) of the $LiNbO_3$ substrate. Next, the wire was placed between the center strip-line of the coplanar waveguide comprising Cr/Au conductive strip as schematically illustrated in the inset of Fig. 2. We show the magnetoresisntance (MR) of Ni wires oriented (i) parallel and (ii) perpendicular to the OF direction in Fig. 2, respectively. Here, an external magnetic field was always applied parallel to the longitudinal axis of the Ni wire in plane. The MR results are in good agreement with the Kerr microscopy observations and micromagnetic simulation including additional magnetic anisotropy from the heterojunction.

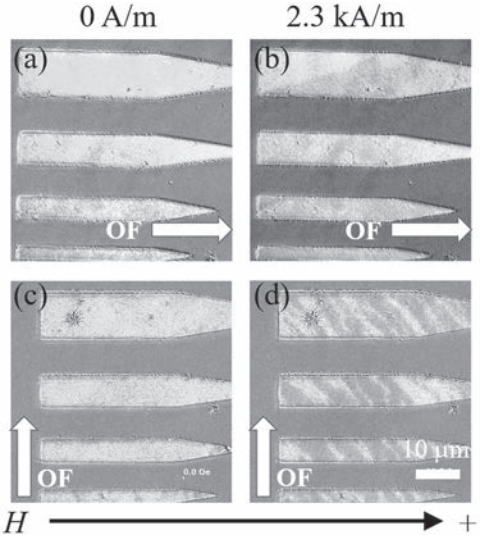

Figure 1 Kerr microscope images of 30-nm-thick Ni wires aligned (a) (b) parallel and (c)(d) perpendicular to the OF direction of $LiNbO_3$ substrate. An external magnetic fields of (a)(c) 0 and (b)(d) 2.3 kA/m are applied parallel to the longitudinal axes of the wires.

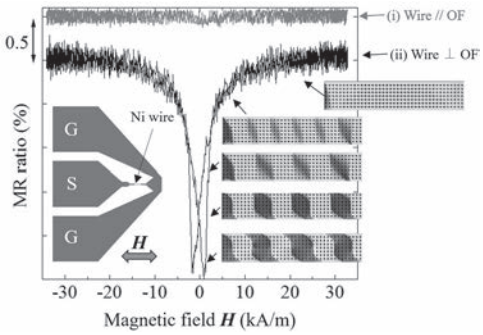

Figure 2 Magnetoresistance (MR) ratios of Ni wires oriented (i) parallel and (ii) perpendicular to the OF direction of the $LiNbO_3$ substrate are shown. The insets show the schematic of measurement system consisting of Ni wire placed on the center strip line of coplanar waveguide and micromagnetic simulation results.

Q1-11. Tailoring magnetization reversal modes by curvature in thin magnetic slabs. *R.M. Corona*[1,4], S. Castillo-Sepulveda[2,4], P. Landeros[3,4] and D. Altbir[1,4] *1. Departamento de Física, Universidad de Santiago de Chile, Region Metropolitana, Chile; 2. Universidad Autónoma de Chile, Santiago, Chile; 3. Fisica, Universidad Tecnica Federico Santa Maria, Valparaiso, Chile; 4. Center for the Development of Nanoscience and Nanotechnology, Santiago, Chile*

In the last years, a strong interest has been focused on the properties of curved magnetic structures [1-2]. An important aspect of these systems is the possibility of controlling the magnetic behavior at the nanoscale by changing the curvature, something that opens new possibilities for the fabrication of new devices. From the theoretical side, this interest has been reinforced by the development of a function that allows calculating the exchange energy of nanomagnets with arbitrary shapes [3-4]. And from the experimental side, curvature changes of magnetic properties in cylindrically curved magnetic segments with different radii of curvature were addressed by Streuble et al. [5]. Authors conclude that such geometric decrease magnetostatic interactions allowing higher areal density when used for racetrack memory devices. In this work, we studied the magnetization reversal as a function of curvature. Mainly transversal and vortex-like domain walls (DW) are responsible for the magnetization reversal. Using a theoretical formalism, we obtain a phase diagram for the DW mechanism as a function of curvature.

Q1-12. Racetrack Memory with Continuous Loop Built from Ferromagnets of Metal and Insulator. *S. Honda*[1,2], T. Yae[1] and T. Ohsawa[3] *1. Department of Pure and Applied Physics, Kansai University, Suita, Japan; 2. Center for Spintronics Research Network, Osaka University, Toyonaka, Japan; 3. Department of Electrical and Electronics Engineering, Numazu National College of Technology, Numazu, Japan*

In a racetrack memory (RM) the magnetic domains are used for binary digits [1]. The magnetic domains are moved by a spin-transfer torque from a spin-polarized current (STT). By the realization of the RM with a continuous loop, it is expected to increase the integration and the access speed to the bit near the edges of a ferromagnetic metal (FM) wire. However, it is difficult to generate a loop current in the RM with a continuous loop. In this study, we suggest the RM with a continuous loop built from the lateral nanowire of ferromagnetic insulator (FI) and FM junction as shown in Fig. 1 and demonstrate the movement of the magnetic domains in the FI and the FM using the micromagnetic simulation based on the Landau–Lifshitz equation with the STT term. We considered the straight wire of FM/ FI/ FM lateral junction structure, which was assumed the structure near the FI in Fig.1. The magnetic parameters of FM and FI were set to the parameter based on our previous study [2]. We put the FI into a region without the STT. We employ a magnetic skyrmion bubble domain as the magnetic domain. Figure 2 shows the simulation result in the wire with the thickness of 5 nm and the FI length of 20 nm. The skyrmion located in the FM of the left-hand side was moved in the right-hand direction by the STT. After arriving at the FI, the skyrmion went through the FI while changing its shape. And then the skyrmion passed through the FI and moved in right-direction while returning its shape to the original shape. The skyrmion was able to pass through the FI by the STT in the FM. When its diameter was enough larger than the FI length, the skyrmion went through the FI at the approximately same velocity and shape as the motion in the FM. However, the velocity of the skyrmion while going the FI decreased with increasing the FI length, and the skyrmion stopped in the FI when its diameter was shorter than FI length.

Q2-01. Ferromagnetic resonance equation expressed by anisotropy fields and its application to an axis in hexagonal-crystal *c*-plane.
O. Kohmoto[1] and Y. Matsushima[2] *1. Resona Laboratory, Ina, Japan; 2. Physics, Okayama University, Okayama, Japan*

Many incorrect ferromagnetic-resonance equations have been appearing in the literature because the equations derived by using the anisotropy fields are not completely established. Anisotropy fields (H_a) were introduced in the equation by Morrish [1] because the Kittel theory had not been completed [2]. Morrish used three H_a values along the *x*-, *y*- and *z*-axes and these expressions were modified by Ohta [3]. The Ohta equation for a sphere is $\omega=\gamma[(H+H_{az}-H_{ay})(H+H_{az}-H_{ax})]^{1/2}$ (1) A formulation by Chikazumi used one H_a value [4]. Recently, Celinski *et al.* presented a resonance equation by using one H_a value, including the demagnetizing factors, as [5] $\omega=\gamma\{[H+H_a+(N_x-N_z)M_s][H+H_a+(N_y-N_z)M_s]\}^{1/2}$ (2) Presented in this paper is the derivation of a new equation using two H_a values along the *z*-axis derived from the effective demagnetizing factors. The static field H is set along the *z*-axis. The effective demagnetizing factors (N_x^e, N_y^e) are simplified as [6] $N_x^e=(1/M_s^2\sin\varepsilon)[(\partial G/\partial\theta)_{\theta=\varepsilon}-(\partial G/\partial\theta)_{\theta=0}]_{\phi=0}$ (3) $N_y^e=(1/M_s^2\sin\varepsilon)[(\partial G/\partial\theta)_{\theta=\varepsilon}-(\partial G/\partial\theta)_{\theta=0}]_{\phi=\pi/2}$ (4) where G is the magnetocrystalline energy and ε is the small angle measured from the zenith. Equations (3) and (4) are modified to obtain a resonance equation as $\omega=\gamma\{[H+H_a^{zx}+(N_x-N_z)M_s][H+H_a^{zy}+(N_y-N_z)M_s]\}^{1/2}$ (5) where H_a^{zx} and H_a^{zy} are anisotropy fields along the *z*-axis when M is slightly declined to the *x*- and *y*-axes, respectively. The equation can be applied to a hexagonal-crystal *c*-plane. The *c*-axis and the static field are set along the *x*-axis and *z*-axis, respectively, as shown in Fig. 1. The angular change of the anisotropy field is $H_a=-[(2K_{u1}/M_s)+(4K_{u2}/M_s)]\cos^2\phi$ (6) where ϕ is the azimuthal angle. Then $H_a^{zx}=-2K_{u1}/M_s-4K_{u2}/M_s$ at $\phi=0$ and $H_a^{zy}=0$ at $\phi=\pi/2$. Therefore, the resonance equation for a sphere is $\omega=\gamma\{[H-2K_{u1}/M_s-4K_{u2}/M_s]H\}^{1/2}$ (7) The above equation including the K_{u2} term is rarely seen in the literature [1,3,4,5]. Equation (7) cannot be derived from Eq. (2) having one H_a term. Also, it cannot be derived from Eq. (1) having three H_a values along the *x*-, *y*- and *z*-axes because $H_{ax}=2K_{u1}/M_s$. Note that the magnetization precesses around the *z*-axis and the motion is influenced by only the H_a along the *z*-axis.

Q2-02. Controlled splitting of ferromagnetic resonance in 1-D modulated magnonic crystals. *P.N. Sherpa*[1], S. Khanal[1] and L. Spinu[1] *1. AMRI/ Physics, University of New Orleans, New Orleans, LA, United States*

Various novel studies and the possibility of using patterned magnetic nanostructures in current & future technologies have triggered an intensive research in the field of Spintronics over the last few decades. Magnetic memories, microwave filters, magnonic logic devices, on-chip data communication are few of the examples where these patterned magnetic structures have shown enormous potentials. In this study, we consider a slab of a thin film with a periodically modulated surface. Multiple samples with a varying periodicity modulation were fabricated using a top-down approach. Periodic grooves with fix thickness were created by etching a slab of a thin film from the surface. The width of the grooves was varied to creates a spatial variation in the internal magnetic field and boundary conditions whose effects can be studied through the static and dynamic properties of the sample. Angular variation of ferromagnetic resonance provided even more in-depth nature of the resonance modes. Through micromagnetic simulation of experimental structure, modes such as Backward Volume Magnetostatic (BVM) and Damon-Esbach (DV) were also identified. In this study, the width of the groove (a) was varied which increased the distance between each consecutive hill. Four different samples were created by varying the parameter a: S1 (a = 1500nm), S2 (a=1000nm), S3 (a=500nm) and S4(a=200nm). Standard MOKE technique was used to study the static properties of the sample. The experimental results thus collected are presented in figure 1. In sample S1, each hill is separated by a significant distance (a=1500nm). This allows each hill to act as a single nanowire sample which produces a distinct square shaped MHL response. But as we decrease the distance between the hills (a), we see more interference from the neighboring hills which decreases the overall coercivity and smooths the magnetization switching process. The standard VNA-FMR method was used to study the dynamic properties of the sample at room temperature. To better understand this peculiarity micro-

magnetic simulations were also performed with Mumax on LONI Queen Bee Supercluster.

Q2-03. Thickness dependent static and dynamic properties of Co_2MnGa Heusler films. *P. Swekis*[1,2], A. Markou[1], Y. Chen[1], S. Klingler[3,4], M. Weiler[3,4], S.T. Gönnenwein[2] and C. Felser[1] *1. Solid State Chemistry, Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 2. TU Dresden, Dresden, Germany; 3. Technical University of Munich, Munich, Germany; 4. Walther Meißner Institute, Munich, Germany*

Co-based Heusler compounds are a widely studied class of materials in particular for spintronic applications due to a number of magnetic and electronic properties, such as high spin polarization and elevated Curie temperatures [1]. In particular, the interest in the Co_2MnGa compound rose recently due to the theoretically predicted large anomalous Hall Effect [2] originating from Weyl points close to the Fermi energy, suggesting an interplay between magnetism and topology [3]. To utilize this material for spintronic applications, it is necessary to characterize the properties in relevant dimensions and structures, such as thin films. In this sense, the orientation dependent dynamic response to gigahertz frequencies becomes particularly interesting. Here, we characterized the magnetic properties Co_2MnGa films, deposited by magnetron sputtering on MgO [001], with various thicknesses (10-80 nm). In particular, ferromagnetic resonance (FMR) experiments were performed in order to determine their damping, g-factor, the effective magnetization and the anisotropy constants. First results show a thickness dependent behavior of all parameters and comparable anisotropies to MBE grown films [4]. Additionally, several characteristics were observed in the resonance behavior, such as additional coinciding resonance modes (Fig. 1) separating with increasing film thickness, magnetic dragging with the applied field along the in-plane easy axis (Fig. 2) and oscillations in the frequency dependent linewidth.

University of Kyiv, Kyiv, Ukraine; 5. Technische Universitet Kaiserslautern, Kaiserslautern, Germany*

Low energy consumption enabled by charge-free information transport, which is free from ohmic heating, and the ability to process phase-encoded data by nanometer-sized interference devices at GHz and THz frequencies are just a few benefits of spin-wave-based technologies. Moreover, when approaching cryogenic temperatures, quantum phenomena in spin-wave systems pave the path towards quantum information processing. In view of these applications, the lifetime of magnons—spin-wave quanta—is of high relevance for the fields of magnonics, magnon spintronics, and quantum

computing. In our study, the relaxation behavior of parametrically excited magnons having wavenumbers from zero up to 5×10^5 rad cm^{-1} was experimentally investigated in the temperature range from 20 K to 340 K in single crystal yttrium iron garnet (YIG) films epitaxially grown on gallium gadolinium garnet (GGG) substrates (Fig. 1) as well as in a bulk YIG crystal—the magnonic materials featuring the lowest magnetic damping known so far. As opposed to the bulk YIG crystal in YIG films we have found a significant increase in the magnon relaxation rate below 150 K—up to 9.5 times the reference value at 340 K—in the entire range of probed wavenumbers. This increase is associated with rare-earth impurities contaminating the YIG samples and with a slight contribution caused by the coupling of spin waves to the spin system of the paramagnetic GGG substrate at the lowest temperatures. In order to sustain a long magnon lifetime, low-temperature magnetic experiments in YIG must be performed in chemically-pure and substrate-free samples. [1] The work is supported by the DFG within the SFB/TR 49.

[1] L. Mihalceanu, et al, (arXiv:1711.07517) (2017)

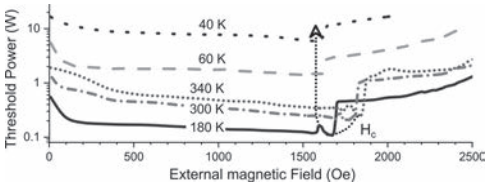

Fig. 1: The shift in threshold power of parametrically pumped magnons is illustrated for a 53 µm thick YIG film on GGG in the temperature range of 40 K to 340 K. An increase of the threshold power relates to an increase in magnon-relaxation time. The dotted arrow indicates the shift of the critical point H_c, close to the ferromagnetic resonance.

Q2-05. Thermal control of the magnon-photon coupling in a notch filter coupled to a yttrium iron garnet/platinum system. *V.M. Castel*[1,2], J. Ben Youssef[3,2], N. Vukadinovic[4], A. Manchec[6], F. Magnon-photon coupling has been investigated in microwave resonators (3D cavity [1] and planar configuration [2]) loaded with a ferrimagnetic insulator such as yttrium iron garnet (YIG). More recently, research groups [1][3] have developed an electrical method to detect magnons coupled with photons. This method has been established by placing a hybrid YIG/platinum (Pt) system into a microwave cavity, showing distinct features not seen in any previous spin-pumping experiment. These latter studies have been realized in a 3D cavity (with high-Q factor), but insertion of a hybrid stack including a highly electrical conductor such as Pt has been reported to induce a drastic enhancement of the intrinsic loss rate. Here, we demonstrate thermal control of the magnon photon coupling at room temperature in a compact design based on a planar resonator (notch filter) resonating at 4.74 GHz and a hybrid YIG (6 µm)/Pt (6 nm) system. The planar configuration of our rf device has a limited Q factor but avoids the negative impact of the YIG/Pt stack. The thermal control of frequencies hybridization at the resonant condition is realized by current-induced Joule heating in the Pt film, which causes an out-of-plane temperature gradient. The effect of the Pt heating, shown in Fig 1, is not only a shift of the resonance (tuning) but also an increased broadening (decoupling) caused by inhomogeneous heating. The device permits us to control the transmission spectra and the magnon-photon coupling strength at room temperature and reveal a potentially applicable tunable microwave filtering function.

Q2-06. Ferromagnetic Resonance Study on Two-dimensional van der Waals Crystals. *X. Shen*[1] and Y. Wu[1] *1. Department of Physics and State Key Laboratory of Surface Physics, Fudan University, Shanghai, China*

Recent interests in two-dimensional ferromagnetic van der Waals Crystals are driven by their rich electronic and optical properties [1, 2], which is of great significance to the development of spintronic applications. It has been reported that the single atomic layer ferromagnetic materials, such as $Cr_2Ge_2Te_6$ and CrI_3, have been realized by magneto-optic Kerr effect. It is clear that further magnetic dynamic studies would provide deeper understanding on the magnetic properties on those two-dimensional ferromagnetic van der Waals materials. In this contribution, we report the results of magnetic resonance of chromium trihalides (CrI_3, $CrBr_3$, and $CrCl_3$) based on a broad band coplanar waveguide in the temperature range of 10K-300K. Through ferromagnetic resonance (FMR) technique, we found that below Curie temperature (Tc), CrI_3 and $CrBr_3$ have strong perpendicular magnetic anisotropy, which decreases with the temperature, and $CrCl_3$ just shows a weak in-plane magnetic anisotropy. For all of these chromium trihalides, the microwave absorption show maxim intensity near Tc. It is surprising that the magnetic resonance signal can be observed far above Tc, and can be observable even near room temperature. All the chromium trihalides show the same dispersion curve with zero magnetic anisotropy above Tc, which can be well fitted by Kittle formula. The FMR above Tc is due to the magnetic moment induced by the applied field, which is confirmed by the SQUID measurements on $CrBr_3$. In addition, the FMR linewidth has the minimum value near Tc, suggesting the lowest damping parameter at Tc. Our studies reveal magnetic dynamics of chromium trihalides crystals, which is important for further understanding the magnetic properties of two-dimensional ferromagnetic materials.

Q2-07. Hybridizing Ferromagnetic Magnons to Microwave Photons in planar hybrid inverted split-ring resonator/YIG film system. B. Bhoi[1], B. Kim[1], J. Kim[1], Y. Cho[1] and *S. Kim[1] 1. Department of Materials Science and Engineering, Seoul National University, Seoul, The Republic of Korea*

The study of light-matter interaction is a central subject in photonics and quantum-information technology. In particular, the coupling of microwave photons to magnons has received much attention due to its potential applications in coherent information storage [1-3]. In the present study, using a planar hybrid system of an inverted split-ring resonator (ISRR) and a YIG film, we experimentally demonstrated strong anti-crossing effects of the ISRR's photon mode and YIG's magnon modes with an effective photon-magnon coupling strength ($g_{eff}/2\pi$) of 90 MHz at a microwave frequency (f) of 3.79 GHz [4]. The spin-number-normalized coupling strength was determined to be $g_{eff}/2\pi\sqrt{N} = 0.194$ Hz, higher than those reported so far, which highlights the system's great potential for quantum information processing. Furthermore, we found that $g_{eff}/2\pi$ can be increased up to 64 % simply by changing ϕ from 90° to 0°, where ϕ is the angle between the in-plane magnetic field (H) and the transverse direction of the device. Additionally, we observed, in the anti-crossing region, fine features originated from the excitation of magnetostatic surface waves (MSSWs) and backward-volume magnetostatic waves (BVMSWs). In order to elucidate the underlying physics, the experiment was further extended by performing fine scan measurements which reveal a set of well-defined anti-crossing effects to the right (left) side of the fundamental Kittel mode as ϕ was changed from 0° to 30° (30° to 90°). Also, the number of anti-crossings gradually decreased as ϕ deviated from both 0° and 90°. This result demonstrates coherent magnon-photon coupling for BVMSW modes ($0 \leqq \phi \leqq 30°$) and MSSW modes ($30° \leqq \phi \leqq 90°$) as well as for Kittel modes. Using the coupled oscillator model, the coupling strength corresponding to each specific spin-wave mode was found to decrease with the mode index. Our experimental results pave the way for the design of new types of high-gain magnon-photon coupling systems in planar geometry and also establish a new approach to the exploration of magnetostatic modes in magnetic systems. Such multi-mode coupling is very interesting aspects for signal processing, magnon conversion, and quantum memory.

Q2-08. Level Attraction and Synchronization in Hybridized Magnon-Photon Systems. *M. Harder[1]**, Y. Yang[2,1], B. Yao[2], C. Yu[1,3], Y. Gui[1] and C. Hu[1] *1. Department of Physics and Astronomy, University of Manitoba, Winnipeg, MB, Canada; 2. State Key Laboratory of Infrared Physics, Chinese Academy of Sciences, Shanghai, China; 3. Nantong University, Nantong, China*

Recent observations of spin-photon hybridization have spawned the actively growing field of cavity spintronics. Interest in this emerging domain has come from both the quantum information and spintronics communities, the former inspired by the potential for enhanced coherence rates in ferromagnetic systems [1] and the latter motivated by new avenues for spin current control offered by hybridization [2]. Indeed great strides have already been made on both fronts, with, for example, the appearance of novel memory architectures, microwave to optical conversion techniques and the demonstration of non local spin current manipulation. These myriad achievements are all founded on the physics of level repulsion due to electrodynamic phase correlation between the spin and photonic subsystems, which is characterized by the emergence of a gap in the eigenspectrum [3]. However, analogue systems in cavity optomechanics and atomic physics have shown that another form of hybridization, level attraction, also exists. The physics of level attraction is deeply connected to the physical ideas of exceptional points, PT symmetry and synchronization. Moreover, the relationship between level attraction and negative energy modes has been studied in the context of evading quantum measurement back action. In this work we present the first experimental observation of level attraction in a coupled spin-photon system. We demonstrate that this new form of hybridization is characterized by synchronization of the hybridized modes, which occurs independently of dissipation or coupling rates. Furthermore we present a versatile platform where continuous in-situ tuning between level attraction and level repulsion is realized. Our spin-photon system therefore enables the general study of new hybridization states which exist between the two limiting cases of level repulsion and level attraction. In addition, our discovery of level attraction in hybridized magnon-photon systems paves a new path for utilizing light-matter coupling in cavity spintronic and quantum magnonic applications.

Q2-09. Pulsed Versus Forced Excitation Of Magnetization Dynamics by Laser Pulses or Surface Acoustic Waves. P. Kuszewski[1,2], *L. Thevenard[1,2]*, S. Shihab[1,2], M. Kraimia[1,3], L. Becerra[1,2], A. Lemaître[4], J. Duquesne[1,2] and C. Gourdon[1,2] *1. Institut des NanoSciences de Paris, Sorbonne Université, Paris, France; 2. CNRS, Paris, France; 3. Laboratoire de Physique des Matériaux: Structure et Propriétés, Faculté des Sciences de Bizerte, Bizerte, Tunisia; 4. Centre de Nanoscience et Nanotechnologie, CNRS, Université Paris-Saclay, Marcoussis, France*

Given the potential of spin waves for applications a number of studies have focused on their excitation and detection in the recent years. Magnetization dynamics has hence been triggered by various stimuli, including ultrashort laser pulses [1] and more recently continuous surface acoustic waves (SAW) (in magnetostrictive materials) [2, 3]. In the low amplitude regime laser pulses and SAW exemplify pulsed (broad band) and forced (monochromatic) excitation of a linear 2D oscillator, respectively. In the latter case the oscillator frequency can be tuned down across the frequency of the SAW by applying a magnetic field along the hard magnetic axis. We focus on time-resolved optically detected magnetization dynamics triggered by these two stimuli. Probe laser pulses are phase-locked to either pump laser pulses or to SAWs, which are generated by interdigitated transducers at harmonics of the laser frequency [4]. We present results on the archetypal ferromagnetic semiconductor GaMnAs. Its anisotropy being temperature and strain dependent can be advantageously engineered for magnetization precession to be launched efficiently by either stimuli [1]. Moreover, the existence of both polar Kerr effect and linear magnetic dichroism enables the reconstruction of the full magnetization trajectory [5], and in the case of SAW excitation, the disentanglement of acousto- and magneto-optical signals [4]. For both laser pulse and SAW excitations we show experimentally and theoretically the efficiency of the exciting torques, the field dependence of the precession, and the 3D magnetization trajectory. In particular the ellipticity of the trajectory is found to be much smaller for forced excitation far from resonance than for pulsed excitation (Fig. 1). Whereas time-resolved precession dynamics in principle provides information equivalent to frequency domain experiments, i.e. SAW ferromagnetic resonance [2], we show that it provides additional valuable information like a clear signature of the onset of the non-linear precession regime [3].

Q2-10. Stroboscopic imaging of spin waves induced by SAW. *B. Casals*[1], N. Statuto[2], J. Hernandez Ferras[2], R. Cichelero[1], A. Hernández-Mínguez[3], L. Aballe[4], M. Foerster[4] and F. Macià[1] *1. Magnetic Materials and Functional Oxides, ICMAB-CSIC, Bellaterra, Spain; 2. Condensed Matter Physics Department, University of Barcelona, Barcelona, Spain; 3. Paul-Drude-Institut für Festkörperelektronik, Berlin, Germany; 4. ALBA Synchrotron Light Facility, Cerdanyola del Vallès, Spain*

In this talk we will show stroboscopic images of large angle precessing spin waves over areas of a few millimeters generated through strain waves. Surface acoustic waves (SAWs) are propagating strain waves that can be generated through oscillating electric fields at the surface of piezoelectric material. Thus, using SAWs might offer an efficient means of controlling not only static states of magnetization but also dynamical magnetization states such as spin waves. Indeed, recent studies have demonstrated that magnetic states can be dynamically changed at the SAWs frequencies (GHz) [1]. Moreover, SAWs have been used for detecting ferromagnetic resonances and for spin pumping [2, 3]. Here we report an experimental study on Photo-emission electron microscopy (PEEM) that images the magnetization dynamics in ferromagnetic thin films of Ni deposited directly onto a piezoelectric material ($LiNbO_3$) capable to produce directional SAW. Being able to synchronize the SAW with the synchrotron repetition rate allow us to acquire instant images of the magnetization and at the same time of the SAWs strain distribution. By exciting at different SAW frequencies (100 MHz -1 GHz) we have observed SAW induced spin waves (see figure) of different wavelength propagating on a large area of a few millimeters. Our work provides interesting perspectives for developing magnonic devices.

Q2-11. Microwave resonance of micrometer sized uniaxial chiral helimagnetic crystals. *F. Goncalves*[1,2], Y. Shimamoto[1], T. Sogo[1], Y. Kousaka[4,2], K. Inoue[3,2] and Y. Togawa[1,2] *1. Department of Physics and Electronics, Osaka Prefecture University, Osaka, Japan; 2. Chirality Research Centre, Hiroshima University, Hiroshima, Japan; 3. Chemistry, Hiroshima University, Higashihiroshima, Japan; 4. School of Science, Okayama University, Okayama, Japan*

In a magnetic crystal with structural chirality, the chiral spin soliton lattice (CSL) emerges as the ground state when a magnetic field is applied perpendicular to the helical axis (Fig.1 (a)). The CSL consists of nonlinear periodic arrays of 2π domain walls and exhibits phase coherence over macroscopic length scale [1]. Materials with such properties are excellent candidates for spintronics and microwave applications [2,3,4] as the CSL phase may be seen as a 'naturally' occurring nanostructured system whose spin texture is reconfigurable whilst topologically protected by the crystalline structure [5,6]. In this context, it is very important to examine the suitability of the CSL as a means to control absorption and propagation of electromagnetic waves. We report broadband frequency magnetic resonance measurements of micrometer sized crystals of the chiral uniaxial helimagnet $CrNb_3S_6$. The resonance behaviour is examined in two distinct microwave excitation configurations: (I) where the helical axis (*c*-axis) is parallel to the in-plane microwave field (h_{MW}) and (II) where the *c*-axis is perpendicular to h_{MW}, as illustrated in Fig.1 (b)-(c). On both (I) and (II) the static magnetic field *H* is set perpendicular to the *c*-axis. Remarkably, a clear difference in the resonance frequency is found in the CSL phase ($H < H_C$) between configurations (I) and (II), showing that the resonance strongly depends on the orientation of the driving microwave field with regards to the *c*-axis [7]. This effect is observed in frequencies ranging from 15 to 22 GHz and is stable over the entire CSL phase. A comprehensive study on the effect of the sample size on the resonance of the CSL is presented to demonstrate the degree of tunability of the overall resonance behaviour. Our results may contribute to the development of novel microwave based signal processing and filtering devices.

Q3-01. Weak ferromagnetism of $(Fe_{1-x}Ni_x)Si$ with B20 Structure.
T. Tsutaoka[1], K. Ueda[1] and K. Kaneshige[1] *1. Graduate School of Education, Hiroshima University, Higashi-Hiroshima, Japan*

The transition metal monosilicide FeSi crystalizes in the cubic B20 structure with the space group $P2_13$ [1]. Meanwhile, NiSi is stable in the MnP-type B31 structure with the space group *Pnma* [2]. The Co doped $(Fe_{1-x}Co_x)Si$ has helimagnetic order and skyrmion lattice has been discovered [3]. In this study, the polycrystalline samples of Ni doped $(Fe_{1-x}Ni_x)Si$ (x=0-0.5) were prepared and magnetic and electrical properties have been investigated. Polycrystalline ingots were prepared by arc-melting the constituent elements of 4N Fe, Ni and 6N Si in high purity argon atmosphere using a tri-arc furnace. Powder X-ray diffraction (XRD) indicated the all samples were in single phase with the B20 cubic structure. The magnetic and electrical resistivity measurements were performed using a SQUID magnetometer and conventional four-terminal method. Magnetization curves of $(Fe_{1-x}Ni_x)Si$ at 2k are shown in Fig.1. FeNi compound shows weak ferromagnetic property; the magnetization value shows 0.07 m_B/f.u at 50 kOe. By the substitution of Fe by Ni, magnetization is suppressed; ferromagnetic property is maintained at x = 0.5. This weak ferromagnetic property can be attributed to the Dzyaloshinskii-Moriya interaction between Fe magnetic moments. The temperature variation of magnetic susceptibility in the paramagnetic state does not obey the Curie-Weiss law. Curie temperatures T_C determined from the χ -T curves locates below 4.0 K. The electrical resistivity ρ of $(Fe_{1-x}Ni_x)Si$ is shown in Fig. 2 as a function of temperature. At x = 0, the *r* increases with decreasing temperature indicating a semiconductive property. With increasing x, the *r* is substantially suppressed; a metallic property can be seen at x = 0.4 and 0.5. This property has been reported in $(Fe_{1-x}Ir_x)Si$ system, too [4].

Q3-02. Transport Properties of Heusler Compounds $Fe_{3-x}Mn_xSi$ (x=1.6, 1.7, and 1.8) under the Magnetic fields.
R. Kato[1], T. Nonoyama[1], R. Ooka[1], I. Shigeta[1] and M. Hiroi[1] *1. Department of Physics and Astronomy, Graduate School of Science and Engineering, Kagoshima University, Kagoshima, Japan*

The Heusler compound Fe_2MnSi is predicted to be a half-metal based on first-principles band structure calculations; a half-metal has 100 % spin-polarized conduction electrons. [1] In reality Fe_2MnSi exhibits a ferromagnetic transition at T_C~230K and an antiferromagnetic (AF) transition at T_A~ 60K, and is not a half-metal.[2,3] A recent study revealed that $Fe_{1.3}Mn_{1.7}Si$ exhibits, in addition to the transitions at T_C~85K and T_A~67K, another AF transition at T_{A2} ($T_{A2} < T_A$) at low magnetic fields; the phase below T_{A2} will be referred to as the AF2 phase and the one for $T_{A2} \le T \le T_A$ as the AF phase.[4] In previous studies, in the temperature dependence of the electrical resistivity in zero magnetic field, clear changes at T_C and T_A in $Fe_{3-x}Mn_xSi$ were observed[2,3]. So we perform measurements of electrical resistivity, magnetoresistance (MR), and Hall-effect for $Fe_{3-x}Mn_xSi$ (x=1.6, 1.7, and 1.8) to investigate the properties of the AF2 phase and the transition under magnetic fields. Figure 1 shows the results of the MR ratio, $\Delta\rho(B)/\rho_0 = (\rho(B) - \rho_0)/\rho_0$, at different temperatures for $Fe_{1.3}Mn_{1.7}Si$, where $\rho(B)$ is the resistivity at a magnetic field of B and ρ_0 is that at 0 T. As seen in Fig.1, at low magnetic fields we observed the point where the MR effect changes from positive to negative one, which is indicated by the arrow in the figure. In Fig.2 the points thus determined are plotted in the B-T phase diagram. In this figure T_{A2} obtained from the temperature dependence of the magnetization $M(T)$ at different B is also shown.[5] These points basically coincide with each other. Hence we could estimate the AF2- AF transitions for x=1.7 from the MR measurement. Although similar results were obtained for x=1.8, the AF2-AF transition shifts toward high magnetic field. An anomalous Hall-effect was observed for x=1.6 and 1.7 but not for x=1.8. This result is consistent with that of magnetization measurements which shows the disappearance of the ferromagnetic transition for x=1.8.[5]

Q3-03. Fe doping effects on the anomalous specific heat and XAFS oscillation in antiferromagnetic metal of Mn_3Si. *H. Hiraka*[1], K. Ohoyama[2], M. Kosaka[3] and D. Matsumura[4] *1. Radiation Science, Korea Atomic Energy Research Institute, Daejeon, The Republic of Korea; 2. Ibaraki University, Hitachi, Japan; 3. Saitama University, Saitama, Japan; 4. Japan Atomic Energy Agency, Hyogo, Japan*

Heusler-type intermetallic compound Mn_3Si is regarded as a potential half-metallic antiferromagnet for spintronics technology. Also, from scientific viewpoints, it exhibits intriguing physical properties: the relatively large $\gamma \sim 70$ mJ K^{-2} mol^{-1}, the specific heat and magnetic susceptibility insusceptible to magnetic fields (> 10 T) [1], the large Weiss temperature ($\Theta \sim -650$ K) as compared with $T_N = 21$ K, etc. The mechanism of these properties has not been elucidated yet. In order to get a clue to understand the novel features, we first investigated Fe doping effects on the specific heat using single crystals of $Mn_{3-x}Si_x$ with $x = 0.2$ ($T_N = 21$ K) and 1.0 (45 K). The large γ of $x = 0.2$ decreased considerably for $x = 1.0$. However, the net entropy plotted as a function of the reduced temperature by T_N was almost unchanged between the two; this result is consistent to nearly the same magnitudes of magnetic moments for the two compounds. The spin degree of freedom is possible to contribute to the characteristic γ. In addition, we measured Mn *K*-edge XAFS spectra of powder crystals with $x = 0$, 0.6, 1.0, and 1.5 to explore the local structure around Mn. Unexpectedly, for $x = 0$, the fine structure in XANES was substantially suppressed and, at the same time, the EXAFS oscillation became quite smooth. Normal XAFS spectra appeared when the amount of Fe dopant increased. Although we have no clear explanation for this anomalous XAFS of $x = 0$, the Fe doping dependence looks common to that of the specific heat. In our presentation, we will discuss a relationship between the the bulk magnetic properties and the microscopic local structure, and a possible spin-lattice coupling in this antiferromagnetic metal.

Q3-04. Magnetic properties of perovskite $Ca_{1-x}Sr_xFeO_3$. *H. Kawanaka*[1], E. Kawawa[2], F. Iga[4], A. Kondo[3], K. Kindo[3] and Y. Matsuda[3] *1. Electronics and Photonics Research Institute, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; 2. Graduate School Science and Engineering, Ibaraki University, Mito, Japan; 3. Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan; 4. Faculty of Science, Ibaraki University, Mito, Japan*

We synthesized $Ca_{1-x}Sr_xFeO_3$ containing Fe^{4+} with high valence by low temperature heat treatment with the ozone oxidization. We investigated the magnetic properties of perovskite $Ca_{1-x}Sr_xFeO_3$ superconducting quantum interference device magnetometry, and high magnetic field measurements with a pulse magnet, respectively. Metamagnetic transitions with hysteresis were observed in the magnetization curves for all compositions. Generally, perovskite iron oxides with the formula of $AFeO_3$ (A : Sr or Ca) contain high-valence Fe^{4+} [1,2]. $SrFeO_3$ has a perovskite cubic lattice structure and displays metallic conductivity. The magnetic structure of $SrFeO_3$ has helical magnetic order. The proper screw spin order of $SrFeO_3$ has the propagation vector q along the <111> surface below 134 K. The spiral spin order on the same surface has a ferromagnetic interaction. The angle between the spins of adjacent planes is 40° [3]. Ishiwata et al.[4] investigated the magnetization of $SrFeO_3$ under a high magnetic field (42 T). The saturated magnetic moment was observed at 38 T, with a value of 3.5 μ_B. In contrast, $CaFeO_3$ has a perovskite-type orthorhombic structure with $GdFeO_3$ lattice distortion. $CaFeO_3$ shows metallic conductivity above 290 K, and acts as an insulator below 290 K. In other words, the metal–insulator transition of $CaFeO_3$ takes place at 290 K, at which point its structure changes from orthorhombic (Pbnm) to monoclinic (P21/n) [5]. Alloys of $Ca_{1-x}Sr_xFeO_3$ containing Fe^{4+} with unusual valence have been synthesized under high oxygen pressure and their resistivity and magnetism have been investigated[6]. Interestingly, the resistivity of $Ca_{1-x}Sr_xFeO_3$ decreases as Ca in $CaFeO_3$ is substituted for Sr (i.e., as the Sr content increases), but this behavior change occurs between $x = 0.4$ and $x = 0.5$. That is to say, this composition region displays abnormal behavior. Here we report the preparation of $Ca_{1-x}Sr_xFeO_3$ using the ozone oxidation method, which allows samples to be prepared more easily than by high pressure synthesis. We performed to observe the magnetization process of $Ca_{1-x}Sr_xFeO_3$ under strong magnetic fields (60, 100 T). Therefore, we also clarify the electronic state of Fe in the magnetization process of $Ca_{1-x}Sr_xFeO_3$.

Q3-06. The substitution effect on itinerant ferromagnetism in CrAlGe with an orthorhombic $TiSi_2$-type structure. *H. Masumitsu*[1], S. Yoshinaga[1], Y. Mitsui[1], R.Y. Umetsu[2], M. Hiroi[1], Y. Uwatoko[3] and K. Koyama[1]
1. Kagoshima University, Kagoshima, Japan; 2. Tohoku Universty, Sendai, Japan; 3. Institute for Solid State Physics, University of Tokyo, Kashiwa, Japan

Cr-based ternary compound CrAlGe with an orthorhombic $TiSi_2$-type structure shows ferromagnetism below the Curie temperature T_C of 80 K. The spontaneous magnetization M_s is 0.41 μ_B/f.u. [1]. This compound is classified as a weak itinerant ferromagnet [1]. It was reported that the T_C and M_s decreased by applying hydrostatic pressure [2]. On the other hand, it is also reported that CrAlGe has the coexistence of ferromagnetic and spin glass states [3]. Furthermore, the first principles calculation on CrAlGe suggested that this compound shows the half-metallic properties [4]. In this study, for further investigation for the magnetism of this compound, substitution effects on magnetic properties in CrAlGe were investigated. $Cr_{1-x}TM_xAlGe$ (TM = Ti, V, Mn, Fe, Ni, and Cu) samples were prepared by arc-melting in an argon gas atmosphere. The obtained samples were annealed at 1073 K for 1 day or 2 days and then quenched into iced water. The powder X-ray diffraction (XRD) at room temperature was carried out for characterization of the phase. The magnetization measurement was performed by using superconducting quantum interference device (SQUID) magnetometer. Fig. 1 shows the XRD pattern of $Cr_{1-x}TM_xAlGe$ for TM = Ti, V, Mn and Cu at room temperature. Although the tiny diffraction peaks of impurity phase were confirmed, the main diffraction peaks for TM = Ti, V, Mn, and Cu were indexed by the orthorhombic $TiSi_2$-type structure. It was confirmed that large impurity phases were observed for TM = Fe and Ni. Fig. 2 shows the magnetization curves of $Cr_{1-x}Mn_xAlGe$ measured at 5 K. The curves of $x = 0$ was deduced from Ref. 1. The value of M_s at 5 K was evaluated to be 0.631 μ_B/f.u. and 0.613 μ_B/f.u. for $x = 0.05$ and 0.1 respectively, which were higher than that of CrAlGe [1]. In addition T_C also was enhanced by substition of Mn. These behaviors were consistent with our previous results [5]. In the presentation, the itinerancy of the CrAlGe-based alloy will be discussed by Takahashi's spin fluctuation theory.

Q3-07. Change of magnetism in $Mn_{1-x}M_xAlGe$ (M = V, Fe, Cu). *K. Noguchi*[1], H. Masumitsu[1], Y. Mitsui[1], R.Y. Umetsu[2], M. Hiroi[3], Y. Uwatoko[4] and K. Koyama[1] *1. Kagoshima University, Kagoshima, Japan; 2. Tohoku Universty, Sendai, Japan; 3. A pseudo two-dimensional ferromagnet MnAlGe with the tetragonal Cu_2Sb-type structure has Curie temperature T_C of 517 K [1]. Mn atoms with a magnetic moment locate only in the c-plane. It is considered that the compound has the two-dimensional magnetic structure because the Mn-Mn distance along the c-axis is much larger than that in the c-plane. MnAlGe alloy has a uniaxial magnetic anisotropy along c-axis [1]. So far, the substitution effects on MnAlGe have been studied. It was reported that T_C decreased by Fe, Co, and V substitution. On the other hand, the substitution of Cr for Mn enhanced T_C [2]. Quite recently, it was reported that the magnetic moment of Cr was ordered antiparallel to that of Mn and $Mn_{1-x}Cr_xAlGe$ was the ferrimagnetic properties [3]. In this study, for further investigation of magnetism in MnAlGe-based system, $Mn_{1-x}M_xAlGe$ (M = V, Fe, Cu) alloys were prepared. The polycrystalline $Mn_{1-x}M_xAlGe$ with x up to 0.5 were prepared by arc-melting in an argon gas atmosphere. The obtained specimens were annealed at 873 K for 3 days, and subsequently quenched into ice water. Powder X-ray diffraction experiments at room temperature were carried out for the characterization of crystal structure. The magnetization was measured by vibrating sample magnetometer. Fig. 1 shows the saturation magnetization M_S and T_C of $Mn_{1-x}V_xAlGe$. The value of M_S of MnAlGe was 1.40 μ_B/f.u. at room temperature and T_C was 506 K. The M_S monotonically decreased with increasing x. Fig. 2 shows the reciprocal magnetic susceptibility curves. At $x = 0$, the $1/\chi - T$ curve showed linear relationship above T_C. With increasing x, the curve bent, which did not follow the Curie-Weiss law. It was suggested that the substitution by V for Mn in MnAlGe changed the magnetism from ferromagnetism to ferrimagnetic behavior. This behavior is similar to the Cr substitution [3].

Q3-08. Local Spin Moments and Local Environment of Fe in the $Fe_{7-x}Me_xCh_8$ (Me=Ti,V,Co; Ch=S,Se) Compounds: Hard X-ray Emission and Absorption Spectroscopy Study. *A. Svyazhin*[1,2], N. Selezneva[3], N. Baranov[2,3], E. Kurmaev[2], S. Lafuerza[1] and P. Glatzel[1] *1. European Synchrotron Radiation Facility, Grenoble, France; 2. M.N. Mikheev Institute of Metal Physics, Yekaterinburg, Russian Federation; 3. Ural Federal University, Yekaterinburg, Russian Federation*

The $Fe_{7-x}Me_xCh_8$ (Me is a 3d transition element, Ch=S,Se,Te) family of chalcogenides attracts attention because of the close interplay between the structural and magnetic properties. Upon substitution of Fe with Co, the Néel temperature decreases, and the compounds with x>4 are paramagnets [1,2]. This decrease of the T_N is accompanied by gradual reduction of the inter-layer distance. Two physical scenarios were proposed to explain this chemically-induced transition from a magnetically-ordered to a weakly-paramagnetic state: 1) 3d band broadening due to the reduction of the interlayer distance and increased overlapping of 3d orbitals, and 2) high-spin to low-spin transition due to changes in crystal field [3,4]; the dominating mechanism remains unknown. In this work, we address the local spin moments of Fe atoms (m_{Fe}) and the changes of the local structure around them in $Fe_{7-x}Me_xCh_8$ (Me=Ti,V,Co) by means of hard x-ray absorption and emission spectroscopy to understand the key factors driving their magnetic properties. Spectroscopic investigations at the K-edge of iron, including core-to-core (ctc) and valence-to-core (vtc) X-ray emission (XES) and X-ray absorption spectroscopy (XAS-XES), were carried out on beamlines ID20 and ID26 of the ESRF. Based on the analysis of ctc-XES line shapes, m_{Fe} decreases in the $Fe_{7-x}Co_xCh_8$ series but does not collapse at x>4.2, as was suggested before [4]. The lack of long-range magnetic order at x>4.2 can, therefore, be explained by a breakdown of direct long-range Fe-Fe exchange interaction due to removal of Fe atoms. In the whole family of these chalcogenides m_{Fe} increases almost linearly with the inter-layer spacing up to ≈5.7 Å, and saturates above irrespective of the chemical composition and type of chalcogen (see Figure). Analysis of vtc-XES in V-substituted compounds suggests no influence of the crystal field on the size of m_{Fe}. The two latter results suggest that the behavior of m_{Fe} is better described within the itinerant electron model, and the observed reduction of m_{Fe} in $Fe_{7-x}Co_xCh_8$ series occurs due to 3d band broadening.

Q3-09. A model phase diagram for itinerant electron metamagnetic systems. *B. Bernhard*[1] *1. Departamento de Física, Universidade do Estado de Santa Catarina, Joinville, Brazil*

The metamagnetic transition in itinerant electron systems is investigated within the Stoner theory. It was shown in Ref. [1] that, for a simple cubic lattice, the calculated ground state phase diagram and its evolution with temperature are in qualitative agreement with the widelly accepted description based on the Wohlfarth-Rhodes-Shimizu theory, based on a Landau expansion, and supplemented by the Yamada's treatment of spin fluctuations [2]. The microscopic parameters of our model are the bandwidth W and the on-site Coulomb repulsion U. From the analysis of the magnetization isotherms, we obtain the temperature-dependent phase diagram, which exhibits a quantum critical end point as a function of the ratio W/U. In principle, a direct quantitative comparison with experiments in itinerant electron metamagnetic (IEM) systems would require a self-consistent computation using realistic band-structure calculations. On the other hand, one observes that quite good quantitative estimates can be made using a model system with a suitable density of states around the Fermi level. We propose a systematic procedure to make such comparisons with experiments in IEM systems, with emphasis to RCo_2 compounds (where R is a rare-earth element). First, it is important to describe coherently the componds with non-magnetic R=Y,Lu,Sc, comparing their corresponding critical fields and critical temperatures. Next, we investigate the pseudo-binary compounds, $R(Co,Al)_2$, and obtain the corresponding phase diagram as a function of doping. We also discuss briefly a strategy to address the more complex case of magnetic R elements, for R=Dy,Ho,Er, where the presence of local moments has to be included in the model Hamiltonian.

Q4-02. A Study on the Reduction of Cogging Torque for the Skew of a Magnetic Geared Synchronous Motor. I. Jo[1], G. Jeong[2], W. Ji[1], H. Lee[1] and *C. Park*[1] *1. Korea National University of Transportation, Uiwang-si, The Republic of Korea; 2. Electrical Engineering, Hanyang University, Seoul, The Republic of Korea*

The existing drive systems of a railway vehicle are composed of a traction motor, a mechanical reduction gear, and a wheel, which complicate the structure of the drive system and limit the miniaturization and weight reduction of each component [1]. In addition, conventional drive systems have the problems of increased maintenance costs due to mechanical wear and low efficiency due to additional power loss for mechanical gears. Therefore, it is necessary to develop new technology that can improve the power density and maintainability of the output system in the driving systems of the railway. As an alternative to these problems, research on magnetic gears to replace mechanical gears has been carried out variously all over the world. The magnetic geared synchronous motor(MGM), which combines the magnetic gear and the permanent magnet synchronous motor, has a different structure from the conventional electric device. Magnetic gears have no wear and no lubrication since the input and output shafts are physically separated and have no mechanical contact. In addition, the magnetic geared synchronous motor has a high torque density and an advantage that the volume occupied in the axial direction can also be remarkably reduced. However, magnetic geared synchronous motors generally generate cogging torque due to the difference in magnetoresistance between the two rotors and the pole piece during power transmission, unlike other motors [2]. This cogging torque has a great influence on the noise and vibration of the motor. Therefore, the design should be reduced as much as possible. To solve this problem, a method of applying a skew to the motor is used. In this paper, to reduce the cogging torque of a magnetic geared synchronous motor, the models are compared to the cogging torque of a model with skew applied to a pole piece and a model with skew applied to a pole piece and a permanent magnet, and derived the optimum angle and skew model accordingly.

Q4-03. Comparative Study on the Characteristics of Magnetic-geared PMSM for Electric Vehicles according to Gear Ratio Variation. *C. Park*[1] and H. Lee[1] *1. Korea National University of Transportation, Uiwang-si, The Republic of Korea*

Conventional driving system of hybrid electric vehicle (HEV) or electric vehicle(EV) are composed of traction motor, mechanical or magnetic reduction gear, and wheels, so that the structure of the driving system is complicated and there is a limit in reducing the size and weight of each component. In addition, the conventional driving system has problems of increase in maintenance cost due to transmission oil leakage and tooth wear of the ruction gear, and low efficiency due to additional power loss by the mechanical gear. Therefore, it is necessary to develop a new technology that can increase the output power density and maintainability of the conventional system in a driving system for HEV or EV. Currently, research on magnetic gears to replace mechanical reduction gears is being carried out variously all over the world [1]-[3]. Fig. 1 demonstrates the structure of an MG-PMSM system as opposed to a conventional driving system. In this study, the design technique of the MG-PMSM for electric vehicles is examined in the application of the MG-PMSM being structurally integrated with a magnetic gear to the electric vehicle driving system. In designing the MG-PMSM models, this study presents an additional process that allows for the simultaneous design of pole-pieces consisting of the low-speed outer rotor, which is based on the PMSM design process for inner-rotors that apply the loading distribution method, commonly used in traction motors for

electric vehicles. A comparative analysis of the three 1kW-class MG-PMSM models, in terms of electromagnetic properties, is performed to assess their general performance. Fig. 2 shows the cross section of the basic 1kW-class MG-PMSM models designed in this study. 3 models show performance levels that met the design requirements, while Model B had better torque performance than Model A and C. Yet, the magnetic flux density of both models is distributed asymmetrically at the air gaps and the core of the stator, and less than 90 percent of the torque is delivered to the inner rotor.

Q4-04. Influence of DC-Biased Magnetic Induction on Magnetic Property of Silicon Steel. *J. Chen*[1], D. Wang[1], Y. Jiang[1], X. Teng[1] and S. Cheng[1] *1. National Key Laboratory of Science and Technology on Vessel Integrated Power System, Naval University of Engineering, Wuhan, China*

DC-Biased magnetic induction, that is DC and AC field commonly exist in the magnetization. It not only exists in transformers, but also in stator permanent-magnet (PM) motors. It is reported that leads to additional loss. A lot of work was done in recent papers. In 2017, S. Xue wrote that hysteresis loss and the eddy current loss have different characteristics in terms of the influence of dc bias flux density[1]. Although several iron loss models[2-5] consider the effect of DC-biased induction, which are phenomenological models based on pure mathematic fitting and some assumptions without mentioning the physical background[2]. According to original loss separation theory [6, 7], iron loss is divided into static hysteresis, classical eddy current and excess loss. This paper aims to clearly quantify the DC-biased field effect on each of iron loss components. Rather than 1Hz in [1], quasi-static magnetic test based on ballistic method[8] is used to obtain static hysteresis loss due to good repeatability and accuracy. To investigate the classical eddy current loss under DC-biased induction, we directly measure the electrical resistivity of steel. For each grade of steel sheet we insert 8 pieces which are electrically insulated with each other by additional non-conductive layer into Epstein frame. Then we excite the steel by feeding primary winding with DC, AC or DC+AC current, respectively. At the same time, DC current is injected to one of 8 pieces to measure the electrical resistivity of non-oriented(NO) and grain-oriented(GO) steel sheet under magnetic field of different style(DC, AC, DC+AC) and amplitudes. Flux meter is used to deduce the DC magnetic induction of silicon steel when excited with DC field. The influence of DC-biased magnetic induction on excess loss can be figured out by subtracting static hysteresis and eddy current loss from total iron loss. The result shows that all the three kinds of field doesn't influence the electrical resistivity of silicon steel, hysteresis and excess loss are responsible for the iron loss increase, which lays a solid physical foundation for the iron loss modeling with DC biased induction, and eliminates the non-physical assumptions.

Q4-05. Analysis of Magnetization and Demagnetization Characteristics for Spoke-type Permanent Magnet Machine with Rotor Overhang and Non-rare Earth Magnet. *J. Seo*[1] and A. Ro[1] *1. Keti, Yakdae Wonmigu Bucheon, The Republic of Korea*

This study describes the design improvement of a motor for home appliances with non-rare earth permanent magnets (PMs). A spoke-type rotor structure is selected that allows the magnetic flux to be concentrated effectively to overcome the energy deficiency of the ferrite PMs, which is about 15% of the rare earth PMs. It is possible to increase the air gap flux density by increasing the cross sectional area of the PM with respect to the magnetic pole surface even if the outer diameter of the rotor is constant [1]. The shape of the rotor and stator core is improved to meet the required performance at a smaller size, and the driving stability and productivity are ensured through magnetization and demagnetization analysis. The analysis results is verified using the manufactured prototype. The overhang structure is applied to the rotor to minimize the reduction of the air gap flux due to the decrease of the stack length. This structure can further increase the air gap flux density by the increased amount of PMs, thereby improving the flux linkage and output power [2]. According to the results, the PM overhang model generates a EMF equal to or higher than that of the rotor overhang model while reducing the use of electric steel sheet in the rotor core. It is advantageous in terms of reduction of rotor weight and manufacturing cost. Spoke-type PM motors have the advantage of concentrating magnetic flux, but there is a high possibility of incomplete magnetization and irreversible demagnetization of PM [3]. The magnetization test on the manufactured model shows that the performance degradation of PM is insignificant in spite of rotor overhang structure. The analysis of the PM operating point trajectory shows that no irreversible demagnetizations are produced under the condition of low temperature and high load.

Q4-06. Vibration and Acoustic Noise Analysis of Iron-core Reactor under Sinusoidal and PWM Excitations. H. Gao[1], S. Wang[2], Y. Li[1] and *J. Li*[2] *1. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China; 2. State Key Laboratory of Control and Simulation of Power System and Generation Equipments, Tsinghua University, Beijing, China*

I. Abstract The problem of the vibration and noise of the reactor in the power system is becoming more and more prominent. Siemens vibration test analysis platform and LMS software test platform were used to measure the vibration of different positions of the reactor to obtain the vibration and noise spectrum of the reactor, and the modal analysis for the reactor was carried out in this paper. Some data about the vibration and noise of the reactor under sinusoidal and PWM excitation are obtained, which provide research for the vibration and noise reduction of the reactor. II. Introduction Reactors as one kind of magnetic components are widely used in electric power system, series reactor can limit short circuit current, shunt reactor can absorb excess reactive power, and it can act as a filter when installed behind the inverter. Reactors in operation will produce vibration and noise due to the magnetostriction, maxwell force and lorentz force[1]. Different from the transformer, maxwell force occurs in the air gap of the reactor. The vibration and noise of the reactor are also increasingly prominent, especially in the case of high frequency with harmonic[2], the phenomenon of vibration and noise will be very obvious, threatening the safety and stability of operation in equipment and system. III. Conclusion In this paper, the vibration and noise of iron-core reactor under sinusoidal excitation, excitation injecting harmonic content and PWM excitations were tested and analyzed. The base frequency of magnetostrictive causing the vibration is 100 Hz, as shown in Fig. 1, it is found that the vibration of the reactor under sinusoidal excitation are mainly concentrated in the vicinity of integer times of 100 Hz, when the vibration frequency of reactor coincides with the natural frequency of reactor, the vibration of reactor can also cause larger amplitude. As for under the excitation of PWM, as shown in Fig. 2, the vibration frequency of the reactor are mainly concentrated on the switching frequency and the integer times of the switching frequency.

Q4-07. Performance enhancement of Q Factor and inductance of Integrated RF Inductors. *X. Wang*[1], H. Chen[1] and N.X. Sun[1] *1. Electrical and Computer Engineering, Northeastern University, Boston, MA, United States*

Integrated inductor working at GHz frequency range has been widely used in smartphone, wearable devices, wireless communications, etc. For the applications, high-quality factor and density of inductance are needed. High-quality-factor and density of inductance of integrated solenoid inductors were achieved by inserting magnetic materials. From the analysis of inductor model, we find that the thickness of solenoid core thickness and the permeability of the magnetic materials are also critical for inductance and quality factor. Therefore, we report the effect of polyimide thickness on the performance of integrated inductors with solenoid structures. Compared with inductors with 4 μm gap, the inductors with 14 μm thick gap show over 300% and 700% enhancement in inductance and quality factor, respectively. The peak quality factor is as high as 16 at ~1 GHz for inductors with 14 μm thick polyimide, which is the largest value so far for integrated inductors with the air core. Magnetic annealing is used to increase the permeability of magnetic materials. The inductance shows 300% enhancement compared with non-magnetic annealing. These results indicate that by increasing the thickness of via open and magnetic annealing are promising for increasing the quality factor and inductance of inductors.

Q4-08. Comparative Study of Novel Dual Stator Machines Having Different Biased PM Configurations. H. Yang[1], Z. Zhu[2], H. Lin[1] and *S. Lyu*[1] *1. School of Electrical Engineering, Southeast University, Nanjing, China; 2. Department of Electronic and Electrical Engineering, The University of Sheffield, Sheffield, United Kingdom*

I. INTRODUCTION Nowadays, doubling the stator is employed to increase the torque density of the conventional permanent magnet (PM) machines [1]. The dual-stator (DS) stator-PM machine [2]-[4] can facilitate the PM heat dissipation, but also have robust rotor. Nevertheless, the inner and outer stators in the preceding structures are structurally duplicated, resulting in the geometric conflicts between the PM excitations and windings on the stator. This paper aims to propose novel DS biased PM machines (DS-BPMMs) only having interior PM (IPM) and surface-mounted PM (SPM) excitations in the inner stator, which are illustrated in Fig. 1. The proposed machines can be geometrically considered as the synergies of an outer-rotor stator PM machine plus a separate outer stator similar to traditional fractional-slot machines. As a result, the space tradeoff between PM and copper areas are alleviated. II. PERFORMANCE COMPARISON The coil and phase flux linkages of the two machines are shown in Figs. 1 and (c) and (d). The flux linkage of single coil is bipolar for IPM machine, while unipolar for SPM machine. However, the resultant phase flux linkage of SPM structure is bipolar, which is mainly attributed to the opposite connection of armature windings in the same phase. The open-circuit back-EMFs are shown in Fig. 2(a). Obviously, the significantly high EMFs can be observed in the IPM case, which is attributed to its higher phase flux linkage due to its bipolar coil flux linkage. Accordingly, the SPM machine exhibits relatively lower torque capability and higher torque ripple compared to the IPM counterpart as reflected in Fig. 2(b). III. EXPERIMENTAL VALIDATION The IPM configuration is manufactured as shown in Fig. 2(c). The finite element (FE) and measured back-EMF waveforms are shown in Fig. 2(d), in which the good agreement between FE and test results is achieved. The design considerations and experimental validation will be presented in the full paper.

Q4-09. Optimized Design of High Speed, High Power Motor for Four-Legged Robot Actuator Using the Weighted Sum Method and Response Surface Method. *T. Lee*[1], J. Mo[1], D. Hong[1,2] and B. Woo[2] *1. Energy and Power Conversion Engineering, University of Science and Technology, Changwon-si, The Republic of Korea; 2. Korea Electrotechnology Research Institute, Changwon-si, The Republic of Korea*

A hydraulic actuator is commonly applied at quadruped robots which are required to high power but there is disadvantage in terms of space and weight. The disadvantage of hydraulic actuator can be resolved with electric actuator based on motor. However, the performance of electric actuator has lower than hydraulic actuator [1]. In this paper, a high speed and high power hollow shaft type motor which is based on surface mounted permanent magnet synchronous motor (SPMSM) is presented to resolve the disadvantages of hydraulic actuators. Deciding what material to use in the motor application is important, especially when it comes to permanent magnets, or hard magnetic materials, such as samarium cobalt (SmCo)

and neodymium iron boron (NdFeB). NdFeB was more suitable for high speed, high power motor based on the results of 2D finite element analysis according to different magnet type for initial 20 poles/ 24 slots model in Fig. 1 (a), (b). When designing an electric motor, the pole-slot combination must be selected considering the electrical and mechanical characteristics such as the winding factor, the maximum parallel circuit, the forced vibration mode, and the cogging torque period [2]. In this paper, 20 poles/ 24 slots combination was selected in Fig. 2 with referring to the winding factor, forced vibration mode and maximum number of parallel circuits. As to the multi-objective optimization of SPMSM, First, the output torque was chosen for the objective function within constraint conditions which are less than 2 (%) of torque ripple, more than 92 (%) of efficiency and with about 46 (%) of slot fill factor. Second, 2 methodologies such as weighted sum method (WSM) response surface method (RSM) were employed to derive the optimized model. When the compared between WSM model and RSM model, the result of RSM model was better than WSM model. RSM model's output torque and torque constant increased to 2.31 (%) as compared with the WSM model. Moreover, the torque ripple reduced to 17.18 (%) and efficiency increased to 0.17 (%). The experiment data will be dealt with in final paper.

Q4-10. Fe/C-Decorated Fe_2B/C Nanocapsule Hybrid with Improved Gigahertz Electromagnetic Absorption Properties. *S. Or*[1] and X. Liu[1]
1. Electrical Engineering, Hong Kong Polytechnic University, Hong Kong, Hong Kong

Magnetic/dielectric core/shell-structured nanocapsules have received considerable research interest because of their synergetic effects between magnetic and dielectric losses for absorbing electromagnetic (EM) waves in the microwave range of 1–18 GHz at smaller masses and thicknesses. The major obstacle to widespread use of the nanocapsules in EM wave absorbers is their almost untunable EM absorption properties constrained by the limited material phase variety in the single core/shell structure [1],[2]. In this paper, we report an obvious improvement in the gigahertz EM absorption properties in a novel core/shell-structured, nanocapsule-assembled magnetic/dielectric hybrid, featuring Fe/C nanocapsules of ~ 4 nm diameter decorated on the surfaces of Fe_2B/C nanocapsules of ~50 nm mean diameter (denoted as Fe/C@Fe_2B/C hybrid), and resulting from the simultaneously enhanced dielectric and magnetic losses enabled by the increased interfacial polarizations between the Fe/C and Fe_2B/C interfaces and the introduction of the tip effect from the small Fe/C nanocapsules. The Fe/C@Fe_2B/C hybrid is prepared by an arc-discharge process followed by an ion-exchange process. The phase, morphology, microstructure, composition, and charge state of Fe_2B element of the Fe/C@Fe_2B/C hybrid are investigated (Fig. 1), while their EM absorption properties are evaluated in the corresponding paraffin-bonded composites with 50 wt.% Fe/C@Fe_2B/C hybrid over the 2–18 GHz microwave range (Fig. 2). The results indicate the presence of a giant reflection loss (*RL*) of -49.5 dB at 10.5 GHz with a small absorber thickness (*d*) of 2.1 mm in conjunction with a very wide effective absorption bandwidth (for *RL*<-10 dB) of 7.5 GHz (9–16.5 GHz) at *d* = 1.9 mm. The present study provides a new prospective for realizing wideband/tunable EM wave absorbers in general and for fine-tuning their properties to meet application requirements in specific.

Q5-01. Magnetic and Structural Characterization in the Multiferroic $Bi_{4.2}(La\ Nd\ Pr)_{0.8}Fe_{0.5}Co_{0.5}Ti_3O_{15}$ Compounds of the Aurivillius Family Towards their use as Ferroelectric Capacitors. *C.E. Moreno Crespo*[1], D. Ramírez Rosales[1], S. Arellano Ahumada[1] and A. Peláiz Barranco[2]
1. Departamento de Física y Matemáticas, Instituto Politécnico Nacional, Mexico City, Mexico; 2. Facultad de Física, Universidad de La Habana, La Habana, Cuba

The bismuth-based layer-structured compounds with the formula $(Bi_2O_2)^{2+}(A_{n-1}B_nO_{3n+1})^{2-}$ have attracted much attention because of the potential candidates as single-phase multiferroics by doping magnetic species at the B-site into ferroelectric matrices [1]. The Aurivillius compounds are built from intergrowths of $(Bi_2O_2)2+$ and perovskite-like layer $(A_{n-1}B_nO_{3n+1})^{2-}$, where n denotes the number of perovskite blocks [2, 3]. $Bi_4Ti_3O_{12}$ (n=3) as a prototype of Aurivillius phase was previously studied for nonvolatile memory because of large spontaneous polarization and high ferroelectric Curie temperature. By inserting $BiFeO_3$ into $Bi_4Ti_3O_{12}$, a typical $Bi_5FeTi_3O_{15}$ (n= 4) phase with a four-layered structure can be formed. Huang et al. realized a weak ferromagnetism at room temperature in $Bi_{4.15}Nd_{0.85}FeTi_3O_{15}$ [4]. Mao et al. found that the Co-substituted for the Fe compound $Bi_5Fe_{0.5}Co_{0.5}Ti_3O_{15}$ presents an enhanced ferromagnetism with the remnant magnetization 0.0039 emu/g at room temperature [1]. In order to shed light on understanding the nature of the ferromagnetism in then n= 4 Aurivillius compounds, we investigated $Bi_{4.2}X_{0.8}Fe_{0.5}Co_{0.5}Ti_3O_{15}$ by using the magnetic and electrical measurements, x-rays diffraction and electronic paramagnetic resonance, with X=La,Nd and Pr. Layer-structured, $Bi_{4.2}X_{0.8}Fe_{0.5}Co_{0.5}Ti_3O_{15}$ ceramics were synthesized using the traditional ceramic method. The material exhibits an Aurivillius phase with an orthorhombic symmetry, which was determined by x-rays diffraction measurements. The magnetic measurements yielded relatively high remnant magnetization values (from 0.36 emu/g to 0.44 emu/g) (Figure 1).

Q5-02. Strong magnetoelectric effect in pulse laser deposited $[Ba(Zr_{0.2}Ti_{0.8})O_3\text{-}0.5(Ba_{0.7}Ca_{0.3})TiO_3]/CoFe_2O_4$ bilayer thin film. *J. Rani*[1], V. Kushwaha[2] and C. Tomy[2] *1. Physics, Vardhaman College, Bijnor, Bijnor, India; 2. Physics, IIT Bombay, Mumbai, India*

The multiferroic materials or structures, which exhibit the coupling between two or more ferroic properties such as ferroelectricity, ferromagnetism/ferrimagnetism, etc have generated great interest in recent years for their promising applications in electronic devices such as sensors, energy harvesting, four stage memories, spintronics etc. The single phase multiferroic materials rarely have a strong ME effect at room temperature which limits their usage in practical applications [1]. Therefore, extra efforts have been directed towards ME composite material which is composed of piezoelectric and magnetic materials because of their great design flexibility and better ME coupling than the intrinsic multiferroics [2]. Multiferroic $[Ba(Zr_{0.2}Ti_{0.8})O_3\text{-}0.5(Ba_{0.7}Ca_{0.3})TiO_3]/CoFe_2O_4$ bilayer thin film (abbreviated as [BZT-0.5BCT]/CFO) has been deposited on Pt/Si (100) substrate using pulsed laser deposition technique. The bilayer film shows polycrystalline nature and clean interface between [BZT-0.5BCT] and CFO layers which were confirmed by the X-ray diffraction and high resolution transmission electron microscopy investigations, respectively. The XRD analysis indicates the growth of bilayer film without any impurity phase. The homogeneous growth of bilayer thin film is confirmed by atomic force microscopy. The dielectric analysis reveals a significant decrease (~39 % at typical frequency 100 Hz) in the dielectric constant at room temperature on the application of magnetic field. Saturation polarization of the bilayer film shows a substantial improvement on the application of a magnetic field. Our bilayer film exhibits high magnetoelectric coupling coefficient (α_E), both in transverse as well as in longitudinal. The results suggest an in-principle usability of this system for multifunctional device applications.

Q5-03. Flexible multiferroic laminate composites with giant zero-biased magnetoelectric characteristics for wearable magnetic sensor. *J. Qiu*[1], X. He[1], Y. Long[1], Q. Chang[1] and H. Liu[1] *1. College of Optoelectronic Engineering, Chongqing University, Chongqing, China*

Recently, flexible wearable sensors has attracted more and more attention. However, there are few studies on flexible wearable magnetic sensors despite magnetic sensors are very useful and influential for human life. Compared to traditional magnetic sensors, the flexible magnetic sensors gradually become a research hotpot in the last few years[1,2]. Magnetoelectric (ME) composites sensor was proposed as a candidate for the next-generation magnetic sensor, due to its high sensitivity, compact size and room-temperature operation. The traditional ME laminate composites consisting of piezoelectric ceramics /magnetostrictive are usually brittle, non-bendable, fatigue. For better wearable applications, the polymer-based flexible multiferroic composites could be a good solution. Additionally, in order to obtain large ME effects, most of the reported ME composites require an external bias magnetic field, which will increase the device sizes and costs[3,4]. To overcome the limitations, zero-biased ME effects is a feasible way to solve this problem. Therefore, this paper reports a series of flexible multiferroic laminate composites based FeCuNbSiB/PVDF for wearable magnetic sensors. The ME voltage coef-

ficients(MEVC) under zero-biased magnetic field were investigated. The experimental results indicate that the maximum zero-biased MEVC of 14.4 V/cmOe is obtained at 2st resonance frequency which is longitudinal vibration resonance frequency when the length is 36 mm (Fig.1). The induced zero-biased ME voltages of the laminate composites show an excellent linear relationship to H_{ac} both at the low frequency (1 kHz) and the resonant frequency (70 kHz) as shown in Fig. 2. The laminate composites show very good ME coupling characteristics even under extreme bending conditions. As a result, the proposed flexible multiferroic laminate composites with giant zero-biased ME coupling characteristics show promising applications for highly sensitive wearable magnetic sensors.

Q5-04. Withdrawn

Q5-05. Magnetic-field-sensitive dielectric anomaly of the electron-doped manganite $CaMn_{1-x}Sb_xO_3$. *H. Taniguchi*[1], H. Takahashi[1], A. Terui[1], S. Kobayashi[1], M. Matsukawa[1] and R. Suryanarayanan[2]
1. Department of Physical Science and Materials Engineering, Iwate University, Morioka, Japan; 2. Université Paris-Sud, Orsay, France

Many multiferroics have been discovered in manganites such as $YMnO_3$ [1, 2], $TbMnO_3$ [3, 4] and $MnWO_4$ [5, 6, 7], and fascinate researchers due to the interesting physics as well as the practical magnetoelectric function. In previous studies, we have synthesized polycrystalline $Ca_{1-y}Sr_yMn_{0.85}Sb_{0.15}O_3$ and investigated the dielectric properties [8]. A broad peak which is sensitive to a magnetic field is found in the temperature dependence of the real part of the dielectric constant. In this study, we measured the dielectric constant of $CaMn_{1-x}Sb_xO_3$ (x = 0.1, 0.12, 0.13, 0.15, 0.2) under several magnetic fields in order to reveal the Sb substitution effect on the dielectric anomaly of this system. As shown in Fig. 1, all the samples exhibit a broad peak in the real part and a shoulder structure in the imaginary part. Moreover, the peak height is suppressed by a magnetic field. By increasing the Sb content x from 0.1 to 0.2, the temperature of the dielectric peak is remarkably enhanced from 47 K to 159 K. We speculate that the formation of a dipole ordering starts at the dielectric peak temperature and accelerates at the shoulder temperature. The sensitivity of the peak to a magnetic field suggests a magnetoelectric coupling in this system. The controllability of the dielectric anomaly temperature by the Sb content suggests that $CaMn_{1-x}Sb_xO_3$ is hopeful to an application, and one of future issues would be the search for the Sb content at which the anomaly temperature becomes maximum.

Q5-06. Magnetic excitations of multiferroic $Ca_2CoSi_2O_7$ studied by high-field ESR. *M. Akaki*[1] and M. Hagiwara[1] *1. Center for Advanced High Magnetic Field Science, Graduate School of Science, Osaka University, Toyonaka, Japan*

Since magnetic-field-induced electric polarizations were observed below the magnetically ordered temperature in åkermanite materials $Ca_2CoSi_2O_7$ [1,2] and $Ba_2CoGe_2O_7$ [3,4], their multiferroicities have attracted much attention. The electric polarizations depend on the field and spin directions, which is explained by the transition-metal-ligand (*p-d*) hybridization mechanism. In multiferroic materials, anomalous magnons such as an electromagnon have been observed by electron spin resonance (ESR) and THz spectroscopy. It is noteworthy that almost pure spin-quadrupolar excitations based on magneto-

electric coupling were observed in $Sr_2CoGe_2O_7$ by multifrequency ESR [5]. In this study, we focused on $Ca_2CoSi_2O_7$ which shows the following anomalous magnetic behavior [2]. The magnetization along the [110] direction shows a magnetization jump at 11 T, and the electric polarization parallel to the c-axis flips simultaneously. The magnetization along the *c*-axis increases linearly up to 18 T and shows a magnetization plateau, the magnitude of which is slightly smaller than the saturation magnetization up to 50 T, and a step-like increase to the saturation value at ~60 T. To clarify the origins of these anomalous magnetization curves from the microscopic viewpoint, we have performed ESR experiments of single crystals of $Ca_2CoSi_2O_7$ in high magnetic fields. We found many ESR straight branches (magnon and electromagnon excitations) for the *c*-axis in the plateau region. We discuss the magnetoelectric properties in the plateau region from these ESR branches and their relation to the magnetic excitations in different field regions.

Q5-07. Nonreciprocal spin-wave damping in multiferroic $GaFeO_3$.
T. Omi[1], M. Akaki[2], N. Abe[3], Y. Tokunaga[1], S. Kimura[4], M. Hagiwara[2] and T. Arima[1] *1. Advanced Materials Science, The University of Tokyo, Kashiwa, Japan; 2. Center for Advanced High Magnetic Field Science, Graduate School of Science, Osaka University, Toyonaka, Japan; 3. Department of Advanced Materials Science, The University of Tokyo, Kashiwa, Japan; 4. Tohoku University, Sendai, Japan*

Recently, the nonreciprocal directional dichroism (NDD) of an electromagnetic wave caused by the dynamical magnetoelectric effect in multiferroic materials has been intensively investigated. Polar magnets are expected to show NDD in the Voigt configuration, i.e., k // ($P \times M$) [1]. Here, k is the wave vector of incident wave, P and M describe the polarization and the magnetization, respectively. There have been several experimental reports on NDD of electromagnetic waves in polar magnets at various frequency regions so far[2]. NDD with the excitation of magnons will be expected in microwave region. A candidate material showing such a NDD of microwave is a multiferroic $GaFeO_3$. This polar magnet belongs to the orthorhombic crystal system. The spontaneous polarization P exists along the b axis. The ferrimagnetic transition temperature is about 210 K and the magnetic easy axis is c axis[3]. The magnetic space group. NDD is expected in k // ($P \times M$) // a configuration. We conducted a ferromagnetic resonance (FMR) measurement on $GaFeO_3$ and successfully observed NDD of unpolarized microwaves of a frequency range from 140 GHz to 300 GHz by the reversal of k or by M. By investigating the relation between the frequency and the resonant magnetic field, it was revealed that NDD emerged with the excitation of the ferrimagnetic uniform-mode magnon. To clarify the origin of NDD, FMR spectra was fitted by assuming the Lorentz-type magnetic susceptibility. The analysis proposes that the spin-wave damping constant would be asymmetric with the magnetic-field reversal, while other fitting parameters were almost symmetric. Furthermore, the sign of the difference of was reversed by the inversion of k. These results suggested that nonreciprocal spin-wave damping effect occurred in $GaFeO_3$.

Q5-08. Codopant driven ferromagnetism in $K_{0.5}Na_{0.5}NbO_3$ ferroelectric solid solution.
K. Shalini[1] and N. Giridharan[1] *1. Physics, National Institute of Technology, Tiruchirappalli, India*

Multiferroics or ferro-electromagnets are the imminent generation in novel multifunctional materials parades magnetic spin, electric dipole and ferroelastic ordering. Their potential applications are multistate memories, actuators, sensors, transducers, data storage devices, non-volatile memories and spintronic devices. The cross-coupling between ferromagnetism (FM) and ferroelectricity (FE) ferroic parameters afford the leeway to encode the information with an electric field and read it with magnetic field and vice-versa which is ensued as four logic states. Single phase multiferroic (SPM) materials such as BiFeO3, ErMnO3, TbMn2O5 have boundaries like low temperature multiferroicity, low magnetoelectric coupling constant, very weak FE & FM responses. Several fabrication trials endeavoured nowadays such as a) oxide based dilute magnetic ferroelectrics (O-DMF), enticement of SPM by doping of transition metal (TM) or rare-earth (RE) ions in ferroelectric b) composites creation between piezo and magnetostrictive phases. In our work, SPM materials are synthesized by tailoring the ferroelectric Potassium Sodium Niobate (KNN) through O-DMF technique through codoping of transition metal ions such as Fe, Co. Orthorhombic single phase formation confirmed at 1100°C and maximum solubility limit of TM ions found to be 10 mol%. XRD and XPS studies evidenced the absence of metal clusters (FeCo) and secondary phases. Room temperature ferromagnetism (RTFM) with better remanent polarization accomplished afresh in (Fe,Co) KNN samples compared to previous literatures. Muti-valence states of TM ions, lattice oxygen and oxygen vacancy studied from XPS analysis established FM through its exchange interactions and mechanisms. Absorption graph exploration displays the tuning of bandgap overlays the prospect for opto-electronic device application and manifestation of defect states. (Co, Fe) substituted KNN ceramics retained ferroelectric polarization, dielectric permittivity and encouraging ME from the magnetoelectric voltage coefficient (αME) measurement.

Q5-09. Low temperature structural properties of multiferroic compounds: $YBa_{1-x}Sr_xCuFeO_5$ (x = 0, 0.5). *S. LAL*[1], K. Mukherjee[1] and C. Yadav[1] *1. School of Basic Sciences, Indian Institute of Technology Mandi, Mandi, India*

Double perovskites materials are represented by general formula A'A"B'B"X_6; where (A', A") sites are occupied by rare or alkaline earth metals, (B', B") sites are occupied by transition metal ions and X site is generally occupied by the oxygen or halide ions. Layered perovskite materials are derivatives of double perovskites in which one of the oxygen is removed from the A' plane. Layered perovskite materials with general formula LnBaM'M"O_5(Ln = alkaline or Rare earth ions, M', M" = transition metal) exhibits interesting structural, magnetic and multiferroic properties. Oxygen deficient layered perovskite $YBaCuFeO_5$ are one such compound which has the magnetic and electric transition temperature above 200 K [1]. $YBaCuFeO_5$ has two antiferromagnetic transitions at 440 K(paramagnetic to commensurate antiferromagnetic) and 230 K (commensurate to incommensurate antiferromagnetic). The dielectric anomaly have been reported in this compound at 247 K. The magneto-dielectric coupling have been reported in this compound in the incommensurate or spin spiral region. The magnetic and the dielectric transition can be tuned by applying additional chemical pressure or increasing distortion in the system. With Sr doping the magnetic transition shift towards high temperature whereas dielectric transition shifts towards low temperature [2]. The temperature dependent (20 K ≤ T ≤300 K) x-ray diffraction on $YBa_{1-x}Sr_xCuFeO_5$ (x=0.0 and 0.5) compounds shows lattice contraction on lowering temperature without any structural transition. The partial replacement of Ba with Sr leads to thedecrease in lattice parameters, resulting in theenhanced chemical pressure on the unit cell. Our low temperature structural and magnetic studies on $YBa_{1-x}Sr_xCuFeO_5$ (x=0.0 and 0.5) show a link between c-axis lattice parameter and magnetic transition temperature in these compounds.

Q6-01. 5f Ferromagnetism Approaching Ambient Temperatures: High Pressure Study of UCu_2P_2. *L. Havela*[1], J. Prchal[1], J. Valenta[1], M. Divis[1], I. Turek[1], M. Henriques[2], F. Honda[3] and D. Kaczorowski[4] *1. Department of Condensed Matter Physics, Charles University, Prague, Czechia; 2. Institute of Physics, Academy of Sciences of the Czech Republic, Prague, Czechia; 3. Institute for Materials Research, Tohoku University, Oarai, Ibaraki, Japan; 4. Polish Academy of Sciences, Institute of Low Temperature and Structure Research, Wroclaw, Poland*

Besides tuning the onset of 5*f* magnetism to $T = 0$, an opposite task, to reach as high ordering temperatures as possible, is equally interesting. It can bring the 5*f* band magnetism, yielding sizeable orbital moments and giant magnetic anisotropy, to the ambient temperatures. We identified what can be a route to high ordering temperatures in U systems. A reference case is UH_3, a ferromagnet with $T_C = 165$ K, achieved for short U-U spacings of 330 pm. At such distance U magnetic moments usually only start to appear, below that the ground state is superconducting. Ab-initio calculations [1] identified that a shift of the U-6*d* and 7*s* states above the Fermi level (electrons transferred to H-1*s* states) can be responsible, as it reduces the 5*f*-6*d* hybridization. Looking at similar transfers in materials with higher U-U spacing we selected binary and ternary pnictides, which indeed exhibit systematically stable U moments and high ordering temperatures. Among ferromagnets, the record holder is UCu_2P_2 with $T_C = 216$ K [2]. Close to the verge of localization purely 5*f*-band picture cannot explain experimental findings. In particular, a large pressure increase of T_C or T_N was often observed, which can be understood by a two-band model, with pressure first increasing inter-site exchange interaction and only then destabilizing the moments [3]. We found a similar impact of pressure for UCu_2P_2. Ac-susceptibility and resistivity data reveal a robust pressure increase of T_C, followed so far to 4 GPa. The T_C value of 255 K and persisting positive derivative give a hint that room temperature ferromagnetism in purely 5*f* ferromagnet may be achieved. The experiment is complemented by ab-initio fully relativistic spin- and orbital-polarized calculations, revealing the changes of populations of individual type of states. It is shown that the total moment 1.9 μ_B/f.u. consists of spin $M_S = 2.0$ μ_B and orbital $M_L = -3.9$ μ_B moments. The calculations correctly reproduced the easy magnetization direction, which is the *c*-axis of the hexagonal structure. The anisotropy energy is 8.2 meV/U atom, i.e 131 K. This work was supported by the Czech Science Foundation under the grant No. 18-2344S.

Understanding complex electronic phases, such as charge density wave (CDW) and superconductivity (SC), in two-dimensional (2D) confined geometry offers an interesting perspective towards a comprehensive account of collective electron interactions. $TaSe_2$ provides an ideal and clean platform to investigate how CDW order evolves in a true 2D limit. In its bulk form, the SC in $TaSe_2$ is almost completely suppressed, while CDW has a relatively moderate temperature scale [1]. The complexity stemming from coexisting temperature and energy scales of CDW and SC, observed in other transition metal dichalcogenides [2, 3], is expected to be absent in $TaSe_2$. We have successfully grown single-layer $TaSe_2$ on bilayer graphene substrate using molecular beam epitaxy [4]. The electronic structure and CDW transition have been studied using angle-resolved photoemission (ARPES), scanning tunneling microscopy and spectroscopy (STM/STS), and density functional theory (DFT) calculations. We have found that 3 x 3 CDW order persists with slight increase in transition temperature despite dramatic changes in the low energy electronic structure and Fermi surface topology [4]. Enhanced spin-orbit coupling and lattice distortion in the single-layer play a crucial role in the formation of CDW order. Our findings provide a deeper understanding on the nature of CDW order in the 2D transition metal dichalcogenides.

Q6-03. Metal-insulator transition in Mott-insulator $FePS_3$. *M. Tsurubayashi*[1], K. Kodama[1], M. Kano[3], K. Ishigaki[2], Y. Uwatoko[2], T. Watanabe[1], K. Takase[1] and Y. Takano[1] *1. Department of Physics, Nihon University, Tokyo, Japan; 2. Institute for Solid State Physics, University of Tokyo, Kashiwa, Japan; 3. Human Science and Common Education, Nippon Institute of Technology, Saitama, Japan*

We have investigated the pressure dependence of the electrical resistivity of $FePS_3$. $FePS_3$ is a cation-ordered $CdCl_2$ type layered compound [1] and known to be a Mott-insulator by the resonant photoelectron spectroscopy measurement [2]. $FePS_3$ was reported to show a metal-insulator transition at about 6 GPa by applying pressure. However, details were unknown [3]. Previously, we investigated the pressure dependence of the crystal structure and the magnetic properties of MPS_3 (M = Mn, Fe) up to about 2 GPa [4]. In this study, the electrical resistivity between 2 K and room temperature is measured under the pressure up to 12 GPa. While the temperature dependence of the electrical resistivity is insulating up to 10 GPa, it becomes metallic above 11 GPa. The magnitude of the electrical resistivity ranges from 10^{-6} to 10^{-1} Ωm at the metallic state. Assuming that the temperature dependence of the electrical resistivity in the insulating region is an activation type, the activation energy increases continuously with decreasing the pressure. It is well extrapolated to the ambient pressure value, 0.6 eV [5]. The temperature dependence of the electrical resistivity in the metalic region below 100 K is analyzed by a power law such as $\rho(T) = \rho_0 + AT^n$ [6]. The value of n takes about 2 at 11 and 11.5 GPa. The electrical resistivity becomes almost temperature independent below 20 K at 12 GPa.

Exotic phases of matter [1,2] produced by the DMI [3,4] have recently drawn great attention for the challenge posed in terms of their theoretical understanding and the potential technological applications. One of the manifestations of the DMI is weak ferromagnetism, i.e. the existence of a spontaneous net magnetization in certain classes of antiferromagnetic materials. A prominent example is represented by the isostructural weak ferromagnets ACO_3 (A = Co, Mn, Ni) and $FeBO_3$ (Fig. 1): although these compounds have been known since the seminal papers on the DMI [3,4], some intriguing aspects of their physics have not been investigated yet. In particular, our first-principles calculations (LDA+U+SO) [5] predict a systematic variation of both the magnitude and the sign of the DMI-induced moments canting angle as a function of the transition metal (A) and a clear evolution of the orbital contribution to the magnetic moment, which is expected to be anomalously large in $CoCO_3$. Here we report on a novel investigation of the magnetic properties of $(Co,Ni,Mn)CO_3$ and $FeBO_3$ by means of resonant [5,6] and non-resonant [7] x-ray magnetic scattering. The elusive sign of the moments canting angle is encoded in the phase of the diffracted signal, which can be accessed through the interference between magnetic scattering and resonant quadrupole scattering [5,6]. On the other hand, the peculiar polarization dependence of the non-resonant magnetic amplitude allows separate access to the spin and orbital magnetic moment. The experimental data are remarkably consistent with the theoretical predictions and unveil a dramatic interference effect in the scattering amplitude in $CoCO_3$ (Fig. 2) induced by the unquenched orbital moment. Our results pave the way to a better understanding of the exchange interactions at the origin of exotic phases of matters and prove the ability of modern first-principle calculations to reliably model their evolution.

Q6-06. Magnetic-field driven Pr-valence change in $(Pr_{1-y}Sm_y)_{1-x}Ca_xCoO_3$. *T. Naito*[1] and H. Fujishiro[1] *1. Iwate University, Morioka, Japan*

A metal-insulator transition (MIT) and spin-state transition (SST) is known to take place simultaneously in $(Pr_{1-y}RE_y)_{1-x}Ca_xCoO_3$ (RE=rare earth elements) system. This MI-SST originates from the fact that the spin-state of Co^{3+} changes between the intermediate (or high) and low spin states. Recently, several works revealed that the valence shift of a part of Pr ions from trivalent to tetravalent played an important role in the MI-SST by the X-ray absorption spectroscopy (XAS) at the Pr L_3 edge [1]. On the other hand, we have studied a magnetic-field effect on the MI-SST to control the SST, because the magnetic-field stabilizes the higher spin states and should influence the transition temperature. As a result, we found that the MI-SST temperature decreases with increasing magnetic-field, and finally the MI-SST is fully suppressed. For instance, the magnetic-field of 9 T wiped out the MI-SST in $(Pr_{0.9375}Y_{0.0625})_{0.7}Ca_{0.3}CoO_3$ sample with the transition temperature of 41 K at zero field [2]. In this paper, we have studied the XAS at the Pr L_3 edge in magnetic-field up to 10 T for $(Pr_{1-y}Sm_y)_{1-x}Ca_xCoO_3$ system to examine the relationship between the magnetic-field effect and the valence of Pr ions. For $(Pr_{0.8}Sm_{0.2})_{0.7}Ca_{0.3}CoO_3$ with the transition temperature of about 50 K, a $4f^2$ peak due to Pr^{3+} increases with increasing magnetic-field at 50 K, and returns to the starting spectrum at 0 T by removing the magnetic-field. The valence

of Pr estimated from the XAS spectra changes from approximately 3.14 at 0T to 3.09 at 10 T. The decrease in Pr-valence by applying magnetic-field is consistent with the suppression of the MI-SST. We discuss the mechanism of the change in Pr-valence induced by the magnetic-field.

Q6-07. Co-site substitution effects on the simultaneous metal-insulator and spin-state transition in $(Pr_{1-y}Gd_y)_{1-x}Ca_xCoO_3$. *T. Naito*[1] and H. Fujishiro[1] *1. Iwate University, Morioka, Japan*

A metal-insulator transition (MIT) and spin-state transition (SST) is known to take place simultaneously in $(Pr_{1-y}RE_y)_{1-x}Ca_xCoO_3$ (RE=rare earth elements) system. This MI-SST originates from the fact that the spin-state of Co^{3+} changes between the intermediate (or high) and low spin states. Several works revealed that the valence shift of a part of Pr ions from trivalent to tetravalent played an important role in the MI-SST by the identification of the Pr^{4+}-related Schottky peak in heat capacity measurements [1] and by X-ray absorption spectroscopy (XAS) at the Pr L_3 edge [2]. The increase of the fraction of Co^{3+} by the valence change of Pr ions induced the MI-SST. In this paper, we have studied that a Co-site substitution effect by various metal elements (M=Mn, Fe, Ni, Ga, etc.) on the MI-SST in $(Pr_{1-y}Gd_y)_{1-x}Ca_x(Co_{1-z}M_z)O_3$, to clarify the relationship between the fraction of Co^{3+} and the MI-SST. For M=Mn, the transition temperature increased with increasing the amount of Mn. The introduction of Mn^{4+}, revealed by the XAS, increases the fraction of Co^{3+}, and resulted in the increase of the transition temperature. On the other hand, for M=Ni, the transition temperature decreased with the amount of Ni, and finally the MI-SST was fully suppressed at z=0.05. The results of the Ni-substitution is quite similar to the magnetic-field effect, in which the MI-SST disappeared above a strong magnetic field [3]. Although the valence of Ni was not determined by the XAS, we found that the ferromagnetic element also suppress this transition.

Q6-08. Resistive switching kinetics probed from crosshatch surface of $La_{0.7}Sr_{0.3}MnO_3$ films. Z. Liang[1,2], *Z. Wang*[1] and P. Wu[2] *1. Beijing National Laboratory for Condensed Matter Physics, Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2. Department of Physics, University of Science and Technology Beijing, Beijing, China*

Recently, the resistive switching (RS) effect in metal-oxide-metal heterodevices has attracted increasing attention. Although the device working principle is generally recognized to be relied on local electromigration of oxygen vacancies [1], a concrete picture for resistive switching, in particular, the switching kinetics is still lacking. In this work, we investigate the memristive switching behavior in $La_{0.7}Sr_{0.3}MnO_3$ (LSMO) films which own crosshatch surface due to a tailored misfit strain relaxation. By employing local current-voltage measurements, we find that the LSMO film of a dense line crosshatch surface displays the RS from high resistive state to low resistive state at a positive voltage which is obviously higher than that for the film of a crosshatch surface with sparse line features. Furthermore, the conductive atomic force microscopy reveals that the average current response in the former film exhibits a double exponential-like decay with the scanning numbers. We interpret the experimental results by the motions of single isolated and clustered oxygen vacancies in local strain field and electric field [2,3]

Session Q7
NEW MAGNETIC MATERIALS III
(Poster Session)

Masato Kotsugi, Chair
Tokyo University of Science, Tokyo, Japan

Q7-01. Effect of CoFeB thickness for sensing properties in magnetic tunnel junctions with perpendicular synthetic antiferromagnetic Co/Pt pinned layer for magnetic sensor devices with wide-dynamic-range. *T. Ogasawara*[1], M. Oogane[1], M. Tsunoda[2] and Y. Ando[1] *1. Department of Applied Physics, Tohoku University, Sendai, Japan; 2. Department of Electronics Engineering, Tohoku University, Sendai, Japan*

Magnetic tunnel junctions (MTJs) is one of the promising candidates for magnetic sensor devices due their low cost, low energy consumption and small size as well as high sensitivity because of the large tunnel magnetoresistance (TMR) effect. The MTJ-based sensors can provide novel applications such as current monitoring sensors for electric vehicle (EV) which require both wide dynamic range and low nonlinearity (NL). In this work, we investigated the CoFeB thickness dependence of sensor performances in CoFeB/MgO/CoFeB-MTJs. All of films were deposited on thermally oxidized Si (001) substrates at room temperature using dc/rf magnetron sputtering apparatus with base pressure less than 1.0×10^{-6} Pa. The MTJ devices with structure of substrate/Ta(3nm)/Ru(10)/Pt(2)/$[Co(0.28)/Pt(0.16)]_9$/Co(0.28)/Ru(0.4)/Co(0.28)/$[Pt(0.16)/Co(0.28)]_5$/ Co(0.28)/Ta(0.2)/$Co_{40}Fe_{40}B_{20}$(1.0)/MgO(2)/$Co_{20}Fe_{60}B_{20}$(t_{CoFeB} = 1.5 – 2.0)/Ta(5)/Ru(8) were fabricated and their TMR effect was measured by dc four probe method after the post-annealing at 300°C. Fig. 1 shows TMR curves in MTJs with different free layer thickness t_{CoFeB} under out-of-plane magnetic field. The slope of TMR curves in a low magnetic field was varied due to the change of anisotropy field H_k of CoFeB free layer by t_{CoFeB} due to chnage of H_k. In particular, MTJs with t_{CoFeB} = 1.50 nm exhibited a high sensitivity of 0.053 %/Oe thanks to both a large TMR ratio and relatively low H_k, which is the highest value among the reported works on MTJs-based sensors using perpendicular pinned layers. We also evaluated NL, given by $(R_{meas.}-R_{fit.})/(R_{meas.max}-R_{meas.min})\times100$ % FS within the range of ±1 kOe. As shown in Fig. 2, the maximum magnitude of NL strongly depends on the magnitude of H_k because tunneling resistance is inversely proportional to H [1] according to Stoner-Wohlfarth [2] and Slonczewski models [3]. In addition, we found the reduction of NL by the estimation from conductance (G-H) curves. The lowest NL of the conductance was 0.2 % FS at t_{CoFeB} = 2.0 nm. This result is greatly useful to develop MTJ-based sensors with wide-dynamic-range and small-nonlinearity.

Q7-02. Flexible Hall-Effect Devices Fabricated via Recursive Transfer Print of Graphene onto Polymeric Lamination Film. U.Y. Inkaya[1], K. Çelik[2] and *A. Oral*[3] *1. Physics, Middle East Technical University, Ankara, Turkey; 2. Firat University, Elazig, Turkey; 3. Orta Dogu Teknik Universitesi, Ankara, Turkey*

Having zero bending stiffness [1], graphene is a promising material for manufacturing flexible electrodes. Graphene grown via chemical vapor deposition on copper foil can be transfer-printed onto commercially available polymeric lamination film by using hot rollers and etching the copper layer with aqueous ferric chloride solution [2]. By recursively applying this lamination process from 1 to 10 times, we formed graphene-based multilayered ultra-thin conductive films on the 80μm-thick lamination film, thereby made flexible electrodes. Cross-shaped flexible Hall-effect devices were manufactured by cutting the Hall cross out of the laminate and selectively etching the copper layer, which provided electrical contact pads (Figure 1). The graphene was grown on 20μm-thick copper foil via atmospheric pressure chemical vapor deposition. Resultant devices were characterized via atomic force microscopy (AFM) and Hall-effect measurements, which showed that the charge carriers in the conductive film were holes. AFM study of the conducting film resulted in convergent behavior of RMS roughness values as the number of laminations increases. The Hall coefficient values changes from ~ 400 to 30 Ω/T for the number of laminations from 1 to 10, respectively. Moreover, there is an approximately linear relation between the hole concentration obtained from the Hall coefficient values and the number of laminations, which indicates a layered structure in the films. In addition, Joule heating experiments showed that the graphene-based films can withstand the temperatures of up to 100°C.

Q7-03. Electric Field Control of Interfacial Magnetism through Ionic Liquid Gating. Z. Hu[1], Z. Zhou[1] and *M. Liu*[1] *1. Electronic Materials Research Laboratory, Key Laboratory of the Ministry of Education & International Center for Dielectric Research, Xi'an Jiaotong University, Xi'an, China*

To overcome the fundamental challenge of weak natural response of antiferromagnetic (AFM) materials under a magnetic field, voltage manipulation of ferromagnetic (FM)/AFM interaction has been developed to realize ultrafast, high-density, and power efficient antiferromagnetic spintronics. However, since the alternative spins at the FM/AFM interface are strongly pinned by the AFM layer, these electric field control processes are usually confined at low temperature or require magnetic field assistance. Here we report a low voltage, room temperature modulation of synthetic antiferromagnetic multilayer with FM/nonmagnetic (NM)/FM structure, where two FM layers separated by a NM metallic spacer layer have indirect interaction through interlayer exchange coupling. According to the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction theory, whether the FM layers are ferromagnetically or antiferromagnetically coupled is determined by the thicknesses of NM layer. In this system, robust transition between FM and AFM ordering is realized, and up to 80% of perpendicular magnetic moments manage to switch with a low applied voltage of 2.5 V. We relate this ionic liquid gating-induced RKKY interaction modification to the disturbance of itinerant electrons inside synthetic antiferromagnetic heterostructure and the corresponding change of its Fermi level. Electric field tuning of spin interaction may enable the next generation of switchable spintronics between antiferromagnetic and ferromagnetic modes with both fundamental and practical perspectives.

Q7-04. External Loading Effects on Guided Wave Magnetostrictive Sensor Using a Surface-bonded Nickel Patch. *B. Yoo*[1] and D.J. Pines[1] *1. Aerospace Engineering, University of Maryland, College Park, MD, United States*

This paper presents external loading effects on an ultrasonic guided wave magnetostrictive sensor using a nickel disc patch surface-bonded to a thin waveguide structure. Magnetostrictive Patch Transducers (MPT) are alternative and promising devices for well-known piezoelectric transducers and have been widely used for structural health monitoring and damage detection applications based on the guided wave technique [1,2]. Since MPTs are operated by magnetoelastic coupling principles, unwanted external magnetic and elastic fields may influence the MPT's guided wave sensing and actuating characteristics such as performance and radiation pattern. Lee *et al.* reported the analysis of dynamic and static magnetic interferences in an omnidirectional MPT using a nickel patch, demonstrating the associated cross-talk signal induction and distortion of the guided wave radiation pattern [3]. Also, waveguide structures embedding magnetostrictive patches may encounter compressive and tensile loads by various exterior factors like environmental vibrations and aerodynamic forces. However, there is no study to investigate the effect of external loadings on MPT systems. Recently, Downing *et al.* discussed the magnetostriction increase of highly textured Galfenol and Alfenol thin sheets due to the application of compressive pre-stress [4]. In this work, we apply in-plane tensile and compressive loads to a polycrystalline nickel patch, firmly attached to the surface of a thin aluminum plate, based on buckling effect of the plate. A schematic diagram of the experimental setup is shown in Fig.1. Multiple PZT wafer actuators mounted to the plate generate guided waves and the MPT composed of a ring-type sensing coil and biasing magnets detects changes in the magnetic flux density of the patch induced by elastic wave interactions. Although the MPT using the original nickel patch appears to have omnidirectional sensing profile, the MPT under planar stress exhibits a specific directional sensing pattern due to stress-induced anisotropic magnetostriction. Strain gauges and Hall effect sensors are also used to verify the patch deformation and the corresponding magnetic property variation.

Q7-05. Reversibly switching the phases of $SrCoO_x$ film at room temperature using a flexible solid-state electrolyte gate. *Y. Chen*[1], D. Wang[1], L. Wei[2] and S. Yan[1] *1. School of Physics, Shandong University, Jinan, China; 2. School of Microelectronics, Shandong University, Jinan, China*

Electric field induced oxygen nonstoichiometry is an important means to control the materials functionalities. Multivalent transition metal oxides (TMOs), which have rich functionalities originating from the flexible valence state of the transition-metal ions, have attracted intensive attention for their potential applications. Among these TMOs, strontium cobaltite, $SrCoO_x$, is an ideal platform for the study of reversible electro-control of the oxygen nonstoichiometry and associated property changes, as it has two structurally distinct topotactic phases which exhibit highly contrasting electronic and magnetic ground states depending on the Co oxidation state. Furthermore, the oxygen vacancy in strontium cobaltite is quite mobile with a low migration energy, favoring the electric-field-controlled oxygen evolution. The $SrCoO_{2.5}$, with an oxygen-vacancy-ordered brownmillerite (BM) structure, is an antiferromagnetic (AFM) insulator with trivalent Co^{3+}, whereas $SrCoO_3$, with a simple perovskite structure, is a ferromagnetic (FM) metal with tetravalent Co^{4+}. Thus the AFM-insulator/FM-metal switching could be achieved by controlling the oxygen non-stoichiometry. High-temperature annealing under an oxidative/reductive atmosphere and room-temperature electrochemical redox reaction in a liquid electrolyte are two conventional ways to control the oxygen nonstoichiometry in transition-metal oxides. However, incapability of integration and packaging is significant drawback of devices operating with liquid electrolyte. Practical advantages may be gained by replacing the liquid electrolyte with a flexible solid-state gating which is printable and solution processable. Here, we fabricated a new flexible solid-state electrolyte gated device to investigate the effect of electric field gating on electrical transport and magnetic properties of SrCoOx films. A reversible crossover of the SrCoOx film between the brownmillerite and the perovskite phase under a small DC voltage was achieved at room temperature, which indicates SrCoOx film is a promising material with potential application in resistive random access memory and spintronic devices.

Q7-06. *ByAxon*: Towards an active bypass for neural reconnection. T. González[1], B. Rodilla[1], V. Muñoz[1], R. Guerrero[1], P. Perna[1], L. Perez[2,1], *J. Camarero*[3,1] and R. Miranda[3,1] *1. IMDEA Nanociencia, Madrid, Spain; 2. Universidad Complutense de Madrid, Madrid, Spain; 3. Universidad Autónoma de Madrid, Madrid, Spain*

Current neural interfacing approaches are based on detecting and/or triggering electric potentials mainly at the brain level, in order to diagnose or treat different neurological disorders. In many newly proposed innovations a rigid sensing/triggering active part needs to be in close contact with the neural tissue, which produce scars and reactions in the tissue, complicating the correct performance of long-term implants. The ultimate non-contact sensing magnetoencephalography devices detect magnetic-field pulses generated by potentials at the brain, but require cryogenic temperatures, and are restricted to diagnose applications in specialized medical centres. Present electrodes are used to develope new brain-machine interfaces, employing electrical potentials read at a person's brain to activate a response of a computer/robot. These devices can be a huge help for paralyzed patients due to spinal cord (SC) injuries. Still, important present drawbacks are the large number of cables and electrodes they require and, specially, the lack of sensory feedback. We introduced here our aproach, called *ByAxon* [1]. A new generation of nanostructured room temperature LSMO-based low-noise AMR sensors and stimulation electrodes are defined to build an active implant that could work directly at SC level. This implant will be primary focused on restoring the transmission of electrical signals in the injured SC, acting as an *bi-directional local bypass*, something not possible with current technology. This can potentially lead to a bypass to regain sensory functions by reading signals arriving from the dorsal ganglia to the SC immediately below the lesion and using them to trigger new activation of sensory undamaged neurons above the injury, allowing the signal to reach the brain again. In a broader picture, this could serve as a basis for a new generation of advanced neural interfaces applications with utility in retinal implants, brain-recording systems for patients with epilepsy, and deep brain stimulation devices for Parkinson disease. ByAxon nanotechnology promises significant outcomes towards the development of an active local bypass providing much-needed breakthroughs in future neuromedicine.

Q7-07. Dual Beam Modulated Magneto-Optical Measurement setup. *S.C. Acharya*[1], W.J. Geerts[1], B.D. Collier[1] and M. Talukder[1] *1. Physics, Texas State University, San Marcos, TX, United States*

The Magneto-Optical measurement method is often used to study magnetic properties of thin films and multilayers. Although it is an indirect measurement technique, it has various advantages compared to the traditional

vibrating sample magnetometry, including a higher sensitivity, and being a non-contact method allowing to conveniently measure hysteresis curves remotely through a vacuum window or through a security fence in case of a high voltage transformer. One often employs a photo-elastic modulator (PEM) in the MO measurement setup to increase the S/N ratio of the measured Kerr or Faraday signals. A standing sound wave in the optical head of the PEM adds a time dependent phase shift between two orthogonal components of polarized laser beam by strain induced birefringence. This leads to a modulation of the intensity at 2f that is proportional to the Kerr or Faraday rotation of the sample. Such a single beam detection method has shown to be sensitive to intensity, frequency, and beam direction fluctuation of the laser light source as well to temperature and frequency drifts of the modulator. To improve the setup we explored a dual beam approach as has been used before in setups without modulator. The beam transmitted through (or reflected by) the sample was split in two high quality linearly polarized beams by a Wollaston Prism. Both beam leave the Wollaston prism at +/- 7degrees. The intensity of the beams were measured by two Thorlabs PDA50 silicon detectors. Wollaston prism, wedges, and detectors were mounted in a Newport URS75 high resolution optical rotation stage (0.0005 mdegrees stepsize) which allows us to rotate all components of the detector unit displayed below together. The motorized rotation stage was mounted on a manual stage that allows us to translate and tilt the Wollaston prism with respect to the laser beam. Preliminary experiments show that the difference between the 2f signals is proportional to the Kerr rotation but insensitive for 2f components caused by interference of the laser beam in the PEM. The sum signal is very sensitive to the interference effects in the modulator and can be of great use as a monitor for the actual retardation of the PEM [2].

Q7-08. Mössbauer Studies of Ferrite Based MRI Temperature Contrast Agents. *N.A. Alghamdi*[3], M. Przybylski[1,4], J. Zukrowski[1], J.H. Hankiewicz[2], R.E. Camley[3] and Z. Celinski[3] *1. Academic Centre for Materials and Nanotechnology, AGH University of Science and Technology., Krakow, Poland; 2. BioFrontiers, University Colorado Colorado Springs, Colorado Springs, CO, United States; 3. Physics, University of Colorado, Colorado Springs, Colorado Springs, CO, United States; 4. Faculty of Physics and Applied Computer Science, AGH University of Science and Technology, Krakow, Poland*

Ferrite particles can be also used to obtain temperature maps with MRI (tMRI). [i], [ii] If a composition is properly chosen, ferrite particles can exhibit a rapid change of magnetization with temperature. This property can be employed in the strong magnetic field of an MRI scanner. The dipolar field created by the magnetic particles changes the local field sensed by ^{1}H ions. As a result, the absolute temperature can be obtained from intensity of T2* weighted MRI images. To achieve the highest temperature resolution, magnetic particles need to possess the following properties: (1) rapid change of magnetization vs. temperature in the field of the MRI scanner, and (2) nearly zero magnetization at the highest measured temperature. To find the best material for tMRI, we examined MgZn and CuZn ferrites. To achieve the optimum properties, we employed Mössbauer spectroscopy (MS) and magnetometry, complemented by XRD Rietveld analysis of the ferrite particles. Fig. 1 shows an example of the temperature dependence of magnetization of studied ferrites in high magnetic fields. Fig. 2 depicts the MS spectra at 80K for a few compositions of MgZn ferrites. The analysis of these spectra allowed us to determine the occupancy of different Fe sites in spinel structure independently from XRD analysis. We observed that the magnetization relaxation in $Cu_{1-x}Zn_xFe_2O_4$ ferrites was fully suppressed only at 6 K, with a well-defined magnetic splitting (results not shown). The spectra can be fitted as a sum of two components with Gaussian magnetic hyperfine parameter distributions. The average magnetic hyperfine field, B_{hf}, of 510.1 kG corresponding to both the components (512 and 506 kG) is similar to the average B_{hf} measured for Fe_3O_4 at 6 K. This means that the substitution of Fe with Cu-Zn does not remarkably change the average magnetic hyperfine field at Fe nuclei. From our analysis of the spectra for $0.4 < x < 0.8$, we conclude that with increasing x Cu and Zn atoms are preferentially substituted into the B site. As a result, with increasing x the magnetization decreases in agreement with SQUID measurements.

Q7-09. Antiferromagnetic spintronics based on Mn_2Au: switching and read-out. *S. Bodnar*[1], L. Šmejkal[1], T. Jungwirth[2,3], O. Gomonay[1], A. Sapozhnik[1], H. Elmers[1], M. Kläui[1] and M. Jourdan[1] *1. Institute of Physics, Johannes Gutenberg University, Mainz, Germany; 2. School of Physics & Astronomy, University of Nottingham, Nottingham, United Kingdom; 3. Department of Physics, Academy of Sciences of the Czech Republic, Praha, Czechia*

In antiferromagnetic (AFM) spintronics, information is encoded by the direction of the Neel vector, which is defined by the vectorial difference of the sublattice magnetizations. For spintronic applications, one requires efficient methods for reading and changing the Néel vector orientation (writing). In case of AFMs with non-centrosymmetric magnetic sublattices, it was predicted that a current induced spin-orbit torque can change the orientation of the Neel vector [1]. This was indeed recently demonstrated for the compound CuMnAs [2]. However, for spintronics applications the up to now only alternative compound Mn_2Au provides several advantages, as it is a good metallic conductor with a high magnetic ordering temperature and does not contain toxic components. In our work, we report about current-induced Neel vector manipulation in Mn_2Au [4]. Reversible and consistent changes of the longitudinal resistance and planar Hall voltage of star-patterned epitaxial Mn_2Au (001) thin films were generated by pulse current densities of the order of 10^7 A/cm^2. Rotation of Néel vector leads to changes of the anisotropic magnetoresistance (AMR) in a range of 6 %, which makes this material a perfect candidate for possible memory applications. In addition, the value of the AMR agrees with theoretical calculations based on density functional theory (DFT) [3].

Q7-10. Liquid Acoustic Wave (LAW) Sensor for Biomagnetic Field Detection. *M. Schweichel*[1], S. Kaps[1], Y.K. Mishra[1], R. Adelung[1] and J. Carstensen[1] *1. Materials Science and Engineering, Kiel University, Kiel, Germany*

Biomagnetic field detection tools like magnetocardiography (MCG) and magnetoencephalography (MEG) need the ability to measure magnetic fields of low frequency and amplitudes in the sub-picoTesla range. The superconducting quantum interference device (SQUID) sensors, at the moment the state-of-art device for this application, exhibit drawbacks like the need for strong cooling and very sophisticated shielding, etc.[1] In this context, magnetoelectric (ME) sensors could be a very promising alternative. A ME sensor consists of a magnetostrictive layer, that converts magnetic field changes into mechanical strain, coupled with a piezoelectric layer, which translates the deformation into a voltage.[2] Typically the magnetostrictive material used in ME sensors is solid. This might lead to part of the magnetic field energy, that should be detected, getting lost on stretching the atomic bonds of the material upon deformation. An approach to reduce these losses is to use a material consisting of a fluid matrix filled with magnetic particles, a so-called magnetorheological fluid (MRF). Without any magnetic field, the magnetic particles in MRF are randomly distributed in the entire matrix. Upon applying a magnetic field, the particles form chains along the magnetic field lines, which causes a change in the viscosity and the acoustic behavior of the MRF. The change in acoustic behavior, which is a modification of the sound velocity with the applied magnetic field can be used in a new type of sensor, called liquid acoustic wave (LAW) sensor. The LAW sensor setup consists of a tube with a piezoelectric plate on either side and MRF in between the plates. One of the piezoelectric plates is used as loudspeaker, while the other one acts as microphone. A sinusoidal wave is continuously transmitted through the MRF and changes in amplitude and phase can be detected. By doing this, the changes in the acoustic behavior of the MRF with respect to the applied magnetic field can be easily detected. Preliminary results about the fabrication of and results from LAW sensors will be demonstrated and briefly discussed in the presentation.

Q7-11. Barkhausen noise analysis for monitoring stress and damage accumulation in Fe-Co magnetostrictive alloy wire. *T. Yamazaki*[1], Y. Furuya[2] and W. Nakao[1] *1. Materials Science and Engineering, Yokohama National University, Yokohama, Japan; 2. Tohoku University, Sendai, Japan*

The use of inverse magnetostrictive effect (also known as Villari effect), which exhibit a change in the magnetic susceptibility of a ferromagnetic material when subjected to mechanical stress, plays an increasingly important role in IoT society. Here we propose a novel sensor material for real-time monitoring stress and damage accumulation using magnetic Barkhausen noise (MBHN) generated in textured Fe-Co magnetostrictive alloy wire. MBHN analysis opens the door to the dynamic domain study of magnetostriction phenomena for significant applications such as actuators, energy harvesters and force sensors [1, 2]. As shown in Fig. 1, MBHN is the magnetic flux change generated by the movement of domain walls (DWs) due to the pinning/unpinning effect in microstructural factors [3, 4]. Therefore, MBHN signals have been attracting a great deal of attention because it is highly sensitive to minute changes in microstructure or local stresses in materials that can be measured in a non-contact and non-destructive manner. However, MBHN is too complex to theoretically estimate the signal and cannot quantitatively understand the mechanism and meaning of the generated waveform. Therefore, a method of MBHN analysis for diagnosing the physical state of materials should be established. In this study, stress and damage dependency of MBHN signal calculated by Fast Fourier Transform (FFT) analysis were investigated under changing tensile stress in order to clarify micro-magnetostrictive behavior caused by dynamic DWs motion using textured Fe-Co alloy wire that we had reported previously [5]. Figure 2 shows the strain-stress curve and the picture of MBHN measurement system. The RMS value of BHN signal calculated from FFT analysis showed a good sensitivity (0.18 mV/MPa) and a large linearity in the stress range of 0-400 MPa which is almost the same elastic deformation region. The relationship between MBHN of this test specimen and the damage accumulation examined by repeating 1 to 10 tensile preloads will be discussed.

Perovskite half-metallic manganites hold promise for spintronic applications, but are not yet available in today devices because of the lack of control of their magnetotransport properties. The reason for this relies on the complexity of the physical scenarios governing the interplay between a wide variety of coupled interactions. Different magnetoresistance (MR) contributions, such as colossal MR, Lorentz MR, spin-dependent scattering at grain-boundaries, domain-walls and other magnetic inhomogeneities, typically hide the switchable anisotropic magnetoresistance (AMR) that is more amenable for technological applications. In this work, we demonstrate the ability to engineer room temperature (RT) large anisotropic magnetoresistance (AMR) in half-metallic La0.7Sr0.3MnO3 (LSMO) thin films by exploiting vicinal surfaces as substrate for the epitaxial PLD growth. These surfaces induce a surface symmetry-breaking, and hence specific magnetic anisotropy, which is responsible of the magnetization reversal pathways [1] and consequently of the magnetoresistance responses [2]. By combining simultaneous magnetization (vectorial Kerr) and transport measurements [3], we therefore disentangle the different contributions to the total magnetoresistance response [2], i.e., colossal magnetoresistance (CMR) and AMR, and demonstrate that AMR is in fact the dominant contribution (see Fig.1). Moreover, we show that the artificially tailored film surfaces induce an extrinsic magnetic anisotropy that is responsible for the large AMR tunable. In addition, by conveniently choosing the magnetization-current configuration, AMR can be tuned in sign and intensity [2]. These findings have a strong impact on the real applications of manganite-based devices for the high-resolution low field magnetic sensors or spintronics, with potential to

lower magnetic detectivity at values of nT $Hz^{-1/2}$ or below and benefiting from the very low noise of LSMO thin films in order to be able to detect neuron activity at RT, which could serve as a basis for a new generation of advanced neural interfaces applications [4].

Q7-13. Asymmetric MI effect in exchange-biased multilayered FeNi.
U. Kilic[1,2], *C.A. Gonzalez-Fuentes*[3], C. Ross[4] and C. Garcia[3] *1. Physics, North Campus KB 331-O, Bogazici University, Istambul, Turkey; 2. Electrical Engineering Department, Nebraska University at Lincoln, Lincoln, NE, United States; 3. Physics, UTFSM, Valparaiso, Chile; 4. Dept. Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, MA, United States*

The dependence of the asymmetrical magnetoimpedance (MI) response on the directions of both the magnetic field and the exchange bias has been studied for a [FeNi(60 nm)/IrMn(35 nm)]x5 multilayer system. The antiferromagnetic (AFM) layers create an exchange bias that shifts both the hysteresis loop and the MI response of the FeNi; the strength of this coupling depends on the thicknesses of both the ferromagnetic (FM) and the AFM layers. Tuning the exchange bias angle and the applied magnetic field direction provides a practical method to control the symmetry and the magnitude of the MI response [1, 2]. The observed asymmetric response can be attributed to the coexistence of two anisotropies, the induced exchange bias anisotropy, and the magnetocrystalline anisotropy. Both are distinct components of the exchange-coupled Stoner-Wohlfarth energy density which forms a basis for simulations within the conventional Landau-Lifshitz-Gilbert framework. The model reproduces the main features of the experimental results, providing a deeper understanding of the effect of the anisotropy components on the MI characteristic curve and ratio. Impedance ratio versus magnetic field for an exchange bias angle Φ_{EB}, and different directions of the applied magnetic field is shown in Figure 1. The results can be used for the development of an asymmetrical MI exchange biased thin-film element in an auto biased linear magnetic field sensor.

Q7-14. Pressure effects on martensitic transformation and magnetic properties in magnetic shape memory alloy $Pd_2Mn_{1+x}Sn_{1-x}$.
H. Okada[1], Y. Yamazaki[1] and T. Kanomata[1] *1. Tohoku Gakuin University, Tagajo, Japan*

Heusler alloys with $L2_1$ structure have attracted great interests in fields of material science. In particular, Ni-Mn based Heusler alloys have been expected to be candidates for novel high performance multifunctional materials. In Ni-Mn-In and Ni-Mn-Sn Heusler alloys, an interplay between martensitic transformation and magnetic transition gives rise to metamagnetic shape memory effect.[1] It has been reported that existence of Ni atom plays an important role for these functionalities of the Ni-Mn alloys. [2] Recently, we have found that, like the Ni-Mn alloys, Pd-Mn-Sn alloy exhibits a transition from ferromagnetic austenite to paramagnetic martensitic phases resulting in magnetic-field-induced reverse martensitic transformation associated with metamagnetic transition. [3] In this work, in order to understand the interplay between martensitic transformation and magnetic transition of Pd-Mn-Sn alloys, we have investigated pressure effect on the structural and magnetic properties of $Pd_2Mn_{1+x}Sn_{1-x}$. Under ambient pressure, the martensitic transformation temperature and the Curie temperature of austenite phase are observed at M_s = 150 K and T_C = 214 K for $Pd_2Mn_{1.44}Sn_{0.56}$ and M_s = 195 K and T_C = 216 K for $Pd_2Mn_{1.47}Sn_{0.53}$, respectively. The M_s increases with increasing applied pressure with 15 K/GPa of pressure coefficient for both alloys. The T_C of austenite phase is also increased by applying pressure with 7 K /GPa for $Pd_2Mn_{1.44}Sn_{0.56}$ and 5 K/GPa for $Pd_2Mn_{1.47}Sn_{0.53}$. The larger pressure coefficient of martensitic transformation temperature indicates that the martensite phase become stable under high pressure. As the result, disappearance of ferromagnetic austenite phase is observed in $Pd_2Mn_{1.47}Sn_{0.53}$. In fact, a pressure-induced martensitic transformation at room temperature is detected in the vicinity of 8 GPa by high pressure X-ray diffraction experiment. Although it has been reported that the structural and magnetic properties of the Ni-Mn alloys strongly depend on number of valence electron,[4] we can conclude that shrinkage of unit cell volume also plays an important role for martensitic transformation and magnetic transition in Heusler alloys with $L2_1$ structure.

Q8-01. Magnetic Tracking of Cardiac Catheters Using Flexible Magnetic Tunnel Junction Sensors. M. Hawsawi[1], S. Amara[1], *A. Almansouri*[1], H. Mohammed[1], G. Torres Sevilla[1], G. Jakob[2], S. Jaiswal[2,4], M. Kläui[2], A. Haneef[3], A. Saoudi[3], M. Hussain[1] and J. Kosel[1] *1. Computer, Electrical and Mathematical Science and Engineering Division, King Abdullah University of Science and Technology (KAUST), Thuwal, Saudi Arabia; 2. Physics, Johannes Gutenberg - University Mainz, Mainz, Germany; 3. King Abdullah International Medical Research Center, Riyadh, Saudi Arabia; 4. Singulus Technologies AG, Kahl am Main, Germany*

During cardiac catheterization, surgeons use catheters for the diagnosis and treatment of the cardiovascular system. To perform the procedure, x-ray images along with contrast agents are used to visualize the heart and track the orientation of the catheter. While this procedure is minimally invasive, the use of contrast agents can lead to acute renal dysfunction especially in high-risk patients [1] and the continuous use of x-ray imaging is harmful for both the patient and medical staff. Current navigation solutions are either bulky or expensive and, hence, a better alternative is needed [2,3,4]. Due to recent advantacements in thin film technologies as well as flexible electronics, extremely sensitive magnetic sensors can be fabricated [5,6]. In particular, Magnetic Tunnel Junctions (MTJs) hold great potential in navigation systems due to their high sensitivity and low power consumption. This paper presents the fabrication of flexible magnetic tunnel junction sensors that can be implemented on the tip of a cardiac catheter for orientation tracking. The MTJs were fabricated using standard fabrication processes followed by thinning of the silicon substrate from the back side. The MTJ stack was deposited using a magnetron sputtering system, and the silicon substrate was thinned gradually from 500 μm to 15 μm using a soft-etch-back method [7,8]. The resistance of the flexible sensors changed in response to the angle of an external magnetic field comparable to the one of the Earth (Fig. 1). The sensors were attached to the tip of a diagnostic cardiac catheter with a diameter of 2.3 mm, which shows that they met the intended minitaurization criterion (Fig. 2). The weight of the catheter only increased by 8 μg and the diameter increased by 17 μm, ensuring that the properties and handling of the cardiac catheters are not modified. The energy consumption of the sensor is 0.15 μW and the sensitivity is 4.93 %/Oe. Therefore, these sensors can be used to develop a low-energy, low-cost smart navigation system that can track the catheter's orientation while minimizing the side effects.

Q8-02. Improved Magnetic Field Sensitivity for FeCuNbSiB and Micro Planar Coil Laminate with Different Layer Structures. *Y. Wang*[1], Y. Wen[1] and P. Li[1] *1. School of Electronic Information and Electrical Engineering, Shanghai Jiaotong University, Shanghai, China*

The sandwich magnetic inductor has been widely used as transformer, magnetic recording head and radio frequency inductor [1]-[4]. When the inductor is applied with ac current, and exposed to the external dc magnetic field, the permeability of magnetic material is varied with dc field and its inductance is varied. To further improve the performance when it is used as magnetic sensor, we have studied the magnetic sensor based on FeCuNbSiB (5 mm × 15 mm × 0.028 mm) and micro planar coil (width 0.065mm, thickness 0.1mm) laminate with different layer structures, only five-layer laminate is shown as Fig.1. At 1KHz optimum operation frequency, we have studied inductance ratio (IR) and inductance ratio sensitivity to dc magnetic field (dIR/dH) for FeCuNbSiB and micro planar coil laminate with different layer structures, shown as Fig.2 (a) and (b), respectively. Here F and C denote FeCuNbSiB and micro planar coil, respectively. It is interesting to found that the relative IR for FCFCFCF, FCFCF and FCF are 409%, 665% and 372% in Fig.2 (a), respectively. The maximum IR of FCFCF laminate is about 1.79 times higher than classic sandwich structure (i.e. FCF) [4] and 1.63

times higher than seven-layer laminate (i.e. FCFCFCF). The maximum IR increases with increased FC layers and then gradually decreases. The reason is the tradeoff between increased mutual inductance between increasing coil numbers and increased demagnetizing field (i.e. decreasing the effective permeability and corresponding inductance) from increasing magnetic layers when FC layers increase. The dIR/dH for FCF, FCFCF and FCFCFCF laminates are -28%/Oe, -45%/Oe and -38%/Oe, respectively. Both FCFCF and FCFCFCF laminates provide higher magnetic field sensitivity compared to the classic sandwich magnetic inductor [1]-[4]. Compared to the NiFe/Cu/NiFe multilayer thin films (31%/Oe sensitivity at 70 MHz frequency) based on giant magnetoimpedance (GMI) effect [5], our FCFCF and FCFCFCF laminates also provide higher sensitivity and lower operation frequency, which avoid the high cost for radio frequency current source.

Q8-03. The Effect of Stray Fields and Interlayer Exchange Coupling in Patterned $Fe_{88}Cu_{12}$/MgO Superlattices. *T. Warnatz*[1], B. Skovdal[1], F. Magnus[2], H. Stopfel[1], I. Chioar[1] and B. Hjörvarsson[1] *1. Physics and Astronomy, Uppsala University, Uppsala, Sweden; 2. Science Institute, University of Iceland, Reykjavik, Iceland*

The quest for large tunnel magnetoresistance has stimulated substantial research activities addressing the properties of ferromagnetic/insulating/ferromagnetic structures. An interlayer exchange coupling (IEC) across the insulating layer has been observed, which strongly depends on the crystalline quality of e.g. Fe/MgO trilayers [1]. Tuning the insulating layer thickness can therefore be used to stabilize different remanent states in Fe/MgO superlattices using the interplay between IEC and magnetocrystalline anisotropy [2]. Furthermore, alloying Fe with small amounts of Cu can be used to weaken the magnetocrystalline anisotropy [3], while maintaining the bcc crystalline structure [4]. Here, we present magnetic properties of circular islands patterned from superlattice thin films with an even number of magnetic layers (fig. 1). When patterning multilayered structures into circular islands, an additional energy term can become prominent - the stray field at the edges of the layers [5, 6]. The multilayered islands exhibit size dependent saturation fields (fig. 2), due to the changes in the edge-surface to volume ratio, which scales with the inverse island diameter [7]. When the lateral size of the elements is large, the magnetocrystalline anisotropy and IEC dominate the resulting order. Reducing the diameter to 150nm results in a domination of the magnetic ordering by the stray field [8]. These results are essential for designing patterned ferromagnetic/insulator/ferromagnetic tunnel junctions with customized magnetic properties. By tuning the stray field coupling (altering the island diameter) [7,8] and interlayer exchange coupling (alternating the thickness of the insulating layer) [1,2] a control of the response can be tailored almost at will. These effects can thereby be used to obtain desired functionality in both sensing and controlling devices.

Q8-04. X-Ray Magnetic Circular Dichroism of Boron Substituted Ni-Mn-In Thin Films. *S. Pandey*[1], A.T. N'Diaye[2], I. Dubenko[1], A. Aryal[1], D. Mazumdar[1], S. Roy[2], S. Stadler[3] and N. Ali[1] *1. Physics, Southern Illinois University Carbondale, Carbondale, IL, United States; 2. Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA, United States; 3. Louisiana State University, Baton Rouge, LA, United States*

Ni-Mn-In-B thin films were synthesized on Si substrates using ultra-high vacuum magnetron sputtering. Metamagnetic transitions with thermal hysteresis have been observed on 30 nm thin films using the magnetization measurements. The temperature dependences of the magnetization curves were found to be similar to those of the bulk counterpart. Electronic and magnetic properties of Ni-Mn-In-B thin films were studied using X-ray absorption spectroscopy (XAS) and X-ray magnetic circular dichroism (XMCD). From the XAS and XMCD spectra, we have observed that Ni plays a dominant role in the overall magnetism. Element-specific XMCD hysteresis loops of Ni in the NiMnInB films were measured as a function of temperature and observed minimum magnetic hysteresis at martensitic transformation. Possible mechanisms responsible for the changes in electronic and magnetic properties of thin films through the effect of redistribution of d electrons are discussed. Q8-05. Electrical detection of artificial skyrmion in synthetic antiferromagnetic nanostructures at room temperature. *F. Ma*[1,2], Q. Feng[3], S. Li[1], P. Pan[2], Y. Li[2], X. Jin[2], Q. Lu[3] and W. Lew[1] *1. School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore; 2. School of Physics and Technology, Nanjing Normal University, Nanjing, China; 3. High Magnetic Field Laboratory, Chinese Academy of Sciences, University of Science and Technology of China, Hefei, China*

Magnetic skyrmions, a topologically protected novel spin configuration, have been observed in noncentrosymmetric bulk crystals; thin films of noncentrosymmetric crystals; and ultrathin layers and multilayers with a surface or interface induced Dzyaloshinskii-Moriya interaction (DMI). Since the compatibility with CMOS device technology and the intrinsic parameters tenability by varying the thickness of the layers and the composition at the interface, the metallic multilayers with the presence of nanoscale skyrmion show high promising for spintronic memory and logic devices [1-5]. From the device integration point of view, one of the most crying needs is the ability of measuring these topological spin textures through their contribution to the electrical transport properties of a device. Here, we demonstrate the room temperature (RT) observation and electrical detection of artificial skyrmions in synthetic antiferromagnetic (SAF) nanostructures using magnetic force microscopy (MFM) and Hall resistivity measurements. The skyrmion-like domians were observed in nanodots of various diameter from 200nm to 1200 nm at RT under a finite external field by MFM measurement. It is found that the skyrmion nucleation is attributed to the interlayer exchange coupling in the SAF trilayer, which is in contrast to the skyrmions in the multilayers with interlayer dipolar coupling [2-5]. Then, the anomalous Hall signal of either a single skyrmion or multiple skyrmions in a cross Hall bar were detected and analyzed. The measured transverse Hall resistance exhibits a multi-step switching along with the external field. By comparing with the field-dependent MFM images, we found that the Hall resistance is correlated to the skyrmion nucleation/annihilation as well as the size/number of the skyrmion.

Q8-08. Magnetic Properties of Nickel Films on Surface Acoustic Wave Devices. *S.A. Mathews*[1], N.S. Bingham[2], R. Suess[1], K. Charipar[1], R. Auyeung[1] and N. Charipar[1] *1. Materials Science and Technology Division, Naval Research Laboratory, Washington, DC, United States; 2. National Research Council Fellow, Naval Research Laboratory, Washington, DC, United States*

Combining magnetostrictive materials with surface acoustic wave (SAW) devices enables magnetic sensors that exploit the ΔE-effect without the need for cantilevers, membranes, or other free-standing structures[1]. We report the fabrication and testing of magnetic SAW devices comprised of a magnetostrictive layer and interdigital transducers (IDTs) on a piezoelectric substrate. The acoustic wave created by the IDTs propagates through the region with the magnetostrictive layer, such that changes in the modulus of the magnetostrictive layer alter the acoustic propagation. Aluminum IDTs and magnetostrictive regions comprised of 5 nm of Ti (adhesion layer) and 100 nm of Ni were fabricated on 128° Y-cut $LiNbO_3$ substrates. All films were deposited by e-beam evaporation and patterned by lift-off photolithography. The IDTs launch a Rayleigh-type acoustic wave at approximately 98 MHz which propagates in the crystallographic x-direction of the substrate. The change in frequency of one-port and two-port SAW oscillators was measured as a function of DC bias field. The results were compared to vibrating sample magnetometer measurements (VSM). Devices were characterized "as deposited", after annealing at 325°C for 2 hours, and after annealing in a magnetic field (400 Oe, perpendicular to the x-direction). VSM measurements indicate that annealed devices show a strong uniaxial anisotropy with the easy axis parallel to the x-direction of the substrate (Figure 1). Annealing in a magnetic field did not significantly alter the anisotropy. The normalized change in frequency shown in Figure 2 is on the order of 10^{-4}, consistent with similar devices reported in the literature[2]. These frequency measurements, along with RF characterization of the SAW devices will be presented and discussed in terms of the ΔE-effect[3] and the effective anisotropy field. In addition to serving as high-sensitivity magnetic sensors, these devices may provide additional information about the magnetization process and the interaction of surface acoustic waves with Ni films.

Session Q9
PERMANENT MAGNETS IN THE $ThMn_{12}$ STRUCTURE
(Poster Session)

Hiroki Tsuchiura, Chair
Tohoku University, Sendai, Japan

Q9-01. Magnetic properties of $SmFe_{12}$-based magnets produced by spark plasma sintering method. T. Saito[1] and *F. Watanabe*[1] *1. Chiba Institute of Technology, Chiba, Japan*

There has been a great deal of interest in Nd-Dy-Fe-B magnets due to their high maximum energy product. However, there is an extremely short supply of rare-earth materials, particularly Dy, in the international market. A trend toward reduction of Dy content can be seen in the research and development of rare-earth magnets [1], and demand has arisen for the development of a new permanent magnet that does not contain Dy. RFe_{12} (R = rare earth) compounds have been attracting renewed interest as promising candidates for Dy-free magnets [2,3]. It has recently been reported that the $SmFe_{12}$ phase possesses both a high saturation magnetization and a high anisotropy field, which are essential for permanent magnets [4]. In this study, we produced $SmFe_{12}$-based magnets by the spark plasma sintering (SPS) method. The structures and magnetic properties of the $SmFe_{12}$-based magnets produced by the SPS method were examined. $SmFe_{12-x}Ti_X$ (x = 0–2) alloy ingots were prepared by induction melting under an argon atmosphere and then ejected through an orifice with argon onto a copper wheel rotating at a surface velocity of 50 ms^{-1}. The resultant melt-spun ribbons were comminuted into powders and then consolidated into bulk materials at 873–1073 K under an applied pressure of 100 MPa by the SPS method. The powders were successfully consolidated into bulk magnets regardless of the Ti content. X-ray diffraction and thermomagnetic studies confirmed that these bulk materials consisted of the $SmFe_{12}$ phase. The magnetic properties of the magnets produced by the SPS method were deeply dependent on the composition of the specimen and on the sintering temperature. Figure 1 shows the hysteresis loops of the $SmFe_{11}Ti$ melt-spun ribbon and the $SmFe_{11}Ti$ magnet produced at 1073 K by the SPS method. The $SmFe_{11}Ti$ melt-spun ribbon was amorphous and thus showed a low coercivity. However, the $SmFe_{11}Ti$ magnet produced by the SPS method consisted of the $SmFe_{12}$ phase and exhibited a large coercivity.

Q9-02. Elastic and Magnetoelastic Properties of Fe-rich Tetragonal Y-Fe Compounds: Phenomenology and Electron Theory. *J. Inoue*[2,1], T. Yoshioka[2] and H. Tsuchiura[2] *1. Department of Applied Physics, Univsersity of Tsukuba, Tsukuba, Japan; 2. Department of Applied Physics, Tohoku University, Sendai, Japan*

Rare-earth – iron intermetallic compounds which are essential for permanent magnets have often tetragonal lattices. Explanation of the anisotropic properties of magnetic, elastic and magneto-elastic (ME) properties of the tetragonal compounds in terms of their electronic states is crucial for the basic physics and technological development of novel permanent magnets. Although the magnetic anisotropy (MA) has been intensively studied so far, the elastic and ME properties have yet to be studied in detail by electron theory. To this end, we first derive phenomenological expression of the elastic and ME energies as a function of lattice deformation in tetragonal lattices. After clarifying the relationship between the elastic and ME constants and the electronic states of the lattices, we perform numerical calculations for iron-rich tetragonal Y-Fe compounds, in particular, $Y_2Fe_{14}B$, hypothetical YFe_{12} (YF), and $YFe_{11.5}Ti_{0.5}$ (YFT). We adopt the first-principle method to calculate the ground state energy of the system and the elastic constants. We found that even the hypothetical YF compound has a local energy minimum as a stable state, and that YF and YFT are softer than $Y_2Fe_{14}B$. We further show that the strain dependence of the magnetization is larger in YF and YFT than in $Y_2Fe_{14}B$, in consistent with the tendency of weak ferromagnetism in Fe-rich Y-Fe compounds. The numerical results also show that the lattice constants of YFT are larger than those of YF, suggesting that the lattice expansion stabilizes the ferromagnetic state in transition-metal doped YFe_{12} compounds. The phenomenological theory gives a relationship amang ME constants, MA and small lattice deformation under constant volume. The relationship provides a way to calculate ME constants in the electron theory, however, high numerical accuracy is desired because the ME constants are much smaller than elastic constants. We therefore adopt a second-order perturbation method [1, 2] to calculate MA and ME constants. Results and discussion will be given in the presentation.

Q9-03. Surface magnetic anisotropy in $SmFe_{12}$ and $NdFe_{12}$ systems. *T. Yoshioka*[1,2], D. Suzuki[1] and H. Tsuchiura[1,2] *1. Department of Applied Physics, Tohoku University, Sendai, Japan; 2. ESICMM, National Institute for Materials Science, Tsukuba, Japan*

Because of increasing demands for high performance permanent magnets for use in high-power motor drives, intensive studies are being carried out to invent new magnetic materials as good as, or better than Nd-Fe-B. The family members of RFe_{12} and its derivative materials with the $ThMn_{12}$ structure are the possible candidates because high spontaneous magnetization is expected due to their high fraction of Fe. Thus, they have become the object of a considerable renewed interest. Within these family members, in particular, $NdFe_{12}$ and $SmFe_{12}$ attract particular attention because they have been found to exhibit promising properties [1, 2]. Quite recently, we have pointed out that the Nd ions exposed on the (001) surface of the $Nd_2Fe_{14}B$ structure not only lose their uniaxial local magnetic anisotropy but also exhibit planar anisotropy. It has also been found that the switching field of a single fine particle of the magnet can be reduced. We can expect that the same thing

may happen also in RFe$_{12}$ systems. In this contribution, we focus on the local magnetic properties around the surfaces of NdFe$_{12}$ and SmFe$_{12}$ systems. We here define a crystal field Hamiltonian for R ion in these systems with simple surfaces based on first-principles calculations. As an example, we show (001) surface model structure for the Co substituted SmFe$_{12}$ system in Fig. 1. The leading crystal field parameter $A_2^0\langle r^2\rangle$'s are also shown. We found that the absolute value of $A_2^0\langle r^2\rangle$'s for Sm on the (001) surface are increased. This may indicate that in contrast to the Nd$_2$Fe$_{14}$B structure the local uniaxial anisotropy around (001) surface in SmFe$_{12}$ structure can be enhanced. Indeed, as shown in Fig. 2, we have confirmed the enhancement of temperature dependent anisotropy constants not only K1 but also K2 on (001) surface, which values are obtained from the high-order crystal field parameters. We will discuss the magnetic anisotropy at finite temperatures in several 1-12 type rare-earth compounds with various surfaces.

Q9-04. Magnetic Properties of 1:12 Alloys: An Ab Initio Study.
O. Vekilova[1], O. Eriksson[1] and H.C. Herper[1] *1. Physics and Astronomy, Uppsala University, Uppsala, Sweden*

The discovery of Nd$_2$Fe$_{14}$B, the best permanent magnet to date, has stimulated the search for good permanent magnets among intermetallic compounds containing rare earth elements and 3d transition metals, specifically Fe. The iron-based compounds are very promising because of their large magnetic moments due to the high concentration of Fe, rather high coercivity and high Curie temperature. One of the best candidates are the 1:12 compounds with the ThMn$_{12}$-type structure [1]. However, it has been shown that light rare earths and iron cannot form a stable binary 1:12 compound, and a third element must be added to stabilize the ternary RE(Fe,M)$_{12}$ phase, where M=Ti, V, Si, Mo and etc. [2-3]. Such substitution results in a significant decrease in the saturation magnetization of the compound not only because the M atom does not carry a magnetic moment but also because it causes a reduction of the magnetic moments of surrounding Fe atoms [3]. The change in the structure due to the substitution of iron by other elements can also influence magnetocrystalline anisotropy and Curie temperature. A number of attempts to stabilize the compounds with the decreasing concentration of M element have recently been made. Most of the known 1:12 compounds are stable when they have 10 atoms of Fe and 2 atoms of an impurity in the unit cell (REFe$_{11}$M). An example is SmFe$_{10}$V$_2$. However, NiFe$_{11}$Ti is known to be stable even with one Ti atom per formula unit (see Fig. 1). Recent experiments show that it is also possible to stabilize the 1:12 phases with reduced concentrations of V or Ti. In this work the magnetic properties of the 1:12 compounds were studied theoretically from first principles. Starting from the known stable NiFe$_{11}$Ti, SmFe$_{11}$Ti and SmFe$_{10}$V$_2$ phases we tried to improve the magnetic properties by reducing the content of Ti and V respectively. The phase stabilities of NdFe$_{11-x}$Ti$_x$ and SmFe$_{10-x}$V$_x$ were calculated and compared to the available experimental data. A new stable compound with promising magnetic properties was revealed. This work is supported by the European Research Project NOVAMAG (EU686056) and STandUP for energy (Sweden).

Rare-earth (R)-iron alloys are a backbone of permanent magnets. Recent increase in price of rare-earths has pushed the industry to seek ways to reduce the R-content in the hard magnetic materials. For this reason strong

magnets with the $ThMn_{12}$-type of structure came into focus. Functional properties of $R(Fe,T)_{12}$ (T-element stabilizes the structure) compounds or their interstitially modified derivatives, $R(Fe,T)_{12-X}$ (X is an atom of hydrogen or nitrogen) are determined by the crystal-field and exchange interaction parameters [1-4]. We chose the ferrimagnetic Tm-containing compounds, which are most sensitive to magnetic field and demonstrated that $TmFe_{11}Ti$-H reaches the ferromagnetic state in the magnetic field of 52 T. Knowledge of the exact crystal-field and exchange parameters and their variation in compounds modified by interstitial dopings is a cornerstone of the quest for hard magnetic materials with low rare-earth content. In this work, we calculated the crystal-field and exchange parameters using high-field magnetization data for $TmFe_{11}Ti$ and $TmFe_{11}TiH$ [2]. The magnetization curves were obtained experimentally in fields up to 60 T at 4.2 K along main crystallographic axes. By using the calculated parameters we succeeded in modeling the magnetization curves for $TmFe_{11}Ti$ and $TmFe_{11}TiH$ up to 100 T. This allowed us to study the field-induced transitions taking place in magnetic fields exceeding 60 T. This work was supported by the Russian Foundation for Basic Research, project no. 16-03-00612, 18-02-00994 and by the Hochfeldlabor Dresden, part of the EMFL.

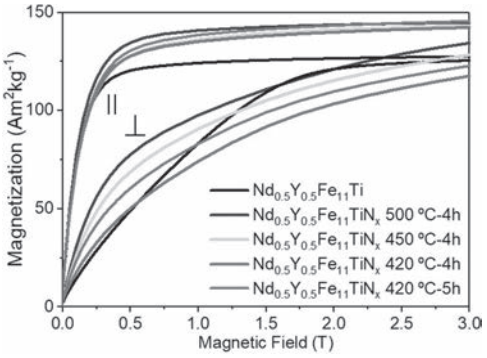
Iron-rich intermetallic phase of $ThMn_{12}$ tetragonal structure received much focus as new promising permanent magnet materials with high saturation magnetization and anisotropy field. Since most binary RFe_{12} phase are not thermodynamically stable and no practical bulk form is realized, partial substitution of Fe with element M such as Ti, V, Si, Co, etc has been conducted to stabilize the tetragonal structure and highly-textured binary thin films epitaxially grown on single-crystal substrates can be obtained recently. To fabricate and enhance the magnetic properties of RFe_{12} of bulk form, the refinement of grain size, modification of the grain boundary phase, etc is needed to investigate with the bottom-up process using the constituent materials less than meso-scale (<10 μm) and nano-scale dimension. Meso(nano)-scale crystalline $Sm(Fe,M)_{12}$ with M =Ti, V, Co bulk magnets were prepared by solid-state reaction under an argon inert atmosphere using the fine element powders. The mixed powders with different composition were grounded and the pressed pellets were heat-treated at 700-1000°C in Ar (or Ar-4% H_2) gas flow for 30-60 min. Tetragonal 1:12 phase was formed with the additional impurities like SmO with fcc structure and some phases like $SmFe_5$, $SmFe_9$, Sm_2Fe_{17} were also detected in X-ray diffraction. Also it is found that Sm-rich bulk sample significantly reduce the soft α-Fe phases which is completely disappeared at $Sm_{20}Fe_{80}$ heat-treated at 950°C in Ar-4%H_2. Multi-phases with the main 1:12 phase and sub phases having different composition and morphology was shown to have an impact on the magnetic properties like coercivity. More detailed microstructure and phase analysis with magnetic properties of 1:12 bulk samples will be discussed including the effect of additional elements of Ti, V, and Co.



Q9-07. Is There a Magnetic Moment of Ti in $Sm(Fe_{1-x}Co_x)_{11}Ti$ (x = 0 and 0.2) ?. *H. Suzuki*[1], A. Nambu[2] and M. Okamoto[2] *1. Magnetic Materials Company, Hitachi Metals, Ltd., Kumagaya, Japan; 2. Research & Development Group, Hitachi, Ltd., Hatoyama, Japan*

The Fe-based $ThMn_{12}$ (RFe_{12}) structure has an equilibrium phase only when M elements (M is Al, Si, Ti, V, Cr, Mn, Mo, W, etc) are substituted into part of the Fe [1]. In a first principle calculation (FPC), since the magnetic moments of the M element are aligned antiferromagnetically to those of the Fe element, the decrease in the total magnetization is greater than that in Fe concentration. M elements are, however, often treated as a non-magnetic element in neutron diffraction analysis, because there are no direct experimental evidence of their magnetic momentum and their directions. Therefore, setting representative system $Sm(Fe_{1-x}Co_x)_{11}Ti$ (x = 0 and 0.2), which are matrix phases of permanent magnets, to search the origin of the total magnetization reduction, we evaluated Ti moment with X-ray magnetic circular dichroism (XMCD) and identified the strength of them with powder neutron Rietveld analysis (PNRA). Moreover, the results of experiments were verified by using the FPC. Samples using the 99.9+ % grade materials were fabricated with rapidly quenched method for composition uniformity. After being annealed at 1100°C for 0.3 hours in an Ar atmosphere, these samples consisted of the single phase mostly. Figure shows X-ray absorption spectroscopy (XAS) taken with opposite X-ray helicities and XMCD spectra of (a) Co and (b) Ti with partial fluorescence yield (PFY) method in $Sm(Fe_{0.8}Co_{0.2})_{11}Ti$ at room temperature. XMCD spectra are calculated as a difference of two XAS spectrum shown in each figures. The peaks of L_{II} and L_{III} edges detected in an opposite direction corroborate the XMCD signals. We tentatively assign peaks indicated by yellow allows to metal component, while peaks indicated by gray allows to oxides. Since XMCD signals of the Ti from the metal components were detected in an opposite direction to those of the Co, it was cleared that the Ti have a magnetic moment and their momentum coupled antiferromagnetically to ones of the Co. It should be noted that it is believed that the momentum of the Co and the Fe are ferromagnetic. We are to show the improved fitting results of PNRA with a ferrimagnetic model and data supported it by the FPC of $Sm(Fe_{1-x}Co_x)_{11}Ti$.

Q9-08. Improving the properties of $NdFe_{11}Ti$ for permanent magnet applications by Y substitution and nitrogenation. *A. Martín-Cid*[1], O. Tosun[3], A. Gabay[3], D. Salazar[1], J.M. Barandiarán[1,2] and G. Hadjipanayis[3] *1. BCMaterials, Leioa, Spain; 2. University of the Basque Country (UPV/EHU), Bilbao, Spain; 3. Physics and Astronomy, University of Delaware, Newark, DE, United States*

Rare Earth (RE) permanent magnets (PM), based in Nd-Fe-B, have an increased demand for electric vehicles and wind generators as well as robots for industry and services, hard drives, refrigerators, phones, etc. Scarcity of RE, categorized as critical raw materials, and environmental problems related with their production [1] have led to the search for new RE-free/lean alloys as alternatives for permanent magnets development. Therefore, a renewed interest has arisen on the $REFe_{12}$ compounds with the tetragonal $ThMn_{12}$ (1:12) structure [2]. These compounds present an inherent lean content of RE (7.7 at.%) as compared with $Nd_2Fe_{14}B$ (11.8 at.%) magnets. Among the 1:12 compounds, $NdFe_{12}$ with interstitial N is of special interest as it presents intrinsic hard magnetic properties superior to those of $Nd_2Fe_{14}B$ [3]. Binary $REFe_{12}$ compounds, however, need a third element, such as Ti, Mo, Si or V, to stabilize the 1:12 structure. Such a third element reduces the saturation magnetization and the Curie temperature of the alloy. Using Ti, only one atom per formula is enough for stabilizing the phase, leading to better magnetic properties among other stabilizing elements [4]. Recent theoretical predictions [5] indicate that substituting Y for Nd in $Nd_{1-x}Y_xFe_{11}Ti$ will greatly improve the magnetic anisotropy. The preference of N atoms to sit between the Y atoms, instead of Nd ones, also hints for an easier nitrogenation in the presence of Y. In this work, we report the synthesis of $Nd_{0.5}Y_{0.5}Fe_{11}Ti$, by arc-melting of the pure constituents, followed by an annealing at 1175 °C to obtain the 1:12 structure. This alloy was afterwards nitrogenated at different times and temperatures to improve its magnetic properties. Preliminary results yield an increase of the magnetic anisotropy field from 1.75 T to over 3 T, while the Curie temperature increased from 270 °C up to 390 °C and the saturation magnetization is above 120 Am^2kg^{-1}. These properties present great perspectives for PM applications. This work has been funded by the EU-Horizon2020 project NOVAMAG-686056 and DOE-DE-FG02-90ER45413.

Q10-01. First Principles Description of Correlation Driven Lattice Energetics in *R*NiO_3 Compounds by DFT+DMFT. *A. Hampel*[1] and C. Ederer[1] *1. Materials Theory, ETH Zurich, Zurich, Switzerland*

Perovskite rare-earth nickelates, *R*NiO_3, display a rich phase diagram with coupled structural, magnetic, and electronic degrees of freedom. All compounds with *R* from Pr to Lu undergo a metal-insulator transition (MIT) that is accompanied by a structural distortion [1], which breaks the symmetry between formerly equivalent Ni sites and can be understood as a charge disproportionation of the Ni^{3+} cations into Ni^{2+} and Ni^{4+}. Both the transition temperature as well as the strength of the charge disproportionation vary strongly as function of the rare-earth ion. We explore the complex interplay between lattice distortions and electronic correlation effects in these compounds. To do so, we decompose the structure into distortion modes, which allows us to determine the structural ground state of the system by varying the different structural degrees of freedom individually and comparing total energies calculated within charge self-consistent density functional theory plus dynamical mean field theory (DFT+DMFT) approach. Moreover, we employ the constraint random phase approximation (cRPA) method to calculate interaction parameters in the e_g-e_g correlated subspace and reveal a strong reduction of the effective Coulomb interaction *U* due to screening, which also increases across the series from *R*=Lu to La. Accurate structural trends across the series are then derived and the subtle influence of the interaction parameters *U* and *J* is analyzed. Therefore, our results demonstrate the successful description of the coupled structural and metal-insulator transition in rare-earth nickelate compounds without empirical parameters.

Institute for Theoretical Physics, Heidelberg University, Heidelberg, Germany*

Resonant inelastic x-ray scattering (RIXS) has proven to be a versatile and effective tool to measure magnetic excitations[1]. Thanks to recent advances in the instrumentation at the ID32 beamline at the ESRF, we have been able to study the nickelate $NdNiO_3$ (NNO) using RIXS at the Ni L_3 edge. In general, these rare-earth perovskites undergo a metal-insulator transition at T_{MIT} accompanied by the formation of a pattern of expanded (Ni_A) and compressed (Ni_B) NiO_6 octahedra as a result of bond-disproportionation[2,3]. The Ni sites have separate peaks in x-ray absorption spectra (at E_A and E_B) and different spin moments ($S_A > S_B$). Below T_{MIT}, the spins order in a non-collinear configuration with ordering vector Q = (1/4, 1/4, 1/4) in pseudocubic notation and adjacent spins approximatively orthogonal to each other (↑←↓→)[4]. We measured RIXS spectra varying the transferred momentum along the [111] direction for a 40 nm-thick NNO film, both above and below $T_{MIT} \approx 200$ K. The properties of each Ni site can be investigated by tuning the incoming energy E_i to their respective resonances. Removing the elastic peak at zero energy loss, a magnetic excitation is visible when $E_i = E_A$ and for $T < T_{MIT}$ (Fig 2a-b). The peak is made clearer by subtracting the corresponding high-temperature spectra (Fig 2c-d). On the contrary, the spectra taken with $E_i = E_B$ do not show any magnetic peak. The dispersion and the magnetic spectra have been calculated using a four-sublattices model and we obtained excellent agreement with the measured spectra, showing that the magnetic excitations are indeed heavily suppressed when $E_i = E_B$. In summary, our study demonstrates the site-selective capabilities of RIXS and it is the first determination of exchange parameters and magnetic configuration in film of rare-earth nickelates.

Q10-03. Relation between magnetic ordering and crystal structure during Mott transition in NiI_2 and $NiBr_2$. *V. Potapkin*[1], G. Konstantin[2], V. Cerantola[3], A. Kurnosov[4] and A. Pakhomova[2] *1. Institute for Mineralogy, Westfälische Wilhelms-Universität Münster, Münster, Germany; 2. Deutsches Elektronen-Synchrotron (DESY), Hamburg, Germany; 3. European Synchrotron Radiation Facility, Grenoble, France; 4. Bayerisches Geoinstitut, Universität Bayreuth, Bayreuth, Germany*

The system MX_2 (M: transition metal, X: halogen) have been attracting attention for a long time. Indeed, it is one of the key model system for studying strong correlations in general and Mott transition in particular. Ni based metal dihalides are ideally suited for investigating Mott type Insulator→-Metal transitions(IMT) due to Nickel $3d^8$ electronic configuration. That configuration is of great interest for investigation of Mott related transitions as correlation can be suppressed only through electron delocalization and not spin paring or other effects related to the electron symmetry breakage. The pressure induced Mott IMT was first observed by means of ^{129}I Mossbauer spectroscopy in NiI_2. In this compound the IMT appears at ~19 GPa. In powder XRD studies no discontinuous changes in lattice parameter or unit cell volume were detected[1], suggesting a purely electronic transition. Such behavior was in sharp contrast to other dihalides like FeI_2, $FeCl_2$[2] or CoI_2[3], where the IMT is accompanied by a discontinuous change in structural parameters. The absence of a significant pressure-induced change of the structure accompanying the IMT in NiI_2 would therefore be an exceptional case. Here we present a high pressure single crystal study of NiI_2 performed at room temperature (RT) up to 40 GPa with a focus to determine relation between IMT also associated with collapse of magnetic ordering and crystal structure. Results shows NiI_2 maintains R-3m symmetry in the whole pressure range but indicate subtle second order transition. Up to ~15 GPa volume decrease mainly through c-axis rapid contraction. At ~15 GPa, when T_N increase above RT, the structural parameter χ angle defining distortion of NiI_6 octahedron becomes practically incompressible, until IMT/magnetic ordering collapse at 19 GPa. After transition, structure compression happens isotropically. Approaching the NiI_2 system as a reference one, we have determined characteristic criteria corresponding to the onset of IMT – χ parameter and c/a lattice ratio. Knowing structure response to IMT in NiI_2 system allowed us to determine the pressure of IMT in $NiBr_2$, thus investigate collapse of magnetic order in $NiBr_2$ through XRD.

Q10-04. Doping-Induced States near the Mott Transition in the Presence of Antiferromagnetic Order. *M. Kohno*[1] *1. National Institute for Materials Science (NIMS), Tsukuba, Japan*

The most significant characteristic of the Mott transition is emergence of electronic states in the Mott gap following doping. Here, by taking into account spin fluctuation around the mean-field ground state using the random-phase approximation, the doping-induced states are shown to appear exhibiting the spin-wave dispersion relation shifted by the Fermi momenta on doping an antiferromagnetically ordered Mott insulator. This characteristic contrasts with that of the mean-field approximation where doping does not induce electronic states in the Mott gap, because the spin-flip excitation has an energy gap of the order of the Coulomb interaction in the Mott insulator in the mean-field approximation. Since electronic states exhibiting the momentum-shifted magnetic dispersion relation emerge in the Mott gap on doping antiferromagnetically ordered Mott insulators as well as paramagnetic Mott insulators [1, 2, 3], this is a general and fundamental characteristic of the Mott transition.

Q10-05. Muon spin spectroscopy study of the magnetic field and pressure-induced quantum phase transition in $CsFeCl_3$. *A.M. Nikitin*[1], Z. Shermadini[1], R. Scheuermann[1], G. Simutis[1], R. Khasanov[1], N. Kurita[2], H. Tanaka[2], C. Rüegg[3,4], A. Amato[1] and H. Luetkens[1] *1. Laboratory for Muon-Spin Spectroscopy, Paul Scherrer Institut, Villigen PSI, Switzerland; 2. Tokyo Institute of Technology, Meguro-ku, Japan; 3. Laboratory for Neutron Scattering and Imaging, Paul Scherrer Institut, Villigen PSI, Switzerland; 4. Department of Quantum Matter Physics, University of Geneva, Geneva, Switzerland*

$CsFeCl_3$ is a gapped quantum magnet with a singlet ground state that exhibits a putative magnetic field-induced Bose-Einstein condensation of magnons leading to a long-range antiferromagnetic order for fields above $H_c = 4$ T and at temperatures below $T_N = 2.6$ K [1]. This compound crystallizes in a hexagonal crystal structure [2], in which the magnetic Fe^{2+} ions are octahedrally coordinated by six Cl^- ions. The Fe ions form ferromagnetically coupled chains along the c-axis and are antiferromagnetically coupled within the hexagonal plane. The gap in this system originates from non-dimerized $S = 1$ spins where the $S_z = 0$ state is gapped from the doublet $S_z = \pm 1$ state due to the single ion anisotropy D. Recently, the rare case of a pressure-induced quantum phase transition was reported for this system with a critical pressure of 0.9 GPa [3]. We have carried out an extensive experimental investigation of the pressure and field-induced ordered states by muon spin rotation and relaxation (μSR). μSR allows to investigate the magnetism on a microscopic level and to obtain the ordered volume. The pressure dependent measurements have been performed using a piston-type clamp pressure cell reaching up to 2.0 GPa and temperatures down to 0.25 K. The measurements in field were carried out in magnetic fields up to 4.5 T and temperatures down to 20 mK. These measurements have been performed with the magnetic field parallel to the single ion anisotropy axis (c-axis) for which Bose-Einstein condensation of magnons is predicted. The obtained results show that $CsFeCl_3$ is in a dynamic magnetic state at low pressures and it possesses static long-range magnetic order at pressures above p_c as evidenced by spontaneous zero field μSR oscillations. We have obtained the ordered volume and the Néel temperature as a function of pressure from transverse field μSR measurements. The high field results confirm the magnetic ordering of the system above the critical field. We will discuss the differences and similarities between pressure and field-induced states in the context of BEC quantum critical phases.

Q10-06. Pressure-induced quantum critical phenomena and magnetic order in the chiral compound $YbNi_3Ga_9$: AC-calorimetric measurements up to 12 GPa. *T. Otaki*[1], K. Umeo[2], Y. Arai[3], T. Takabatake[1] and S. Ohara[4] *1. Graduate School of Advanced Sciences of Matter, Hiroshima University, Higashi, Japan; 2. N-BARD, Hiroshima University, Higashi, Japan; 3. Science, Hiroshima University, Higashi, Japan; 4. Department of Physical Science and Engineering, Nagoya Institute of Technology, Nagoya, Japan*

In recent years, chiral magnets such as $Cr_{1/3}NbS_2$ and MnSi have received renewed interests as the materials where the chiral soliton lattice (CSL) and skyrmion lattice are realized [1,2]. The Yb-based compounds $YbNi_3X_9$ (X = Al, Ga) crystallize in the trigonal $ErNi_3Al_9$-type structure with a chiral space group *R*32, making them potential candidates for systems exhibiting chiral magnetic structures as well as quantum critical phenomena. $YbNi_3Al_9$ exhibits a helical magnetic order at $T_M = 3.4$ K. By the substitution of Cu for Ni, a CSL is realized in magnetic fields *B* applied perpendicular to the helical axis ($B \perp c$) [3]. $YbNi_3Ga_9$, on the other hand, is a valence fluctuation system with the Sommerfeld coefficient γ of 30 mJ/K^{2}mol at ambient pressure. In this system an antiferromagnetic (AFM) order is induced at $T_N \sim 3$ K above $P_c = 9$ GPa [4, 5]. Furthermore, at $P = 8.5$ GPa $< P_c$, the field dependence of χ_{ac} suggests a first-order metamagnetic transition at $B \perp c = 0.7$ T, which is attributed to the first-order valence transition [5]. In order to investigate the first-order valence transition near P_c and the magnetic phase above P_c in $YbNi_3Ga_9$, we have measured the specific heat *C* by ac calorimetry under pressures up to 12 GPa and magnetic fields up to 8 T for $B \| c$ and $B \perp c$. By increasing pressure up to 8.6 GPa ($< P_c$), the γ value increases to 1 J/K^{2}mol. Thereby, C/T is proportional to $-\ln T$ for $1.5 \text{ K} < T < 5$ K. Furthermore, at 8.6 GPa, the field dependence of C/T exhibits a maximum at $B \perp c = 0.6$ T, which field value agrees with that of the first-order metamagnetic transition [5]. At $P = 9.3$ GPa, a broad peak in C/T appears at $T_N = 1.5$ K reflecting the AFM order. With increasing *P* further, the peak shifts to higher temperatures and becomes a sharp λ-type peak at 5 K for $P \geqq 11$ GPa. By using the data of $C(T, P)$ obtained under $B \perp c$, we have constructed *B*-*T* phase diagrams at each *P*. The results at $P \geqq 11$ GPa have another field-induced ordered phase (FIOP) appearing only for $B \perp c$. We discuss the origin of the FIOP in relation to the CSL for $Yb(Ni_{1-x}Cu_x)_3Al_9$ and A-phase for MnSi [2] and EuPtSi [6].

Q10-07. Identify the High-Temperature High-Magnetic Field Phase Boundary of the Valence Transition in $CeOs_4Sb_{12}$. *P. Ho*[1], J. Singleton[2], M. Jaime[2], M.B. Maple[3], K. Sasmal[3] and T. Yanagisawa[4] *1. Physics, California State University, Fresno, Fresno, CA, United States; 2. National High Magnetic Field Laboratory, Los Alamos National Laboratory, Los Alamos, NM, United States; 3. Physics, University of California, San Diego, La Jolla, CA, United States; 4. Department of Physics, Hokkaido University, Sapporo, Japan*

The filled skutterudite compound $CeOs_4Sb_{12}$ displays Kondo insulating behavior with accompanied by a ~1 K antiferromagnetic (AFM) / Spin-Density-Wave (SDW) order state. In penetration depth and magnetic susceptibility measurements, we found a Fermi-surface reconstruction in $CeOs_4Sb_{12}$ and an unusual phase boundary in the temperature *T* vs magnetic field *H* diagram associated with the valence transition from the Ce^{4+} to Ce^{3+} state [1]. However, the high temperature phase boundary (> 15 K), currently described by the susceptibility data, is hard to define. Since a valence transition can strongly influence the electron-phonon coupling, we combined the experiment features from measurements of magnetostriction, magneto resistance, and high temperature skin depth to clarify this intriguing phase boundary. Q10-09. Anomaly in electric transport behavior across Verwey transition in nanocrystalline Fe_3O_4 thin films. *M. Bohra*[1] *1. Physics, Mahindra Ecole Centrale, Hyderabad, India*

Investigation of Verwey transition (i.e. metal-insulator transition) particularly in nanosize Fe_3O_4 continue to be an avenue for researchers [1]. Herein, nanocrystalline Fe_3O_4 thin films were grown by adopting two different reduction approaches (1) vacuum annealing (2) wet H_2 annealing. While vacuum annealed films shows Verwey transition with lower resistivity compared to the bulk Fe_3O_4, the same was not observed in electric transport properties of wet H_2 annealed films. However, this transition was clearly seen in the temperature dependence of magnetizations of both sets of Fe_3O_4 thin films. This seems to indicate that the electric transport and magnetization are independent processes; it's just coincidence to happen at same place of Verwey transition at 120 K in strongly correlated Fe_3O_4 system. Different electric transport properties in both sets of Fe_3O_4 films could be ascribed to different grain boundary density, inhomogeneities and residual atomic-H at grain boundaries emanating from complex different reductions treatments.

Q11-01. Research of Harmonic Effects on Core Loss of Soft Magnetic Composite Materials. Y. Li[1], *X. Yu*[1], Q. Yang[2,1] and C. Zhang[1] *1. Hebei University of Technology, Tianjin, China; 2. Electrical Engineering, Tianjin Polytechnic University, Tianjin, China*

The wide application of high voltage direct current transmission and power electronic equipment have introduced a lot of harmonics. It is necessary to investigate the effects of harmonics on core loss. In this paper, a frequency domain feedback system, implemented in LabVIEW, is used to control the order, content and phase angle of harmonics superposed on the fundamental waveform, as shown in Fig.1. Core loss measurement of SMC under both sinusoidal and non-sinusoidal excitations is carried out. Initially, B waveform is controlled to be 1 T at 50 Hz, plus a 0.1 T third harmonic, with the phase angle varying from 0° to 360°.The measured loss and calculated values from Bertotti frequency domain equation under different phase angles are shown in Fig.2(a). It is found that the loss follows the sine trend, running up to maximum at 0°and minimum at 180°. However, the calculated value of Bertotti frequency domain equationis is constant and independent of phase angle. Secondly, B waveform is controlled to be 1 T at 50 Hz, plus a third harmonic at 0° phase angle, with a variable amplitude from 0 T to 0.5 T. Core loss increases as the harmonic content increases. The measured loss and calculated values under different amplitude are shown in Fig. 2(b). For the case of a specific phase angle, although the variation of calculated values follows the trend of measured losses, large error still exists and demonstrates a fast rising trend with the harmonic amplitude increasing. For the 5th harmonic, the effects of harmonic content on core loss is as the same as 3rd, while the effects of harmonic phase angle on core loss is opposite. Hysteresis loops are shown in Fig. 2(c)-(f). It is found that the frequency domain equation can follow the trend of measured loss where only the content of harmonic varies. However, it fails to predict the variation of measured loss in the condition of variable phase angle. The same conclusion can be drawed in higher harmonic orders, like 5th, 7th and so on.

Q11-02. Loss Characteristics and Model Verification of Soft Magnetic Composites under Non-Sinusoidal Excitation. Y. Li[1], *X. Yu*[1], Q. Yang[1], S. Yue[1] and C. Zhang[1] *1. Hebei University of Technology, Tianjin, China*

Three dimensional magnetic circuit presents in magnetic components such as the core of the motor stator, where the input voltage of magnetic is often non-sinusoidal wave. Research of the loss characteristics under actual operating conditions is of great significance to the optimal design of the motor. Firstly, a testing platform for the magnetic properties of the ring sample is constructed and sinusoidal excitation experiment is executed on soft magnetic composites SOMALOY^{TM}500 to verify the Steinmetz formula. Secondly, a parameter corresponding to the magnetic induction intensity is obtained by studying the relationship between the parameters in the formula. The loss under different frequencies are shown in Figure 1. The measured data are fitted to obtain the parameters. Hence the loss value can be calculated according to Steinmetz formula. It is proved that there is a certain error in the actual working condition if the Steinmetz formula is used to calculation of the loss. The percentage error between calculated value and measured value is 13.87%. With the modified coefficient, the prediction error is reduced to 8.13%. Finally, the modified parameters are applied to the MSE formula, then the calculated and measured value under complex non sinusoidal excitation with different harmonic frequency, content and phase angle are compared. Comparison of core loss with different contents under 3rd harmonic is shown in Figure 2. The result shows that the difference between the calculated value of loss and the measured value is very small, thus verifying the accuracy of the modified model.

Q11-03. Complementary design of nano-carbon/magnetic microwire hybrid fibers for tunable composite absorber. *F. Qin*[1] and D. Estevez[1] *1. Materials Science and Engineering, Zhejiang University, Hangzhou, China*

Hybridizing nanocarbons, such as carbon nanotubes (CNT) or graphene, with magnetic metals is a powerful strategy towards designing high-performance microwave absorber due to the resulting synergetic loss mechanisms and tunable electromagnetic properties [1,2]. Herein, CNT and reduced graphene oxide (rGO) have been respectively coupled with amorphous wire through electrodeposition in a complementary fashion. Through CNT thickness the final magnetic character of the hybrid fibers can be controlled due to the induced stresses that resulted in an additional magnetic anisotropy. On the contrary, the GO coating barely affects the shape of the hysteresis loops. Built upon such hybrid fibers, we developed a type of functional composites for microwave absorption. The absorption performance of the hybrid fibers proves to be tunable via controlling the thickness and morphology of the CNT or by regulating the number of oxygen-functional groups of rGO through thermal annealing. The CNT/wire hybrid structure effectively strengthens both the interfacial polarization of CNT through the support of circular-shaped conductive substrate, and the ferromagnetic resonance of wire through the coupling with magnetic impurities in CNT. As for the rGO/wire fiber, dual-band absorption occurs in the sample annealed at 900°C with an optimal absorption loss of -35dB at 11.3GHz, derived from dielectric loss mechanisms such as removal of functional groups and induced defective structure in combination with enhanced magnetic losses in the hybrid structure. Overall, hybrid fibers derived from the complementary design opens up new horizons to scale up the excellent assets of nanocarbons into the macroscale and develop functional adaptive materials for high-frequency applications.

Q11-04. Electromagnetic properties of $Fe_{50}Co_{50}$/Cu granular composite materials containing flaky particles. *T. Kasagi*[1], K. Kono[2], T. Tsutaoka[3] and S. Yamamoto[4] *1. National Institute of Technology, Tokuyama College, Shunan, Japan; 2. Graduate School of Education, Hiroshima University, Higashi, Japan; 3. Graduate School of Education, Hiroshima University, HIgashi-Hiroshima, Japan; 4. Graduate School of Engineering, University of Hyogo, Himeji, Japan*

Double negative (DNG) materials with simultaneously negative permeability (MNG) and negative permittivity (ENG) have been the subject of considerable interest in this decade. In order to realize DNG real material, the granular composite materials combining ferromagnetic and metal particles have been studied in the RF to microwave frequency range [1, 2]. In these granular composites, the MNG and ENG properties can be realized by the magnetic resonance of ferromagnetic particles and the low frequency plasmonic state (LFPS) in the percolated metal granular composite structure, respectively. In this study, the relative complex permeability and permittivity spectra of the granular composites combining flaky $Fe_{50}Co_{50}$ microparticles with flaky Cu ones, $(Cu_xFeCo_{1-x})_{0.65}PPS_{0.35}$ (x: volume fraction of embedded Cu particles, PPS: Polyphenylenesulfied resin), have been studied in the RF to microwave frequency range to realize DNG materials. The relative complex permittivity spectra are shown in Fig. 1. The x=0.06 composite exhibits dielectric property; the real part, ε_r', is almost constant and the imaginary part, ε_r", is almost zero. Meanwhile, in composites with x=0.18 and 0.22, LFPS is achieved; the ε_r' shows a negative value below a characteristic frequency, f_0. The f_0 shifts to higher frequency with increasing x. Figure 2 shows the relative complex permeability spectra. The real part, μ_r', of the x=0.06 composite is about 4 at 100 MHz and decreases with frequency, μ_r' shows a negative value above 4 GHz. On the other hand, at x=0.18 and 0.22, negative permeability spectra are observed above approximately 80 MHz. Therefore, DNG property is realized in the frequency range from 80 MHz to 9 GHz for x=0.22 and from 80 MHz to 7 GHz for x=0.18. The DNG frequency band of these FeCo/Cu flaky particle composites is relatively broad among the granular composites combining ferromagnetic and metal particles [2]. Furthermore, the DNG characteristic in the RF to microwave frequency range can be realized with low particle content. These tendencies may be due to the shape effect of embedded particles in composite.

Q11-05. Microwave Absorption Properties of $Nd_2Co_{17-x}Si_x$ / Paraffin Composite. G. Qiao[1], W. Yang[1], C. Wang[1], s. Liu[1] and *J. Yang*[1] *1. School of Physics, Peking University, Beijing, China*

In this work, we report the magnetic and microwave absorption properties of $Nd_2Co_{17-x}Si_x$ ($0.0 \le x \le 2.0$) / paraffin composite samples. The powders shows a sheet-like structure with a length of 5 μm and a thickness of 200 nm. The substitution of Si element can significantly adjust the inherent magnetic and dielectric properties of $Nd_2Co_{17-x}Si_x$. The improvement of dielectric properties makes it easier for $Nd_2Co_{17-x}Si_x$/ paraffin nanocomposites to satisfy the impedance matching and enhance microwave reflection loss (RL). In addition, the effective bandwidth (QB, RL ≤-10dB) also increases significantly. When the Si substitution amount is 0.5, the composite achieves a microwave absorption loss of up to -37.0 dB and an effective bandwidth of 3.7 GHz (12.7-16.4 GHz) at a working frequency of 14 GHz with a sample thickness of only 1.2 mm. This performance has exceeded many of the reported microwave absorbing materials.

The reflection loss of $Nd_2Co_{17-x}Si_x$ ($0.0 \le x \le 2.0$) / paraffin nanocomposites with different thicknesses varies with the frequency.

Q11-06. Electromagnetic properties of $Au/Fe_{53}Ni_{47}$ Hybrid Granular Composite Materials. *K. Kono*[1], T. Tsutaoka[1], T. Kasagi[2] and S. Yamamoto[3] *1. Graduate School of Education, Hiroshima University, Higashi, Japan; 2. National Institute of Technology, Tokuyama College, Shunan, Japan; 3. Graduate School of Engineering, University of Hyogo, Himeji, Japan*

The substances with simultaneously negative values of permittivity (ENG) and permeability (MNG) is called Left Handed (LH), or Double Negative (DNG) materials. The Double Negative (DNG) electromagnetic properties have been observed in granular composite materials such as $Cu/Fe_{53}Ni_{47}$, $Ag/Y_3Fe_5O_{12}$ hybrid composites in the RF to microwave range [1, 2]. In this study, $Au/Fe_{53}Ni_{47}$ hybrid granular composite materials has been prepared to investigate the electromagnetic properties by measuring the relative complex permeability and permittivity spectra over the microwave frequency range with the goal to achieve the double negative permeability and permittivity spectra without the external magnetic field. The $Au/Fe_{53}Ni_{47}$ hybrid composite materials denoted by $(Au_xFeNi_{1-x})_yPPS_{1-y}$ ($x = 0$ to 0.24, $y = 0.8$), where x and y are the volume fraction of particles. Samples were prepared by mixing the Au and $Fe_{53}Ni_{47}$ microparticles with poly-phenylene sulfide (PPS) resin in a die and pressing at a pressure 21.2 MPa, heated the mixture at 300 degree C for 20 minutes and pressing at a pressure of 31.8 MPa in the cooling process down to the room temperature. The samples were shaped in the toroidal form (inner diameter of 3 mm and outer diameter of 7 mm) with the thickness of about 1 to 2 mm. The permittivity and permeability spectra were measured by transmission/reflection method using the standard 7/3 mm coaxial airline techniques in the frequency range from 10 MHz to 10 GHz. Real part of complex permittivity ε_r and permeability μ_r spectra of $(Au_{0.2}FeNi_{0.8})_{0.8}PPS_{0.2}$ are shown in Fig.1. Since the $(Au_xFeNi_{1-x})_{0.8}PPS_{0.2}$ hybrid composite shows electrical percolation at about $x = 0.2$; metallic conduction is achieved. Hence, the permittivity spectra of $(Au_{0.2}FeNi_{0.8})_{0.8}PPS_{0.2}$ indicated the low frequency plasmonic state with the Drude type ENG characteristic bellow $f_0 = 4.5$ GHz. In this composite, the negative permeability was also obtained by the magnetic resonance of $Fe_{53}Ni_{47}$ particles. Hence, combining these two ENG and MNG properties, a DNG characteristic can be obtained in the frequency range from 300 MHz to 1.8 GHz without the external magnetic field.

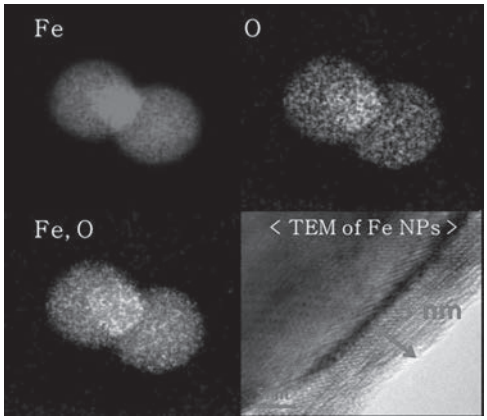
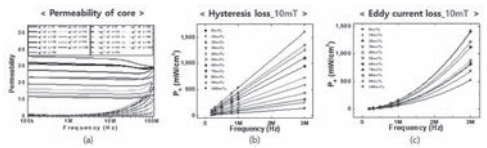
Q11-07. Proportions of reversible and irreversible magnetization processes along hysteresis loops of selected soft magnetic composites. Z. Bircakova[1], *P. Kollar*[1], M. Jakubcin[1], J. Fuzer[1], R. Bures[2] and M. Faberova[2] *1. Institute of Physics, Faculty of Science, P.J. Šafárik University, Kosice, Slovakia; 2. Institute of Materials Research, Slovak Academy of Sciences, Košice, Slovakia*

Soft magnetic composites (SMCs) are composed of small ferromagnetic particles insulated from each other, possessing some specific properties e.g. low energy losses at medium to higher frequencies or magnetic isotropy. The aim of this work was to find the proportions of reversible and irreversible magnetization processes along hysteresis loops from the measurements of differential and reversible permeability along the loops at DC magnetization and to find relations between these proportions and magnetic properties of SMCs. Three types of SMCs were investigated: Fe-phenolphormaldehyde resin samples with different resin content (5 and 15 vol. %) and Fe particle size distributions (peaks at 45 and 160 μm), the commercial Somaloy® 700 (Höganäs AB Sweden) and the mixtures of Somaloy and Vitrovac® 6155 (Vacuumschmelze, Germany). Differential permeability along hysteresis loops was obtained from DC loops measured by DC fluxmeter-based hysteresisgraph and reversible permeability along hysteresis loops was measured using the developed setup. Proportions of reversible and irreversible processes were calculated at each point along hysteresis loops. It was found that proportions of reversible processes increase with increasing induction (absolute value) within one loop, but in a different way for each material. These differences as well as the average values within the loops were found to be in significant relation with ferromagnetic content in SMC, inner demagnetizing fields, coercive force, energy losses and numbers of movable domain walls, which all lead to the information about magnetization processes character – if realized mostly by domain wall displacements or magnetization vector rotations. It was found that with the increasing resin content the higher proportions of reversible processes overall indicate lower number of movable domain walls participating in magnetization process due to higher inner demagnetizing fields lowering the interaction between particles and making magnetization reversal more energy consuming. Similar result was found for samples with smaller particles and with higher Vitrovac content.





Reversible permeability along hysteresis loop (a) and the calculated proportions of reversible processes (b)

Q11-08. Soft Magnetic Metal-Polymer Hybird Composites Mixed with Nano-Sized Iron Powder for Power Inductors. S. Lee[1], *H. Kim*[1], J. Yeo[1,2], J. Kim[2], S. An[2] and B. Lee[1] *1. Department of Physics and Oxide Research Center, Hankuk University of Foreign Studies, Yongin-si, The Republic of Korea; 2. Samsung Electronics, Suwon-si, The Republic of Korea*

Recently, soft magnetic composites (SMCs) have been used as power inductor materials for high current because their high saturation magnetization (Ms) allow them to offer better DC-bias characteristics than ferrites with low Ms[1,2]. However, SMCs must be studied further because they offer lower relative permeability (μ') than ferrites[3]. The packing fraction should be increased to increase the μ' and particle size needs to be reduced to reduce energy loss. In this study, we investigated AC magnetic properties and energy loss of the cores. When we made toroidal cores, we added Fe nanoparticles (NPs) with a particle size of about 100nm to Fe-6.5Si powder with D_{50} of 12.6μm to increase the μ'. The metal powder composition upon adding Fe NPs was (100-x) wt% Fe-6.5Si + (x) wt% Fe NPs. Fig. 1. shows the TEM image of the Fe NPs and the thickness of the oxide passivation layer was about 5 nm. Due to Fe NPs having inflammable property, it needs to be passivated. This passivation layer increases the inter-particle resistivity and reduces the inter-particle eddy current loss at high frequencies. Fig. 2. (a) shows the permeability of the toroidal cores. The μ' of core made of only Fe-6.5Si powder was about 23. The μ′ was increased with the addition of Fe NPs and the highest is about 35 at 20wt% Fe NPs. When Fe NPs were added more than 20wt%, the μ' was decreased, and the μ' of the core made of only Fe NPs was about 11. As shown in Fig. 2. (b) and (c), by adding Fe NPs, both hysteresis loss and eddy current loss are increased. For 20wt% Fe NPs, the hysteresis loss was 104 mW/cm^3, and the eddy current loss was 89 mW/cm^3 at 1MHz.

Q11-09. Magnetic Properties of Metal-Free Nitrogen-Doped Graphene Quantum Dots. *M. Sultan*[1], V. Makarov[1], F. Mendoza[1], W. Jadwisienczak[4], D.G. Barrionuevo Diestra[1], M. Sajjad[2], B. Weiner[3] and G. Morell[1] *1. Department of Physics, University of Puerto Rico, San Juan, PR, United States; 2. Department of Physics and Astronomy, Western Kentucky University, Bowling Green, KY, United States; 3. Department of Chemistry, University of Puerto Rico, San Juan, PR, United States; 4. School of Electrical Engineering and Computer Science, Ohio University, Athens, OH, United States*

Metal-free nitrogen doped graphene quantum dots (N-GQD) were synthesized and, for the first time to our knowledge, their magnetic properties were investigated. The results indicate that N-GQDs exhibit superparamagnetic behavior. The specific size, shape and zigzag edge structure of N-GQDs were taken into account to explain the origin of the observed magnetism. The magnetization dependence led to estimating the N-GQD material magnetic permeability for different ambient temperatures. From the zero-field-cooled (ZFC) and field-cooled (FC) magnetization measurements, carried out at 50 Oe magnetic field strength, we estimated the blocking temperature T B to be around 300 K. On the basis of the experimental data analysis, the magnetic permeability, number of correlated spins per single N-GQD, and number density of superparamagnetic N-GQD per gram of material were estimated. The excellent magnetic properties together with optical properties manifested by N-GQDs have the potential to lead to high performance biomedical and data recording devices.

Q11-10. Engineering Nanocomposites Graphene Quantum Dots and Magnetic Nanoparticles; Synthesis, Optical and Magnetic Properties. *M. Sajjad*[1], V. Makarov[2], M. Sultan[2], W. Jadwisienczak[3], B. Weiner[4] and G. Morell[2] *1. Department of Physics and Astronomy, Western Kentucky University, Bowling Green, KY, United States; 2. Department of Physics, University of Puerto Rico, San Juan, PR, United States; 3. School of Electrical Engineering and Computer Science, Ohio University, Athens, OH, United States; 4. Department of Chemistry, University of Puerto Rico, San Juan, PR, United States*

In this conference, we will present our recent results in the synthesis and engineering of graphene quantum dots (GQDs) and iron oxide (Fe_3O_4) nanocomposites (NC) by using a pulsed laser discharge technique. GQDs together with magnetic nanoparticles have shown a unique set of optical and magnetic properties for future energy and medical applications. Here, we report on high resolution transmission electron microscopy (HRTEM) images that have shown a high yield of pure GQDs with 2-10 nm diameter. The hexagonal structures and lattice fringes associated with the C-C bond in GQDs were clearly identifiable. The structural and optical changes in GQDs and GQDs-Fe_3O_4 NC samples induced by UV light were investigated by absorption and emission spectroscopy over the deep UV–visible spectral range. The photoluminescence spectra have shown sub-band transitions in GQDs-Fe_3O_4 NC. Magnetic properties of the GQDs-Fe_3O_4 NC samples have shown room temperature ferromagnetism induced by pure Fe_3O_4 nanoparticles and from the substantial spin polarized edges of GQDs nanoparticle. It is concluded that the observed optical and magnetic properties could be further tailored in the studied nanocomposites for prospective medical applications.

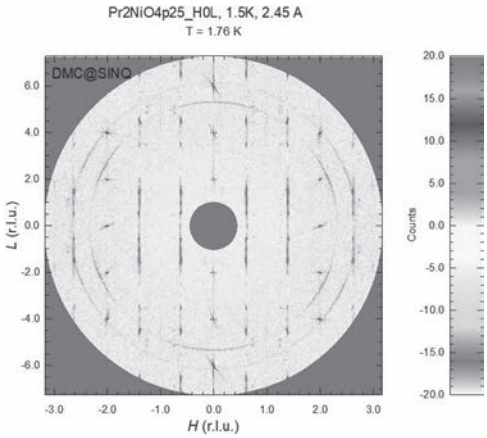
Q12-01. Experimental Observation of J_{eff}=1/2 state in Cuprate System $CuAl_2O_4$. *H. Cho*[1,2], S. Kim[1,2], C. Kim[1,2] and J. Park[1,2] *1. Department of Physics, Seoul National University, Seoul, The Republic of Korea; 2. Department of Physics, IBS-CCES, Seoul, The Republic of Korea*



The effect of spin-orbit coupling in cuprate systems is usually neglected in condensed matter physics. One reason is that many cuprate systems have crystal structures where copper ions sit at octahedral sites and, usually subject to the Jahn-Teller distortion. The other is that the spin-orbit coupling constant of cuprate (~50 meV) is far smaller than that of Ir (5d) or Ru (4d) ions. However, the orbital degeneracy of Cu^{2+} ions can be restored by putting copper ions at tetrahedral sites. In this case, the ground state can in principle form in an insulating pseudo spin J_{eff}=1/2 state even due to the small spin-orbit coupling. $CuAl_2O_4$ with copper ion at tetrahedral A-site of the spinel structure is a good candidate material to have the J_{eff}=1/2 state [1]. In this study, our optical conductivity measurement shows coincidence with theoretical conductivity calculated by DFT band [2], showing the possible emergence of J_{eff}=1/2 state for $CuAl_2O_4$.

Q12-02. Magnetic properties and structure as a function of hole doping and disorder in $Pr_{2-x}Sr_xNiO_{4+\delta}$. *M. Frontzek*[1], J. Schefer[2], L. Keller[2], S. Mishra[3], W. Paulus[4] and M. Ceretti[4] *1. Neutron Scattering Division, Oak Ridge National Laboratory, Oak Ridge, TN, United States; 2. Laboratory for Neutron Scattering, Paul Scherrer Institut, Villigen, Switzerland; 3. EMPA, Duebendorf, Switzerland; 4. Institut Charles Gerhardt, Université de Montpellier, Montpellier, France*

The Ruddlesden Popper phase $Pr_2NiO_{4+\delta}$ ($\delta = 0 \ldots 0.25$) has received considerable interest as material for solid oxide fuel cells due to it's ability to intercalate oxygen and a high oxygen diffusion rate. On the electronic side, it's closeness to the superconducting $La_2NiO_{4+\delta}$ makes it an interesting object to investigate the magnetism as an image of the electronic properties in these systems. The undoped Pr_2NiO_4 is a commensurate insulating antiferromagnet with T_N = 325 K [1, 2]. Hole doping either through Sr-doping on the Pr-site or through additional oxygen intercalation leads to the suppression of the commensurate antiferromagnetic order. The suppression is likely connected to the electronic phase separation in these systems which show up as stripe-order of Ni^{2+}/Ni^{3+} at higher doping concentrations [3]. In the Sr-doped case the ions are statistically distributed on the Pr-sites thus creating disorder. In the x = 0.5 case, this leads to the breakdown of the long-range magnetic order and only 2-dimensional (in-plane) correlations are observed. In contrast, the isoelectronic oxygenated compound exhibits inherent order through a superstructure formation from the intercalated oxygen ions. The resulting oxygen superstructures are different for different intercalated oxygen contents, but widths of the reflections are similar to the main lattice reflections indicating a well ordered structure through a large volume. The resulting magnetic structures at low temperatures are a superposition of 2-dimensional order and long range order as can be seen in the reciprocal space map at low temperatures in Fig. 1. In our contribution we will present a detailed single crystal neutron diffraction study of three compounds from the series $Pr_{2-x}Sr_xNiO_{4+\delta}$ comparing the fully oxygenated δ = 0.25 with the isoelectronic Sr-doped compound with x = 0.5. Additional, the magnetic structure of the half oxygenated compound with δ = 0.12, which still exhibits commensurate long-range order is compared.

Q12-03. Magnetic frustration in the intermetallic $Dy_2Co_3Al_9$. *M. Henriques*[1], D. Gorbunov[2], B. Ouladdiaf[3], N. Qureshi[3], C. Salazar-Mejia[2], J. Gronemann[2], A.V. Andreev[1], M. Uhlarz[2], Y. Skourski[2], V. Petricek[1] and J. Wosnitza[2,4] *1. Institute of Physics, Czech Academy of Sciences, Prague, Czechia; 2. Hochfeld-Magnetolabor (HLD-EMFL), Dresden, Germany; 3. Institut Laue Langevin, Grenoble, France; 4. Institut für Festkörper- und Materialphysik, TU Dresden, Dresden, Germany*

Magnetic frustration in intermetallic systems remains largely unexplored in comparison with isolating materials. Interesting properties might emerge in intermetallic compounds in which magnetic moments and conduction electrons arising from different sub-lattices can couple via short-range correlations [1]. $Dy_2Co_3Al_9$ crystallizes in a layered orthorhombic structure with several similar Dy-Dy distances [2-4]. Consequently, the fine balance between the exchange and anisotropy interactions might be easily perturbed. In the present work, we investigate a $Dy_2Co_3Al_9$ single-crystal by use of magnetization (*M*), specific-heat (*C*), electrical-resistivity (ρ), and neutron-diffraction measurements. Below 7 K, the *M*(*T*) dependence displays three anomalies. The specific heat shows that the two phase transitions at T_N = 6.2 K and T_1 = 5.2 K, are of second order, whereas the transition observed at T_2 = 3.7 K is of first order. The compound displays a metallic character and the residual resistivity ratio between 300 and 2 K is about 25. Field-dependent magnetization data indicate that the three magnetically ordered phases of $Dy_2Co_3Al_9$ are antiferromagnetic. Neutron diffraction data reveals that in the range $T_2 < T < T_N$ the magnetic structures of $Dy_2Co_3Al_9$

are elliptical oblique cycloids. For $T_1 < T < T_N$ (phase I) the spins rotate in the (110) plane, whereas for $T_1 < T < T_2$ (phase II) they rotate in a plane $\theta \approx -30°$ away from (110). The modulation period is ≈ 57 Å for the former and ≈ 124 Å for the latter. The largest spin components are inclined by $\phi_I = 11°$ and $\phi_{II} = \pm 9°$ with respect to [100] in phases I and II, respectively, and they amount to 3.25 μ_B/Dy at $T_1 = 5.8$ K and 5.1 μ_B/Dy at $T_{II} = 4.5$ K. Below $T_2 = 3.7$ K (phase III) the magnetic structure becomes commensurate with the crystal structure, and it is a simple arrangement of antiferromagnetic planes where the spins are oriented along [001] alternate with planes with spins oriented parallel to (110). The Co atoms seem to not carry ordered magnetic moments in $Dy_2Co_3Al_9$. The number and structure of magnetic phases reflect a fine balance between exchange and anisotropy interactions and suggest an important role of geometrical frustration in the magnetism of $Dy_2Co_3Al_9$.

Q12-04. Magnetic correlations and hopping conduction in mixed valent single layered $La_{1.2}Sr_{0.8}CoO_4$. *A. Ahad*[1], K. Gautam[2], K. Dey[2], S. Majid[1], F. Rahman[1], R. Choudhary[2] and D. Shukla[2] *1. Physics, Aligarh Muslim University, Aligarh, Aligarh, India; 2. Material Science, UGC-DAE,CSR, Indore, India*

La_2CoO_4 is a single layered antiferromagnetic insulator [1]. Hole doping in the parent compound stabilizes the structure [2]. Doped series $La_{2-x}Sr_xCoO_4$, $x > 0.5$ moves towards the metallicity due to delocalization effect [2]. The concentration of holes in the host matrix decides the ratio of Co^{2+}/Co^{3+} and magnetic phase diagram. Spin-states of the Co^{3+} ion in the doped series has an important role in magnetic correlations [3]. The low-spin state is non-magnetic and the appearance of magnetism is related to intermediate or high-spin state. In a recent report we have qualitatively estimated the spin-states in $La_{2-x}Sr_xCoO_4$ series [2]. In our present report, we have studied the magnetic correlations and electrical transport behavior in the x = 0.8 member of $La_{2-x}Sr_xCoO_4$ series. Fig. 1 represent the Rietveld refined x-ray diffraction pattern. Fig. 2 comprises the field cooled (FC) and zero field cooled (ZFC) magnetization measurements, shows the signature of some exotic phases like spin-glass or cluster glass. Inset (b) of Fig. 2 shows the field cooled MH loop at 5 K. High coercivity and non-saturation up to high field (7 T), signaling presence of competing interactions [4]. This signature and the bifurcation between FC and ZFC together reveals the spin-glass or the magneto-crystalline anisotropy [5]. However, the closeness of T_{lrr} and peak in ZFC indicates the type of spin-glass as canonical spin-glass [4]. We also observe the deviation from the Curie-Weiss law in the high-temperature region (see Inset (a) of Fig. 2). These reveal the presence of Griffith like phase [6] or could be due to some disorder present in the system. Frequency dependence of dielectric loss reveals two independent relaxation mechanisms that may be correlated to the hopping conduction among different Co ions possessing different spin states.

$FePS_3$ is structurally and magnetically two-dimensional, with a magnetic ground state in which spins are ordered as ferromagnetic chains coupled antiferromagnetically. At ambient pressure, it is an insulator with a direct gap of approximately 0.5 eV and a room temperature resistivity of approximately 104 Ωcm. We present the results of magnetization and resistivity measurements under applied pressures up to 120 kbar (12 GPa) in piston-cylinder clamp cells, sintered diamond Bridgman anvil cells and diamond anvil cells using a cryogenic argon pressure medium. The band gap

is seen to close and the sample becomes metallic at around 100 kbar, but with an additional upturn in the resistivity at low temperature that remains to be fully explained. We additionally present structural data from powder x-ray diffraction experiments under pressures up to 300 kbar. Multiple phase transitions are observed, corresponding to significant changes to the unit cell, and a change of symmetry into a trigonal phase is seen above 180 kbar. This high-pressure phase appears to be close to a fully three-dimensional system due to a significant collapse of the inter-plane separation, and we relate the metallization to the formation of this phase. We also present theoretical band structure calculations of the high-pressure phase, showing band overlap and metallic properties, in agreement with experiment.

C.R.S. Haines, M.J. Coak, G. I. Lampronti, C. Liu, H. Hamidov, A. R. Wildes, D. Daisenberger, P. Nahai-Williamson and S.S. Saxena arXiv:1801.10089 (2018)

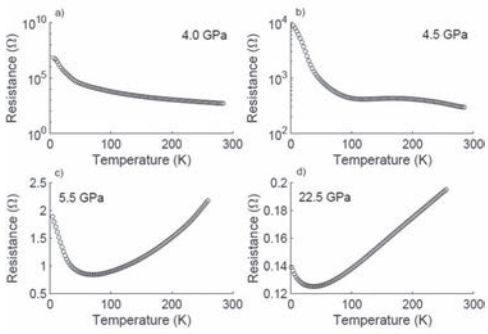

Fig. 1. Resistance of $FePS_3$ against temperature for 4 increasing pressures, estimated as a) 4.0 GPa, b) 4.5 GPa, c) 5.5 GPa and d) 22.5 GPa. A transition from insulating to metallic behaviour is seen as pressure is increased, as well as an upturn in the resistivity at low temperatures in the high pressure measurements.

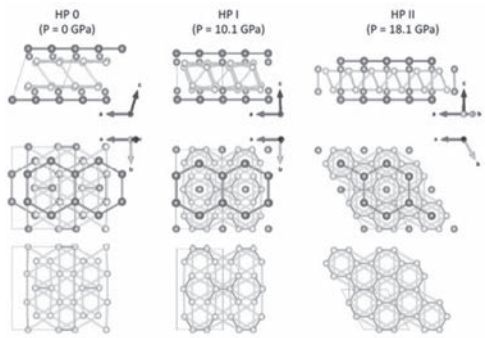

Fig. 2. Schematics showing the evolution of the structure of $FePS_3$ with pressure. The three refined structures at their corresponding pressures are drawn to scale. The Fe atoms are shown in brown, the P atoms are shown in purple, and the S atoms are shown in yellow. The views show different projections of the same number of unit cells, hence the 'sulphur only' figures show only those sulphurs between two adjacent *ab* planes. Also shown are all interatomic bonds for r <= 3.6 Angstroms.

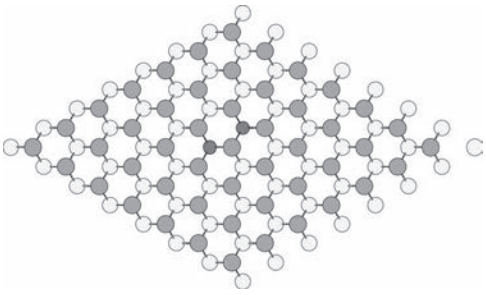
Q12-06. J_{eff}=1/2 Exciton Fano Resonances in Pyrochlore Iridates with All-in/All-out Magnetic Order. *A. Boris*[1], A. Yaresko[1], T. Larkin[1], K. Rabinovich[1], A. Krajewska[1,2], T. Takayama[1,2], H. Takagi[1,2] and B. Keimer[1] *1. Max Planck Institute for Solid State Research, Stuttgart, Germany; 2. Institute for Functional Materials and Quantum Technology, University of Stuttgart, Stuttgart, Germany*



Pyrochlore iridates are considered very promising candidates for the realization of exotic quantum states of matter such as Weyl semimetals and topological Mott insulators. Their phase diagram is predicted to have these quantum phases over a certain range of relative correlation U/W and spin-orbit coupling l/W strengths [1]. We used spectroscopic ellipsometry to determine the dielectric function of $A_2Ir_2O_7$ (A = In, Lu, Y) polycrystalline samples in the spectral range from 10 meV to 6.5 eV at temperatures from 7 K to 300 K. Comparing the spectra with the results of relativistic LSDA+U band structure calculations for the noncollinear all-in/all-out magnetic state, we quantitatively classify pyrochlore $A_2Ir_2O_7$ as spin-orbital J_{eff}=1/2 Mott insulators with the on-site Coulomb interaction U ≈ 1.5 eV and the electronic bandwidth W = 0.3 ÷ 0.5 eV. Exciton doublets with pronounced Fano line shapes were identified in $Y_2Ir_2O_7$ and $Lu_2Ir_2O_7$ upon cooling below the magnetic ordering temperatures T_N = 150 K and 145 K, respectively. The formation of exciton complexes observed at the absorption edge is accompanied by distinct phonon anomalies in the infrared spectra. Our results indicate considerable effects of long-range Coulomb interaction and spin-orbit-lattice coupling in the 5d-pyrochlore compounds and the need for a detailed analysis of their influence on the J_{eff}=1/2 states. Newly synthesized $In_2Ir_2O_7$ does not exhibit the absorption edge and phonon anomalies below T_N = 45 K and thus serves as a reference.

Q12-07. Electronic structures and magnetic properties of metal-doped WS_2 monolayer in *ab initio* calculations. J. Hyun[1] and *M. Kim*[2] *1. Institute of Advanced Materials and Systems, Sookmyung Women's University, Seoul, The Republic of Korea; 2. Department of Applied Physics, Sookmyung Women's University, Seoul, The Republic of Korea*

Two-dimensional (2D) transition-metal dichacogenides (TMDs) materials hold promise for flexible and transparent electronics applications due to the range of their band gaps from 1 to 2 eV. Among them, MoS_2 and WS_2, which are nonmagnetic semiconductors, form an exciting family of transistors [1-3]. Accordingly, extensive studies have been performed to investigate the feasible ways to introduce magnetism to TMDs. In previous studies, transition metal (TM) dopings are reported to effectively induced magnetism into MoS_2 and to stabilize ferromagnetic (FM) or antiferromagnetic (AFM) ordering depending on the type of dopant [4]. However, the magnetic property of other TMDs has been scarcely studied. In this presentation, we report the result of density functional theory (DFT) calculations on the TM-doped WS_2 monolayer with 4% impurity concentration where two 3d transition metal atoms such as Mn, Fe, Co, and Cu are substitutionally doped by replacing W atoms employing the 7×7 supercell. The doping site preference is examined by comparing the total energy of systems with different inter-atomic distance between the TM dopants, which revealed that the TM dopant location in the nearest neighbors as shown in Fig.1 is the most stable state. In addition, we compared the AFM and FM phases and found that the FM phase is energetically preferred to the AFM phase. The total magnetic moment of FM phases for the Mn-, Fe-, Co-, and Cu-doped WS_2 monolayer is 2.00, 2.00, 4.00, and 1.99 μ_B, respectively. While most of the magnetic moments are localized at the doped metal atoms Mn, Fe, Co, and Cu of which spin moments are 1.27, 0.71, 1.07, and 0.25 μ_B, respectively, the induced magnetic moments on W as well as S atoms are also significant and play important role in determination of magnetic phase stability. This work was supported by the Basic Science Research Program (2017R1A2B4012972) through the NRF of Korea and the Program for Returners into R&D through the Center for Women In Science, Engineering and Technology (WISET-2017-583) funded by the Korea government (MSIP).

Q12-08. Fundamental mechanisms of spin depolarization in half-metallic ferromagnet CrO_2 revealed by high-resolution spin-resolved photoemission spectroscopy. *H. Fujiwara*[1], K. Terashima[2], M. Sunagawa[1], Y. Yano[1], T. Nagayama[1], T. Fukura[1], F. Yoshii[1], Y. Matsuura[1], M. Ogata[1], T. Wakita[2], K. Yaji[3], A. Harasawa[3], K. Kuroda[3], S. Shin[3], Y. Muraoka[1,2] and T. Yokoya[1,2] *1. Graduate School of Natural Science and Technology, Okayama University, Okayama, Japan; 2. Research Institute for Interdisciplinary Science, Okayama University, Okayama, Japan; 3. Institute for Solid State Physics, The University of Tokyo, Tokyo, Japan*

Chromium dioxide (CrO_2) was predicted to be a half-metallic ferromagnet which has metallic electronic structures with an energy gap at the Fermi level (E_F) for any one electronic spin state in the ground state.[1] In addition, recently, CrO_2 has been predicted to host triple point fermions, as well as additional Weyl points, which potentially opens a field of spintronics based on topologically non-trivial half-metals.[2] As a notable advantage, CrO_2 always shows more than 90% spin polarization, which is the highest value exhibited by a candidate half-metal at low temperature.[3–5] However, CrO_2 exhibits precipitous thermal depolarization in magnetic tunneling junctions, which is inconsistent with temperature dependence of its macroscopic magnetization.[6] This is believed to originate from interfacial magnetism.[7] Depolarization mechanisms based on electronic structure have not yet been identified experimentally, because of the absence of proper experimental technologies for investigating the spin-resolved fine electronic states. In this report, through electronic-state investigation using high-resolution spin-resolved photoemission spectroscopy, we demonstrate the fundamental mechanisms of spin depolarization in CrO_2. We observed an appearance of a distinct minority spin state near E_F and a corresponding depolarization with a bending structure as shown as a gray dotted line in Fig. 1. This depolarization seldom contributes to demagnetization because the integrated density of states of the minority spin state is much smaller than that of the occupied spin-polarized 3*d* bands. The origin of this depolarization has been identified as the many-body effect, because the behavior of the distinct minority spin state was quite similar to that predicted from dynamical mean-field theory[8]. Our work emphasizes the importance of investigating spin-resolved electronic states near E_F with sub-meV energy resolution to understand magnetotransport behavior of half-metals. In our presentation, we also propose specific ways for preserving the high spin polarization at room temperature.

The lacunar spinel GaV4S8 is known to undergo a structural phase transition from cubic to rhombehedral at 44 K. In this transition, the tetrahedra that magnetic V atoms live on distort and separate into a basal plane and an apical V. Below this transition, the material undergoes a series of phase transitions as a function of temperature and magnetic field. Multiferroicity and skyrmions have been observed [1] We have performed neutron diffraction measurements under magnetic field to determine the magnetic form factor of this material in the magnetically ordered phase. We use these measurements to comment on the question of whether moments are distributed over a tetrahedron, or if they primarily lie upon the single apical site of a tetrahedron. We also perform small angle neutron diffraction measurements. as a function of temperature and field to establish the phase diagram for our particular crystal. We will present initial results on the dynamics within the Skyrmion phase as a function of a driving magnetic field.

Q12-11. The Swedish QuEST for BIFROST and Novel Quantum Materials. *J. Hellsvik*[1,2], Y. Sassa[3], E. Nocerino[4], R. Toft-Petersen[5,7], M. Geilhufe[1], S. Borysov[1,5], A. Balatsky[1], O. Eriksson[3], C. Rüegg[6] and M. Månsson[4] *1. Nordita, Stockholm, Sweden; 2. KTH Royal Institute of Technology, Stockholm, Sweden; 3. Uppsala University, Uppsala, Sweden; 4. Applied Physics, KTH Royal Institute of Technology, Stockholm, Sweden; 5. DTU Technical University of Denmark, Copenhagen, Denmark; 6. Neutrons and Muons, Paul Scherrer Institute, Villigen PSI, Switzerland; 7. European Spallation Source (ESS), Lund, Sweden*

This project aims to strengthen the Swedish community within inelastic neutron scattering and particularly in the area of quantum materials. It will ultimately allow Swedish researchers to become early expert users of the BIFROST [1] as well as other spectrometers at ESS. We have formed a strategic alliance between KTH, Uppsala University, Nordita, PSI, the BIFROST team (DTU/ESS), along with a series of international experts in the field. To realize the main goal our project contains several specific points: Sample synthesis of organo-metallic compounds will be done both virtually through a unique database (OMDB) at Nordita [2,3] and band structure modeling, as well as in practice by setting up a dedicated organo-metallic synthesis laboratory (OMSL) at UU. The CAMEA spectrometer [4,5], which is now being assembled at PSI Switzerland, is based on the same technology as BIFROST. Hence, there is a golden opportunity to use CAMEA as a "training ground" for early expert users of BIFROST. We will partake in the CAMEA commissioning perform initial experiments on quantum materials. Further, we will also develop necessary sample environment/tools needed in order to maximize the early use of BIFROST. This includes sample holders, pressure cells as well as to initiate the development of a high-field magnet. In connection with the experiments we will also develop the data analysis/visualization and theory/modeling tools [S(Q,E)], [6,7,8] which are absolutely crucial for the understanding and publication of the experimental data. Such tools will also be used for predicting magnetic properties in the materials design (OMDB + OMSL). This is a highly ambitious yet feasible project that aims to build for the future and ESS in Sweden. It is also important to understand that the different parts are highly interconnected in a closed iterative feedback loop gathered around INS where *e.g.* the sample synthesis and theory team will participate in the actual experiments, and vice versa (see Fig. 1). Funding: This project is funded by the Swedish Research Council (VR) through a project grant in neutron scattering (Dnr. 2016-06955).

Q12-12. Coupled spin dimers driven by charge and *p*-orbital ordering in an open-shell *p*-electron Rb_4O_6 compound. *D. Arcon*[1,2] *1. Institute "Jozef Stefan", Ljubljana, Slovenia; 2. Faculty of Mathematics and Physics, University of Ljubljana, Ljubljana, Slovenia*

The Verwey transition in Fe_3O_4, a complex structural phase transition concomitant with a jump in electrical conductivity by two orders of magnitude, has been a benchmark for charge ordering (CO) phenomena in mixed-valence transition metal materials [1]. CO is of central importance, because it frequently competes with functional properties like superconductivity or metallic ferromagnetism. Here, we demonstrate an archetypical Verwey-type transition in an open *p*-shell anionic mixed-valence compound using complementary diffraction and spectroscopic techniques [2]. In Cs_4O_6 a phase change from a cubic structure with a single crystallographic site for the molecular O_2^{x-} building units to a tetragonal structure with ordered superoxide O_2^- and peroxide O_2^{2-} entities (Fig. 1) is accompanied by a drastic drop in electronic conductivity and molecular charge fluctuation rates. In a sister compound Rb_4O_6, the analogous CO process is followed by *p*-orbital ordering [3,4], which establishes a network of antiferromagnetically coupled O_2^- (S = 1/2) dimers. High-field electron paramagnetic resonance detected direct singlet-to triplet transitions and weaker lines attributed to multiple-triplet bound states. These results establish Rb_4O_6 as a new system belonging to valence bond solid family where multiple-triplet bound states in the magnetic excitation spectrum play an essential role. The simple CO pattern of molecular units thus suggest Cs_4O_6 and Rb_4O_6 as model systems for disentangling the complex interplay of charge, lattice, orbital, and spin degrees of freedom in Verwey-type CO processes.

Charge ordering in Cs_4O_6: in the high-temperature cubic phase, the fourth charge is delocalised between all O_2 units, whereas it localises in the low-temperature tetragonal phase, where two distinct entities paramagnetic O_2^- ($S = 1/2$) and nonmagnetic O_2^{2-} form.

Session Q13
SPIN-CHARGE CONVERSION AND SPIN-ORBIT TORQUE V (Poster Session)

Xuepeng Qiu, Chair
Tongji University, Shanghai, China

Q13-01. Spin-orbit torques in silicene zigzag nanoribbons. *S. Chen*[1]
1. Department of Applied Physics and Chemistry, University of Taipei, Taipei, Taiwan

Silicene, a group IV nanosheet [1,2], possesses lattice buckling and exhibits a larger intrinsic spin orbit (SO) coupling [3] supporting greater spin-orbit torques (SOTs) than graphene. Here we study the SOT in silicene nanoribbons of zigzag edges. We obtain the SOT based on a Green function formalism which are separated into Fermi sea (T_s) and Fermi level (T_l) contributions. The former only contributes to the field-like torques T_{FL}, while the later accounts for the current-induced torques giving both T_{FL} and anti-damping T_{AD} that is responsible for the magnetic switching (MS). The T_{AD} and T_{FL} are identified by the out-of-plane spin accumulations induced by the inverse spin-galvanic effects [4–6]. Due to the particle-hole symmetry of Dirac materials, the trokance induced by the applied bias is an odd function of the Fermi energy E_F; contrarily, at zero bias, the torque is even in E_F. This symmetry implies the bias-inducedT_l is zero at the Dirac point. The torques are independent of the azimuthal angle of the ferromagnet magnetization and are symmetric in magnetization polar angle. For large in-plane magnetizations, the maximum (among different E_F) T_{FL} occurs at the Dirac point. Under certain small magnetizations characterized by the SO coupling, the maximum T_{AD} is also identified at the crossing point of two Dirac linear bands (Figs. 1 and 2). We find that the buckling potential is essential to achieve MS (inset in Fig. 1). Reversing the applied electric fields yield a reversal of the anti-damping torque. Accordingly, silicene provides a full electric control of the torques.

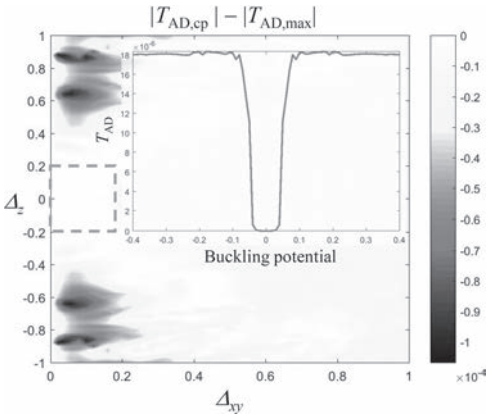

Figure 1. Subtraction of $|T_{AD,cp}|$ and $|T_{AD,max}|$ as a function of the in-plane Δ_{xy} and out-of-plane Δ_z ferromagnet magnetizations. Here $T_{AD,cp}$ is the anti-damping torque at the crossing point of two Dirac linear bands, and $T_{AD,max}$ is the maximum anti-damping torque among all different Fermi energies. The blue dashed line indicates the condition or region within which $T_{AD,max}$ and $T_{AD,cp}$ coincide. The inset shows T_{AD} as a function of the buckling potential.

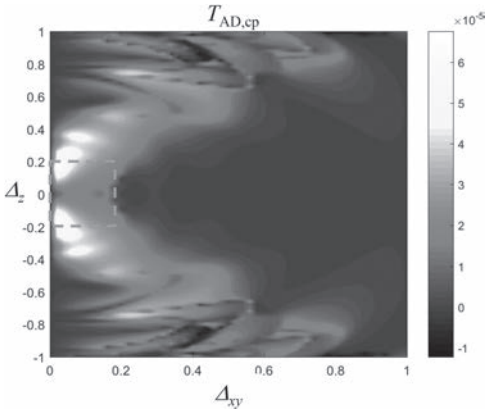

Figure 2. $T_{AD,cp}$ as a function of the in-plane Δ_{xy} and out-of-plane Δ_z magnetizations. The blue dashed line indicates the condition or region within which $T_{AD,max}$ and $T_{AD,cp}$ coincide.

Q13-02. Detection of spin-orbit torques generated from interfacial spin-orbit scattering at Pt/Co interface. *Y. Hibino*[1], T. Koyama[1] and D. Chiba[1] *1. Department of Applied Physics, The University of Tokyo, Tokyo, Japan*

In-plane current induced Spin-Orbit torques (SOT) in heavy metal (HM) / ferromagnetic metal (FM) bilayer structures have attracted much attentions in the field of spintronics in a way of manipulation of magnetization vector. [1] SOT is generated by the spin current due to the spin Hall effect (SHE) [1], meanwhile it has been predicted that the interfacial spin-orbit scattering (ISOC) at the HM/FM interface can generate an additional spin current. [2,3] This ISOC-induced spin current would flow in the out-of-plane direction and its polarization direction is determined by the FM magnetization. In this work, we investigate the ISOC-induced spin current though the current-induced effective field measurement using Py/Pt/Co structure. [4] The Co layer is perpendicularly magnetized due to the interface anisotropy at Pt/Co while the Py has in-plane magnetization. A large ISOC-induced spin current is considered to be generated at the Pt/Co interface due to the strong Spin-orbit coupling. When this additional spin current flows into the Py layer by in-plane current injection, it might cause an additional SOT on the Py via spin transfer mechanism. From the measurement, we observed an additional effective field which cannot be explained by the symmetry of SHE-induced SOT. In addition, the sign of it is reversed when the magnetization of the Co layer is reversed. This result might indicates that the ISOC-induced spin current exists in this system and can induce an additional SOT to the Py magnetization. This work was partially supported by Grant-in-Aid from JSPS-KAKENHI and Spintronic Research Network of Japan (Spin-RNJ).

Magnetization switching process in thin multilayers, which stands behind the writing of contemporary magnetic random access memories (MRAM), in practice can be realized by spin transfer torque (STT), voltage controlled magnetic anisotropy (VCMA) or spin-orbit torque (SOT) [1]. In the last phenomena, spin polarized current is generated in material possessing large spin-orbit coupling, typically heavy metal such as W, Ta or Pt. However, to initiate the switching process, an exteranl magnetic field has to be applied, which hampers potential applications. Various ways were proposed to overcome the nessesity of external field, such as usage of antiferromagnets [2], coupling ferromagnets with another ferromagnetic layer [3] or using two metals wich different spin orbit coupling sign [4]. In this paper, we take advantage of Pt heavy metal, which is both a source of the spin current and also the spacer that induces ferromagnetic coupling between two Co layers [5]. Multilayer of the following structure: Ti(2)/Co(3)/Pt(0-4)/Co(1)/MgO(2)/Ti(2) (thickness in nm) was sputter deposited on thermally oxidized Si wafer. Independent measurement of bottom (Ti(2)/Co(3)/Pt(4)) and the top (Pt(4)/Co(1)/MgO(2)/Ti(2)) structures using vibrating sample magnetometer and vector network analyzer ferromagnetic resonance indicated in-plane (perpendicular) anisotropy in thicker (thinner) Co layers. Electric transport properties were measured in the Hall bars of length between 50 and 400 μm and width between 5 and 40 μm. By varying the thickness of Pt spacer we tune the coupling energy between two Co layers, which is manifested by changes of switching fields in thiner Co(1) measured by the anomalous Hall effect (AHE) – Fig. 1. Afterwards, for the Hall bar with Pt thickness corresponding to an intermediate ferromagnetic coupling, the magnetization switching induced solely by in-plane current is demostrated - Fig. 2.

Magnetic insulators (MIs) attract tremendous interest for spintronic applications due to low Gilbert damping and absence of Ohmic loss. Magnetic order of MIs can be manipulated and even switched by spin-orbit torques (SOTs) generated through spin Hall effect and Rashba-Edelstein effect in

heavy metal/MI bilayers [1-3]. SOTs on MIs are more intriguing than magnetic metals since SOTs cannot be transferred to MIs through direct injection of electron spins. Understanding of SOTs on MIs remains elusive, especially how SOTs scale with the film thickness. Here, we observe the critical role of dimensionality on the SOT efficiency by systematically studying the MI layer thickness dependent SOT efficiency in tungsten/thulium iron garnet (W/TmIG) bilayers. We first show that the TmIG thin film evolves from two-dimensional (2D) to three-dimensional (3D) magnetic phase transitions as the TmIG thickness (t_{TmIG}) increases. The TmIG saturation magnetization (M_S) increases significantly with the t_{TmIG} (Fig. 1a) due to suppression of both thermal fluctuation and surface modification effect [4]. By measuring the temperature dependence of M_S, we are able to extract the critical exponents [5], which changes from 2D to 3D cases as the t_{TmIG} increases (Fig. 1b). Then, we report the significant enhancement of the measured SOT efficiency with the t_{TmIG} (Fig. 1c). We attribute this enhancement to the increase of the M_S in concert with the suppression of thermal fluctuation (Fig. 1d). Ideally, the increase of M_S in the ultrathin regime enhances spin mixing conductance quadratically [6-7]. Deviation from the ideal case will be discussed. At last, we demonstrate the current-induced SOT switching in the W/TmIG bilayers with the t_{TmIG} up to 15 nm. The work done at UCLA was supported by the DOE-EFRC-SHINES and SRC-FAME.

Spin current converted from the charge current flow in the bottom heavy metal layer or at an interface can transfer spin angular momentum to local spins in an adjacent ferromagnetic layer, then eventually switch the magnetization. In order to manipulate magnetization with low current density, large charge-to-spin conversion efficiency so-called effective spin Hall angle (θ_{SH}^{eff}) is required. Recently, it has been reported the giant θ_{SH}^{eff} can be generated in a magnetic multilayer or superlattice [1-3], nonetheless, detailed study about the origin of large spin-orbit torque (SOT) in magnetic superlattice is still lacking. In this study, we investigate the SOT in [Co/W/Pt] superlattices of which W and Pt with opposite sign of θ_{SH}^{eff} are expected to induce large SOT. Superlattices of Ta(1.5 nm)/Pt(1 nm)/[Co(0.6 nm)/W(t)/Pt(1 nm)]$_{10}$/MgO(2 nm)/Ta(3 nm) were deposited on silicon oxide substrate. The tungsten thickness (t) was varied from 0 to 1.0 nm. In order to quantify the θ_{SH}^{eff} in the superlattices, the second harmonic voltage measurements were performed [4]. As shown in Figure 1(a), the θ_{SH}^{eff} in terms of thickness shows a peak (~3.2) at t=0.6 nm. Moreover, we find that the trend of θ_{SH}^{eff} is similar to the effective magnetic anisotropy energy (K_l^{eff}). The perpendicular orbital moment relative to the effective spin moment ($m_o/m_{s,eff}$) measured at 0 degree also shows the same trend as θ_{SH}^{eff} and K_l^{eff} as shown in Figure 1(b). Therefore, our results indicate that such high θ_{SH}^{eff} is related to the orbital hybridization, thereby intrinsic band structure of the superlattice.

Q13-07. Spin-Orbit Torque Ferromagnetic Resonance in Transferred-Topological Insulator/Normal Metal/Ferromagnetic Metal Heterostructure. *Y. Liu*[1], C. Chen[1], S. Yang[1], L. Chang[3], S. Lee[2], M. Hong[4] and J. Kwo[1] *1. Physics, National Tsing Hua University, Hsinchu, Taiwan; 2. Institute of Physics, Academia Sinica, Taipei, Taiwan; 3. Institute of Physics, Academia Sinica, Taipei, Taiwan; 4. Graduate Institute of Applied Physics and Department of Physics, National Taiwan University, Taipei, Taiwan*

Topological insulators (TIs) have been regarded a potential material for spintronic application because of its large spin-orbit coupling (SOC) and the spin-momentum locking in the surface state. Researchers have utilized the spin orbit torque FMR (ST-FMR) technique to evaluate the efficiency of the spin-to-charge conversion of TI surface state by synthesizing TI and ferromagnetic metals. Severe chemical interaction may occur at the interface of TI and ferromagnetic metal.[1,2] Furthermore, even with a chemically abrupt interface, recent theoretical study indicated that TI surface state may still be disturbed, in conjunction with a ferro-magnet (FM).[3] One way to avoid these problems is to insert a normal metal between TI and FM, which is chemically inert to TI and also preserve the TI surface state. Au have been predicted as a good candidate which fulfills the requirements above.[2,3] In this work, we performed the TI transferring technique on the MBE-grown Bi_2Se_3/Sapphire. The exfoliated Bi_2Se_3 were transferred onto the Au/Py bilayer. The ST-FMR device were then fabricated shown in Fig. 1, and the inset shows the surface morphology of the TI film after the transferring process. As shown in Fig. 2, we observed the symmetric component of the ST-FMR line shape was enhanced with respect to the asymmetric counterpart in the transferred Bi_2Se_3/Au/Py sample, when compared to Au/Py. The result indicates a spin current is generated from the TI surface state that provides an additional anti-damp like torque to Py via the Au interlayer. Our approach based on the thin film transferring technique provides a new route for studying the spin-to-charge conversion efficiency of TI surface state with

a more chemically abrupt interface than previous works, thus circumventing possible artifacts in evaluating the spin orbit torque.

Q13-08. Anomalous Spin-Orbit-Torque Switching In Co/Pt Multilayer-based Synthetic Antiferromagnets. L. Zhu[1], X. Xu[1], K. Meng[1], Y. Wu[1], J. Miao[1] and *Y. Jiang*[1] *1. School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China*

Spin-orbit-torques (SOTs) switching has been observed in perpendicular magnetic anisotropic (PMA) Co/Pt multilayers with high thermal stability and small switching current.[1, 2] SOTs arise mainly from two origins: the spin current generated by spin Hall effect and the effective magnetic field induced by Rashba interaction.[1] Moreover, synthetic antiferromagnets (SyAFs) can be switched by SOTs, and the switching behavior is different from the usual SOTs switching rule [3] of the macrospin model [4]. Therefore, it is essential to clarify the mechanism of SyAFs based SOTs switching. In this work, we explore SOTs switching in Co/Pt multilayer-based SyAFs. The sample was deposited by magnetron sputtering with the stacking structure of Si/SiO_2/Ta (2)/Pt (5)/$[Pt (1)/Co (0.4)]_3$/Ru (0.8)/$[Co (0.4)/Pt (1)]_5$ (thickness in nanometer) and patterned into a Hall-bar device using electron beam lithography (EBL) and an Ar ion milling technique. Figure 1 presents the Hall resistance curve (R_{AHE}) and the normalized magnetization curve (M/Ms) as a function of out-of-plane magnetic field with a DC current of 1mA. Both of the M-H and R-H loops indicate an antiferromagnetic (AFM) interlayer coupling as well as a strong PMA in the structure. As shown in Fig. 2, magnetization can be switched and the orientation depends on the direction of external field. Moreover, the switching orientation changes with a larger in-plane external field, indicating the anomalous switching mechanism in SyAFs. According to our study, the total thickness of magnetic layer Co is up to 3.2 nm, which is much thicker than previous reports, which is meaningful for real application in SOT-MRAM devices.

Q13-09. Dynamical Role of the Orbital Degree of Freedom in the Intrinsic Spin and Orbital Hall Effects. *D. Go*[1], C. Kim[2] and H. Lee[1] *1. Department of Physics, Pohang University of Science and Technology, Pohang, The Republic of Korea; 2. Department of Physics and Astronomy, Seoul National University, Seoul, The Republic of Korea*

The spin Hall effect (SHE) allows for electric generation and detection of the spin current, which is essential in spintronics devices. Particularly, the intrinsic mechanism is responsible for the large SHE of heavy metals, such as Pt, Ta, W due to their sizable spin-orbit coupling (SOC). In non-magnetic materials, the SOC is the only interaction by which the spin (S) can be coupled to an external electric field, which may be approximated as ~ L*S, where L is the orbital angular momentum near the atomic nucleus. Although L is typically quenched due to the crystal field at equilibrium, its dynamical role in non-equilibrium is largely unexplored. In this work, we regard L as an independent degree of freedom and examine its dynamical role in the intrinsic SHE. Unlike the spin, the orbital character is locked to the crystal momentum k in the band structure, even for centrosymmetric crystals [Fig. 1(a) and 1(b)]. In the presence of both inversion and time-reversal symmetries, the expectation value of L is zero for all states in the Fermi sea, which is a manifestation of the orbital quenching. However, by the application of the external electric field (E // x), states with different orbital characters (i.e. radial and tangential) hybridize each other and experience the time-evolution at different rates as shown in Fig. 1(a). As a consequence, non-equilibrium L is generated at the Fermi surface with the opposite signs depending on whether ky is positive or negative [Fig. 1(b)]. Although the total L in the Fermi sea is zero, the orbital current ~ Lz*Vy becomes finite. This is the orbital Hall effect (OHE) and it occurs independently of the SOC. In the presence of the SOC, the SHE follows the OHE as a concomitant effect.

For a *p*-orbital system, for example, when the total angular momentum j is 1/2(3/2) the direction of the SHE is the opposite(same) to that of the OHE [Fig. 1(c) and 1(d)]. We found that both of the SHE and OHE are almost independent of the degeneracy lifting of different orbitals by the crystal field. Our work not only provides a route to enhance the SHE by utilizing the orbital degree of freedom, but also opens a door to a new physics of the orbital, such as the OHE.

Q13-10. Interfacial Oxygen Induced Enhancement of Spin-Orbit Torques. *J. Nath*[1,2], A. Trifu[1,2], S. Auffret[1,2], G. Gaudin[1,2] and I. Miron[1,2] *1. SPINTEC (CEA/CNRS), Grenoble, France; 2. Université Grenoble Alpes, Grenoble, France*

The increased memory demand in the last decade has led to a faster development of Magnetic Random Access Memories (MRAM) such as the Spin-Transfer Torque (STT) and the Spin-Orbit Torque (SOT) MRAMs. In SOT-MRAM, a current injected into a heavy metal (HM) layer with high Spin Orbit Coupling (SOC) gives rise to various torques that act on the magnetization of an adjacent Ferro-Magnetic (FM) layer. These torques, namely the Damping-Like (DL), switches the magnetization during the write operation [1-2]. Here we present the enhancement of DL torques by oxygen implantation of the FM/HM interface in Ta/Cu/Co/Pt hetero-structures. Interfacial oxygen at cobalt - metal oxide interfaces is known to give rise to Perpendicular Magnetic Anisotropy (PMA) due to the increased asymmetric band splitting of the Co 3*d* bands [3-4]. However its effect on SOTs is only starting to be explored experimentally [5-7]. Figure 1 shows the DL field corresponding to the thickness of the top platinum layer. A higher concentration of oxygen atoms reach the Co/Pt interface with decreasing Pt thickness. And we observe no significant variation of the DL torques up to a certain thickness. However when the amount of interfacial oxygen crosses a certain threshold, we see a sharp increase in the torques, signifying a dominant interfacial effect in our samples. Further, we observe an enhanced increase of torques in the sample with the thinner copper layer as less current is shunted through the Cu layer. Such an enhancement of torques could lead to a lower write current, and thereby higher energy efficiency and bit density of SOT-MRAMs. This increase in torques also correspond to an increase in PMA, which determines the thermal stability of perpendicular Magnetic Tunnel Junctions. Hence, the oxidation of the FM/HM interface could lead to longer retention times and a net reduction in the write energy of SOT-MRAMs.

Q13-11. Current-induced magnetization switching using an electrically insulating spin-torque generator. *H. An*[1] and K. Ando[1] *1. Keio University, Yokohama, Japan*

Current-induced magnetization switching through spin-orbit torques is the fundamental building block of spin-orbitronics, which promises high-performance, low-power memory and logic devices. The spin-orbit torques generally arise from spin-orbit coupling of heavy metals. However, even in a heterostructure where a metallic magnet is sandwiched by two different insulators, a nonzero spin-orbit torque is expected because of the broken inversion symmetry; an electrical insulator can be a source of the spin-orbit torques. We demonstrate current-induced magnetization switching using an insulator as shown in Fig.1. We show that oxygen incorporation into the most widely used spintronic material, Pt, turns the heavy metal into an electrically insulating generator of the spin-orbit torques, which enables the electrical switching of perpendicular magnetization in a ferrimagnet sandwiched by insulating oxides. We also show that the spin-orbit torques generated from the Pt oxide can be controlled electrically through voltage-driven oxygen migration (the detail of this work is illustrated in reference 1). These findings open a route toward energy-efficient, voltage-programmable spin-orbit devices based on insulating metal oxides.

Q13-12. Non-local spin transport in ferromagnetic nanowires subject to spin-orbit torques. *E. Iacocca*[2,1], T. Silva[1] and M. Hoefer[2] *1. NIST, Boulder, CO, United States; 2. Applied Mathematics, University of Colorado, Boulder, Boulder, CO, United States*

The spin transfer torque (STT) effect [1], whereby a spin-polarized current exerts a torque on the magnetization that locally compensates damping, has been the cornerstone of spintronic devices. The spin-orbit torque (SOT) is an alternative torque that results from charge-to-spin transduction in materials with strong spin-orbit interaction. Despite different physics, SOTs are typically used as a replacement for STT [2]. A novel use of SOT features a non-local compensation of damping that can dynamically sustain extended, chiral magnetic textures along ferromagnetic nanowires. For one-terminal devices, we term such textures dissipative exchange flows (DEFs) [3]. From its analytical description, a DEF can be regarded as a train of wide Néel domain walls with the same chirality and spatially-dependent wavelength. Novel DEF features are: (1) spin transport in the form of exchange flow (non-collinear magnetization) over micrometer distances afforded by chirality, (2) precession of the in-plane magnetization with an average constant amplitude along the nanowire and a sub-GHz frequency inversely proportional to damping, and (3) an anisotropy and nanowire length dependent threshold related to the energy required to induce a domain wall. These features are in stark contrast to spin waves whose threshold and frequency are set by damping and anisotropy field, respectively, and whose amplitude decays exponentially. In two-terminal devices, equal and opposite SOTs at the two terminals can sustain static textures analogous to spin density waves (SDWs) [4]. Such static textures are necessarily dissipationless, but they still can participate in the long-range transport of equilibrium spin current via exchange flow, a.k.a. spin superfluidity [5]. Interestingly, SDWs can be stabilized by anisotropy upon removal of SOTs. These predictions hold even in the presence of non-local dipole fields as shown by micromagnetic simulations. The distinctive features of non-local spin transport along ferromagnetic nanowires subject to SOTs could lead to the development of a novel class of chiral, magnetically-textured devices that enable the study of intriguing, fundamental effects and the realization of spin current circuitry.

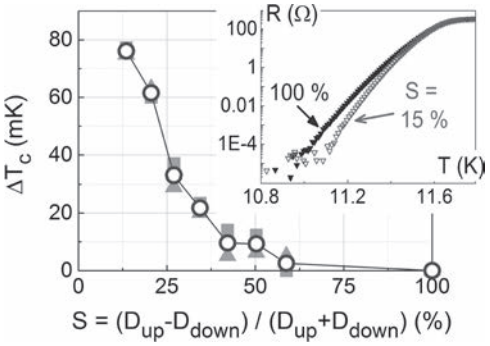
Materials exhibiting controllable magnetic phase transitions are currently in demand for many spintronics applications. Here we investigate from first principles the electronic structure and intrinsic anomalous Hall, spin Hall and anomalous Nernst response properties of the FeRh metallic alloy which undergoes a thermally driven antiferromagnetic-to-ferromagnetic phase transition. It is found that there are important changes in the anomalous transport properties across the phase transition, and they are linked to the underlying Berry curvature structure of the energy bands. Specifically, the suppression of the anomalous Hall and Nernst effects in the antiferromagnetic state and a sign change in the spin Hall conductivity across the transition are found. We suggest that the thermally driven changes in the Hall properties can be used for a reliable spin current detection procedure. The method is able to differentiate the spin Hall effect from other anomalous transverse effects, and so provides a solution to an important problem for practical spin current detection. The advantages and implications of this scheme, together with the possibility of experimental implementation, are also discussed.



Session Q14
SURFACE AND INTERFACE EFFECTS II
(Poster Session)

Gong Chen, Chair
University of California, Davis, Davis, CA, United States

Q14-01. Interface proximity effects near a domain wall in antiferromagnet/superconductor heterostructures. G. Forestier[1], O. Gladii[1], R.L. Seeger[1], S. Auffret[1], I. Joumard[1], C. Gomez[2], A. Buzdin[3,4] and *V. Baltz[1] 1. SPINTEC, Univ. Grenoble Alpes / CNRS / INAC-CEA / GINP, Grenoble, France; 2. G-INP / CIME Nanotech, Grenoble, France; 3. Univ Bordeaux, CNRS, UMR 5798, LOMA, Bordeaux, France; 4. Univ Cambridge, Dept Mat Sci & Met, Cambridge, France*

While antiferromagnetic textures show some advantages over ferromagnetic analogs,[1,2] because they lack net magnetization they are difficult to detect. We demonstrate transport singularity near antiferromagnetic domain walls due to interface proximity effects in antiferromagnet/superconductor heterostructures. Thus far, most such studies have utilized ferromagnet/superconductor heterostructures, where Cooper pair quasiparticles made of opposite spins experience the exchange field averaged over the superconducting coherence length and induce superconductivity into the ferromagnetic layer over a finite length.[3] A magnetic domain wall with opposite spins on either side of the wall lowers the averaged exchange field and provides an additional and more efficient superconducting pathway in the ferromagnetic layer. We discuss in this work series of experimental results for antiferromagnet/superconductor heterostructures. We created domains in the antiferromagnet and varied the antiferromagnetic configuration from multi- to single-domain. The gradual enhancement of the superconducting critical temperature with the amount of domain walls in the antiferromagnet demonstrates that the length scales into play allow for the penetration of superconducting states localized near antiferromagnetic domain walls.[4]

Q14-02. Effect Of Buffer Layers On The Magnetic Behaviour And Thermal Stability Of CoFeB Film. *J. Dwivedi*[1], M. Gupta[2], V.R. Reddy[2], A. Mishra[1], V. Srihari[3], K.K. Pandey[3] and A. Gupta[4] *1. School of Physics, Devi Ahilya University, INDORE, India; 2. UGC-DAE CSR, Indore, India; 3. High Pressure & Synchroton Radiation Physics Division, Bhabha Atomic Research Centre, Mumbai, India; 4. Amity Center for Spintronic Materials, Amity University, Noida, India*

Ultrathin films of CoFeB exhibit high value of perpendicular magnetic anisotropy (PMA) when deposited on MgO and refractory metals (RM) which make them promising candidate for perpendicular magnetic tunnel junctions. There are several theoretical and experimental works which reported that using RM as a buffer layer, PMA of CoFeB film gets enhanced after appropriate post-deposition thermal annealing [1]. Post deposition annealing results in crystallization of amorphous CoFeB film into bcc CoFe phase, with out-diffusion of boron from the CoFeB layer [2]. Partial crystallization of CoFeB layer plays an important role in enhancing tunnel magnetoresistance (TMR) as well as PMA. Therefore, it is important to understand how different refractory metals affect the thermal stability of amorphous CoFeB film, as well as the crystallographic texture of the bcc-CoFe phase. Films having structure; substrate/RM(30nm)/CoFeB(30nm)/RM(2nm) (RM =W, Mo, Hf) were deposited using ion beam sputtering. To monitor the structural transformation in amorphous CoFeB film, X-ray diffraction was used. XRD measurements were done using Bruker D8 Advance diffractometer in θ-2θ mode. It is found that the buffer layer significantly affects the thermal stability of CoFeB film. Film interfaced with Hf is most stable, while that interfaced with Mo is least stable. Figure 1 show representative MOKE hysteresis loops taken as a function of azimuthal angle, of the film in pristine state and after annealing at different temperatures. One can see that all the samples have uniaxial magnetic anisotropy at its as-deposited state and show the isotropic behaviour at its transition temperature. Also, Coercivity exhibits a large increase. After further annealing, with W and Hf buffer layer, there is no change but with Mo buffer layer, anisotropy reappear and decrease in coercivity. In order to understand the origin of magnetic anisotropy in the film, in-plane and out-plane x-ray diffraction measurements have been done using Hard X-ray beamline BL-11 of INDUS-2. It is found that with thermal annealing the film exhibits significant changes in grain texture as well as internal stresses.

Q14-03. Giant magnetic anisotropy in two dimensional honeycomb hafnene monolayer. A. Hashmi[2] and *J. Hong*[1] *1. Physics, Pukyong National Univ, Busan, The Republic of Korea; 2. University of Tsukuba, Tsukuba, Japan*

A few years ago, it was claimed that the two-dimensional ferromagnetic planar Hf monolayer could be synthesized on Ir(111). However, several questions remained unanswered. Herein, we unravel the structural stability of the HF monolayer and its influence on magnetism using first principles calculations. Despite the ferromagnetic state in the planar free-standing Hf layer, extensive systematic calculations with phonon spectra reveal that the planar free-standing Hf layer is unstable and it has a non-magnetic high-buckled structure in the ground state. We also find a structural transition from buckled to flat honeycomb geometry on the Ir(111) substrate. Nonetheless, 2D hafnene has no magnetic state due to strong hybridization with the Ir(111) surface. The evolution from the non-magnetic to the ferromagnetic state combined with structural transition is observed by adding BN as a spacer layer on the Ir(111) substrate (BN/Ir(111)). In addition, we find that 2D Hf on BN/Ir(111) has a giant perpendicular magnetic anisotropy of 3.41 meV.

Q14-04. Effects of Imprinting on Topological Structures in Thin Multilayers with DMI. *N. Kent*[1,2], R. Streubel[3], C.A. Lambert[4], S. Dhuey[5], M. Im[2] and P. Fischer[1,2] *1. Spin textures and their dynamics hold the key to understand and control the properties, behavior and functionalities of novel magnetic materials. New avenues to control magnetic materials open up through enhanced complexity and new functionalities, which can impact the speed, size and energy efficiency of spin driven applications. Advanced imaging tools that provide magnetic sensitivity to spin textures at high spatial resolution, ultimately at buried interfaces and in all three dimensions, and high temporal resolution to capture the spin dynamics across scales, are therefore of large scientific interest. We will report on a recent study of topological spin textures that were imprinted due to coupling between a 30nm thin permalloy (Py) nanodisk with diameters from 250-1000nm and a multilayer Ir/Co/Pt film with strong DMI. Using element-specific magnetic soft x-ray microscopy we were able to image the magnetic structure of the Py nanomagnets and the spin texture in the DMI film independently. We found a significant increase of the imprinted domain period (240nm) in the DMI film compared to the free film (180nm), which can be traced back to a locally varying stray field energy. Depending on the size of the nanodisks, we observed a change of the skyrmion diameter, and we directly observe target Neel skyrmions stabilized by a radial symmetry enforced by the Py disk. We confirm that these structures have a uniform chirality enforced by the DMI of the thin film by observing an asymmetric expansion of the domain walls as a function of applied magnetic field.

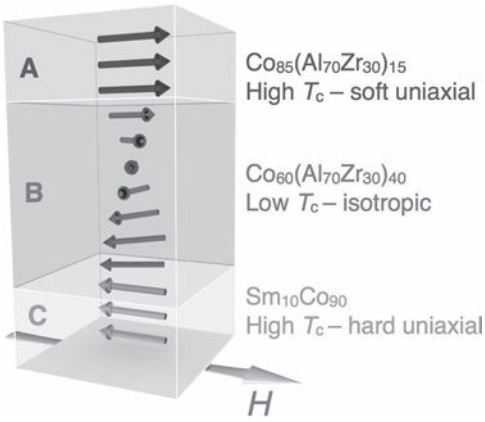
Q14-05. Interfacial Dzyaloshinskii-Moriya interactions in W/CoFeB/MgO film systems with varying the thickness of W layer. *G. Kim*[1], A.S. Samardak[2], Y. Kim[1], I. Cha[1], A. Ognev[2], A. Sadovnikov[3], S. Nikitov[4] and Y. Kim[1] *1. Department of Materials Science & Engineering, Korea University, Seoul, The Republic of Korea; 2. School of Natural Sciences, Far Eastern Federal University, Vladivostok, Russian Federation; 3. Nonlinear Physics, Saratov State University, Saratov, Russian Federation; 4. IRE RAS, Moscow, Russian Federation*

For the development of next-generation magnetic memory or logic devices, understanding microscopic origins of interfacial magnetic properties such as perpendicular magnetic anisotropy (PMA) and interfacial Dzyaloshinskii-Moriya interaction (iDMI) are important. In particular, the iDMI has drawn considerable attention because it can generate additional exchange energy term and manipulate intra-atomic magnetization dynamics. The iDMI appears when a thin ferromagnetic (FM) layer is in contact with a heavy metal (HM). The strong spin-orbit coupling (SOC) of HM, broken inversion symmetry at the interfaces and hybridization of unfilled orbitals of FM and HM atoms induce the iDMI [1]. The prominent effect of iDMI is observed in layered systems with PMA such as Pt/Co/AlO_x and Pt/CoFeB/AlO_x [2]. In this study, we investigated the iDMI energy density in W/CoFeB/MgO trilayers with different phases of W layer. To induce phase transition we varied the thickness of W layer from 1 nm to 15 nm and used different annealing temperatures. All the samples annealed at both 300^{o}C and 400^{o}C exhibited well pronounced PMA. Estimated iDMI energy density using BLS



spectroscopy showed oscillation behavior as a function of W layer thickness. Since it is known as that iDMI and PMA have the same interface originated magnetic properties, we calculated surface contribution of PMA energy and found that it showed similar oscillatory behavior to the iDMI energy with different W thicknesses. Both these two physical properties showed two maximum values at amorphous and alpha-W phases, while minimum value at beta-W phase. We think that their variation occurs because of the changing in the lattice parameter of W when it underwent the phase transformation. Also, we could confirm interatomic distance between W and CoFeB is important factor that determine the strength of iDMI energy.

Q14-06. Long-range Magnetic Proximity Effects in Amorphous Exchange-spring Magnets. F. Magnus[1,3], K.A. Thorarinsdottir[1], *T.P. Hase*[2], G. Andersson[3] and B. Hjörvarsson[3] *1. Science Institute, University of Iceland, Reykjavik, Iceland; 2. Physics, University of Warwick, Coventry, United Kingdom; 3. Dept of Physics and Astronomy, Uppsala University, Uppsala, Sweden*

The magnetic proximity effect refers to an induced magnetic ordering in a non-magnetic material which is brought about by proximity to a magnetically ordered material. It is an interface effect and has generally been considered to be short-ranged, extending no more than a few atomic layers into the non-magnetic material. The influence of such a proximity effect can be diverse, ranging from increases in the ordering temperature of low-Tc layers, non-oscillatory interlayer exchange coupling, spring-magnet behaviour and exchange bias. Therefore, it is crucial to gain a better understanding of magnetic proximity effects since they can have a strong influence on magnetic nano-devices, which are composed of layers of magnetic and non-magnetic materials [1]. Here, we show that in certain types of amorphous heterostructures the magnetic proximity effects can extend several tens of nanometers. In $Co_{85}(Al_{70}Zr_{30})_{15}/Co_{60}(Al_{70}Zr_{30})_{40}/Sm_{10}Co_{90}$ trilayers (Fig. 1) we observe exchange-spring magnet behaviour, where the magnetically soft $Co_{85}(Al_{70}Zr_{30})_{15}$ layer is pinned by the hard $Sm_{10}Co_{90}$ layer, at temperatures 50% above the intrinsic ordering temperature of a 10-nm-thick $Co_{60}(Al_{70}Zr_{30})_{40}$ middle layer. This can only be explained by an induced magnetic order throughout the middle layer. In addition, we observe an exchange bias on the top layer due to the $Sm_{10}Co_{90}$ bottom layer at three times the ordering temperature of a 40-nm-thick $Co_{60}(Al_{70}Zr_{30})_{40}$ middle layer. This shows that two different proximity induced magnetic phases exist, with different extension and temperature dependence [2]. Furthermore, the scaling of the total magnetic moment with layer thickness has been measured on $Co_{85}(Al_{70}Zr_{30})_{15}/Co_{60}(Al_{70}Zr_{30})_{40}$ multilayers. We find that the magnetic moment scales almost linearly with the thickness of the $Co_{60}(Al_{70}Zr_{30})_{40}$ layers up to 10 nm at three times their intrinsic ordering temperature. This suggests that the proximity effect induces an almost constant magnetization throughout such thick layers.

Q14-10. The Dzyaloshinskii-Moriya interaction in the epitaxial Fe/Pt(110) system: Theory and Experiment. *H. Nembach*[1,2], G. Chen[3], B. Zimmermann[4], A.K. Schmid[5], K. Liu[3], J. Shaw[1] and S. Blügel[4] *1. NIST, Boulder, CO, United States; 2. JILA, University of Colorado at Boulder, Boulder, CO, United States; 3. Physics Department, University of California, Davis, CA, United States; 4. Peter Grünberg Institut and Institute for Advanced Simulation, Forschungszentrum Jülich, Jülich, Germany; 5. Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, CA, United States*

The interfacial Dzyaloshinskii-Moriya interaction (DMI) interaction gives rise to chiral magnetic structures. The DMI is particularly sensitive to symmetry. By far most work on interfacial DMI is based on (111) oriented interfaces or (111) textured films exhibiting a C_{3V} symmetry, for which the DMI is isotropic and can be described by one micromagnetic parameter. This is different for systems with C_{2V} symmetry. Here the DMI is anisotropic, the micromagnetic description requires two parameters and in this case the DMI can support not only skrymions but also antiskyrmions as least-energy configurations. We prepared a 1.8 nm thick Fe film on a Pt (110)-orientated single crystal by molecular beam epitaxy to explore systems with C_{2V} symmetry. We conducted density-functional theory calculations (DFT) and compared the results with experiment. A low-energy electron diffraction image (LEED) of the Fe film is shown in fig. 1. We used Brillioun Light Scattering Spectroscopy to determine the angular dependence of the frequency of the Damon-Eshbach mode for both field polarities. The DMI induced frequency-shift and the magnetic anisotropy both show a two-fold symmetry. The strongest DMI is along the [001]-direction, which coincides with the magnetic easy axis, see fig. 2. The DFT calculations were carried out for a thickness of up to 6 ML Fe using the Korringa-Kohn-Rostoker Greenfunction method, which employs infinitesimal rotations to extract parameters of a Heisenberg model. The calculations showed the same trend as the experiment for the DMI and for the magnetic anisotropy. The ratio of the two independent components of the spiralization tensor and for the fcc (110)-oriented surface describes the anisotropy of the DMI. We found that the ratio determined from experiment and from theory are in good agreement. These results demonstrate that DFT calculations can quantify the

strength and symmetry of the DMI. B.Z. and S.B. acknowledge funding from European Union's Horizon 2020 program (no. 665095–FET-Open project MAGicSky). Work at UCD supported by NSF (DMR-1610060) and UCOP MRP-17-454963

Session Q15
THEORY AND MODELLING OF NANOSTRUCTURES III (Poster Session)

Marijan Beg, Chair
European XFEL GmbH, Schenefeld, Germany

Q15-01. Mapping of the Magnetic Anisotropy in Nanostructured Permanent Magnet: a Micromagnetic Study. *H.T. Nong*[1], T.K. Mai[2], F. Schoenstein[1], N. Jouini[1] and S. Mercone[1] *1. Laboratoire des Sciences des Procédés et Matériaux (LSPM) - UPR 3407 du C.N.R.S. Institut Galilée - Université Paris13, VILLETANEUSE, France; 2. Hoya Glass Disk company, Hanoi, Vietnam*

Controlling the competition between the shape and the magneto-crystalline effect in cobalt-based nano-objects is a major challenge in order to maximize their coercive field value. This is mandatory in order to use them as building blocks in new nanostructured rare earth free magnets. In this work we present a full detailed study by micromagnetic simulation on the reversal magnetization behavior of an *ensemble* of nano-objects. The goal of the study is to simulate the reality of the bulk nanostructured magnets obtained by a bottom up process reported into literature [1,2]. We performed here micromagnetic simulation of bundles of nanowires by using the NMAG package [3]. This software is indeed well suited to describe the complex shape of the nano-objects. The magnetization reversal mechanism of the different nanowires has been studied throughout the calculations of magnetization curves along the easy axis (x) and as a function of the angle between this axis and the direction of the external magnetic field applied (θ). We could compare the magnetic results obtained for a prefect aligned *ensemble* of nanowires with the one recorded in the case of various percentages of misalignment (see Figure 1 (a) - 25% of nanowires in this figure are not aligned respect to the easy axis x, α being the angle of misalgnment). The nanostructured bulk system built by the compaction of 27 nano-magnets, has been studied as a function of the nano-objects alignment. The percentage of nanowires not aligned was varied between 25% and 75% in order to study the effect of this misalignment on the magnetic properties of the bundle. Also the effect of the angle (α) of the nanowires misaligned from the easy axis, has been carefully studied. The mapping of the reversal magnetic behavior of the bundle as a function of all the cited parameters (α, θ, # of nanowires not aligned) allows to pinpoint the driving factors for the optimization of the magnetic energy of the nanostructured magnets. These latter will be largely discussed during the presentation.

Q15-02. First Principles Model of Magnetic Nanoparticle Behavior in Various Fluid Environments. *P. Malik*[1] and B. Shapiro[1] *1. Bioengineering, University of Maryland, Olney, MD, United States*

Magnetic nanoparticles (MNP's) have garnered lots of interest in various bioengineering fields for applications such as targeted drug delivery and cell manipulation. Characterization of MNP behavior in magnetic fields is an important step towards realizing these applications. This model will allow particle design to be optimized and rapidly prototyped as part of a magnetic system. The MNP's considered in this model are spheres comprised of magnetic cores encapsulated by a non-magnetic material. In this model, four forces are considered to be acting on each particle; the force due to a magnetic gradient, dipole-dipole interactions, steric hindrance, and viscous drag. The model is a quasi-steady-state model, since the particles are assumed to reach steady-state velocity very quickly due to their small mass, meaning acceleration terms are set to zero. The model is being verified with velocity and chaining length comparisons, as a reference to chaining behaviors, to PLGA nanoparticles with magnetic cores. Currently, the model has been verified for single, and two particle behavior, but has run up against

ODE solver issues for multi-particle simulations. The large derivatives of the Leonard-Jones potential and dipole interaction forces cause these simulations to quickly obtain highly unrealistic velocities.

Q15-03. Enhancement of the Energy Product in Soft- and Hard-magnetic Mixtures. *N. Kim*[1], H. Han[1], D. Jung[1] and K. Lee[1] *1. School of Materials Science and Engineering, Ulsan National Institute of Science and Technology, Ulsan, The Republic of Korea*

For developing rare-earth free permanent magnets, the soft- and hard-magnetic mixtures have been extensively investigated [1,2]. Although the magnetic mixtures have theoretically explicit prospect for rare-earth free permanent magnets with proper energy product [3,4], no significant improvement has not been found yet because of their complicated dependence on the microstructure such as a grain size, shape, anisotropy distribution, exchange coupling among grains, and different phases. In order to elucidate the magnetic mixture for rare-earth free permanent magnets, it is necessary to develop a clear model in which various microstructural elements are considered. In this works, we studied the magnetic mixtures composed of MnBi (hard), and FeCo (soft) by micromagnetic simulations according to various ratio of two phases, their microstructures, and their couplings. As a model system, we adopt the 160×160×40 nm^3 sized rectangular prism in which MnBi and FeCo phases are formed in different grains as shown in Fig. 1(a). We assumed that the easy axis of magneto-crystalline anisotropy is z-axis and it distributes normally in each grain with standard deviation of 0.03. To estimate energy product, the hysteresis loops were calculated by applying external magnetic field ranging from -5 T to 5 T along z-axis and B- and H-fields were obtained directly from them. As shown in Fig. 1 (b), the energy product varies dramatically according to the ratio of mixture. In the presentation, we will discuss about the energy product enhancement by modulating the microstructures and the ratio of soft- and hard-magnets in mixtures.

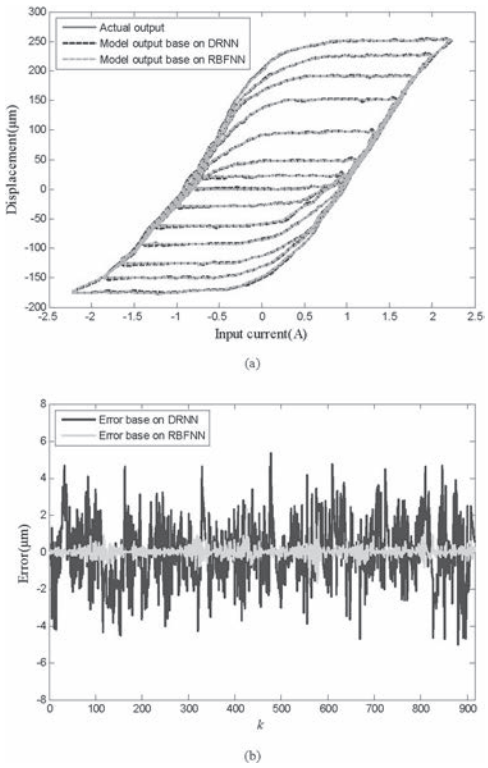
Q15-04. Field dependence of the blocking temperature at increasing size: An empirical approach for cobalt ferrite nanoparticles. *C.R. Stein*[1,2], M.S. Almeida[1], M.E. Gusmão[1], M.N. Borges[1] and P.C. Morais[2,3] *1. Physics, Federal Institute of Rondônia, Porto Velho, Brazil; 2. Physics, University of Brasília, Brasília, Brazil; 3. School of Chemistry and Chemical Engineering, Anhui University, Hefei, China*



The present study reports on the synthesis and magnetic characterization of cobalt ferrite nanoparticles (CFN) co-precipitated in alkaline medium at increasing temperatures, from 30 °C up to 95 °C [1,2]. Hysteresis cycles (*M* versus *H*) were recorded at 5 K, 100 K and 300 K whereas field-cooled (FC) and zero-field-cooled (ZFC) magnetization curves (*M* versus *T*) were obtained in the range of 5 K to 300 K while varying the applied field in the range of 50 Oe to 100 Oe. X-ray diffraction data of the as-synthesized CFN revealed samples with high degree of crystallinity and average crystallite size in the range of 5 nm to 8 nm as the synthesis temperature increases from 30 °C to 95 °C [3]. At room temperature (300 K) the as-synthesized CFN revealed closed hysteresis cycles, typical of superparamagnetic behavior [4], and open hysteresis cycles at lower temperature (5 K), with well-defined coercive field values [5]. Additionally, the FC and ZFC data revealed a typical superparamagnetic regime at higher temperatures and a progressive blocking of the CFNs' magnetic moment centered around the blocking temperature (T_B) while cooling down the samples towards 5 K. While typical analyses of the room-temperature hysteresis cycles were conducted by averaging out the first order Langevin function with a lognormal distribution function of magnetic moments a new approach for the field dependence (H) of the blocking temperature (T_B) is herein proposed.

Q15-05. NARMAX Model-based Hysteresis Modeling of Magnetical Shape Memory Alloy Actuator. Y. Yu[1], P. Yang[1] and *M. Zhou*[1] *1. Jilin University, Changchun, China*

As a representative of intelligent material actuators, magnetical shape memory alloy (MSMA) actuator play a key role in micro drive technologies, which has the characteristics of miniature-light weight and large energy density. However, the inherent hysteresis of MSMA actuator has hindered its application [1]. In order to describe the hysteresis in MSMA actuator, the hysteresis modeling of MSMA actuator has attracted the interest of researchers [2]. Nonlinear Auto Regressive Moving Average Exogenous (NARMAX) model belongs to a black-box nonlinearity model, which has a great ability of capturing the complicated nonlinearity characteristics. In this study, NARMAX model is employed to describe the hysteresis nonlinearity in MSMA actuator. NARMAX model is composed of a nonlinear function and exogenous variable function. It is a challenging problem to identify the parameters of the NARMAX model. To save the multi-valued mapping problem of the hysteresis nonlinearity characteristic, the double polarity sigmoid function is first selected as the exogenous variable function of the NARMAX model. Owing to the great nonlinearity function approaching capability, neural network method is used to identify the parameters of the NARMAX model in this study. Radial basis function neural network (RBFNN) has the advantage of strong generalization ability, high accuracy and global optimal property, which is used to identify the nonlinearity function in the NARMAX model [3]. In the process of identification, the center and variance of the radial basis function and the weights of the hidden layer to the output layer are derived, and then make sure that the output of the NARMAX model based on RBFNN can approximation to the output of MSMA actuator. To verify the effectiveness of the proposed model, a series of contrast simulations are implemented. As shown in Fig.1, the maximum modeling error of the NARMAX model based on RBFNN is 2.23μm, it is reduced by 3.04μm compared with that of the NARMAX model based on diagonal recurrent neural network (DRNN). Simulation results prove that the NARMAX model based on RBFNN can accurately describe the hysteresis in MSMA actuator.

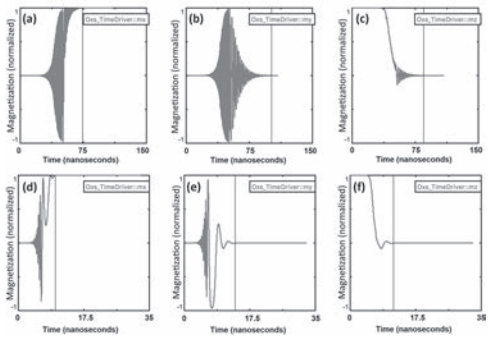
Q15-06. Quantum Torque of a Torsional Oscillator Coupled to Molecular Magnets. *G. Kim[1] 1. Physics and Astronomy, Sejong University, Seoul, The Republic of Korea*



Molecular magnets(MMs) and the quantum properties they show are an extremely topical area. There are two major reasons for studying MMs: the search for macroscopic quantum phenomena and the possible applications of MMs in spintronics. Various aspects of the phenomena such as quantum resonant tunneling and Rabi oscillation have been investigated. Among them, mechanical force of quantum origin has been proposed in connection with quantum tunneling between classically degenerate magnetic states in MMs. This issue was first raised by Chudnovsky et al.[1], who studied mechanical forces of quantum origin that have no counterpart in classical physics. In fact, such forces are well known in condensed matter physics, e.g., recent application to topological insulators. Focusing on MMs, they showed that the gradient of the energy gap between the two states of the doublet can produce the oscillation of the quantum force when the magnet is placed in a microwave field and a spatially varying static magnetic field. Later, Kim[2] studied the quantum force in MMs coupled to a nanoresonator. A natural extension of the quantum force in two-level physics is quantum torque of a torsional oscillator generated by a tunneling spin. Experiments[3] have been performed in characterizing MMs in a nanoelectromechanical system obtained by grafting MMs on a carbon nanotube or nanocantilever. They have demonstrated that a mechanical torque induced by the rotation of the magnetic moment may be used for developing high-sensitivity magnetic probes. In this talk, we propose a torque of a quantum origin related with spin tunneling in a system of MMs coupled to a nanoresoantor. Applying a transverse magnetic field and an ac field, we consider a quantum-mechanical problem of a rotationally oscillating body in a spin tunneling. In the presence of the level splitting created by the gradient of the transverse field we study diverse torque dynamics which depend upon several mechanical parameters as well as ac frequency. We show that the magnitude of the coupling strength plays a crucial role in quantum torque of nanoresonator transferred from quantum dynamics in MMs. These features are expected to be tested in existing experimental techniques.

Q15-07. Micromagnetic Modelling of Switching and Spin Relaxation in Rectangular Magnetic Nanostructures under 1 GHz AC Microwave Magnetic Field. F. Sahbaz[1] and *M.C. Onbasli[1] 1. Electrical and Electronics Engineering, Koc University, Istanbul, Turkey*

Detailed understanding of spin relaxation processes as a function of magnetic properties, geometry and time in nanostructures is essential in order to develop ultrafast spintronic logic and memory devices. In spin-wave dynamics, different competing mechanisms emerge due to spin-spin, spin-phonon, spin-photon or spin-orbit interactions at sub-nm to mm length scales and at sub-picosecond to millisecond time scales [1]. In this study, we developed OOMMF micromagnetic models to investigate the effect of increasing damping on the spin relaxation behavior of nanostructured rectangular Yttrium Iron Garnet ($Y_3Fe_5O_{12}$, YIG) excited under 1 GHz ac external magnetic field along x axis. The nanostructures are initially magnetized along +z direction. Our OOMMF model solves the Landau-Lifschitz-Gilbert equation with precession and damping terms only. The external ac field can represent a microwave excitation of spin waves or microwave write signals. The time evolution of normalized vector magnetic components were calculated for 100 nm-long nanostructures with different widths (10-150 nm), Gilbert damping ($\alpha = 10^{1}$-10^{-4}), M_s = 140 kA/m, exchange stiffness A=3.65 pJ/m. In a second set of simulations, YIG size is fixed (100 x 150 nm^2) and the transient spin relaxation times were calculated for different thicknesses (10-75 nm) and damping ($\alpha = 10^{1}$-10^{-4}). Fig. (a-c) and (d-f) show the relaxation of magnetization vector components for $\alpha = 0.01$ and 0.1, respectively. For thin rectangular (100 x 150 nm^2) structures, increasing damping helps stabilize magnetization faster. The stabilization time drops from 75 to 9 ns when α increases from 0.01 to 0.1. Spin relaxation time was found to be below 1 ns (a few hundred ps) when the width is greater than length and if the damping coefficient is enhanced between $\alpha = 0.1$ and 1. Finally, we propose to use magnetic insulators with enhanced damping and optimized geometry as low-power and wide-bandwidth memory elements.

Q15-08. Atomistic Modelling of Granular Exchange Bias Systems. *S. Jenkins[1]*, R. Chantrell[1] and R.F. Evans[1] *1. Physics, University of York, York, United Kingdom*

Exchange bias is a physical property of a magnetic material which is utilised in the read head of a hard drive. Further improvements to the read head are limited by our understanding of exchange bias and its scaling to nanoscale dimensions. The exchange bias effect occurs when a ferromagnet FM is coupled to an anti-ferromagnet (AFM), causing a shift of the magnetic hysteresis loop. The shift is caused by pinned interfacial spins from the

AFM, these cause a unidirectional field pinning the exchange coupling of the FM spins at the interface[1]. The complexity of AFM materials and their interfaces limits the applicability of simple approaches such as two sublattice AFM or micromagnetic models. To study the exchange bias effect we have developed an atomistic spin model of the antiferromagnet IrMn, considering localised atomic spin moments coupled with Heisenberg exchange reproducing key experimental results including the Neel temperature and magnetic ground state[1]. Here we investigate the grain size distribution and how set/unset grains effects the exchange bias in a IrMn/CoFe FM/AFM bilayer using an atomistic spin model[2]. Atomistic models are computationally expensive, therefore previously exchange bias has only been investigated in single grain structures[1]. Real devices are comprised of hundreds of grains, which means the simulation must model millions of atoms. Using the parallel capability of the vampire software package it is possible to models million atom systems for nanosecond timescales. For a 50nm x 50nm x 8nm structure comprised of 6nm grains, after field cooling and equilibration, a simulated hysteresis loop gave exchange bias fields of between 0.04T and 0.12T for varying grain size distributions as shown in Fig. 1. We will present calculations of nanoscale exchange biased thin films including temperature effects and the role of the grain size distribution on the total exchange bias (Fig. 2). This work used the ARCHER UK National Supercomputing Service (http://www.archer.ac.uk).

Q15-10. Field dependence of the blocking temperature at increasing size: An empirical approach for cobalt ferrite nanoparticles.

C.R. Stein[1], M.S. Silva de Almeida[1], M.N. Borges[1] and P.C. Morais[2,3]
1. Physical, Federal Institute of Rondônia, Porto Velho, Brazil; 2. Anhui University, Hefei, China; 3. Universidade de Brasília, Brasília, Brazil

The present study reports on the synthesis and magnetic characterization of cobalt ferrite nanoparticles (CFN) co-precipitated in alkaline medium at increasing temperatures, from 30 ^{0}C up to 95 ^{0}C [1,2]. Hysteresis cycles (*M* versus *H*) were recorded at 5 K, 100 K and 300 K whereas field-cooled (FC) and zero-field-cooled (ZFC) magnetization curves (*M* versus *T*) were obtained in the range of 5 K to 300 K while the applied field 100 Oe. X-ray diffraction data of the as-synthesized CFN revealed samples with high degree of crystallinity and average crystallite size in the range of 5 nm to 8 nm as the synthesis temperature increases from 30 ^{0}C to 95 ^{0}C [3]. At room temperature (300 K) the as-synthesized CFN revealed closed hysteresis cycles, typical of superparamagnetic behavior [4], and open hysteresis cycles at lower temperature (5 K), with well-defined coercive field values [5]. Additionally, the FC and ZFC data revealed a typical superparamagnetic regime at higher temperatures and a progressive blocking of the CFNs' magnetic moment centered around the blocking temperature (T_B) while cooling down the samples towards 5 K. While typical analyses of the room-temperature hysteresis cycles were conducted by averaging out the first order Langevin function with a lognormal distribution function of magnetic moments a new approach for the field dependence (H) of the blocking temperature (T_B) is herein proposed.

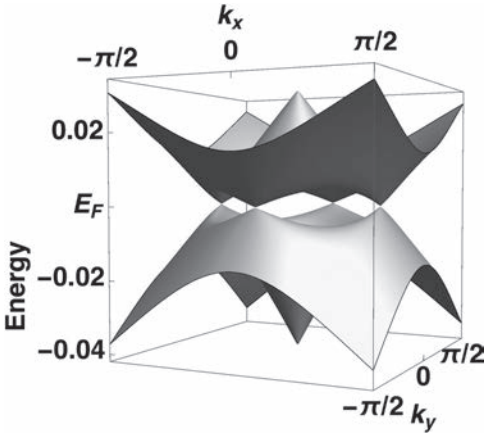
Session Q16
TOPOLOGICAL SCES V: TOPOLOGICAL KONDO SYSTEMS (Poster Session)

Lu Li, Chair
University of Michigan, Ann Arbor, MI, United States

Q16-01. Topological mirror Kondo semi-metals and half-metals in two-dimensional magnetic systems. *K. Kimura*[1], T. Yoshida[1] and N. Kawakami[1] *1. Department of Physics, Kyoto University, Kyoto, Japan*



The concept of topology in condensed matter physics has been widely recognized since the theoretical discovery of topological insulators by Kane and Mele. Non-trivial topological properties of bulk wave function lead to metallic surface (edge) states, topological megnetoelectric effects, etc. Furthermore, there have been some intriguing extensions to Weyl semi-metals and topological crystalline insulators. The topological properties in weakly correlated electron systems have been clarified rather well. Recently, the electron correlation effects on topological properties have attracted much attention because of nontrivial features that weakly correlated electron systems do not show, such as topological Kondo insulators, interaction-reduced classifications, long-range-ordered phases in topological insulators. We here address the topological properties of magnetically ordered phases. There have been several studies on this topic: an antiferromagnetic topological insulator [1] that is realized in the combined symmetry of primitive-lattice translation and time-reversal, and a spin-selective topological insulator [2] that is realized in a spin-conserved half-metallic ferromagnetic phase of heavy-fermion system. In the previous research, such topological properties have been considered without taking spatial symmetry into account, and therefore a natural question arises: what happens if we take into account a specific spatial symmetry. We study topological properties of magnetically ordered phases by taking into account mirror symmetry in heavy-fermion systems. We analyze an effective model of the topological Kondo insulator SmB_6 in a two-dimensional square lattice, and find the following two states [3]: a two-dimensional antiferromagnetic topological state at half-filing characterized by a mirror Chern number and a topological state in a half-metallic ferromagnetic phase around quarter-filling characterized by a Chern number. In our poster presentation, we will discuss these states in detail.

Q16-02. Weyl-Kondo Semimetal and Proximate Phases in Heavy Fermion Systems. *S.E. Grefe*[1], H. Lai[1], S. Paschen[2] and Q. Si[3] *1. Physics and Astronomy, Rice University, Houston, TX, United States; 2. Institute of Solid State Physics, Vienna University of Technology, Vienna, Austria; 3. Rice University, Houston, TX, United States*

Recently we established a strongly correlated topological semimetal phase dubbed the Weyl-Kondo semimetal (WKSM) [1], realized with a periodic Anderson model on a noncentrosymmetric lattice. This robust phase emerges from the Kondo effect, characterized by Weyl nodes with strongly reduced effective electron velocity, corresponding to a narrow band. In the recently discovered noncentrosymmetric heavy fermion semimetal $Ce_3Bi_4Pd_3$, this key experimental signatures have been found to agree within the Kondo regime [2]. In this work, we address the role of space group symmetry on the WKSM phase, and study the overall phase diagram by analyzing transitions from WKSM to nearby phases. Furthermore, amid the rapidly expanding experimental results, we explore the thermodynamic signatures of these phases.

Q16-03. ARPES study of the Möbius Kondo Insulator candidate CeRhSb. S. Seong[1], E. Lee[1], J. Denlinger[2], K. Kim[3], T. Nam[3], B. Min[3], T. Takabatake[4] and *J. Kang*[1] *1. Physics, The Catholic University of Korea, Bucheon, The Republic of Korea; 2. Lawrence Berkeley Laboratory, Advanced Light Source, Berkeley, CA, United States; 3. Physics, Pohang University of Science and Technology, Pohang, The Republic of Korea; 4. Hiroshima University, Higashi-Hiroshima, Japan*

Topological Kondo insulators (TKIs) belong to a class of symmetry-protected topological phases arising from the effects of strong correlation. CeNiSn and CeRhSb are known as Kondo semi-metals (or insulators) with the large anisotropy [1]. It has been predicted theoretically that CeNiSn and CeRhSb are the novel TKI systems having the Möbius-twisted surface states [2]. A unique feature in these systems is that they have the non-symmorphic glide and screw axis symmetries, which bring about the new topological surface band structures of hour-glass type. But this theoretical prediction of the Möbius Kondo Insulator (MKI) has not been confirmed yet experimentally. We have investigated the electronic structure of an MKI candidate CeRhSb by employing angle-resolved photoemission spectroscopy (ARPES) and first-principles band structure calculation. We have measured the Fermi surfaces (FS's) for the three different planes of (100), (010), and (001) planes, which exhibit the metallic FS's having a quite different symmetry for each plane. The dispersive d bands are observed in ARPES, but the Möbius-type surface band structures are not observed. This work suggests that CeRhSb probably does not belong to the MKI system, but that the anisotropic Ce 4f-Rh 4d hybridization plays an important role in determining the electronic structure and the physical properties of CeRhSb.

Q16-04. Non-magnetic element substitution effect in Kondo insulator YbB_{12} and exotic surface effect in this alloy system. *F. Iga*[1,2], W. Matsuhra[2], H. Nakayama[1], W. Hirano[2], K. Yokomichi[2], A. Kondo[5], K. Kindo[5] and H. Yoshizawa[5] *1. College of Science, Ibaraki University, Mito, Japan; 2. Institute of Quantum Beam Science, Ibaraki University, Mito, Japan; 5. ISSP, The University of Tokyo, Mito, Japan*

YbB_{12} is well known as a typical Kondo insulator, Kondo temperature T_K is about 200 K, showing similar physical properties seen in SmB_6 called as the topological Kondo insulator. An energy gap D*E* almost same as T_K develops below 100 K. This energy gap D*E's forming mechanism can be explained by c-f hybridization and coherent Kondo singlet models. We have investigated non-magnetic element substitution effect for YbB_{12} to investigate more detailed relationship between DE* and T_K. Thus, we have clarified that T_K for $Yb_{1-x}R_xB_{12}$, R = Y, Lu, Sc and Zr, shows drastic variation as x increases. It is found that YbB_{12} in a virtual gap-less state would have a peak at about 25 K from magnetic susceptibility of $Yb_{1-x}R_xB_{12}$. The peak temperature Tc^{max} can be extrapolated to 25 K from high-x region. This liner variations on x-dependence for Tc^{max} *show kinks at around x = 0.5 for all substituted element R due to development of an energy gap DE. Furthermore, we will discuss about up-turns shown in magnetic susceptibility below 20 K in* $Yb_{1-x}R_xB_{12}$*. These up-turns appear as development of an energy gap DE* in these alloys and magnetic susceptibility at 2 K shows peak at around x = 0.1. It can be explained by the novel second-gap development in the in-gap state showing metallic behaviors. For x = 0, YbB_{12} has a very small residual density of states at Fermi energy. We will discuss whether this residual DOS in YbB_{12} has relationship with the surface metallic state, including $Yb_{1-x}R_xB_{12}$. This novel exotic state is often said to be originated from surface metallic state with Dirac cone type energy band distribution, already observed in angle resolved photoemission spectra.

Q16-05. Photoemission spectroscopy in 2-dimensional Topological Kondo Insulators. *E. Ramos Rodriguez*[1] *1. Departamento de Física, Universidad Nacional de Colombia, Bogotá D. C., Colombia*

With the renewed interests to know the competence between the strong correlations and topology present in materials like Kondo insulators that give rise to topological Kondo insulators (TKI) behavior as SmB_6 [1,2,3,4,5,6]. The Kondo insulator condition is originated by hibridization of localized $f-$electrons and itinerant *c*-electrons opening a small gap, actually adding the strong spin-orbit coupling generates a surface state inverting the bands that acroos the Fermi level between the gap it gives a topological Kondo insulator condition. The natural framework to study that kind of systems is the periodic Anderson model (PAM) where are taking into account both charge and spin fluctuations. This model is well understood in one dimension where widespread calculations, based in exact diagonalization and density matrix renormalization group techniques are avalaible. In this paper we investigate the main features at low energy scales and how these appear in the single-particle and magnetic excitation spectra with temperature dependence of the *f*-electron spectra for the interpretation of low-energy photoemission spectra (PES) in a cubic lattice, taking into account the spin-orbit coupling implicit in the hibridization, and the correlation between localized states with an interaction Hisemberg type. In a first paper was shown that this model reproduce the TKI condition, where the short-range correlations and Kondo effect are complementary to originate the TKI state [5]. Now we show the influence of this short-range correlations in the spin polarization surface states when the system is in the topological condition.

Q16-06. Electron Spin Resonance in Gd^{3+} doped Kondo insulator SmB_6. *J.C. Souza*[1], P. Rosa[2], R.R. Urbano[1], C. Rettori[1,3], Z. Fisk[4] and P. Pagliuso[1] *1. DEQ, Instituto de Física Gleb Wataghin - Unicamp, Campinas, Brazil; 2. Condensed Matter and Magnet Science, Los Alamos National Laboratory, Los Alamos, NM, United States; 3. Natural and Humans Science Center, UFABC, Santo André, Brazil; 4. Department of Physics and Astronomy, University of California, Irvine, Irvine, CA, United States*

The prediction of a topological Kondo insulator (TKI) phase in SmB_6 has renewed the intense interest for this mixed valence system. The SmB_6 is an interesting platform to observe a TKI phase, and consequently the protected gapless state on the surface, due to the cubic symmetry, the Kondo physics and the Γ_8 crystalline electrical field (CEF) ground state [1]. Although some experimental results indicate this topological nature [2], there is still a lot of controversy in the literature. There is a hypothesis that Sm vacancies (Kondo holes) [3] and/or natural impurities, such as Gd^{3+}, could result in a breakdown of the topology of the system. This possibility raises the interest to explore more microscopic techniques to understand the effects of Gd^{3+} in the SmB_6 compound. In this work, we have performed complementary macroscopic measurements and electron spin resonance (ESR) in $Sm_{1-x}Gd_xB_6$ single crystals ($0 < x < 0.02$). The samples were synthesized by Al flux method. The ESR measurements were performed in X-band ($\nu \approx 9.4$ GHz) and in the temperature range of $4\ K < T < 50\ K$. At T = 4 K, the ESR spectra of Gd^{3+} for highly dilute samples (x = 0.004) is a typical Gd^{3+} spectra, with seven Lorentzian lines in a cubic insulating environment with a crystal field parameter (CFP) $b_4 \approx -9$ Oe. At the same temperature, the Gd^{3+} resonance for more concentrated samples (x = 0.02) evolve to a single Dysonian line, of a metallic environment. These results were not observed in previous reports [4-6]. We will discuss these preliminary results considering that the Gd local environment could be evolving to metallic, even though the bulk would remain insulator, the T-dependence of the line shape [7] and the possibility of intra-gap impurities.

Q16-07. The role of Sm vacancies in partially transforming SmB_6 into a nodal semimetal. *N. Harrison*[1] *1. MPA-MAG, Los Alamos National Laboratory, Los Alamos, NM, United States*

On assuming the unhybridized f-electrons to be dispersionless, as in the classic Kondo insulator model, and conduction electron energy level broadening to originate from their collisions with Sm vacancies [1], we find that a sufficiently large imaginary self energy (recently considered by Shen and Fu) [2] topologically transforms part of the Fermi surface into a nodal semimetal whose nodal quasiparticle velocities are highly asymmetric but whose quasiparticle mobilities are identical. The location of the node coincides with the Fermi surface of the unhybridized conduction electron bands. A nodal metal with these properties naturally explains the sudden growth of the de~Haas-van~Alphen amplitude originating from the bulk at millikelvin temperatures [3], which we attribute a superposition of predominantly conduction electron and f-electron channels, and the weak

linear-in-temperature electrical resistivity at liquid helium temperatures, which recently published data also to be of bulk origin [4].

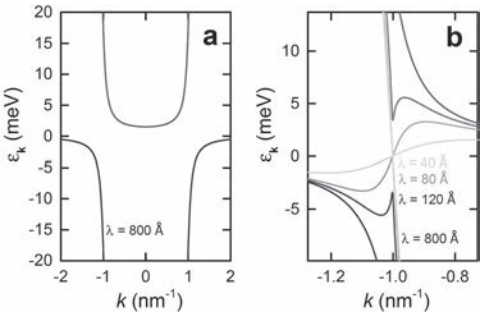

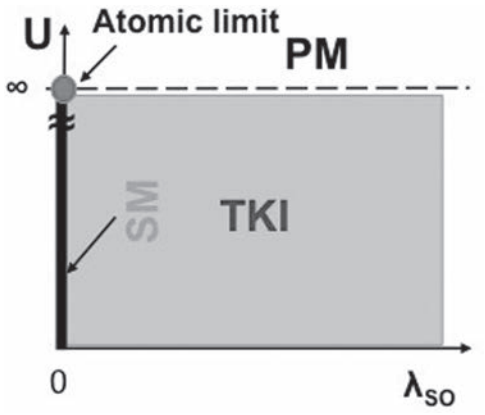

Fig. 1a shows the classic dispersion of a Kondo insulator while figure 1b shows how this is impacted by Sm vacancies, ultimately giving rise to de~Haas-van~Alphen oscillations and a weak bulk linear in temperature conductivity.

Q16-08. Edge Magnetic Quantum Phase Transition in a Kane-Mele-Anderson Lattice Model for Topological Kondo Insulators.

J. Zhu[1] and J. Julien[2] *1. Theoretical Division and Center for Integrated Nanotechnologies, Los Alamos National Laboratory, Los Alamos, NM, United States; 2. Institut Neel CNRS & Universite de Grenoble Alpes, Grenoble, France*

Topological insulators arising from spin-orbit coupling (SOC) have attracted intensive research interest with their novel electronic properties of protected surface or edge states out of an insulating bulk. The electronic correlation and its interplay with the SOC will have even more intriguing consequences. The *f*-electron systems are an ideal candidate for new topological properties with their strong electronic correlations and the SOC. Here we consider a Kane-Mele-Anderson (KMA) lattice model, for which *f*-electrons located on one of the two sublattices experience Hubbard-*U* interaction. By using the Gutzwiller variational wavefunction approach plus a Wilson loop analysis of Z_2 invariant, a bulk phase diagram is mapped out, as shown in Fig. 1. The topological Kondo insulator is robust against strong Hubbard-*U* interaction, and the semimetal or paramagnetic metal appears in the limit of vanishing SOC or infinite Hubbard-*U* and no magnetism is obtained. With the existence of Kondo coherence as a bystander, the critical point is of spin-density-wave nature. More significantly, we find the magnetism can emerge at a ribbon edge terminated by the *f*-orbital sites when the Hubbard-*U* is larger than a critical value. Further the band structure calculations show the splitting of the Dirac edge states promoted by the time-reversal-symmetry-breaking magnetism, which creates a one-dimensional counterpart of Weyl semimetals. This results can be testable by the angle-resolved photoemission spectroscopy on two-dimensional *f*-electron compounds in a honeycomb lattice.

Phase diagram of the KMA model obtained within the Gutzwiller variational wavefunction approach. It consists of the topological Kondo insulator (TKI), the semimetal (SM), and the paramagnetic metal (PM) phases.

PLENARY III: TOPOLOGICAL WEYL MAGNETS: FROM MULTIPOLE TO ROOM TEMPERATURE FUNCTIONS

Leon Balents, Chair
University of California, Santa Barbara, Santa Barbara, CA, United States

INVITED PAPER

11:30

R1-01. Topological Weyl Magnets: from multipole to room temperature functions. *S. Nakatsuji[1,2] 1. Institute for Solid State Physics, University of Tokyo, Kashiwa, Japan; 2. CREST, Japan Science and Technology Agency, Kawaguchi, Japan*

Among magnets, only ferromagnets have been used for applications, for example, as the main active materials for memory devices. On the other hand, antiferromagnets have attracted recent interest for designing next-generation high-density and ultrafast devices because they produce no stray fields and have much faster dynamics. Despite a number of basic research, however, antiferromagnets have not been successfully utilized for applications; as they possess no overall magnetization, such spin states are notoriously difficult to control and otherwise produce only very weak responses to detect them. Here we introduce a new type of functional antiferromagnets with vanishingly small magnetization, namely, topological Weyl magnets that can be easily controlled by magnetic field, produce large responses, and thus could be useful for future applications. Topological Weyl magnets are characterized by a magnetic semimetallic state that harbors Weyl fermions near the Fermi energy. As a parent state of such a magnetic Weyl state, we first introduce a new class of semimetals with quadratic band touchings, the "Luttinger semimetal" [1,2]. We demonstrate the case in pyrochlore iridium oxides that exhibit various exotic phenomena, including a spontaneous Hall effect without magnetization in a spin liquid state [3]. Then, we discuss a new type of functional antiferromagnets, Mn_3X (X = Sn and Ge) as the examples of a topological Weyl magnet [4,5,6]. We show that the cluster multipole order on the kagome lattice of Mn moments can be easily controlled and allows the system to exhibit a variety of new functions at room temperature that have never been seen in antiferromagnetic metals. These include the large anomalous Hall and Nernst effects [4,5,7], large magnetic optical Kerr effect [8] and a novel type of spin Hall effect (magnetic spin Hall effect). Finally, we show that they should be significantly useful for designing antiferromagnetic spintronics, and energy harvesting technology. This work was partially supported by CREST (JPMJCR15Q5) from JST, by Grants-in-Aid for Scientific Research on Innovative Areas "J-Physics" (Grant Nos. 15H05882 and 15H05883) and by Grants-in-Aid for Scientific Research (Grant No. 16H02209) from JSPS.

Session S1
NEW ROUTES AND MATERIALS TOWARD QUANTUM CRITICALITY

Stephen Russell Julian, Chair
University of Toronto, Toronto, ON, Canada

INVITED PAPERS

1:30

S1-01. A Local Quantum Phase Transition in YFe_2Al_{10}. *M.C. Aronson*[1] *1. Department of Physics and Astronomy, Texas A&M University, College Station, TX, United States*

It is now well accepted that the suppression of ordered states, such as magnetism, can give rise to a novel state with highly anomalous metallic characteristics. It remains a challenge to understand the role of the quantum critical fluctuations associated with the T=0 phase transition in inducing this new state, and if there is feedback between the fluctuations and the essential properties of the quasiparticles in the non-Fermi liquid electronic state. A lack of detailed experimental results on suitable QC systems has slowed progress towards this understanding. The quasi-two dimensional metal YFe_2Al_{10} is a very promising system, comprised of layers of nearly square nets of Fe atoms. Despite the strong divergence of the susceptibility, $\chi(T)\sim T^{-1.4}$ there is no evidence for magnetic order above 0.02 K. Inelastic neutron scattering measurements find that the scattering has no indication of incipient magnetic order, rather there is no measureable wave vector dependence, beyond that of the form factor. However, the scattering displays a strong energy divergence, and the Kramers-Kronig analysis indicates that it is these quantum critical excitations that are responsible for the divergence in the magnetic susceptibility. The scattering is also temperature independent, evidence that the imaginary part of the dynamical susceptibility $\chi''(E,T)$ displays E/T scaling, where the absence of any characteristic energy scale beyond temperature is the hallmark of quantum critical systems. The quantum critical fluctuations are very strong in YFe_2Al_{10}, signaling that it is very close to a T=0 phase transition. The neutron scattering measurements reveal that the critical fluctuations are completely local, with each moment fluctuating incoherently, each with the same spectrum of excitations. These findings rule out the possibility that YFe_2Al_{10} is near magnetic ordering, and instead it seems likely that the phase transition corresponds to a purely electronic phase transition, possibly an orbital selective Mott transition, where localized magnetic moments first emerge.

2:00

S1-02. New Methods and New Materials to Study Nematic Quantum Phase Transitions. *I.R. Fisher*[1] *1. Applied Physics, Stanford University, Stanford, CA, United States*

Electronic nematic order has recently received considerable attention in the context of several families of strongly correlated materials. In this talk I will describe new methods to continuously tune the critical temperature of such systems. In particular, I will emphasize that orthogonal antisymmetric strain is an important, and thus far largely neglected, tuning parameter for nematic order. The method, including a description of how to perform an appropriate decomposition in to different symmetry channels, is demonstrated for underdoped compositions of representative Fe-based superconductors. I will also discuss results from applying similar methods to materials that exhibit ferroquadrupole order, a specific realization of nematic order, which can be tuned to a quantum phase transition.

2:30

S1-03. Multidimensional entropy landscape of quantum criticality. *K. Grube*[1], S. Kuntz[1], D.A. Zocco[2], O. Stockert[3], Q. Si[4] and H. von Löhneysen[1] *1. Institute for Solid State Physics, Karlsruhe Institute of Technology, Karlsruhe, Germany; 2. Institute of Solid State Physics, Vienna University of Technology, Wien, Austria; 3. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 4. Rice University, Houston, TX, United States*

Quantum criticality arises near second order phase transitions at zero temperature. Here, in contrast to classical, temperature-driven transitions, the quantum energy of critical fluctuations as given by the Heisenberg uncertainty principle becomes a relevant energy scale, leading to unusual scaling behavior of thermodynamic and transport properties in a wide range of phase space at finite, albeit low temperature. At a quantum phase transition, the competition between different ground states causes an excess of entropy at very low temperature [1,2]. To avoid these instabilities, solid-state systems tend to form new kinds of many-body phases, thus absorbing the surplus of degrees of freedom. So far, quantum phase transitions have been mainly studied by tuning a single nonthermal control parameter resulting in a singular point in phase space. Actual quantum critical systems, however, depend on a manifold of tuning parameters, such as stress, magnetic fields along different crystallographic directions, or changes of chemical composition, leading to a multidimensional quantum critical phase boundary. This dependence on multiple parameters often implies anisotropic behavior that reflects the properties of the underlying characteristic energy scales. In this talk we will show a new method to determine and analyze the anisotropic stress dependence of the quantum critical entropy by using low-temperature thermal-expansion measurements. We construct the multidimensional entropy landscape at the quantum critical transition of $CeCu_{5.9}Au_{0.1}$ and extract the anisotropic scaling behavior [3]. We thus are able to establish a direct link between the steepest gradient of the stress dependence of the entropy towards the quantum critical transition and the anisotropy of quantum critical fluctuations. We extend these investigations by following the quantum critical phase boundary to higher Au concentrations and magnetic fields and study the changes of the entropy landscape and scaling behavior. Finally, we apply our approach to other systems and show that the dependence of the entropy on nonthermal control parameters allows to search for quantum critical instabilities even if no finite-temperature phase transitions can be observed.

S2-01. The Final Chapter in the Saga of YIG. *A. Princep*[1,2], R. Ewings[3], A. Boothroyd[2], S. Toth[4], S. Ward[4] and C. Dubs[5] *1. ISIS Neutron and Muon Source, Rutherford Appleton Laboratory, Oxford, United Kingdom; 2. University of Oxford, Oxford, United Kingdom; 3. ISIS, Rutherford Appleton Laboratory, Didcot, United Kingdom; 4. Paul Scherrer Institut, Villigen, Switzerland; 5. INNOVENT e.V., Technologieentwicklung, Jena, Germany*

The magnetic insulator Yttrium Iron Garnet can be grown with exceptional quality, has a ferrimagnetic transition temperature of nearly 600 K, and is used as the basis for microwave and spintronic devices that can operate at room temperature. The most accurate prior measurements of the spinwave spectrum date back nearly 40 years, but cover only 3 of the lowest energy modes out of 20 distinct magnon branches. Here we have used time-of-flight inelastic neutron scattering to measure the entire spinwave spectrum in a large number of different Brillouin zones with high momentum and energy resolution. We find that the existing model of the excitation spectrum, well known from an earlier work titled "The Saga of YIG", fails to describe the optical magnon modes. These modes have a substantial thermal population at room temperature and must be taken into account to model, for example, the spin-Seebeck effect. Using a very general spinwave hamiltonian we show that the magnetic exchange interactions are both longer-ranged, and more complex, than was previously understood. This result provides the basis for accurate microscopic models of the finite temperature magnetic properties of Yttrium Iron Garnet, necessary for next-generation electronic devices.

S2-02. The effect of hydrostatic pressure on magnetostructural transition in ferromagnetic cobaltites: $Pr_{1-x}Sr_xCoO_3$ (x = 0.4 - 0.6). A. Chanda[1], M. Kumari[1] and *R. Mahendiran*[1] *1. Physics Dept, National University of Singapore, West Singapore*

Hole doping in dielectric paramagnetic $RCoO_3$ by partial replacement of rare earth (R^{3+}) cation by alkaline earth (Sr^{2+}) cation induces ferromagnetism and metallic behavior for $x \geq 0.2$ in $R_{1-x}Sr_xCoO_3$ series [1]. The cobaltite series with R = Pr received a particular attention in recent years because they showed an anomaly in magnetization below the ferromagnetic transition [2.3]. For example, $Pr_{0.5}Sr_{0.5}CoO_3$ is ferromagnetic at T_C = 230 K and shows a downward step at 120 K for H < 500 Oe which transforms into an upward step for H > 500 Oe. Such an anomalous behavior was not found in other rare earth series [2.3]. Lorentz microscopy study indicated that the easy axis rotates by 45 deg between 80 K and 120 K [4]. However, what causes the change of easy axis was not understood for several years. In a recent neutron diffraction work combined with XMCD and magnetic measurements, Garcia-Munoz *et al*. have shown that $Pr_{0.5}Sr_{0.5}CoO_3$ undergoes a structural transition (orthorhombic to tetragonal) around 120 K upon decreasing temperature. The change in magnetic easy axis seems to be strongly coupled to this magnetostructural transition. In our work, we investigated the effect of hydrostatic pressure on T_C and the low-temperature magnetic anomaly. Surprisingly, the low-temperature anomaly shifts up by 24 K under hydrostatic pressure compared to only 7 K increase in

T_C. In addition to the hydrostatic pressure, we have also measured thermal expansion under magnetic fields, which show behavior different from that of the hydrostatic pressure effect: Magnetic field does not shift the magnetostructural transition temperature We are investigating the pressure dependence of TC and the magnetostructural transition in for Sr content varying between 40% and 60 % and discuss the origin(s) of the observed effects.

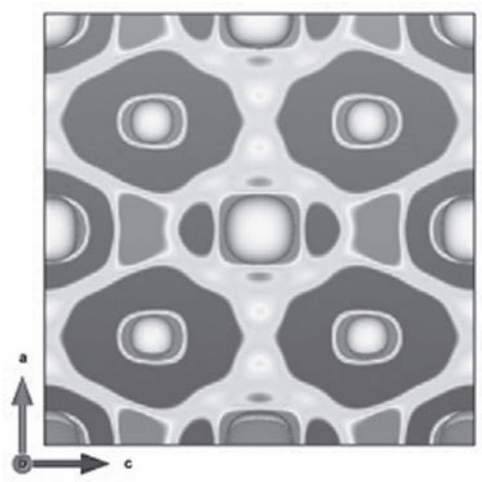
S2-03. Nonreciprocal magnons and magnetic properties of the noncentrosymmetric antiferromagnet α-$Cu_2V_2O_7$. *K. Matan*[1] *1. Physics, Mahidol University, Bangkok, Thailand*



Magnons, the spin-wave quanta, are disturbances that embody a wave propagating through a background medium formed by ordered magnetic moments. In an isotropic Heisenberg system, these disturbances vary in a continuous manner around an ordered spin structure, thus requiring infinitesimal energy as a wavevector approaches a magnetic zone center. However, competing anisotropic interactions arising from broken symmetry can favor a distinct static and dynamic spin state causing a shift of the minimum point of the magnon dispersion to a nonreciprocal wavevector. The first direct evidence of these nonreciprocal magnons in a noncentrosymmetric antiferromagnet will be presented. They are caused by the incompatibility between anisotropic exchange and antisymmetric Dzyaloshinskii-Moriya interactions resulting in competing collinear and helical spin structures. The nonreciprocity introduces the difference in the phase velocity of the counterrotating modes, resulting in the opposite spontaneous magnonic Faraday rotation of the left- and right-propagating spin-waves. The breaking of spatial inversion and time reversal symmetry is revealed as a magnetic-field-induced asymmetric energy shift, which provides a test for the detailed balance relation of the scattering intensity.

S2-04. Neutron Diffraction Study of Co doping effect in the Magnetic Interactions in Ni-Mn-In Metamagnetic Shape Memory Alloys. *J. López-García*[1,2], V. Recarte[3], I. Unzueta Solozabal[4], J. Rodríguez-Velamazán[5], I. Pérez-Landazábal[6], V. Sánchez-Alarcos[7] and F. Plazaola[8] *1. Institut Laue-Langevin, Fontaine, France; 2. Universidad Publica de Navarra, Pamplona, Spain; 3. Universidad Publica de Navarra, Pamplona, Spain; 4. Electricity & Electronics, University of the Basque Country (UPV/EHU), Leioa, Spain; 5. Institut Laue-Langevin, Grenoble, France; 6. Universidad Publica de Navarra, Pamplona, Spain; 7. Universidad Publica de Navarra, Pamplona, Spain; 8. Universidad del Pais Vasco, Bilbao, Spain*

Metamagnetic shape memory alloys, of general formula Ni_2-Mn-X (X= Sn, In, Sb), have been extensively studied in recent years due to their potential applications as smart materials in magnetic refrigeration, actuators or sensors devices among others. These promising applications are based on the interesting properties they show, such as inverse magnetocaloric effect and giant magnetoresistance which are related to the magnetostructural changes taking place during a martensitic transformation. This martensitic transformation is a first order structural transition between a high symmetry ferromagnetic austenite and a low symmetry martensitic phase with weak magnetism, involving a drastic change in the magnetization that is the key of the mentioned properties. On the other side, Co doping enhances and reduces the austenitic and martensitic magnetism, respectively. Therefore, a larger magnetization change occurs during the martensitic transition in co containing alloys. Polarized and unpolarized neutron diffraction have been used in this work to study the magnetic coupling between atoms at different crystallographic sites in Ni-Co-Mn-In and Ni-Mn-In metamagnetic shape memory alloy. These experiments have revealed that Co-doping induces a change from antiferro to ferromagnetic exchange coupling between 4a and 4b sites in the austenitic phase. The spin density maps obtained by polarized neutron diffraction has allowed establishing a hierarchy between the atomic magnetic interactions at different crystallographic sites.

2:45

S2-05. Evidence for Dicke Cooperativity in Magnetic Interactions. *X. Li*[1], M. Bamba[2], N. Yuan[3], Q. Zhang[4], Y. Zhao[5], M. Xiang[3], K. Xu[3], Z. Jin[3], W. Ren[3], G. Ma[3], S. Cao[3], D. Turchinovich[6] and J. Kono[1] *1. Rice University, Houston, TX, United States; 2. Osaka University, Osaka, Japan; 3. Shanghai University, Shanghai, China; 4. Argonne National Laboratory, Lemont, IL, United States; 5. Peking University, Beijing, China; 6. University of Duisburg-Essen, Duisburg, Germany*

The interaction of an ensemble of N two-level atoms with a single-mode light field is one of the most extensively studied many-body problems in quantum optics, first analyzed by Dicke in the context of superradiance. It is known that coherence develops within the ensemble through photon exchange, and the atom-field coupling strength is cooperatively enhanced by a factor of $N^{1/2}$. Here, we have discovered that cooperatively enhanced coupling similar to this canonical light-matter interaction effect occurs in a magnetic solid in the form of matter-matter interaction. In a single-crystal $ErFeO_3$ sample, the paramagnetic Er^{3+} spins coupled with an Fe^{3+} magnon field through the magnetic exchange interaction at a rate Λ (Fig. 1). Pronounced vacuum Rabi splitting appears in terahertz absorption spectra when the electron paramagnetic resonance (EPR) frequency of Er^{3+} is magnetically tuned to approach the Fe^{3+} magnon resonance, from which we determined the value of Λ quantitatively. Through systematic temperature, doping, and magnetic field dependent studies, we found Λ is proportional to $(n_{spin})^{1/2}$, where n_{spin} is the net density of EPR-contributing Er^{3+} spins (Fig. 2). This scaling behavior not only evidences Dicke cooperativity but also enables quantitative determination of the Er^{3+}-Fe^{3+} exchange coupling coefficients. Since the Er^{3+}-Fe^{3+} interaction is important for the formation of multiple correlated magnetic phases in $ErFeO_3$, our finding provides a novel route for understanding, controlling, or predicting new phases of condensed matter using concepts and tools available in quantum optics.

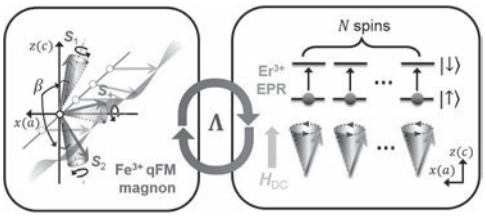

Fig. 1. The quasiferromagnetic (qFM) magnon mode of the Fe^{3+} subsystem couples with the electron paramagnetic resonance (EPR) of *N* Er^{3+} ions at a rate Λ.

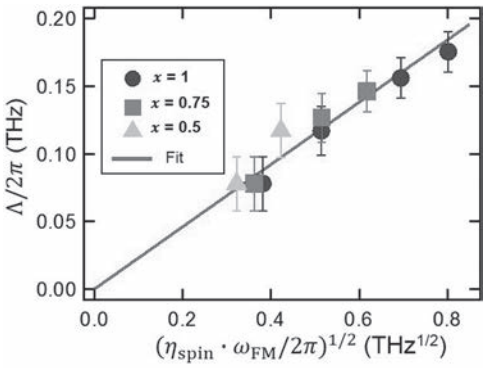

Fig. 2. Er^{3+}-Fe^{3+} exchange coupling rate Λ is proportional to $(\eta_{spin}\omega_{FM})^{1/2}$, where η_{spin} is the net fraction of EPR-contributing Er^{3+} spins, and ω_{FM} is the Fe^{3+} magnon frequency. The values of Λ were extracted from multiple temperature, doping, and magnetic field dependent measurements. *x* is the fraction of Er^{3+} in $Er_xY_{1-x}FeO_3$.

S3-01. Magnetostrictive multilayers for magnetoelectric magnetic field sensors. D. Meyners[1], J. McCord[1] and *E. Quandt*[1] *1. Institute for Materials Science, University of Kiel, Kiel, Germany*

Magnetoelectric (ME) thin film composites show ME coefficients that are larger than that of natural multiferroics by several orders of magnitude, especially when they are operated at their mechanical resonances (1). Furthermore, these materials exhibit large changes of their elastic properties in a magnetic field (2). The composites have high potential for applications, e.g. as very sensitive ac magnetic field sensors for the detection of biomagnetic fields, showing a large dynamic range with a linear response. Thin film magnetoelectrics exhibit an extremely high ME coefficient of up to 20 kV/cmOe at mechanical resonance in vacuum (3) and a limit of detection below 1 pT/Hz1/2 (4). However, these sensors show their high sensitivity and very low limit of detection only at their mechanical resonances, which are generally too high for biomagnetic applications and show a very limited bandwidth. To overcome these limitations several approaches have been investigated: magnetic frequency conversion (5), electric frequency conversion (6), DE-effect sensors (2) and surface acoustic wave devices using the DE-effect. All these techniques operate the sensors at or close to their resonances, either, by application of ac magnetic or ac electric fields, resulting in periodical changes of the magnetization and thus lead to an increase in magnetic domain induced magnetic noise. In this presentation different magnetostrictive multilayer approaches, e.g. exchange coupled multilayers (7) will be discussed in terms of their use as the magnetostrictive component. The aim is to attune the magnetization configuration so that magnetization changes result in pure rotation of the magnetic moments and correspondingly in a strongly reduced magnetic noise contribution. Funding by the DFG via the Collaborative Research Center SFB 1261 is gratefully acknowledged.

S3-02. TMR sensors: challenges and applications. *P. Freitas*[1,2], S. Cardoso[2] and R. Ferreira[1] *1. International Iberian Nanotechnology Laboratory, Braga, Portugal; 2. INESC MN, Lisbon, Portugal*

Recent challenges in the development of TMR sensors are discussed [1]. These involve stacks and linearization schemes (paramagnetic, out of plane, exchange biased free layers, different antiferromagnetic alloys for the pinned exchange biased layer) and for these comparison of sensitivity, noise level (typically into the tens nT/sqrt(Hz) at 10 Hz, temperature dependence (down to 100ppm/ °C). Pinning layer magnetization behavior vs temperature (Hc, Hex) is also discussed and its effect in sensor performance (f e in angular sensors). The effect of high magnetic anneals for free layer optimization are discussed. Sensor architectures (open loop vs closed loop) are presented. Current sensors are used as benchmark for these architectures, either for DC or AC current monitoring, ranging from DC to few hundred MHz, linear ranges up to few hundred A, typical resolution down to 0.8%. ASIC design for sensor interfacing is described. TMR sensors can be also fabricated in unconventional substrates (SOI, polyimide) [2], and coupled with magnetic flux guides to increase sensitivity [3].

2:30

S3-03. Magnetic field sensors based on Surface Acoustic Wave resonators. *K. Dumesnil*[1], V. Polewczyk[1], M. Moutaouekkil[1], H. Mishra[1], S. Petit-Watelot[1], S. Hage-Ali[1], H. Mjahed[1], O. Elmazria[1], F. Montaigne[1], D. Lacour[1], M. Hehn[1], N. Tiercelin[2], Y. Dusch[2], A. Talbi[2] and O. Bou Matar[2] *1. Institut Jean Lamour, CNRS - Université de Lorraine, Nancy, France; 2. IEMN, Université de Lille, Lille, France*

Magnetic Surface Acoustic Wave (MSAW) devices are currently driving an intense research activity both for the investigation of elastically driven magnetization dynamics [1] and for the development of field sensors. SAW sensors are interesting due to their ease of manufacturing, sensitivity, small size, and the possibility to be wireless addressed, especially in the resonator geometry. They are already used to measure a large variety of stimuli [2-3] and during these last ten years, MSAW sensors including a magnetostrictive material, where the SAW resonant frequency can be modified by an external magnetic field, have been also proposed [4-8]. Their use is however mainly limited to relatively low magnetic fields. Furthermore, a clear and complete

understanding of the SAW response under field based on the magnetic phase's properties is still lacking, the occurrence of hysteresis requiring for instance further investigation in connection with magnetic hysteresis. In this study, we report on MSAW sensors that consist of interdigital transducers (IDT) made of different magnetostrictive materials (Ni and $TbFe_2$) or exchange-biased multilayers (Co/IrMn). We first show that the response of a MSAW device (measured for in-plane (IP) and out-of-plane (OOP) applied fields) is more complex than often reported and that a complete analysis of the IDT magnetic properties is essential to unravel and control the magneto-acoustic response. The hysteretic behavior, a key point for the development of field sensors, has been addressed in connection with the magnetic hysteresis, both for IP and OOP configurations. The origin of the OOP hysteretic SAW response has been especially investigated and we show how it can be interestingly suppressed in using exchange-biased bilayers, commonly used in spintronic devices. We show more generally that the proper choice of magnetic material and the control of the magnetic properties helps to build up specific sensors: soft magnetic materials enable to tailor the anisotropy of the SAW field response by engineering the IDT's shape; hard magnetic materials enable to achieve high field unipolar or bipolar field sensor response for fields up to 0.5 T at room temperature.

S3-04. The Control of Non-Collinear Antiferromagnetic Mn_3X (X = Ga, Sn) Thin Film Growth Using a Twinned Ruthenium Buffer Layer.

S. Kurdi[1], J. Koo[2], P. Zilske[2], M. Vickers[1], L.A. Greer[1], Z.H. Barber[1] and G. Reiss[2] *1. Materials Science and Metallurgy, University of Cambridge, Cambridge, United Kingdom; 2. Center for Spinelectronic Materials and Devices, Bielefeld University, Bielefeld, Germany*

Spin electronics (spintronics) has recently gained much traction to overcome the challenge of continued miniaturization of memory devices. Antiferromagnetic materials (AFMs) offer higher stability than ferromagnetic-based devices, with high packing density due to minimal stray fields and insensitivity to external magnetic fields. Such insensitivity is crucial to make "invisible" memories for encryption and safe data storage to meet demands in current information technologies. Proof of concept of such memory devices has been shown by electrically induced switching [1] and through the anomalous Hall effect for non-collinear AFMs [2,3]. Here we have investigated the non-collinear AFM ε-Mn3*X*. To date such compounds have only been studied as single crystal bulk samples [2,4], and it is essential to be able to deposit them as thin films, with precisely controlled structure and crystallography, for future device applications. Vapour deposition and optimization of thin film structures are described, using DC-magnetron sputtering. Here we explain the role of Ru-buffered c-Al_2O_3 substrates on the growth of Mn3*X* (*X* = Ga, Sn). Twinning can be controlled in order to obtain a 12-fold symmetric film, facilitating device fabrication. Detailed structural characterization has been performed with High Resolution X-Ray Diffraction and Atomic Force Microscopy. High quality epitaxy has been achieved and growth parameters have been optimized for several compositions. Furthermore, the variation of lattice parameter as a function of composition is studied. The formation of a hexagonal structure, not present in the bulk, is observed, which is of interest in identifying a new magnetic spin structure.

S4-01. Control emergent magnetic properties in Iridate-based superlattices. *D. Yi[1,2] 1. The Geballe Laboratory for Advanced Materials, Stanford University, Stanford, CA, United States; 2. Applied Physics, Stanford University, Stanford, CA, United States*

Heterointerfaces of complex oxides provide a rich playground to explore emergent phenomena that are not found in the bulk and have been largely studied in 3*d* transition metal oxide (TMO) heterostructures. With recent advances in the synthesis of 5*d* TMOs, heterostructures based on 3d and 5d TMOs offer new model systems to realize emergent functionalities of complex oxides. In this talk, we demonstrate emergent magnetism and perpendicular magnetic anisotropy in iridate-based superlattices. We focus on superlattices comprised of the colossal magnetoresistive manganite $La_{1-x}Sr_xMnO_3$ (LSMO) and the paramagnetic metal $SrIrO_3$. A weak ferromagnetism and a new spin-orbit state are induced in $SrIrO_3$ due to dimensional confinement and interfacial coupling [1]. On the other hand, LSMO shows ferromagnetism in superlattices for all compositions of x (x=0, 0.3, 0.5, 0.8, 1.0) [2]. The stabilization of ferromagnetism in both La rich and Sr rich LSMO superlattices points to an interfacial charge transfer which is confirmed by x-ray absorption spectroscopy measurements [2-4]. Surprisingly, we find a strong interface-induced perpendicular magnetic anisotropy (PMA) for Sr rich compositions, which changes as a function of x. Synchrotron x-ray diffraction and linear dichroism measurements indicate a strong correlation between the PMA and the oxygen octahedral rotations at interfaces [2]. Lastly, we show that the electronic and magnetic properties can be dramatically modulated by an electric field by using ionic liquid gating. Our comprehensive study provides insights into the unique emergent phenomena driven by the 3d-5d heterointerfaces due to the delicate interplay of charge, spin, orbital and lattice degrees of freedom. The emergence of a strong PMA and its modulation also point to the potential of its incorporation in future spintronic applications.

Controlling spin orientation is vital to fundamental and applied efforts related to spin transport, magnetoelectrics, and skyrmion dynamics. Exploiting magnetostriction and shape anisotropy effects is a common approach to tuning magnetic properties in crystalline materials. This is generally accomplished in thin films by imparting a particular strain state during the growth process using thickness-dependent strain relaxation, heteroepitaxy, or shape anisotropy in nanocomposites. A shortcoming of these methods is their inability to manipulate magnetic anisotropy energies within the crystal post-growth or to selectively change the local magnetic character within the as-grown crystal due to their being limited to creating discrete and/or globally static strain fields. Bypassing this, low energy He ion implantation was recently shown to impart single-axis out-of-plane lattice expansion in epitaxial films while leaving the in-plane axes locked to the underlying substrate. [1-4] We show that it is possible to use this “strain

doping" approach to continuously tune across a full range of magnetic anisotropies in an epitaxial spinel oxide film post-synthesis. With $CoFe_2O_4$ films as a model system, low doses of low energy He ion irradiation are shown to drive uniaxial out-of-plane lattice expansion, thereby changing the magnetoelastic energies of the film. Simple magnetocrystalline energy calculations are used to predict spin reorientation transitions and map the evolution of magnetic easy axis as a function of symmetry. This strain doping technique also allows for a range of coexisting anisotropies to be written into a single film by controlling where the He ions are directed, thus providing the ability to design multiple coexisting and varied magnetic properties in a single film--microscopically abrupt and macroscopically gradual changes to preferential spin orientation are observed using Kerr microscopy. The ability to direct magnetic spin orientations in a single crystal wafer across multiple length scales using only crystal symmetry considerations offers a clear path toward the rational design of many spin-driven applications.

We show that Co spins in Co/FeRh epitaxial bilayers grown on W(110) switch reversibly between the two orthogonal in-plane directions as the FeRh layer undergoes temperature driven antiferromagnetic-ferromagnetic (AFM-FM) phase transition [1]. The LMOKE loops were measured fort the Co(1,3nm)/FeRh(5nm) bilayers with an external field applied along [1-10] and [001] in-plane directions during the temperature cycle 350 K →200 K → 350 K. The amplitude of the LMOKE signal ROT_{SAT} corresponding to the saturation state (Fig. 1 top panel) and the normalized remanence Kerr rotation ROT_{REM} (Fig. 1 bottom panel) were determined as a function of temperature. The temperature evolution of the saturation Kerr signal corresponds to the AFM-FM phase transition in the FeRh and is characterized by a typical transition temperature hysteresis. In parallel, the remanence Kerr signal is a fingerprint of the magnetization orientation and its temperature induced evolution is a manifestation of the cobalt SRT between the [1-10] direction (high remanence value) and [001] direction (low remanence state). It is clear from a comparison of the bottom and top panel of Fig. 1 that the temperature driven SRT was characterized by an identical hysteresis to that of the AFM-FM phase transition. Thus, we consider that the SRT was induced by the phase transition of the alloy film. The spin reorientation of Co is driven by the evolution interfacial exchange coupling to FeRh system across the AFM-FM process that is shown schematically in figure 2. In the $FeRh_{AFM}$ state, the cobalt spins cannot simultaneously satisfy the parallel alignment to the opposite Fe spin sublattices of the compensated (110) FeRh plane, which leads to the spin-flop phenomena and abrupt switching of the Co magnetization to the [001] direction. Our results provide a new method of writing information purely by a local temperature change. This work was supported by the National Science Center Poland (NCN) under Project No. 2015/19/B/ST3/00543

There is currently a renewed interest in utilizing antiferromagnetic (AF) materials in spintronics for energy efficient devices. [1,2] AF spin order is hard to control since there is no net moment, and the AF response to

external magnetic fields is weak. One avenue for manipulating an AF spin axis is to exchange couple an AF layer to an adjacent ferromagnetic (FM) layer.[3] Applied external fields are acting on the FM, rotating the FM axis. The AF then follows the FM reorientation due to the interfacial magnetic coupling and establishes a spin spiral in the AF layer.[4] Epitaxial thin films of transition metal oxides (TMOs) in the perovskite structure are interesting candidates, as their magnetic interactions are closely coupled to the atomic lattice structure. Hence, both exchange interactions and magnetic anisotropy are controllable through epitaxy governing atomic structure. In heterostructures of AF $LaFeO_3$ (LFO) and FM $La_{0.7}Sr_{0.3}MnO_3$ (LSMO) an interfacial ferromagnetic Fe moment occurs due to reconstructions of the oxygen octahedral in the LFO layer.[5] Here we present an in-depth study of the emerging magnetism in epitaxial LSMO/LFO (111) heterostructures using x ray and neutron techniques. We show that the interface ferromagnetic moment is present for different strain states, and that epitaxial strain allows for control of the magnetic anisotropy of the reconstructed Fe moments. For orthorhombic substrates ($DyScO_3$, $GdScO_3$) we observed a uniaxial in-plane anisotropy, while for cubic and rhombohedral substrates ($SrTiO_3$, $LaAlO_3$) an easy plane is found. The interface moment is a results of a canting of the AF spins while the bulk of the LFO layer remains AF. Moreover, it is possible to tune the AF spin axis by an external field. Due to the magnetic exchange coupling at the interface, the AF spin axis rotates when an applied field aligns the FM spins along the FM hard axis. However, we do not observe a change in the AF spin axis if the magnetic field is applied along the FM easy axis.

S4-05. Graphene-Ferromagnet Thin-Film Structures with Field-Cool Controllable Perpendicular Magnetization and Coercive Field Asymmetries. *M. Valvidares*[1], P. Gargiani[1], L. Melo Costa[1,2], P. Perna[2], R. Miranda[2] and J. Camarero[2] *1. ALBA Synchrotron Light Source, Cerdanyola del Valles, Spain; 2. IMDEA Nanociencia, Madrid, Spain*

The realization and tuning of interfacial phenomena, such as the exchange bias or magnetic proximity effects in novel bidimensional materials like Graphene, appears relevant from a fundamental perspective as well as for the potential to enable novel applications. We have extensively study a series of epitaxial Graphene-Ferromagnet thin-film structures, combining ultrathin films of ferromagnetic elements intercalated under epitaxial Graphene grown by CVD on single crystal surfaces [1]. Our findings evidence that based on materials choice, thickness, stacking sequence and treatments, it is possible to tailor magnetic anisotropy and interlayer exchange coupling. This has allowed us to, for example, engineer robust Graphene-based synthetic antiferromagnetic structures with properties well-suited to applications[1]. Here we will discuss Graphene-Ferromagnet structures exhibiting a large perpendicular magnetization asymmetry in x-ray magnetic dichroism element specific hysteresis loop measurements at low temperature, whose magnitude and sign is controlled by field cooling. This behaviour seems indicative of the presence of an interfacial frozen-spins magnetic component, which introduces an associated unidirectional magnetic effective interaction on the system. The vertical shift of the hysteresis loop produces an asymmetry on the positive and negative coercive fields, which could be used to define an effective unidirectional offset field in certain analogy to an exchange-bias field[2]. Our results suggest that the Graphene/Ferromagnet interface is key to induce this behaviour, which is otherwise absent in similar structures not incorporating the 2D layer[3]. S5-01. Experimental measurements of the impact of interlocking on the magnetic properties of electrical steel sheets. *A. Daem*[1], M.N. Ibrahim[1,2], P. Sergeant[1,3] and L. Dupré[1,3] *1. Department of Electrical Energy, Metals, Mechanical Constructions and Systems, Ghent University, Ghent, Belgium; 2. Electrical Engineering Department, Kafrelshiekh University, Kafrelshiekh, Egypt; 3. EEDT, Flanders Make, Ghent, Belgium*

The core losses of electrical machines increase with rotation speed and energy density, and have a direct influence on the machine efficiency. When optimizing the design of electrical machines, it is mandatory to take into account the effect of the manufacturing processes on the core losses and efficiency. In this paper, the influence of interlocking on the properties of soft magnetic material is investigated. Interlocking is the process of punching a protuberance in the lamination; this technique is applied in the mass production of electrical machines to assemble the laminated stack from a set of laminations. It is well-known that internal mechanical stress has an impact on the magnetic behavior of magnetic materials [1]. However, the literature lacks a detailed study of interlocking on laminated stacks of electric machines. This paper aims to investigate the effect of the interlocking process on the magnetic properties of the machine core, and to understand the behavior of the magnetic flux around the interlocking dowel (the red mark in fig. 1). This is done using a combined technique of global and local magnetic measurements, applied to ring core samples of M700-50A magnetic material (see fig. 1). The global magnetic measurements are performed using a movable coil applied around a ring core; a sample of the results is shown in fig. 2, indicating a decrease of 8% in maximum flux density near the interlocking dowel. The local magnetic measurements are obtained using the needle probe method [2]. For the latter method a highly accurate and repeatable positioning of the needles is required. Therefore, a 3D positioning system is developed. Finally, a modified iron loss model is proposed in order to include interlocking effects in computing iron losses in an electrical machine.

S5-02. Effect of Heat Treatment under High Magnetic Field on Crystallographic Orientation and Magnetic Properties of Non-Oriented Electrical Steel Sheets. *T. Kinoshita*[1,2], T. Sato[2], H. Shimoji[3], S. Aihara[4] and T. Todaka[2] *1. Technology Research Center, Sumitomo Heavy Industries, Ltd., Yokosuka, Japan; 2. Oita University, Oita, Japan; 3. Dept. of Oita Industrial Research Institute., Oita, Japan; 4. BRIGHTEC co.,LTD, Oita, Japan*

In order to control magnetic properties of non-oriented electrical steel sheets, effects of heat treatment in a magnetic field were studied. In this paper, we report on effects of applied high magnetic field during the heat treatment in comparison to textures of samples. Fig. 1 shows magnetic property change-rates of the samples heat-treated at 1273K without magnetic field, with respect to magnetic properties before heat treatment. The sample heat-treated showed a remarkable change in the magnetic properties: the iron loss was reduced, the permeability under low excitation conditions was improved, and contrarily the permeability at 1.6 T or higher decreased. To clarify the above results under the high temperature condition, electron back scattered diffraction (EBSD) analyses were performed on each specimen.

In addition to the above two conditions, a heat treated sample at 1273K in a high magnetic field (10T) was observed. Fig. 2 shows the crystal orientation distributions in normal direction of the plane (ND) and the inverse pole figures (IPFs) of EBSD. The IPF shows the density of the crystal orientation in ND of the crystal grains in the mapping. Comparing the samples before and after the heat treatment, it could be seen that the crystal grains grew following the heat treatments. In addition, grains parallel to <100> in ND increased. This can be considered as a reason why the permeability was decreased under high temperature condition. However, the crystal grains of the sample that were heat-treated in magnetic field were relatively small. Because the increase of grains parallel to <100> in ND was suppressed, it is expected that it is possible to control the magnetic properties by heat treatment in a magnetic field. Details on the magnetic properties of samples heat treated in a high magnetic field will be reported at the presentation and in the full version of paper.

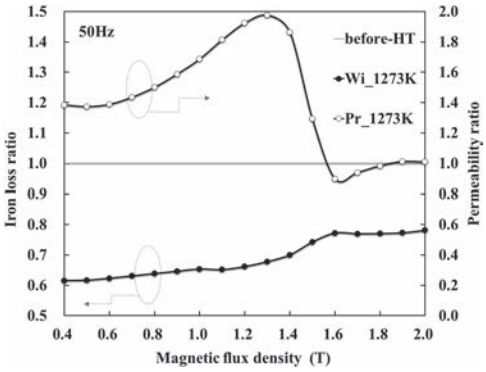

Fig. 1 Iron loss and magnetic permeability change rate of the samples heat treated at 1273K with respect to ones before heat treatment.

2:00

S5-03. Investigation of Electromagnetic Torque Capability Reduction of Electric Machine due to Magnetic Property Deterioration of Laminations. *A. Mollaeian*[1], M. Mehdi[2], E. Ghosh[1], A. Edrisy[2], S. Kim[1], J. Tjong[1] and N.C. Kar[1] *1. Electrical and Computer Engineering, University of Windsor, Windsor, ON, Canada; 2. Material Engineering, University of Windsor, Windsor, ON, Canada*

Estimation of magnetic flux density is crucial for determination of core loss, torque and maximum capability of electric motor. Magnetic flux is adversely affected by residual stress which is more influential close to the edges in a compact motor [1]. It is well established that lamination deterioration increases core loss [2]-[4]. However, comprehensive analysis was not conducted over wide speed range by considering magnetic property discrepancies. This paper proposes a systematic approach to include material degradation through FEA to investigate the effect of permeability(μ) drop in performance characteristics. Specific power losses are measured using Epstine frame for various frequency to model μ of lamination before cutting, presented in Fig1a. To verify core loss variation, magnetic noise is measured using Magnetic Barkhausen Noise measurement(MBNM) for lamination before-after cutting as shown in Fig1b. μ is a local dependent function and depends on 3 parameters: (1) μ of lamination before cutting, (2) maximum μ drop at cut surface and (3) hyperbolic profile to describe local deterioration shape function [5], therefore μ drop can be modeled using $\mu_r(H,x)=\mu_r(H,N=0) - \Delta \mu_{cut}(H).\eta(x)$ $\eta(x) =1-(x/\delta)-a.(x/\delta)(1-(x/\delta))$ for $0 \leq x \leq \delta$ $\eta(x) =0$ for $x>\delta$ where δ is distance respect to cut edge. Using preliminary μ along with regression method a generated look-up table has been implemented in material properties solving Maxwell's equations to investigate continuous and maximum performance characteristics for the developed IM. Furthermore, based on MBNM, core loss coefficients are computed using energy density and implemented in FEA to investigate the magnetic flux and output torque characteristics of IM using $\text{Energy}=\sum \int(V_i)^2 dt$ Due to μ drop, magnetic flux density decreases leading to lesser torque. A comprehensive IM performance analysis for degraded and non-degraded laminations will be presented in full paper.

S5-04. Tailoring the Microstructure of Soft Magnetic Composites for Electric Motor Applications. *D. Schuller*[1], D. Hohs[1], S.L. Schweizer[1], D. Goll[1] and G. Schneider[1] *1. Materials Research Institute, Aalen University, Aalen, Germany*

High performance soft magnetic materials are key elements for the development of next generation electric motor applications. State of the art electrical steel is limited in respect to minimum sheet thickness, maximum silicon content and two-dimensional magnetic flux direction. In contrast, soft magnetic composites (SMC) feature higher operating frequencies and degree of freedom in shaping and design of the motors core construction. SMC are manufactured by a conventional powder metallurgy process by compaction of water sprayed iron powders covered with an electrically insulating coating at pressures of up to 850 MPa. The magnetic properties in general strongly depend on the materials chemical composition and microstructure, including grain size and shape, texture, degree of plastic deformation and elastic strain. Adjusting of the materials particle and grain size distribution and optimizing annealing and compaction steps SMC can be tailored for motor applications. This work, therefore, focuses on quantification of microstructural features of SMC material of different powder particle fractions (between < 50 µm and > 400 µm) and their correlation to magnetic properties. Analysis is carried out on both samples in green condition and samples annealed between 400°C - 600°C during fabrication. For all fractions the permeability increases with annealing temperature (μ_{max} up to 700). Furthermore, the deformation and recrystallization behavior turns out to be different for the different fractions used. This has been investigated in detail by advanced microstructure analysis including determination of misorientation of deformed and recrystallized grains (figure 1 (a)). The fraction from 150 µm to 200 µm shows the grain size distribution with the largest grains (d_{50} ~ 44 µm) and lowest hysteresis loss (PH ~ 7 W/kg, 1 T, 50 Hz) (figure 1 (b)).

S5-05. A Novel Iron Core Structure Design for Power Transformers Considering Joints and Magnetostriction. *J. Li*[1], S. Wang[1], H. Gao[2], J. Hong[1] and M. Liu[2] *1. State Key Laboratory of Control and Simulation of Power System and Generation Equipments, Tsinghua University, Beijing, China; 2. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China*

Introduction: The iron cores and windings of power transformers could produce vibration and noise by magnetostrictive effect, Maxwell stress and Lorentz force. Noise has become a bad environmental pollution source, and the vibration and noise reduction has become an urgent problem need to be solved. The magnetostriction and joints forms of iron cores, are all the difficult reasons to analyze the vibration and noise of transformers. Body: 1. The magnetic field force will be fed into structural finite element with Maxwell stress produced on the interface between iron core and air to calculate the deformation of the magnetic materials when magnetostrictive modeling is performed. In order to fully verify the correctness of the model, the most simple magnetostriction tests will be carried out by using a single closed circle or rectangular electrical steel sheet, as shown in Fig. 1(a). 2. Based on the study of a simple sheet with no joint showed in Fig. 1(a) and (e), a sheet with joint will be used to analyze the vibration and modeling calculation, as shown in Fig. 1(b). Maxwell stress caused by the the joints and magnetostrictive force due to the magnetostriction of sheet are all actually included in the model. Later, further complicated two or more pieces of sheets are designed up and down on the joint of the simple circle or rectangular sheet, as shown in Fig. 1(c) and (d) to simulate the joints forms in the iron cores of transformers with the magnetic flux transition circulation though the joints. 3. In order to improve the effect of vibration and noise deduction sharply, a novel structure design of iron core for power transformer is put forward, with the core and winding position interchange, compared to conventional power transformers, as shown in Fig. 2, and there are many advantages in this design. Conclusion: The experimental verification is put into effect by using a test prototype of power transformer, and the modal test is carried out by using Finite Element (FE) software. The novel iron core structure design of power transformers can give further reference and guidance to the engineering applications.

S5-06. A Novel Wound Field Switched Flux Machine with Zero-Sequence Field Current Excitation. *S. Lyu*[1], H. Yang[1], H. Lin[1] and Z. Zhu[2] *1. School of Electrical Engineering, Southeast University, Nanjing, China; 2. Department of Electronic and Electrical Engineering, University of Sheffield, Sheffield, United Kingdom*

I. INTRODUCTION Due to the absence of permanent magnets and windings on the rotor, stator wound-field synchronous machines (SWFSMs) [1]-[3] have the merits of the eliminations of brushes and slip rings, low cost, high reliability, simple as well as robust structure. Nevertheless, the existence of extra DC windings makes SWFSMs suffer from restricted torque density and redundant DC power source. Thus, the variable flux reluctance machines (VFRMs) [4] with integrated DC bias and AC current excitations are proposed. However, the unipolar coil flux linkage in VFRMs causes relatively low torque density. Therefore, this paper proposes a wound field switched flux machine (WFSFM) with zero-sequence current excitation to improve the torque capability. II. TOPOLOGIES AND OPERATING PRINCIPLE Figs. 1(a) and (b) show the WFSFMs with integrated and separated DC and AC excitations, respectively. In the proposed WFSFM, all the windings are injected with DC biased sinusoidal current by a dual three-phase inverter as shown in Fig. 1(c) [4]. The operating principle of the proposed machine is shown in Fig. 1(d). For each group armature windings, such as A_1 and B_2, when A_1 is injected with DC current, the sinusoidal flux linkage will be induced in B_2. When a DC biased sinusoidal current is applied to A_1 and B_2, the effective electromagnetic energy conversion will be achieved similar to those conventional counterparts [2][3]. III. ELECTROMAGNETIC PERFORMANCE Fig. 2(a) shows the open-circuit coil and phase flux linkage, the DC biases in two coils are cancelled out, and a bipolar and sinusoidal phase flux linkage can be obtained. In Fig. 2(b), the back-EMF

is symmetric and sinusoidal for the proposed machine, while asymmetric and non-sinusoidal for the conventional case. The torque performance of the two machines are compared as shown in Figs. 2(c) and (d). The proposed machine exhibits higher torque and lower torque ripple. The detailed analysis and test results will be presented in the full paper.

At the interfaces between ferromagnets and heavy metals, the broken inversion symmetry provides new ways to manipulate the magnetic state because of a large spin-orbit interaction. The combination of a thin ferromagnetic and a heavy metal layers gives rise to new interface related phenomena, which are normally vanish in bulk, but play a crucial role as soon as the thickness of the ferromagnet reaches to an atomic scale. Very recently, the presence of the Dzyaloshinskii-Moriya interaction (DMI) in an inversion symmetry broken system has been extensively and intensively investigated by performing various methods. When this interface effect is sufficiently strong, a non-collinear spin state has a lower energy than the ferromagnetic one and the interfacial DMI gives rise to chiral structures such as cycloids, helices or syrmions, as the ground state [1]. In this study, we demonstrate an experimental method to straightforwardly measure the DMI, namely Brillouin light scattering (BLS), allow not only the determination of the DMI energy densities but also the investigations of other related interfacial effects such as the interfacial perpendicular magnetic anisotropy (PMA), the proximity-induced magnetic moment, the spin pumping, and so on. Non-reciprocal spin wave dispersions are direct fingerprints of the interfacial DMI, which is already demonstrated recently [2]. First of all, the strong influence of the heavy metal layer thickness and the contribution of the thermal annealing process are also systematically measured by BLS [3,4]. With increasing thickness of the heavy-metal layer, the interfacial DMI and PMA energy densities are rapidly enhanced and they are saturated at a heavy metal layer thickness of 2.4 nm. Finally, we demonstrate that the stacking order of an inversion symmetry broken system directly affects to the interfacial DMI energy density [5]. Lastly, another convenient approach to deduce the DM energy density by using lateral asymmetric triangular-shaped microstructures is circumstantially discussed [6].

S6-02. Depinning, propagation and braking of a single domain wall in an amorphous microwire. E. Calle[1], M. Vázquez[1] and *R. Perez del Real*[1] *1. Instituto de Ciencia de Materiales de Madrid (CSIC), Madrid, Spain*

Due to the strong mechanical stresses induced during the fabrication, amorphous ferromagnetic microwires with positive magnetostriction (i.e., FeSiB alloys) show a reversal magnetization process that consists in the depinning and propagation of a single domain wall (DW)[1]. The measurement of this DW velocity has been traditionally based on a classical Sixtus-Tonks system with several pick up coils that permits to identify the direction of the DWs motion and determine the DW velocity from the time interval between the e.m.f. peaks induced in the pick-up coils [2,3]. As a drawback, this method only allows to measure the average velocity of the DW when it moves between the coils, without supplying any additional information. In this work, we have taken advantage of the spontaneous azimuthal component of magnetization generated by the small effective helical anisotropy created by those fabrication stresses. As a consequence, during the reversal process, not only the axial but also the azimuthal magnetization reverses generating an electromotive force between the ends of the microwire (Mateucci effect) that is proportional to the instantaneous value of the DW velocity, from the creation and depinning to the propagation and braking or annihilation (Figure 1). The detailed analysis of the experimental measurements of the Matteucci effect gives detailed information about the time needed for the DW to reach a constant velocity, as well as about its local fluctuations, mainly related with spatial dependence of the magnetoelastic anisotropy. Performing a theoretical study of the measured instantaneous velocity it has been possible to estimate the time for the DW nucleation and the value of intrinsic parameters like the DW mass and the propagation damping coefficient. From the point of view of technological applications, the study of the instantaneous DW motion is very important to understand and improve the operating features of devices based on DW logic.

Nowadays, data storage has become a key issue. The amount of data generated every year is increasing fast due to the development of internet and cloud computing technology [1]. Therefore, a data storage density breakthrough is essential to answer this ever-growing demand. To address this issue, a theoretical concept for nonvolatile memory cells organized into a three-dimensional matrix has been proposed by Parkin *et al.* [2]. Introduced in the 2000s, the realization of such 3D memory has so far not been achieved. The first step is to fabricate a 3D matrix of magnetic nanowires. Thanks to progress made in electrodeposition of metallic material into a nanoporous membrane, this is now possible [3]. In addition, it has been predicted that the cylinder rotational symmetry allows high velocity domain walls (DWs) motion due to the absence of the Walker breakdown [4]. The next challenge to overcome now in this system is to implement a reliable procedure to move the DWs with a current pulse. In this communication, we report results on DWs motion in cylindrical nickel wires electroplated in alumina templates. To have access to an individual wire, the membrane is dissolved so that wires are dispersed on a wafer surface. We developed a nanofabrication process to contact individual wires (cf. fig 1). It is optimized to minimize the electrodes resistance and to obtain an ohmic contact, so that current pulses of magnitude $2.5x10^{12}$ A/m^2 with up to 100ns half width length can be sent. Thanks to anisotropy magnetoresistance (AMR), we extracted a spontaneous magnetization and a AMR ratio that are consistent with the bulk value. Thanks to this setup, we performed current driven domain walls motion (cf. fig 2), DWs can be moved with a threshold current around $1.0x10^{12}$ A/m^2 with a 30ns current pulse width. The lowest estimate for the DW speed is 350m/s, which suggests a high mobility of DWs under spin-polarized current.

S6-04. Topological defects and strong emergent electric fields in ferromagnetic nanoparticles. *M. Charilaou*[1], H. Braun[2] and J. Löffler[1] *1. Department of Materials, ETH Zurich, Zurich, Switzerland; 2. University College Dublin, Dublin, Ireland*

In ferromagnetic particles beyond the Stoner-Wohlfarth regime, where the dimensions of the solid are larger than the fundamental magnetic length

scale, magnetization switching is closely associated with curling-type processes. As we will show, however, curling cannot complete magnetization reversal without violating topological constraints on the spin texture, leading to pair-creation of topological defects. These defects, identified as hedgehogs, otherwise termed as Bloch points or monopoles, move rapidly through the particle, generating emergent electric fields with substantial magnitude [1]. Hence, the creation and dynamics of topological defects play a key role in the switching processes of nanoscale ferromagnets and, based on these findings, we present a way to generate strong emergent electromagnetic fields with consequently measurable radiation in magnetic nanoparticles.

S6-05. Skyrmion formation in $SrRuO_3$-$SrIrO_3$ epitaxial bilayer.

M. Bacani[1], A. Mandru[1], X. Zhao[1], M. Penedo[1], A. Ahmed[2], K. Meng[2], M.A. Marioni[1], F. Yang[2] and H.J. Hug[1,3] *1. Empa, Swiss Federal Laboratories for Materials Science and Technology, Duebendorf, Switzerland; 2. Department of Physics, The Ohio State University, Columbus, OH, United States; 3. Department of Physics, University of Basel, Basel, Switzerland*

$SrRuO_3$-$SrIrO_3$ bilayers have recently [1,2] attracted attention due to their topological Hall effect (THE) as an evidence of interfacial Dzyaloshinskii–Moriya interaction (DMI), which may lead to the formation of a skyrmion phase. THE has been measured at different temperatures (T) in the bilayer SRO(10 u. c.) / SIO(2 u.c.) epitaxially grown on STO(001) [3]. Strong THE was observed at 5 K, it decreases with increasing T, vanishes at 60 K, reappears at 90 K and persists until T_C(SRO). On the same bilayer we have performed high-sensitivity, high-resolution magnetic force microscopy (MFM) at 10, 30, 60 and 100 K and in fields up to a few Teslas. At 10 K we observe maze pattern of up/down domains of ~70 nm in size. At various locations domains with the same magnetization touch each other, and a narrow 360° wall forms. The numerous appearances of such walls suggest the presence of DMI. If an external field is applied, domains with a magnetization opposite to applied field shrink. At ~2250 mT both smaller bubble domains with sometimes irregular shape and circular domains with a diameter of 10-20 nm that may be stabilized by DMI and not solely by magnetostatics, i.e., skyrmions appear. By cycling the field, skyrmions disappear and reappear at the same locations. This suggests that these locations may exhibit higher DMI or have a lower perpendicular anisotropy. The strong domain wall pinning further supports the existence of a strong variation of the local anisotropy, despite good single crystalline quality of the sample [3]. MFM measurements performed at higher T show that the coercive field decreases with increasing T. MFM data acquired at 60K, where no THE is observed, indicate that fewer skyrmions exist. At 100K, a higher number of skyrmions is observed again. Our measurements prove that a strong THE can occur even though no skyrmion phase but solely small bubble domains and a few skyrmions exist.

S7-01. Femtomagnetics: Critical Behavior within 20 fs Drives Laser-induced Non-equilibrium Spin Dynamics in Ni. *Z. Tao*[1], P. Tengdin[1], W. You[1], C. Chen[1], X. Shi[1], D. Zusin[1], Y. Zhang[1], C. Gentry[1], A. Blonsky[1], M. Keller[2], P.M. Oppeneer[3], H. Kapteyn[1] and M. Murnane[1] *1. JILA, University of Colorado Boulder, Boulder, CO, United States; 2. National Institute of Standards and Technology (NIST), Boulder, CO, United States; 3. Dept. of Physics and Astronomy, Uppsala University, Uppsala, Sweden*

It has long been known that ferromagnets undergo a phase transition from ferromagnetic to paramagnetic at the Curie temperature, associated with critical phenomena such as a divergence in the heat capacity. A ferromagnet can also be transiently demagnetized by heating it with an ultrafast laser pulse[1]. However, to date the connection between out-of-equilibrium and equilibrium phase transitions was not known, nor how fast the out-of-equilibrium phase transitions can proceed. In this work, by combining time- and angle-resolved photoemission (Tr-ARPES) with time-resolved transverse magneto-optical Kerr (Tr-TMOKE) spectroscopies, we show that the same critical behavior also governs the ultrafast magnetic phase transition in nickel. This is evidenced by several observations. First, we observe a divergence of the transient heat capacity of the electron spin system preceding material demagnetization. Second, when the electron temperature is transiently driven above the Curie temperature, we observe an extremely rapid change in the material response: the spin system absorbs sufficient energy within the first 20 fs to subsequently proceed through the phase transition, while demagnetization and the collapse of the exchange splitting occur on much longer, fluence-independent, timescales of ~176 fs. Third, we find that the transient electron temperature alone dictates the magnetic response. The schematic of the laser-induced ultrafast demagnetization in Ni is shown in Fig. 1. We also compared our results with the ultrafast magnetization dynamics measured using the Tr-TMOKE method with a wide range of pump fluences. We found the critical behaviors are essential to explain the fluence-dependent re-magnetization time[2] and the signal averaged over the probed depth needs to be considered. Our results are important because they connect the out-of-equilibrium material behavior to the strongly coupled equilibrium behavior and uncover new understanding of the laser-induced magnetic phase transition in Ni.

Schematic of the critical behavior of ultrafast demagnetization in Ni. After excitation by a femtosecond laser pulse above the critical fluence (F_c), the transient electron temperature (T_e) is driven above the Curie temperature (T_c), inducing high-energy spin excitations within 20 fs which store the magnetic energy. The Fermi-Dirac distributions of electrons are also plotted. Demagnetization occurs later, in ~176 fs, driven by relaxation of non-equilibrium spins and the likely excitation of low-energy magnons. Full recovery of the spin system occurs within ~500 fs to ~26 ps, depending on the laser fluence.

S7-02. Ultrafast demagnetization dynamics observed at $M_{2,3}$ edges of hcp Co - first-principles calculations. *D. Legut*[1], K. Carva[2] and P.M. Oppeneer[3] *1. IT4Innovations, VSB-Technical University of Ostrava, Ostrava, Czechia; 2. Department of Condensed Matter Physics, Charles University, Prague, Czechia; 3. Dept. of Physics and Astronomy, Uppsala University, Uppsala, Sweden*

More information on the evolution of the electronic band structure of a ferromagnetic material during laser-induced demagnetization is needed to understand properly the underlying mechanisms of femtosecond demagnetization dynamics. These can be obtained by combining experiment and modeling. Using ab initio calculations we investigated the effect of a Stoner-like reduction of the exchange splitting, to simulate the previously proposed fast quenching of the exchange splitting, as well as the effect of Heisenberg-like magnon excitations in hcp Co. In our simulations we employed density functional theory calculations using the WIEN2k code [1]. The exchange splitting was reduced to different values employing the methods described in Ref. [2]. To simulate the effects of these mechanisms on the magneto-optical signal, we computed the quasi-static magneto-optical response at the $M_{2,3}$ edges using the Kubo formula [3]. Influence of non-equilibrium electron populations was determined and computed data were compared to ultrafast high-harmonics measurements of time-, energy-, and angle-resolved magneto-optical effects spectra obtained at the $M_{2,3}$

edges of Co films after optical pumping to induce ultrafast demagnetization [4]. These Co films were on insulating substrates to exclude possible effects of superdiffusive spin currents. For the examined timescales the contribution of transversal spin excitations (i.e., magnon excitation) has been found to be appreciably higher than that of exchange splitting reduction that would originate from longitudinal spin flips [4]. Interestingly, the ratio between these two was not growing with time in favor of transversal excitations, as would be expected from models based on electron-magnon interactions. In recent paper [5] we identify that the changes in ε_{xy} are uniform throughout the spectrum, to within our experimental precision. This result suggests that, in the regime of strong demagnetization, the ultrafast demagnetization response is primarily dominated by magnon generation. We estimate the contribution of exchange-splitting reduction to the ultrafast demagnetization process to be no more than 25%. This work was done in collaboration with the experimentalists of Refs. [4,5].

The phenomenon of ultrafast demagnetization demonstrates that the rate at which magnetic order can be changed is not *bottlenecked* by electron-lattice energy transfer [1]. Magnetic order can be changed – lost through laser demagnetization – with a characteristic timescale of order 150 femtoseconds. Here we show that the phenomena of magnetostriction, the stain on the atomic lattice due to magnetization, develops at the same timescale of the magnetic change [2]. The sample used for this study is a free-standing film of granular FePt nanoparticles held together by an amorphous carbon matrix. The FePt nanoparticles are ~13 nm in diameter with their easy magnetic axis (crystallographic *c*-axis) orientated perpendicular to the film. The nature of the structure allows the free movement of the nanoparticles' surfaces in response to a stress. The FePt magnetization is demagnetized using a 50 fs optical laser pulse. The response of nanoparticles' magnetization is measured using small-angle resonant x-ray scattering. The demagnetization is observed to proceed with a characteristic time constant of 146 fs. Ultrafast electron diffraction is used to determine how the atomic structure responds on the same timescale. The results show that upon demagnetization the FePt crystal structure first moves towards a highly distorted state with a strong contraction along the *c*-axis and an expansion along the *a* & *b* axes, before moving towards the expected equilibrium lattice change (see Fig. 1). A detailed analysis of these results shows that a strong magnetic stress term develops at the timescale of the ultrafast demagnetization. We quantify the size and direction of the magnetic stress within FePt. This allows a new insight into how energy and momentum can be transferred to the lattice on an ultrashort timescale via magnetostriction.

S7-04. Quantum many-body dynamics of the Einstein-de Haas effect. *J. Mentink*[1], M. Katsnelson[1] and M. Lemeshko[2] *1. Radboud University, Nijmegen, Netherlands; 2. Institute for Science and Technology Austria, Klosterneuburg, Austria*

In 1915, Einstein and de Haas [1] and Barnett [2] demonstrated that changing the magnetization of a magnetic material results in mechanical rotation, and vice versa. At the microscopic level, this effect governs the transfer between electron spin and orbital angular momentum, and lattice degrees of freedom, understanding which is key for molecular magnets, nano-magneto-mechanics, spintronics, and ultrafast magnetism. Until now, the timescales of electron-to-lattice angular momentum transfer remain unclear, since modeling this process on a microscopic level requires addition of an infinite amount of quantum angular momenta. We show that this problem can be solved by reformulating it in terms of the recently discovered angulon quasiparticles [3], which results in a rotationally invariant quantum many-body theory [4]. In particular, we demonstrate that non-perturbative effects give rise to angular momentum transfer on femtosecond timescales, even if the electron-phonon coupling is weak.

S7-05. Multi-level single shot all-optical magnetization switching mediated by spin-polarized hot electron transport. S. Iihama[1,2], Y. Xu[1], M. Deb[1], G. Malinowski[1], M. Hehn[1], J. Gorchon[1], E.E. Fullerton[1,3] and *S. Mangin*[1] *1. Institut Jean Lamour, Université de Lorraine, Vandoeuvre-lès-Nancy, France; 2. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Ibaraki, Japan; 3. Center for Memory and Recording Research, University of California San Diego, La Jolla, CA, United States*

All-optical switching (AOS) without any external magnetic field is drawing a lot of attention for the development of future ultrafast and energy efficient magnetic memories. In 2011, it was demonstrated that the magnetization of a GdFeCo ferrimagnetic film can be switched by a single femtosecond laser pulse [1,2]. In 2014, AOS in a wide variety of materials was demonstrated [3,4], however the switching in all materials but Gd based ferrimagnets was found to be induced by multiple laser pulses [5]. Only very recently, single pulse switching of a [Co/Pt] layer was demonstrated in an exchanged coupled GdFeCo/[Co/Pt] stack [6]. In the present study, we demonstrate single shot *multi-level* AOS using GdFeCo/Cu/[Co/Pt] spin valve structures. Schematic illustration of this study is shown in Fig. 1. By using magnetically uncoupled stacks we show single-shot and selective reversal of either the GdFeCo layer or both the GdFeCo and [Co/Pt] layers, allowing for a total of 4 magnetic configurations to be written. Figure 2 shows multi-level single shot AOS demonstrated. 4 magnetic configurations (P+, P-, AP+, AP-) can be accessed by properly choosing the irradiated energy. Starting with a saturated sample in the P- state, one can access the P+ state by sending an intense pulse or the AP- state by sending a moderate pulse. One possible mechanism to reverse [Co/Pt] layer is that spin-polarized hot electrons created in GdFeCo transfer the angular momentum to [Co/Pt]. We observed that [Co/Pt] could not be switched in samples for which a Pt spin scattering layer is inserted in the Cu spacer layer. We conclude that the reversal of the [Co/Pt] is attributed to spin polarized hot electron transport [7]. These results provide us a pathway to engineer materials for multi-bit memory cell.

Session S8
NON-CENTROSYMMETRIC SUPERCONDUCTORS

Hiroshi Amitsuka, Chair
Hokkaido University, Sapporo, Japan

INVITED PAPERS

1:30

S8-01. Superconductivity in pressurized $CeRhGe_3$ and related non-centrosymmetric compounds. *L. Sun*[1], H. Wang[1], J. Guo[1], E. Bauer[2], V. Sidorov[3], P. Sun[1], Y. Yang[1], Q. Wu[1], T. Xiang[1] and J.D. Thompson[2] *1. Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2. Los Alamos National Laboratory, Los Alamos, NM, United States; 3. Institute for High Pressure Physics,Russian Academy of Sciences, Moscow, Russian Federation*

The $CeTX_3$ (T = Co, Ir, Rh and X = Si, Ge) family belongs to a subset of heavy-fermion compounds whose crystallographic structure lacks a center of inversion symmetry. In this study, we report the first observation of pressure-induced superconductivity in $CeRhGe_3$, until now the only remaining non-superconducting member of the isostructural family of heavy-fermion compounds $CeTX_3$ (T = Co, Rh, Ir and X = Si, Ge). Superconductivity appears in non-centrosymmetric $CeRhGe_3$ at a pressure of 19.6 GPa and the transition temperature T_c reaches a maximum value of 1.3 K at 21.5 GPa. This finding allows us to establish for the first time systematic correlations between superconductivity and materials properties within this family. These correlations clearly indicate an intrinsic link among Kondo hybridization, spin-orbit coupling and superconductivity. We find that, though ambient-pressure unit-cell volumes and critical pressures for superconductivity vary substantially across the series, all family members reach a maximum T_c^{max} at a common (±1.7%) critical cell volume V_{crit}, and T_c^{max} at V_{crit} increases with increasing spin-orbit coupling strength of the *d*-electrons. These correlations show that substantial Kondo hybridization and spin-orbit coupling favor superconductivity in this family, the latter reflecting the role of broken centro-symmetry. Furthermore, we also find that its pressure-tuned AFM transition temperature (T_N) appears to avoid a continuous decrease to zero temperature by terminating abruptly above a dome of pressure-induced superconductivity. Near 21.5 GPa, evidence for T_N suddenly vanishes, the electrical resistance becomes linear in temperature and the superconducting transition reaches a maximum. Our findings pose an opportunity for new understanding of the underlying mechanism of superconductivity in non-centrosymmetric materials.

S8-02. Superconductivity Without Inversion and Time-Reversal Symmetries. *M.H. Fischer*[1], M. Sigrist[1] and D.F. Agterberg[2] *1. Institute for Theoretical Physics, ETH Zürich, Zürich, Switzerland; 2. Department of Physics, University of Wisconsin-Milwaukee, Milwaukee, WI, United States*

Traditionally, the symmetries that protect superconductivity are time-reversal and parity. Here, we examine the minimal symmetries protecting superconductivity in two dimensions and find that time-reversal symmetry and inversion symmetry are not required, and having a combination of either symmetry with a mirror operation on the basal plane is sufficient. We classify superconducting states stabilized by these two symmetries, when time-reversal and inversion symmetries are not present, and provide realistic minimal models as examples. Interestingly, several experimentally realized systems, such as transition metal dichalcogenides and the two-dimensional Rashba system fall into this scenario, when subject to an applied magnetic field.

S8-03. Magnetic Multipole Fluctuation and Superconductivity in Locally Noncentrosymmetric crystalline. *J. Ishizuka*[1] and Y. Yanase[1] *1. Department of Physics, Kyoto University, Kyoto, Japan*

We investigate a two-sublattice Hubbard model with the sublattice-dependent antisymmetric spin-orbit coupling and Coulomb interaction on the basis of the random phase approximation. We focus on a nonsymmorphic and locally noncentrosymmetric structure; the crystallographic point group is D_{4h} and the local point group symmetry at specific ions is D_{2d}, lacking the $\sigma_{v/d}$ mirror reflection symmetry, such as $BaMn_2As_2$ and Sr_2IrO_4. We find that a magnetic quadrupole, hexadecapole, and toroidal fluctuations appear by the antisymmetric spin-orbit coupling. The d_{xy}+p-wave state induced by these fluctuations is more suppressed by a modulate local parity violation than a globally inversion symmetry breaking. Our obtained gap function has a gapped/node structure protected by the nonsymmorphic symmetry in an inter-sublattice pairing. Furthermore, we obtain two triplet superconductivities, p+s-wave and p+d_{xy}-wave states. The local parity violation prefers to these triplet states, in striking contrast to the globally inversion symmetry breaking.

S8-04. Single crystal growth and unusual magnetic properties of non-centrosymmetric compound $UIrSi_3$. *F. Honda*[1], J. Valenta[2], J. Pospisil[2], M. Vališka[2], P. Opletal[2], J. Kastil[3], M. Míšek[3], M. Divis[2], L. Sandratski[4], J. Prchal[2] and V. Sechovský[2] *1. Institute for Materials Research, Tohoku University, Oarai, Japan; 2. Faculty of Mathematics and Physics, Charles University, Prague 2, Czechia; 3. Institute of Physics, AS CR, Praha, Czechia; 4. Max-Planck-Institute of Microstructure Physics, Halle, Germany*

A lack of inversion symmetry in the crystal structure gives rise to a anti-symmetric spin-orbit interaction, which leads to the possibility of a superconducting state with an admixture of spin-triplet and spin-singlet pairs[1]. A huge upper critical field was observed in a non-centrosymmetric (NCS) heavy-fermion superconductor (HFSC) $CeIrSi_3$ at the quantum critical point [2]. The $BaNiSn_3$-type is one of the most studied NCS structure in *f*-electron systems. The magnetic ordering in these materials is usually antiferromagnetic with complex propagation vectors. We started to study the U compound as analogue to these Ce pressure-induced HFSCs. The U compound is not superconducting but has interesting magnetism. $UIrSi_3$ crystallizes with the $BaNiSn_3$-type and orders antiferromagnetically below 42 K [3]. In order to investigate electronic states of NCS uranium compounds, we have grown a single crystal of $UIrSi_3$, for the first time, with a floating zone method and measured its magnetization, specific heat, and electrical resistivity as functions of temperature, magnetic field and pressure. The results provide clear evidences of Ising-like antiferromagnetism below T_N = 41.7 K. Meta-

magnetic transition was observed at H_c ($\mu_0 H_c$ = 7.3 T at 2 K) with the field along the *c*-axis. At low temperatures (< 28 K) it is a first-order transition and the asymmetry of hysteresis is attributed to gradual re-entry of the spin arrangement from the field polarized paramagnetic regime in fields above H_c to a complex ground state antiferromagnetic structure. The H_c value decreases with increasing temperature whereas the asymmetric hysteresis becomes rapidly reduced and vanishes at 28 K. At higher temperatures it is a second-order transition which is manifested as a cusp at H_c which terminates a pronounced upturn of the *M(H)* dependence in lower fields. The point of change of the order of transition in the established *H-T* magnetic phase diagram, as shown in Fig.1, is tentatively suggested to be the tricritical point (at T_{tc}= 28 K and $\mu_0 H_{tc}$ = 5.8 T) of $UIrSi_3$. Results of neutron diffraction and theoretical prediction of complex magnetic structure will also be presented.

S9-01. α-$RuCl_3$ beyond magnetic order. *R. Valenti*[1] *1. Theoretical Physics, University of Frankfurt, Frankfurt, Germany*

α-$RuCl_3$ has been in recent years at the forefront of experimental searches for materials realizing Kitaev spin-liquid physics. This material exhibits strongly anisotropic and frustrated exchange interactions born out of the spin-orbit coupling of the 4d Ru ions. While this system orders at low temperatures, anomalous excitation response has been detected in inelastic neutron scattering experiments, electron spin resonance, or thermal Hall conductivity as a function of temperature and applied magnetic field. These regimes are thought to host unconventional states that emerge from the suppression of magnetic order. In this talk we will present recent theoretical results [1,2] on the dynamical response at finite temperature and magnetic field for a realistic model of the magnetic interactions in α-$RuCl_3$derived from an ab-initio-based analysis and discuss the comparison with recent experiments. Furthermore we will present ab initio based simulations of α-$RuCl_3$ under pressure where we find a dimerization of the structure that crucially changes the electronic properties of this system and is consistent with recent optical conductivity measurements [3]. We will discuss this behavior in the general framework of Kitaev materials. Work done in collaboration with Steve M. Winter, Kira Riedl, David Kaib, Andreas Honecker, Pavel A. Maksimov, Alexander L. Chernyshev and Radu Coldea.

S9-02. Anomalous spin correlations and excitonic instability of interacting massless Dirac electrons in an organic conductor. M. Hirata[1,2], K. Ishikawa[1], G. Matsuno[3], A. Kobayashi[3], K. Miyagawa[1], M. Tamura[4], C. Berthier[5] and *K. Kanoda*[1] *1. Department of Applied Physics, The University of Tokyo, Tokyo, Japan; 2. Institute for Materials Research, Tohoku University, Sendai, Japan; 3. Department of Physics, Nagoya University, Nagoya, Japan; 4. Department of Physics, Tokyo University of Science, Noda, Japan; 5. Laboratoire National des Champs Magnétique Intenses, LNCMI-CNRS (UPR3228), Grenoble, France*

Electron correlations constitute major sources of interests in the exploration of novel electronic properties. For a system of massless Dirac electrons with conical dispersion, inter-particle Coulomb interactions are expected to be highly unusual since its long-range component is unscreened at the band-crossing Dirac points due to the vanishing density of states, affecting drastically the nature of fermions as established in quantum electrodynamics. In the present work, site-selective NMR spectroscopy and resistivity measurements combined with model calculations find that massless Dirac electrons emerging in a quasi-two-dimensional organic conductor possess highly unusual Coulomb correlations, which leads to an excitonic instability, as was indicated by the following observations: 1) Non-uniform cone reshaping or velocity renormalization[1] (see Fig.1), 2) Anomalous ferrimagnetic spin polarization induced by magnetic field[1], 3) A thousand-time enhancement of the Korringa ratio (the NMR index for spin correlations) from the values in conventional metal[2], 4) A sharp low-temperature increase of NMR relaxation rate indicating spin-triplet excitonic fluctuations – precursors to mass generation associated with chiral symmetry breaking.[2,] and 5) Insulating resistivity behavior at low temperatures[3].

S9-03. Pressure and strain dependent control of structure and band topology in the superconducting type-II Weyl semimetal candidate $MoTe_2$. *C. Heikes*[1], I. Liu[3], W.D. Ratcliff[2], N. Butch[1,3], J. Paglione[3], T. Yildirim[1], T. Metz[3], C. Eckberg[3], H. Cao[4] and Y. Wu[4] *1. NIST Center for Neutron Research, Gaithersburg, MD, United States; 2. NCNR, NIST, Gaithersburg, MD, United States; 3. University of Maryland, College Park, MD, United States; 4. Oak Ridge National Laboratory, Oak Ridge, TN, United States*

The reported pressure dependent superconductivity of the proposed type-II Weyl semimetal $MoTe_2$ has led to speculation about the possibility of a topologically non-trivial superconducting state in this material. The interplay between broken inversion symmetry through a structural phase transition, superconductivity, and reported non-trivial band topology in this system offers a playground for potential interesting and new materials physics. A key question about the topology of this superconducting state is the evolution of the crystal structure of $MoTe_2$ at pressures and temperatures relevant for superconductivity, as the non-centrosymmetric T_d orthorhombic phase is needed for the Weyl state and non-centrosymmetric superconductors themselves are interesting for supporting proposed Majorana modes. We have

grown single crystals of $MoTe_2$, and using a combination of elastic neutron scattering, magnetotransport, and spectroscopic techniques over a range of thermodynamic phase space. I will show that superconductivity can live within both centrosymmetric, non-centrosymmetric, and mixed structure phase states. I will also show that the application of pressure and strain allows us to control this state, and thus likely control the band topology of a superconductor.

2:45

S9-04. Type-I superconductivity with an unusual surface state in the Dirac semimetal $PdTe_2$. H. Leng[1], C. Paulsen[2,3], Y. Huang[1] and *A. de Visser*[1] *1. Institute of Physics, University of Amsterdam, Amsterdam, Netherlands; 2. Institut Néel CNRS, Grenoble, France; 3. Université Grenoble Alpes, Grenoble, France*

Recently, the transition metal dichalcogenide $PdTe_2$ was reported to be a Type II Dirac semimetal [1,2]. Dirac semimetals are the 3D analog of graphene and have a cone-shaped linear energy dispersion around the Dirac point with massless fermions. In Type II Dirac semimetals an extra momentum dependent term in the Hamiltonian breaks Lorentz invariance. This can be accomplished by tilting the Dirac cone, where the Dirac point is the touching point of the electron and hole pockets. Interestingly, $PdTe_2$ is also a superconductor with a transition temperature T_c of 1.6 K [3]. The recent detection of topological features in the band structure raises the question whether superconductivity has a topological nature [2]. We here report an in-depth characterization of the superconducting properties of $PdTe_2$ by means of magnetic and transport measurements on single crystals [4]. Surprisingly, dc-magnetization data show that $PdTe_2$ is a Type I superconductor (see Figure). Our crystals, with a demagnetization factor of $N = 0.12$, also show the intermediate state as evidenced by the differential paramagnetic effect. The superconducting state is characterized by a London penetration depth $\lambda = 39$ nm, a coherence length $\xi = 439$ nm and a Ginzburg-Landau parameter $\kappa = \lambda/\xi = 0.08$. The critical field H_c follows the standard quadratic temperature variation, with $H_c(0) = 13.6$ mT and $T_c = 1.64$ K. Remarkably, for applied fields $H_a > H_c$ superconductivity with a full screening signal persists till 34.9 mT for $T \rightarrow 0$. This we attributed to superconductivity of the surface sheath with a critical field H_c^S. Interestingly, $H_c^S(T)$ cannot be explained by the standard Saint-James behavior for surface superconductivity, *i.e.* a critical field $H_{c3} = 2.39 \times \kappa H_c$ [5]. The unusual phase diagram with bulk and surface sheath superconductivity is discussed in view of the topological electronic structure of $PdTe_2$.

S10-01. Symmetry enhanced first-order phase transition in a two-dimensional quantum antiferromagnet. *A.W. Sandvik[1,2] 1. Physics, Boston University, Boston, MA, United States; 2. Institute of Physics, Chinese Academy of Sciences, Beijing, China*

Theoretical descriptions of quantum phase transitions have indicated the existence of critical points with higher symmetry than those of the underlying Hamiltonian. Points of emergent symmetry have not been expected at discontinuous (first-order) transitions, however, but our recent work show that this may also be a possibility [1]. I will discuss an apparent symmetry enhanced first-order phase transition in a two-dimensional quantum magnet, where phase coexistence at the transition takes the form of an enhanced rotational symmetry in a space of two order parameters. Using quantum Monte Carlo simulations to study a 2D S=1/2 quantum magnet (a model in the J-Q family, with certain 4-spin interactions Q added to the Heisenberg exchange J) hosting the antiferromagnetic (AFM) and plaquette singlet (PS) states recently detected in SrCu2(BO3)2 under high pressure, we observe that the O(3) symmetric AFM order and the Z2 symmetric PS order form an O(4) vector at the transition. The control parameter Q/J rotates the vector from the AFM sector to the PS sector, with the length of the combined order parameter vector always remaining non-zero. This phenomenon should be observable in neutron scattering and other experiments on SrCu2(BO3)2.

S10-02. Investigation of Magnetic Dipole-dipole Interaction using Magnetic Density on Solid Oxygen Based on First-principles Approach. *M. Obata[1], M. Christivana[2] and T. Oda[1] 1. Institute of Science and Engineering, Kanazawa University, Kanazawa, Japan; 2. Graduate School of Natural Science and Technology, Kanazawa University, Kanazawa, Japan*

The solid oxygen has several unique properties. Since oxygen molecule has a magnetic moment in the ground state, it has various magnetic and crystal phases along the wide ranges of temperature and pressure [1,2,3]. The drastic change in crystal structure caused by external magnetic field besides, suggesting the existence of new phase in high magnetic field [4]. The magnetic interaction between molecules in some phases has been studied to reveal the mechanism of these phase transitions from both experimental and theoretical approaches. In the theoretical studies, first-principles approach is one of the promising methods to analyze magnetic interaction. These approaches often neglect the direction of magnetic moment on each molecule, even though the contribution of magnetic moment direction might be important for considering the low–symmetrical shape of oxygen molecule and crystal. The spin direction is determined by the spin-orbit and magnetic dipole-dipole interactions. The effect of spin-orbit interaction is localized on molecule and makes the spin direction to be perpendicular to the molecular axis. On the other hand, in this work, we focused on magnetic dipole-dipole interactions and considered them in the first-principles approach. We have developed the computational method to estimate magnetic dipole-dipole interaction energy including magnetic spin density contribution [5]. The magnetic spin density was obtained from the first-principles calculation with the commonly used approximation for the exchange and correlation energy. We investigated the tendency of spin direction in solid oxygen α, β, and γ phase. These results were found to be consistent with the experimental ones. Moreover, we found that the magnetic dipole-dipole interaction of realistic spin density distribution provides the stable magnetic moments perpendicular to the molecular axis, in contrary to the simple expectation from the isolated-spin moment model on the oxygen atoms.

S10-03. Spin-orbit coupling and magnetic long-range dipolar interaction for coupled spin-lattice dynamics. *J. Tranchida[1], A. Thompson[1], S. Plimpton[1], P. Thibaudeau[2], S. Moore[1] and M. Wood[1] 1. Sandia National Laboratories, Albuquerque, NM, United States; 2. DAM, Commissariat à l'Energie Atomique, Monts, France*

A rigorous massively parallel symplectic algorithm for coupled molecular dynamics and spin dynamics was recently implemented into Sandia's widely-used LAMMPS molecular dynamics code [1]. The approach enables the coupling of lattice vibrations and magnetization dynamics within a single framework, enabling applications to a broad range of phenomena related to magneto-elasticity, and the study of the influence of the micro-structure on the magnetic properties of functional materials. After presenting some general features and capabilities of this new LAMMPS package, we will focus on the ongoing development of two key improvements: new models accounting for the spin-orbit coupling, and scalable techniques to compute the long-range magnetic dipolar interaction. Even if the spin-orbit coupling corresponds to energies that are usually orders of magnitude lower than the magnetic exchange interaction, many technological applications are directly relying on its effects, and it is essential to find appropriate models accounting for it. This is particularly true when spin-lattice simulations are at stake. Based on the work of Néel on pair anisotropy models, a first methodology accounting for the spin-orbit coupling was implemented and parametrized, and allowed us to recover magneto-elastic coefficients in the case of hcp-cobalt. However, this model is insufficient for other magnetic metals such as iron, or iron-cobalt alloys. First-principles calculations within the spin-dependent density functional theory will be performed in order to derive and calibrate new models accounting for the spin-orbit coupling. Our implementation of spin dynamics fully leverages LAMMPS massively parallel scalable algorithms, enabling direct simulation of systems containing > 10 9 magnetic atoms, or equivalently 1μm 3 on modern high-performance computing platforms. At that scale, it is possible to observe the emergence of magnetic domain structures and domain walls. However, treatment of long-range magnetic dipolar interaction is unavoidable, as these interac-

tions stabilize the magnetic domain structures. We use the particle-particle particle-mesh method (P3M) to improve the parallel scaling relative to the simpler Ewald summation method.

S10-04. Parallel Computational Techniques for the Dipole-Dipole Interaction. *R.A. Pepper*[1], M. Beg[2], D. Cortes-Ortuño[1], O. Hovorka[1] and H. Fangohr[2] *1. Faculty of Engineering and the Environment, University of Southampton, Southampton, United Kingdom; 2. European XFEL GmbH, Schenefeld, Germany*

Magnetic dipole-dipole interactions are long range, and hence costly to compute during spin dynamics simulations, dominating the calculation time even for small systems if a naive calculation is used. Because of this, the dipole-dipole interaction is often neglected from calculations. Several techniques have been utilized in order to accelerate these computations to bring the algorithmic cost down to sub-quadratic scaling with the number of spins. Probably the most utilized of these uses the Fast Fourier Transform (FFT) in order to perform a convolution of a precomputed demagnetizing tensor and the magnetization, which works well for systems which sit on a regular lattice. Approximate methods, which utilize a heirarchical decomposition of the simulation space, and evaluations of the multipole expansion of the field can achieve equivalent or better scaling than the FFT accelerated computation, but the scaling relies heavily on the implementation, and these methods are in general difficult to optimize and parallelize. Previous works have shown the use of the Barnes-Hut method (sometimes known as a Treecode Method) and the Fast Multipole Method in atomistic spin dynamics [1, 2] but, to date, no publicly available spin dynamics code utilizes them. Here, we present a novel computational framework in which multipole expansion code is generated through the use of the symbolic algebra package SymPy. [3] We describe the implementation the generated code into the Barnes-Hut method and the Fast Multipole Method to calculate the dipole-dipole interaction. We describe optimization steps which reduce the complexity and increase the performance of the generated code, and the implementation of parallelisation strategies. We compare performance and quantify the error of the approximate methods against the naive calculation, the established best-practice technique of using the FFT for lattice systems, and against other techniques used in current public atomistic spin dynamics codes.

S10-05. Phase diagram of dipolar-coupled XY moments on disordered square lattices. *D. Schildknecht*[1,2], L. Heyderman[1,2] and P. Derlet[1] *1. Paul Scherrer Institut, Villigen-PSI, Switzerland; 2. D-MATL, ETH Zurich, Zurich, Switzerland*

Frustration denotes that not all interactions can simultaneously be satisfied. This often appears in real world magnetic systems and can lead to interesting phenomena like the inhibition of long range order, incommensurate ordering and spin glasses. In those systems the dipolar interaction is often an important perturbation. However the dipolar interaction itself is often intrinsically frustrated due to the interplay of ferromagnetic and antiferromagnetic contributions. This leads for moments, which only interact via dipolar coupling, on the square lattice to a so-called order-by-disorder transition, where the ground state has actually a higher symmetry than the Hamiltonian. This accidental symmetry is however readily destroyed by temperature or disorder and one is left with states following the same symmetry as the Hamiltonian. We derived meaningful order parameters for the relevant phases and employed parallel tempering Monte Carlo simulations to access the full phase diagram for two cases of disorder, namely introduction of vacancies in the otherwise regular grid of dipoles, or the perturbation of the lattice positions by a random displacement. We then compare the two phase diagrams and see many similarities, even though the notion of the disorder in the two systems is quite different. Finally, we will give a possible interpretation of those similarities by means of a flux closure argument.

Institut für Physik, Technische Universität Chemnitz, D-09107 Chemnitz, Germany; 5. Department of Physics, Oakland University, Rochester, MI, United States*

One of the most fascinating topics in current quantum physics are hybridized systems, in which resonators of different quantum systems are strongly coupled. Prominent examples are circular resonators with high quality factors that allow the coupling of optical whispering gallery modes to microwave cavities or magnon resonances. However, the coupling to magnons with finite wave vectors has not yet been achieved due to the lack of efficient excitation schemes. Here, we present the generation of whispering gallery magnons with unprecedented high wave vectors via nonlinear 3-magnon scattering in a µm-sized magnetic vortex state disc. These modes exhibit a strong localisation at the disc's perimeter and practically zero amplitude in an extended area around the vortex core. They originate from the splitting of the fundamental radial magnon modes (see Figure), which can be resonantly excited in a vortex texture by an out-of-plane microwave field. We will shed light on the basics of this non-linear scattering mechanism from experimental and theoretical point of view. Using Brillouin light scattering (BLS) microscopy, we investigated the frequency and power dependence of this nonlinear mechanism. The spatially resolved mode profiles give evidence for the localisation at the disk's boundaries and allow for a direct determination of the modes' wavenumber (see Figure). Furthermore, time resolved BLS in combination with pulsed microwave excitation revealed the temporal evolution of the 3-magnon splitting and its dependence on the applied microwave power. Financial support from the Deutsche Forschungsgemeinschaft within programme SCHU 2922/1-1 is gratefully acknowledged. Samples were prepared at the Nanofabrication Facilities (NanoFaRo) at the Institute for Ion Beam Physics and Materials Research at the Helmholtz-Center Dresden - Rossendorf (HZDR). T1-02. Magnonic band structure in a thin Permalloy film induced by dynamical coupling with a two dimensional array of Permalloy ellipses. *G. Gubbiotti*[1], W. Yang[2], P. Graczyk[3], S. Dhuey[4], M. Krawczyk[3] and H. Schmidt[2] *1. IOM-CNR, Perugia, Italy; 2. University of California, Santa Cruz, Santa Cruz, CA, United States; 3. Faculty of Physics, Adam Mickiewicz University in Poznan, Poznan, Poland; 4. Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, CA, United States*

A standard approach to create a magnonic crystal is to artificially process a continuous medium, to create a periodical profile of magnetic properties, on the scale of the spin wave wavelength.[1] Here we propose an alternative method which is based on the vertical control of the spin-wave properties of a continuous film by the dipolar stray magnetic field generated by an array of magnetic dots. Film and array of dots are coupled by dipole–dipole interaction across 10 nm thick non-magnetic spacer. Array of Permalloy(10nm)/Pt(10nm) elliptical dots was fabricated on top of a 20 nm thick Permalloy film, using electron beam lithography and metal lift-off. The ellipses have lateral dimension of 600x200 nm and are placed into chains with an edge-to-edge distance of 80 along the long axis of the ellipses while the interchain distance is of 400 nm. Using Brillouin light scattering spectroscopy and simulations with finite element method in the frequency domain we compare

the spin wave dispersion measured by applying the external field H=500 Oe along the ellipses chain and by sweeping the wavevector (k) in the orthogonal direction, as shown in Fig. 1(a). We have found that the spin wave dispersion exhibits either propagating and stationary modes. These two types of waves interact giving rise to hybridization effect around k»0.45 (p/a), also opening of magnonic band at the boundary of the first Brillouin zone (k=p/a) is observed, thus demonstrating that the regular pattern of the ferromagnetic elliptical dots influences the DE mode of the underneath Permalloy film through dynamic dipolar field, and the resonant coupling with magnetic modes inside the dots.

T1-03. Direct observation of sub-100 nm spin wave propagation in magnonic wave-guides. N. Träger[1], P. Gruszecki[2], F. Lisiecki[3], J. Förster[1], F. Groß[1], M. Weigand[1], P. Kuswik[3,4], J. Dubowik[3], G.A. Schütz[1], M. Krawczyk[2] and *J. Gräfe*[1] *1. Max Planck Institute for Intelligent Systems, Stuttgart, Germany; 2. Faculty of Physics, Adam Mickiewicz Univeristy in Poznan, Poznan, Poland; 3. Institute of Molecular Phyiscs, Polish Academy of Sciences, Poznan, Poland; 4. Centre of Advanced Technology, Adam Mickiewicz University, Poznan, Poland*

In the research field of magnonics, capabilities of data communication via spin-wave propagation are currently of strong scientific interest. Magnonic computing with guided sub-100 nm wavelengths promises beyond-CMOS data processing technologies like non-Boolean computing algorithms or majority gates substituting several tens of CMOS transistors and making this an exciting candidate for next level computing. Here, we investigate 350, 700 and 1400 nm wide and 50 nm thin and up to 40 µm long Py stripes as magnonic waveguides, using scanning x-ray microscopy (MAXYMUS@ BESSY) with 18 nm spatial and 35 ps temporal resolution. Spin waves were from antennas that generated a uniform RF field in the GHz regime around the Py stripes. We directly observe highly oriented emission of sub-100 nm spin-wave modes with tens of periods, which is beyond the measuring capabilities of conventional techniques. Furthermore, the waveguides are capable of simultaneously carrying multiple modes. Thereby, we observed non-dispersive propagation indicating high transmission velocity with uniform characteristics. Additionally, we observe the decay behaviour revealing information about different coexisting modes and their corresponding damping properties for k≠0, indicating an increased damping at k>>0. These findings will be a crucial basis for magnonic logic relying on ultrashort spin-waves.

T1-04. Computing with spin waves: from magnetoelectric transducers to majority gates. F. Ciubotaru[1], D. Tierno[1,2], G. Talmelli[1,2], H. Ahmad[1,2], J.D. Costa[1,2], I.P. Radu[1], T. Devolder[3] and *C. Adelmann*[1] *1. Imec, Leuven, Belgium; 2. KU Leuven, Leuven, Belgium; 3. C2N, CNRS, Université Paris-Sud, Orsay, France*

Spin waves in magnetic waveguides with sub-micron wavelengths have been proposed as data carriers in future information processing systems [1,2]. In particular, spin wave based majority gates promise significant power and area reduction per computing throughput with respect to conventional CMOS [2,3]. Recently, a first macroscopic demonstrator device has been reported [4]. To render spin wave majority gates competitive with CMOS, the device has to be scaled to small dimensions and the transduction efficiency between electrical and spin wave domains has to be improved. Conventionally, spin waves are excited and detected using inductive antennas with low power efficiency. To improve the efficiency, we have developed spin waves transducers based on spin-orbit torques [5] as well as the magnetoelectric effect [6]. We will experimentally demonstrate spin wave excitation by spin-orbit torque antennas and discuss the relative influence of spin-orbit torques and Oersted fields in an analytic model for spin wave excitation. We will furthermore demonstrate the fabrication of scalable broadband magnetoelectric transducers based on micron-sized piezoelectric actuators and show experimentally that they can excite both coherent propagating spin waves as well as ultrasound waves in Ni/permalloy bilayer waveguides. The scaling of the majority gate to small dimensions will require the usage of waveguides with sub-micron widths. Therefore, we have studied the propagation of

spin waves in such narrow waveguides and the resulting mode formation. We have experimentally assessed the propagation of surface spin waves in waveguides down to 20 nm width and show that the mode formation and the spin wave spectra are strongly influenced by the non-uniformity of the magnetization due to non-uniform demagnetization fields as well as the internal anisotropy field. Finally, we demonstrate the operation of a spin wave majority gate with dimensions in the micron range.

Department of Applied Physics, The University of Tokyo, Tokyo, Japan*

Multiple-*q* spin order, i.e. spin texture characterized by the multiple number of coexisting magnetic modulation vectors *q*, has recently attracted attention as the source of nontrivial magnetic topology and associated emergent phenomena.[1] One typical example is triple-*q* skyrmion lattice state stabilized by Dzyaloshinskii-Moriya interaction in noncentrosymmetric magnets[2], while recent theories also predict the emergence of various multiple-*q* states of different origins, such as frustrated exchange interactions in triangular lattice system[3-5] and spin-charge coupling in itinerant hexagonal system [6,7]. In this presentation, we report the experimental discovery of a triple-*q* magnetic order with unique in-plane vortex-like spin textures in the itinerant hexagonal magnet $Y_3Co_8Sn_4$, through detailed small-angle neutron scattering (SANS) experiments. Our theoretical analysis reveals that the observed triple-*q* spin texture can be consistently explained in terms of the spin-charge coupling mechanism inherent to itinerant magnets, which demonstrates that the traditional DM mechanism is not the only approach to realize the multiple-*q* orders. Notably, the spin-charge coupling mechanism can stabilize multiple-*q* orders even under zero magnetic field without breaking of inversion symmetry, which is in sharp contrast with the case for the traditional DM mechanism. Our findings thus promote spin-charge coupling as a new route for the stabilization of multiple-*q* orders, and trigger further investigation of itinerant hexagonal magnets as a unique material platform to explore the rich phase diagram of topological spin textures.

T2-02. Anomalous Hall effect in disordered Co_2FeSi Heusler-alloy thin films. *B.K. Hazra*[1], M. Raja[2], R. Rawat[3], A. Lakhani[3], S. Kaul[1] and S. Srinath[1] *1. School of Physics, University of Hyderabad, Hyderabad, India; 2. Defence Metallurgical Research Laboratory, Hyderabad, India; 3. UGC-DAE Consortium for Scientific Research, Indore, India*

A wide variation in the disorder strength, as evident from large variation in the longitudinal resistivity (rho_xx) of Co2FeSi (CFS) Huesler alloy thin films of fixed (50 nm) thickness, has been achieved by growing these films on Si(111) substrates at different substrate temperatures. An in-depth study of the effect of disorder on anomalous Hall resistivity (rho_AH) and rho_xx reveals the following. The side-jump mechanism gives a dominant contribution to anomalous Hall resistivity (AHR) in the CFS thin films, irrespective of the degree of disorder. Logarithmic temperature dependence of rho_xx and rho_AH at temperatures below the minimum (Fig. 1 (a)), exclusive to the amorphous CFS films, originates from the scattering of conduction electrons from the diffusons. In these amorphous CFS films, the electron-diffuson (e-d) scattering and weak localization (WL) mechanisms compete with the

inelastic electron-magnon (e-m) scattering to give rise to the minimum in rho_xx(T), whereas the minimum in rho_AH (T) is caused by the competing contributions from the e - d and e - m scattering, as WL does not make any contribution to AHR. In sharp contrast, in crystalline films, enhanced electron-electron Coulomb interaction (EEI), hich responsible for the resistivity minimum (Fig. 1 (b)), makes no contribution to rho_AH (T) resulting no minimum in the AHR. The conventional scaling breaks down completely in the present case, more so in the strongly disordered CFS films (Fig 2(a)). Instead, when rho_AH (T) is corrected for the e-d contribution and rho_xx(T) for both e d and WL contributions (only EEI) in the amorphous (crystalline) films, the AH coefficient, RA(T) perfectly scales with rho_xx(T) for all the CFS thin films (Fig 2(b)).

T2-03. Manipulating Anomalous Hall Antiferromagnets with Magnetic Fields. *H. Chen*[1], T. Wang[2], D. Xiao[3], G. Guo[2], Q. Niu[4] and A.H. MacDonald[4] *1. Physics, Colorado State University, Fort Collins, CO, United States; 2. National Taiwan University, Taipei, Taiwan; 3. Carnegie Mellon University, Pittsburgh, PA, United States; 4. Physics, The University of Texas at Austin, Austin, TX, United States*

The symmetry considerations that imply a non-zero anomalous Hall effect (AHE) in certain non-collinear antiferromagnets also imply both non-zero orbital magnetization and a net spin magnetization. We have explicitly evaluated the orbital magnetizations of several anomalous Hall effect antiferromagnets and find that they tend to dominate over spin magnetizations, especially so when spin-orbit interactions are weak. Because of the greater relative importance of orbital magnetization the coupling between magnetic order and an external magnetic field is unusual. We explain how magnetic fields can be used to manipulate magnetic configurations in these systems, pointing in particular to the important role played by the response of orbital magnetization to the Zeeman-like spin exchange fields. T2-04. Anomalous Hall effect in magnetic topological semimetals. *Y. Sun*[1] *1. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany*

Topological band structures with Weyl points and nodal lines host strong Berry curvature. With topological protection and time reversal symmetry breaking, magnetic Weyl semimetals and nodal line semimetals are deserved to have strong anomalous Hall effect without the requirements of large carrier density. With this motivation, we have predicted the strong anomalous Hall effect in ferromagnetic Weyl semimetal Co3Sn2S2. Owing to the low charge carrier density and large Berry curvature from the nodal line band structure, the AHC and AHA experimentally reach up to 1130 S/cm and 20% respectively. Further, the anomalous Hall effect can even exist with zero net moments in the absence of the symmetry operation that changes the sign of Berry curvature. And the anomalous Hall effect can be strongly enhanced by the special band structure, such as Weyl points and nodal lines. Following this guiding direction, we have predicted a strong anomalous Hall effect in the compensated ferrimagnetic Weyl semimetal Ti2MnAl with vanishing magnetic net moments. Our work is helpful for the comprehensive understanding of the anomalous Hall effect in magnetic materials.

T2-05. Proximity effect induced magnetism in graphene. *E.J. Seifert*[1,2], D.P. Gopalan[2], B. Hunt[2], M. Skowronski[1], A. Haglund[3] and D. Mandrus[3] *1. Materials Science, Carnegie Mellon University, Pittsburgh, PA, United States; 2. Physics, Carnegie Mellon University, Pittsburgh, PA, United States; 3. Materials Science, University of Tennessee, Knoxville, TN, United States*

Observation of the quantum anomalous Hall effect requires high mobility, nonzero magnetization, and spin-orbit coupling. Recently, this effect was observed in magnetically-doped topological insulator films. However, dopants in the film cause increased scattering, making the effect observable only at very low temperatures. In this talk, I will discuss a new all-2D van der Waals system in which it may be possible to observe the quantum anomalous Hall effect. Here, we study the proximity effect between a 2D ferromagnetic insulator CrSiTe3 (CST) and graphene. Through non-local measurements, we observe an effect that is interpreted as an induced nonzero magnetization in graphene at finite field. This paves the way for future observation of the quantum anomalous Hall effect in graphene.

T3-01. Small-Angle Electron Diffraction and its application to Magnetic Materials. *S. Mori*[1] *1. Materials Science, Osaka Prefecture University, Osaka, Japan*

Small-angle electron diffraction (SmAED) experiments in a transmission electron microscope (TEM) have some advantages that a real-space image and electron diffraction with high angular resolution can be obtained [1]. Here we report an electron-optical system with an objective mini-lens to realize SmAED with high-angle resolution of ~10^{-6} rad in the conventional TEM without any special equipment. The schematic electron-optical systems for SmAED mode and Foucault imaging mode are shown in Fig. 1. In this electron-optical system, we are able to switch between SmAED mode and Foucault imaging mode, keeping the crossover position on the SA aperture plane [2,3]. Furthermore, this electron optical system make it possible to carry out Foucault imaging and SmAED experiments in external magnetic fields without changing the illumination system [2]. We applied this electron-optical system to observation of magnetic textures in magnetic materials such as $La_{1-x}Sr_xMnO_3$ and Ba ferrites [4,5,6]. Figure 1 shows a Foucault image exhibiting the 180° magnetic domains in $La_{1-x}Sr_xMnO_3$ for x=0.30. The SmAED pattern with a camera length of 150 m is shown in the inset of Fig. 1(a). The 000 spot in the SmAED pattern was split by the magnetic deflection due to the 180° magnetic domains with magnetic moments anti-parallel between two neighboring domains. Thus, we investigated changes of magnetic domain structures by applying external magnetic field perpendicular to thin film. It was found that a reconstruction of magnetic domains took place when a magnetic field of 50 mT was applied parallel to the optical axe, as shown in Fig. 1(b).

T3-02. Taiwan's new cold neutron triple-axis spectrometer SIKA. *S. Yano*[1], J. Peng[1], G. Deng[2] and C. Wu[1] *1. Neutron Group, NSRRC, Hsinchu, Taiwan; 2. ACNS, ANSTO, Sydney, NSW, Australia*

For many years the triple-axis spectrometer has been utilised by for neutron scatters to study many areas of magnetism and condensed matter physics. With cold neutrons, a triple-axis spectrometer has the capability to investigate physical phenomena with high energy and momentum resolution. Whilst time-of-flight spectrometry is advanced at spallation neutron sources, the cold triple-axis spectrometer has advantages of scanning $S(Q, \omega)$ space at each reciprocal point, measuring critical scattering, availability of a number of sample environment, and so on. A new cold triple-axis spectrometer was installed in ANSTO, OPAL reactor, Australia. The components, capabilities, sample environment, software, statistics, and experimental examples are presented in this presentation. Plans for future progress are also discussed. The authors look forward to welcoming users to promote neutron science with new cold triple axis spectrometer from this community.

T3-03. Probing anisotropy with vectorial FORC-based measurement.
L. Stoleriu[1] and *A. Stancu*[1] *1. Department of Physics, Alexandru Ioan Cuza University of Iasi, Iasi, Romania*

The standard magnetic characterization method based on first-order reversal curves (FORC) diagrams [1,2] is essentially scalar and provides two magnetic components. One is due to irreversible switches of the magnetic entities in the sample and one is related to the reversible changes in the magnetization [3,4]. As most researchers focus their attention mainly on the first component, the reversible component, which in some cases can be of paramount importance in the complete understanding of the magnetic behavior of the studied samples, is unfortunately completely neglected. The two main sources of the reversible component are the reversible changes in the magnetic entities in field ranges which do not imply switches and the magnetization changes due to relaxation processes in the magnetic ensemble. The first source is closely related to the fact that a basically vectorial magnetization process is examined with a scalar-type measurement. As a result, one understands the strong interest in the development of a vectorial FORC-type technique. One solution, which has some limitations, is to make systematic scalar measurements for different angles between the easy axis of the sample and the applied field direction [5]. In this presentation we will show one vectorial FORC (vFORC) technique approach using typical capabilities of a VSM equipment, that is, the xy set of sensing coils, able to measure two components of the magnetic moment instead of only one. We show that this methodology is really sensitive in deconvoluting the contributions given by the components of different anisotropies in a given sample. Also of interest is to find the fingerprint due to different anisotropies types. The results obtained experimentally are compared with physically accurate micromagnetic simulations of these samples in order to understand the performances and the limits of this tool.

T3-04. Multifunctional Oblique Incidence Deposition Devices for Science and Industry.
K. Schlage[1], A. Siemens[1], S. Willing[1,3], L. Bocklage[1,2], C. Adolff[2], T. Gurieva[1] and R. Roehlsberger[1,2] *1. Photon Science, DESY, Hamburg, Germany; 2. The Hamburg Centre for Ultrafast Imaging, Hamburg, Germany; 3. PIER Helmholtz Graduate School, Hamburg, Germany*

Oblique-incidence deposition (OID) is known to offer unique possibilities for anisotropy control in magnetic films. The azimuthal deposition angle allows to precisely define a shape-anisotropy induced in-plane magnetic easy axis and the polar deposition angle as well as the layer thickness enable to adjust the magnetic switching field of the film. We recently showed [1] that OID can even be applied to selectively and independently tailor the magnetic properties of single layers in complex multilayer stacks. As a consequence, new functionalities of magneto-resistive sensor devices can be designed and customized to the desired measuring task for the first time. The angular degrees of freedom during layer deposition combined with the required set of materials and UHV conditions pose a challenge for the technical realization of sample or device preparation. In this contribution we introduce two self-developed UHV sputter deposition chambers that implement the OID method via different approaches. Both are optimized for OID fabrication of magneto-resistive multilayer stacks (AMR, GMR, TMR) but can be used in many ways. The first chamber (Fig.1,2) aims at multifunctional lab-scaled research and development. Its strengths are the flexibility, adaptability, various additional features like possible sample screening via gradients, full automatization and easy handling. The second chamber focuses on transferring the OID method to industrial scale. The technique had to be adapted to cope not only with 200 mm wafers but also with stricter requirements regarding spatial homogeneity of the thin films. Both chambers are ideal for OID sample fabrication and advanced tools to prepare custom-designed multilayer stacks with tunable magnetic properties, spiral structures, gradient samples as well as to coat 3D objects homogeneously and much more.

T3-05. Analysis of Magneto-Elastic Hybridized Effects due to the CEF. *P. Cermak*[1,2], B. Liu[2], A. Schneidewind[2], C. Franz[3], P. Javorsky[1] and C. Pfleiderer[3] *1. Department of Condensed Matter Physics, Charles University in Prague, Prague, Czechia; 2. JCNS, Forschungszentrum Julich, Garching, Germany; 3. Technical University of Munich, Garching, Germany*

The interplay between magnetic moments (electrons) and lattice vibrations (phonons) is a general condensed matter property establishing various significant effects. We are focusing here on rare earth metals, where the magnetic behaviour is strongly influenced by the local point-symmetry of the surrounding electric field - the so-called crystalline electric field, raising large magnetic anisotropies and breaking of electron orbital states. This effect is usually static in momentum; except the CEF transitions between neighboring ions couple and create magnetic excitons [1]. If this coupling is phonon-mediated we speak about magnetoelastic coupling (MEL) [2]. It is claimed that for very strong MEL the creation of an additional magnetic vibornic bound state (VBS) is possible [3], and in the case of weaker coupling one can observe mixed quadrupole-phonon excitations visible as an anticrossing in the inelastic scattering [4]. In addition hybridization with conduction electrons and phonons will cause broadening of the crystal field levels (Becker-Fulde-Keller theory [5]). The understanding of MEL is an important step in searching for the new cooperative and hybridized effects, which could be mediator for unconventional superconductivity. We will present overview of the compounds evincing bound states due to MEL together with methods how to calculate them using open source software CrysFiPy [6]. All possible MEL effects will be then shown on the example of the tetragonal heavy fermion compound $CeAuAl_3$ measured by inelastic and polarized inelastic neutron scattering.

T3-06. Efficiency Improvement of X-Ray Spectroscopy using Machine Learning. *T. Ueno*[1], H. Hino[2] and K. Ono[3] *1. Quantum Beam Science Research Directorate, National Institutes for Quantum and Radiological Science and Technology, Sayo, Japan; 2. Department of Computer Science, University of Tsukuba, Tsukuba, Japan; 3. Institute of Materials Structure Science, High Energy Accelerator Research Organization, Tsukuba, Japan*

X-ray spectroscopy including X-ray magnetic circular dichroism (XMCD) spectroscopy is frequently used experimental technique in the research of magnetic materials. Recently, we proposed the adaptive design of experiment (DOE) for XMCD using a Gaussian process (GP) modeling, a machine-learning technique. It can improve the efficiency of an XMCD measurement [1]. In this study, we applied GP modeling to X-ray absorption spectra (XAS) with various signal-to-noise (S/N) ratios to develop general versatility of the adaptive DOE. A similarity between GP-predicted XAS and noiseless XAS was evaluated to determine convergence of measurement and prediction. We used Pearson correlation coefficient. Moreover, we examined the similarity between GP-predicted XAS from various S/N rations and number of data points to find the most efficient experimental condition without the adaptive DOE. Figure 1 shows the similarity between GP-predicted XAS and simulated-noiseless XAS versus number of measurements. For results without the prior distribution, high S/N spectra converge with fewer numbers of measurements as an overall trend. For results with the prior distribution, similarities except for S/N = 10 become closer to 1 with much fewer measurement as compared to the results without the prior distribution. These results indicate the GP-predicted XAS spectra with fewer data points are very similar to the "true" spectrum. The method is reliable for XAS with S/N larger than 100 with including the prior distribution in the range of the present study. In conclusion, we investigated the application of the GP modeling and similarity measure to improve the efficiency of XAS experiments. The adaptive DOE for XAS experiment effectively decreases energy points to be measured. Moreover, the efficiency is improved by including the prior distribution.

INVITED PAPER

3:30

T4-01. Manipulating Spin using Topological Insulator Heterostructures. *N. Samarth[1] 1. Department of Physics & Materials Research Institute, Penn State University, University Park, PA, United States*

Narrow bandgap semiconductors such as the Bi- and Sb-chalcogenides are known to support two-dimensional (2D) Dirac fermion surface states, characterized by a helical spin-texture in momentum space [1]. The correlation between spin and crystal momentum of the surface states in these three-dimensional (3D) 'topological insulators' lends itself naturally to spintronic devices. We present an overview of concepts and experiments that explore the recent emergence of 'topological spintronics' which aims to exploit efficient spin-to-charge conversion involving the helical states [2,3,4]. We then detail two families of recent experiments. First, we examine the fundamental mechanism whereby circularly polarized light creates directional photo-galvanic currents in topological insulators [5]. Second, we examine the pumping of spin from a ferrimagnetic insulator to a topological insulator [6], with a particular focus on disentangling contributions to spin-charge conversion from surface and bulk states [7]. This work was funded by C-SPIN, ONR, NSF, and NSF MIP 2DCC.

As one of plenty of physical phenomena in ferromagnetic and non-magnetic metal bilayers, an asymmetric magnetoresistance (MR) in Py/Pt bilayer has been recently reported [1-3]. As the current density increases, the asymmetric MR firstly linearly increases up to a threshold, and above the threshold it increases more rapidly. The unique threshold current density behavior of asymmetric MR implies different origin of asymmetric MR below and above threshold current density. To reveal the origin of the threshold behavior of asymmetric MR, we investigate the current density dependence of asymmetric MR under various magnetic fields [2]. The results demonstrate that asymmetric MR below the threshold is not affected by the external magnetic field up to 8.9 T, which is consistent with the scenario of THz magnon generation: THz magnons have an energy of a few meV, which is much larger than the Zeeman energy induced by the magnetic field of 8.9 T (~1 meV computed from $g\mu_B B$ with $g = 2$). On the other hand, the rapid increase of the asymmetric MR above the threshold is strongly suppressed by magnetic field, suggesting that the magnetic excitations with a lower energy scale are involved in the asymmetric MR above threshold. Results of micromagnetic simulation reveal that spin-torque-induced magnetization excitation, lying in gigahertz (GHz) scale, is responsible for the rapid increase of asymmetric MR above threshold current density. Our results suggest that the asymmetric MR has two origins: the spin-torque-induced GHz magnon excitation for components above the threshold and the spin-flip-induced THz magnon excitation for components independent of the threshold.

Ferrimagnets have come into the spotlight because they provide a unique platform to study the antiferromagnetic spin dynamics at a compensation point [1]. However, transport properties of ferrimagnets have less been explored. Recently, the unidirectional magnetoresistance (UMR) has been discovered in ferromagnet/non-magnet bilayer systems [2-4]. This naturally raises a curious question about how the UMR evolves if we replace the ferromagnet with a ferrimagnet. In this work, we investigate the UMR in ferrimagnet/non-magnet bilayers across the compensation point. For this study, $Co_{100-x}Gd_x$ 10/Pt 5 (nm) bilayers were deposited by dc-magnetron sputtering, where x=0, 10, 20, and 30 (at%) is the composition of CoGd alloys. In order to measure the longitudinal (R_{xx}) and transverse (R_{xy}) resistance, we patterned the films into a Hall bar structure. Figure 1 (a) shows the R_{xy} as a function of an out-of-plane magnetic field (H_z), which exhibits an anomalous Hall effect (AHE) of the CoGd alloys. A polarity reversal in the AHE is observed, indicating that the magnetic moment compensation point exists between x=20 and 30 (at%) [1]. Figure 1 (b) and its inset show the UMR as a function of a charge current density (j_x) and an external magnetic field (H_y), respectively. Two important features are observed. First, the sign of the UMR changes across the compensation point. This implies that the symmetry of the UMR is determined by the direction of the Co sub-magnetic moment rather than that of the total magnetic moment, similar to the AHE. Second, we found that the UMR of ferrimagnetic CoGd alloys is much larger

than that of ferromagnetic Co. These results suggests that the ferrimagnets can be more advantageous than ferromagnets in spintronic applications.

T4-04. Spin-polarized electrical transport of NiMnSb at nonzero temperature. *D. Wagenknecht*[1,2], Z. Kašpar[1,3], L. Šmejkal[4,3], K. Carva[1] and I. Turek[1,2] *1. Faculty of Mathematics and Physics, Charles University, Prague, Czechia; 2. Institute of Physics of Materials, Czech Academy of Sciences, Prague, Czechia; 3. Institute of Physic, Czech Academy of Sciences, Prague, Czechia; 4. INSPIRE Group, Johannes-Gutenberg Universität at Mainz, Mainz, Germany*

Calculations from the first principles represent a perfect tool to investigate spintronic materials. Wide range of defects, e.g., chemical or magnetic disorder, may be easily assumed in order to characterize material behavior at real-life conditions. On the other hand, reliable description of temperature-induced disorder (phonons and magnons) still remains a difficult challenge, especially because of numerical expenses. Combined theoretical and experimental study of halfmetalic half-Heusler alloy NiMnSb at finite temperatures will be presented. Electrical transport properties including spin-resolved conductivities are obtained by *ab initio* calculations with incorporated atomic displacements caused by nonzero temperatures. In order to prove correctness of our methods, we measured electrical resistivity and the anomalous Hall effect of real samples. An alloy-analogy model was implemented in our fully relativistic tight-binding linear muffin-tin orbital (TB-LMTO) numerical codes [1,2]. Displacements of atoms from their equilibrium positions (phonons) are analytically averaged by the coherent potential approximation (CPA); therefore, this method is numerically fast and universal. It was successfully used to describe simpler magnetic materials [3] and random Cu-Ni alloys [4]. Comparing computed results with our measurements (Fig. 1) not only proves reliability of the theoretical framework, but it also allows us, e.g., to identify chemical disorder in the samples. Based on densities of states and electrical transport properties at nonzero temperatures, the Ni-rich NiMnSb (prevailing disorder in real samples) was found to have large polarization of the spin-resolved electrical current even at room conditions. The developed approach may be also used to describe any other metalic material and to efficiently deal with a combination of chemical, magnetic, and temperature-induced disorder.

T4-05. Effects of Heavy Metal Microstructure on Spin Transport Phenomena in the Ultrathin Limit. *S.J. Brennan*[1], G. Divitini[1], A. Wittmann[1], T. Vemulkar[1], J. Liao[1], L. O'Brien[2] and R. Cowburn[1] *1. Physics, University of Cambridge, Cambridge, United Kingdom; 2. Physics, University of Liverpool, Liverpool, United Kingdom*

All-metallic spintronic heterostructures have the ability to generate pure spin currents at low resistance-area products via spin-orbit coupling. Heavy metal/ferromagnet (HM/NM) bilayers are often used in this context to extract key spin-dependent parameters such as the spin Hall angle, θ, and the spin diffusion length, λ, of the constituent materials. However, in the ultrathin film limit morphology is highly sensitive to growth parameters, making consistent extraction of the spin-dependent properties challenging. Here, we investigate the role of microstructure morphology on spin transport properties within ultrathin HM/FM bilayers (FM = Co, CoFeB; HM = W, Ta, Ru) by seeding growth on SiO_2 with thin (1 nm) metallic buffer layers including Ta and Ru. The (un)buffered bilayers are characterised by x-ray diffraction and cross-sectional transmission electron microscopy (TEM). Fig. 1 illustrates Pt growth from (a) granular Volmer-Weber-type (VW) growth mode, to (b) continuous, highly textured films due to buffer-enhanced surface wetting. The buffers seed Pt growth, which we find to increase film continuity, texture, lower roughness and reduce film resistivity, ρ. We observe dramatic differences in the magnitude of spin current generation across multiple experiments (spin Hall magnetoresistance (SHMR), spin pumping and spin-orbit torque measurements) as seen in Fig. 2, which can be directly correlated to microstructure. Finally, we demonstrate the observed enhancement in SHMR and spin pumping can be accurately modelled by magneto-electronic circuit theory (MCT), when taking account of film morphology and Elliot-Yafet-dominated spin relaxation. This indicates predominantly intrinsic spin Hall scattering in Pt, in agreement with recent work[1,2]. It also highlights that care must be taken when interpreting SHMR data alone, and potentially provides a resolution to the widely varying values of θ and λ reported across the literature.

In this work, was synthesized electrospun[1] MnFe2O4 nanofibers from precursor solution composed by 15% wt of polyviniylpirrolidone (PVP), with molecular weight Mw 1300 k, $Fe(NO_3)_3$ $9(H_2O)$ and $Mn(NO_3)_2$ H_2O in a mixture of water and alcohol. As spun nanofibers were calcine at 973 K for 1 h in argon atmosphere to remove the polymer matrix and get the magnetic MnFe2O4 nanofibers. In order to understand the properties of the MnFe2O4 nanofibers were characterized by X ray diffraction (XRD), scanning electron microscopy (SEM), high resolution transmission electron microscopy (TEM) and magnetometry (VSM). $MnFe_2O_4$ [2] pure phase was find from XRD with crystallite average diameter <D> equal to 35 nm. From SEM images was determined a polycrystalline fiber morphology with particle average diameter <P> of 50 nm. In a deep analysis from HR-TEM a high crystallinity was observed. From VSM the magnetic behavior for temperature range, from 50 to 350 K, was determined. The ZFC/FC curves exposed a blocking temperature of 175 K. The hysteresis loops measured to 5 different temperatures shown a characteristic ferrimagnetic behavior, with a maximum magnetization increasing for lower temperature and reaching a value of 84 emu/g.

T5-02. Crystal Structure and Magnetism of Colossal Dielectric Oxides $Dy_xSr_{2-x}TiMnO_6$ (x=0, 0.5). R. Mondal[1], K. Biswas[1], T. Ghosh[1], F. K[1], R. Rao MS[1], A. Morozkin[2], S. Quezado[3], S.K. Malik[4], *A.K. Nigam*[5] and R. Nirmala[1] *1. Physics, Indian Institute of Technology Madras, Chennai, India; 2. Moscow Lomonosov State University, Moscow, Russian Federation; 3. Universidade Federal do Rio Grande do Norte, Natal, Brazil; 4. DTFE, Universidade Federal do Rio Grande do Norte, Natal, Brazil; 5. Department of Condensed Matter Physics and Materials Science, Tata Institute of Fundamental Research, Mumbai, Mumbai, India*

There is a great deal of interest to understand the physical properties of Sr_2TiMnO_6 -type oxides that display colossal dielectric behaviour at room temperature over a broad frequency range because of their possible applications in microelectronics. The oxide Sr_2TiMnO_6 exhibits a complex magnetic behaviour that includes the presence of short range ferromagnetic interactions below ~45 K, an antiferromagnetic-like cusp at ~15 K, and a deviation from simple Curie-Weiss behaviour in the paramagnetic region [1]. Neutron diffraction studies of this material revealed the magnetic structure to be an antiferromagnet at 12 K [2]. In this work, magnetic and dielectric properties of Sr_2TiMnO_6 doped with a magnetic rare earth ion, namely, Dy^{3+}, at Sr-site are studied. Polycrystalline $Dy_xSr_{2-x}TiMnO_6$ (x = 0, 0.5) oxides crystallize in cubic structure (Space group Fd-3m, No. 225) at room temperature. The SEM pictures reveal the well-formed microstructure of the samples with grains of size 1 to 10 mm. EDAX analyses confirm the nominal composition. While Sr_2TiMnO_6 antiferromagnetically orders at ~14 K (T_N), the $Dy_{0.5}Sr_{1.5}TiMnO_6$ sample does not show a clear cusp in magnetization. However, this sample shows a tendency to order around 3 K in the dc magnetization data. The magnetization value at 2 K is greatly enhanced for the Dy-substituted sample compared to that in parent Sr_2TiMnO_6. The real part of the dielectric permittivity of $Dy_xSr_{2-x}TiMnO_6$ (x = 0, 0.5) is of the order of 10^4 at room temperature. The colossal dielectric constant values in these samples could be understood in terms of intrinsic hopping conduction and extrinsic Maxwell-Wagner relaxation mechanism. Powder X-ray diffraction data confirm that Sr_2TiMnO_6 does not undergo any structural transition in the temperature range of 300 K to 800 K and reveal normal thermal expansion behaviour. X-ray photoelectron spectroscopy data indeed confirm the presence of mixed valence states for Mn (Mn^{3+} and Mn^{4+}) as expected from magnetization measurements while Ti 2p spectra consist of two peaks that correspond to Ti $2p_{1/2}$ and Ti $2p_{3/2}$. Thus rare earth ion substitution at Sr-site of Sr_2TiMnO_6 offers a way to tune the magnetic properties while preserving the dielectric property.

T5-03. Impact of Epitaxial Strain on Electronic Structure of $La_{2/3}Sr_{1/3}MnO_3$ Ultrathin Films. *M. Zahradnik*[1,2], T. Maroutian[2], G. Kurij[2], G. Agnus[2], P. Lecoeur[2], L. Beran[1] and M. Veis[1] *1. Charles University in Prague, Prague, Czechia; 2. Centre de Nanosciences et de Nanotechnologies, Université Paris-Sud, Orsay Cedex, France*

Ultrathin layers of $La_{2/3}Sr_{1/3}MnO_3$ (LSMO) attract interest for applications in spintronic devices due to their unique combination of physical properties. These perovskite oxides exhibit colossal magnetoresistance [1] and high degree of spin polarization. Manganese ions are present in a mixed valence states of Mn^{3+}/Mn^{4+}, which leads to metallic conductivity and ferromagnetic ordering. The ferromagnetism of perovskite oxides was first explained by double-exchange (DE) interaction [2], which originates from e_g electron transfer between Mn^{3+} and Mn^{4+} ions via O^{2-} 2*p* state. The DE electron transfer probability strongly depends on Mn^{3+}-O-Mn^{4+} geometry, therefore one of the main factors responsible for change of magnetic properties is epitaxial strain induced by lattice mismatched substrate. We fabricated LSMO films on four different substrate materials – $LaAlO_3$ (LAO), $(LaAlO_3)_{0.3}(Sr_2TaAlO_6)_{0.7}$ (LSAT), $SrTiO_3$ (STO) and $DyScO_3$ (DSO). They induce a variety of strains in LSMO films, ranging from large compressive strain on LAO, through small compressive on LSAT and small tensile on

STO, up to large tensile strain on DSO. Using X-ray diffraction, all the films were found to be fully strained and their lattice parameters were quantified. Combination of spectroscopic ellipsometry and magneto-optical (MO) spectroscopy was used to characterize the optical and MO properties of the films. We calculated both diagonal and off-diagonal permittivity tensor elements. Spectra of the off-diagonal elements are shown in Figure 1. They reveal presence of previously reported electronic transitions around the incident photon energies of 2.4 eV [3] and 3.6 eV [4]. Another transition around 4.3 eV is observed only in spectra of films deposited under compressive strain. We show that this transition is likely to originate from crystal symmetry lowering as a direct consequence of the epitaxial strain. It is a manifestation of the key role of strain in controlling the magnetic properties of ultrathin perovskite layers.

T5-04. Temperature dependence of optical and magneto-optical properties of $Tb_3Fe_5O_{12}$ thin films. *L. Beran*[1,2], E.R. Rosenberg[3], J. Setina[1], L. Nowak[1], A. Quindeau[3], C. Ross[4] and M. Veis[1] *1. Institute of Physics, Charles University, Prague, Czechia; 2. Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, MA, United States; 3. Massachusetts Institute of Technology, Cambridge, MA, United States; 4. Dept. Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, MA, United States*

In the field of spintronics, most desired attributes for new materials are perpendicular magnetic anisotropy (PMA) and long spin lifetimes. Ferrimagnetic garnets is one of the promising material groups that could fulfill such requirements together with the ability to tune structural and magnetic properties for the exact purpose of the application. Here we present a systematic study of temperature dependence of optical and magneto-optical properties of $Tb_3Fe_5O_{12}$ (TbIG) thin single crystal films. Investigated 40 nm thick samples were grown on (111) Gallium Gadolinium Garnet (GGG) substrates by pulsed laser deposition. X-ray diffraction measurements confirmed their crystallinity and absence of any other phase. Due to magnetoelastic anisotropy the films exhibit PMA, as was confirmed by means of magneto-optical magnetometry. Atomic force microscopy indicated surface roughness of less than 1 nm taken over a 1 μm^2 area for all used samples. The films show strong magneto-optical Kerr effect (MOKE) in spectral range from 2.4 to 5.6 eV. Here we present temperature dependence of these spectra ranging from 15 to 600 K. In the area between 295 and 325 K the spectra show clear transition through a compensation point (Fig 1). From these data we determined the compensation temperature to be 307.5 K. For full description of optical response of this material we also obtained optical properties by the means of spectroscopic ellipsometry. Furthermore, we used Yeh formalism to calculate off-diagonal term of permittivity tensor. The correctness of this derivation was confirmed by calculation of Farady rotation spectra and compared with measured data (Fig 2). The obtained permittivity tensor shows clear resemblance with other iron-based garnets such as Yttrium Iron Garnet (YIG)[1]. The main difference is noticeable at low temperatures in the region around 3 eV where the spectral features originating in Tb sublattice are located. Closer to compensation temperature we can address spectral features to individual iron sublattice which allows further observation of magnetization ordering under various conditions.

T5-05. Amorphous Magnetic Photonic Crystals Based on Fe_3O_4@ SiO_2 Nanospheres with Non-iridescent Structural Colors. *A. Zheng*[1], L. Zhuang[1], W. Wang[1], J. Zhong[1], T. Wang[1] and L. Ye[1] *1. Sun Yat-sen University, Guangzhou, China*

In recent years, amorphous photonic crystals (APCs) that possess only short-range order have received considerable attention due to their unique structural features, resulting in vivid non-iridescent structural colors[1,2]. APCs show many interesting and unique optical properties, representing a novel kind of optical media despite being much less studied than conventional PCs because of the difficulties in both fabrication and theoretical treatment. In this experiment, amorphous magnetic photonic crystals(AMPCs)based on Fe_3O_4@SiO_2 nanospheres are synthesized by using a two-step method. The formed AMPCs display different structural colors due to the controllable size of Fe_3O_4@SiO_2 nanospheres. Isotropic photonic pseudogap is formed since the sizes of nanospheres are comparable to the visible wavelengths. The reflection spectral peak ranges from 400 to 750 nm. The 2-dimensional fast Fourier transform(2DFFT)gives a clear evidence about the short-range order structure of our AMPCs, and the simulation results match well with the experimental data. These AMPCs show potential applications in color-related fields including paints, cosmetics and textile, etc., and due to the magnetism of our AMPCs, recycling and reuse are possibly realized.

T5-06. Evolution of Griffiths phase and critical exponents by site dilution of Ga^{3+} in $SrRuO_3$. *R. Gupta[1] 1. School of Physical Sciences, Jawaharlal Nehru University, New Delhi, India*

Here, we report the evolution of magnetic behavior in doped Ru based perovskite structure of $SrRu_{1-x}Ga_xO_3$ (x = 0.0, 0.05, 0.1 and 0.2) series. The parent $SrRuO_3$ has an orthorhombic-*Pbnm* structure which also sustained by Ga doping and also showing a significant change in structural parameters at room temperature. The polycrystalline $SrRuO_3$ is known to as an itinerant ferromagnet (FM) with $T_c \sim 160$ K [1] and having massive bifurcation between zero-field-cooled (ZFC) and field-cooled (FC) magnetization below T_c which is decrease by Ga doping. Further analysis of dc magnetization, the inverse susceptibility (χ^{-1}) in paramagnetic (PM) state and high-temperature region fitted by modified Curie Weiss law (CWL) in the form of $\chi(T) = \chi_0 + [C/T-\theta_p]$. The effective PM moment ($\mu_{eff} = [3k_BC/N]^{1/2}$) and θ_p decreases on Ga doping. The χ^{-1} (T) revealed some upward deviation by Ga doping from CWL behavior above T_c due to the formation of FM clusters in the PM background which has characterized as Griffiths phase (GP) [2]. The GP confirm by increasing λ value by linear fitting of $\chi^{-1} = (T - T_c)^{(1-\lambda)}$ ($0<\lambda<1$) and this behavior increases by Ga doping. The evolution of Griffiths temperature (T_G) decreases as the concentration of Ga doping increases. The critical exponent fitting of FC magnetization of $SrRuO_3$ close to T_c has showing mean field type behavior [4] in the form of $M(T) = M_0(T_c-T)^{\beta}$, where β is the critical exponent. By Ga doping, the value of β increases similar to Ti doping at Ru site [3]. The isothermal magnetization at 5 K of $SrRuO_3$ is showing hysteresis which also sustained by Ga doping with decreasing saturation moment (μ_H). The Arrott's plots also confirm FM nature with decreasing value of spontaneous magnetization (M_S) [5]. The observation of Rhodes-Wohlfarth ratio [6], the value of q_c/q_s is increased by Ga doping showing the itinerant nature of $SrRu_{1-x}Ga_xO_3$ series, where $S=q_c/2$ in $\mu_{eff} = g[S(S+1)]^{1/2}$and $q_s = \mu_H$.

T6-01. Noise in Mesoscale Magnetic Dots from Random telegraph Noise to 1/f Noise. B. Costanzi[2], D.E. Endean[3] and *D. Dahlberg*[1]
1. Physics, University of Minnesota, Minneapolis, MN, United States;
2. Physics, Carleton College, Minneapolis, MN, United States;
3. Aerospace, Honeywell International, Plymouth, MN, United States

We have investigated the noise in permalloy magnetic square shaped dots. With the application of a magnetic field to control the energy barriers, individual dots we observe random telegraph noise (RTN). The noise spectrum of chains of dots, the superposition of the RTN of individual dots, exhibits a 1/f noise spectrum. The samples are prepared using e-beam lithography techniques developed at the University of Minnesota[2]; the lengths of the sides of the squares are as small as 40nm; the thickness of the permalloy is 10nm. The dot dimensions best for the noise studies explored have been on the order of 200nm. In this size range the in-plane anisotropy energies are lowest with the net magnetization direction perpendicular to the edges and highest along the diagonals; this results from the interplay of the exchange and dipolar energies[3]. To each dot four non-magnetic leads are attached for four terminal resistance measurements of an individual dot. The direction of the magnetization can be determined by the anisotropic magnetoresistance e.g. if current is passed between two electrodes on one side of a permalloy square and the voltage measured between the two on the other side the measured resistance is different if the net magnetization is co-linear with the current or perpendicular to the current. The magnitude of the energy barrier separating these two states relative to the current magnetization directions can be controlled by application of a magnetic field along the diagonal direction. The in-plane anisotropy energies can be mapped out[4] and over a relatively broad range of temperatures and magnetic fields applied along a diagonal RTN can be observed (see Fig. 1). As seen in this figure as the resistance changes from a high value (net magnetization co-linear with the current), or up state, to a low resistance (perpendicular to the current), or down state, over the course of tens of milliseconds. The average dwell time for the up and down times is given by an Arrhenius law with the argument of the exponential consisting of the ratio of the energy barrier to the thermal energy or T. Given the exponential dependence of the average dwell times sensitivity, small variations in the energy landscape can produce average dwell times that differ by orders of magnitudes between seemingly identical dots. Although the individual dots exhibit RTN, the composite noise from chains of dots exhibit a 1/f noise spectrum with an example of the observed voltage fluctuations in figure 2. This is consistent with the prediction of Van der Ziel[5] over 50 years ago. In studying these emergence of the 1/f noise from the RTN of individual dots we have investigated chains of dots of 9 to 81 dots in length. Summarizing our results, we find a 1/f spectrum of about two decades can arise from chains of only two dots with dwell times separated by about an order of magnitude. In general, we find it takes about one dot per decade of 1/f noise if the dot well times are separated by the number of decades in a given chain. We also find the 1/f noise for the dots chains can rise above the thermal and shot noise around 10 kHz when the signal from a single dot is only 10^{-4} of the total signal measured. Measurement of the distribution of coercivities was used to estimate the distribution of dwell times and we find the distribution consistent with that assumed by Van der Ziel, but with only a handful of dots required to achieve 1/f noise over many decades of frequency space, in contrast to the continuum of RTN signals assumed by Van der Ziel. This work was supported by ONR Grant No. N00014-11-1-0850 and NSF GRANT DMR 1609782. Part of this work was carried out in the Minnesota Nanocenter at the University of Minnesota, and in the University of Minnesota Characterization Facility, both of which are funded by the NSF NNIN.

Skyrmions are swirling spin textures with a great potential in data storage industry, together with their intriguing real space spin topological properties [1-3]. In this talk, we will first discus the experimental progress of electrical control of magnetic skyrmions including generation and manipulation in magnetic multilayers [4-6]. We will demonstrate experimentally the accumulation of skyrmions on the side of devices – the skyrmion Hall effect [7-8]. Thirdly, investigation of sub-50 nanometer skyrmions in a Pt/Co/Ir multilayer [9] in the absence of magnetic field will be conducted by using Lorentz transmission electron microscope, through which we further demonstrated a robust skyrmion phase existing for temperature up to 245 Celsius. We will finally discuss some future research topics.

Femtosecond laser pump-probe technique was utilized to study optical excitation and detection of picosecond shear (S) acoustic pulses (AP) in highly magnetostrictive Terfenol films. We report two magneto-elastic mechanisms of S strains generation in this type of materials. First, transient demagnetostriction, i.e. the laser-induced release of Terfenol static built-in strains and second, ultrafast magneto-elastic mode conversion at Terfenol/dielectric interface. Both are responsible for efficient picosecond shear pulses generation in such highly magnetostrictive material. The frequency bandwidth of the generated strain pulses lies in the order of hundreds of GHz. Our study provides the first experimental insight to the picosecond shear acoustic waves excitation by laser-induced demagnetostriction mechanism. By probing the excited ultrafast longitudinal L and shear S AP during ultrafast demagnetization of Terfenol ($TbFe_2$)/SiO_2 hybrid samples, we demonstrate the possibility to assess crucial information on the spin-lattice relaxation channel. We performed time resolved MOKE spectroscopy on $TbFe_2$, which is known as one of the most magnetostrictive materials. Several acoustic echoes L, S, 2L manifest themselves on top of the demagnetization background, see Fig 1. Their acoustic polarization and arrival time can be estimated knowing the L and S acoustic velocities in SiO_2 layer as well as its thickness. Echoes centered at 555 ps, 935 ps, 1310 ps can be distinguished as SAP from the estimation of their arrival time, which fits the expected time of shear waves propagation in the SiO_2 layer. S pulse of few ps duration evidences the ultrafast release of magnetostriction which is the only possible mechanism of S generation in the present sample[1], while two other correspond to an unexpected mechanism of ultrafast magneto-acoustic mode conversion of the LAP into SAP during the acoustic reflection. Our results show that fs laser excitation of highly magnetostrictive Terfenol thin films leads to generation of ps SAP. These results are of great interest for the viscoelastic investigation of many materials in GHz-THz frequency range[2].

T6-04. Spherical Janus particles with Exchange-Bias caps.
A.I. Tomita[1], R. Huhnstock[1], M. Reginka[1], D. Holzinger[1] and A. Ehresmann[1] *1. Experimental Physics IV, Universität Kassel, Kassel, Germany*

Janus particles (JPs) are the type of dual-faced particles possessing differing chemical or physical characteristics on the two opposing sides and are of potential use in biotechnological applications due to their multitasking abilities. By design, they offer unique opportunities to experimentally study and unravel the advantages brought out by their different parameter dependencies and accessible degrees of freedom. A particular class of JPs are the spherical magnetic JPs typically consisting of a non-magnetic spherical particle and a magnetic cap. In contrast to JPs already discussed in literature, with caps that can have a perpendicular to surface anisotropy, we introduce JPs with caps composed of an Exchange-Bias (EB) layer system, where the volume averaged remanent magnetization vector does not contain the center of mass of the particle. The magnetization distribution in the curved cap is discussed by micromagnetic simulations. The motion characteristics of these JPs in a liquid environment, within engineered stray field landscapes (fabricated by light-ion bombardment induced patterning) superposed by dynamically changing external magnetic field pulses will be discussed.

T7-01. Interface and confinement driven spin correlations in titanate quantum well heterostructures. *S.D. Wilson*[1], R. Need[2], S. Stemmer[1], M. Graf[3], P. Marshall[1], B. Isaac[1], B.J. Kirby[2] and J. Borchers[2] *1. Materials, University of California, Santa Barbara, Santa Barbara, CA, United States; 2. NIST Center for Neutron Research, Gaithersburg, MD, United States; 3. Boston College, Chestnut Hill, MA, United States*

In this talk I will present our recent experimental work exploring magnetic correlations within $SrTiO_3$ quantum wells embedded within a rare earth titanate Mott insulating matrix. Previous studies have shown that control of the confinement of polarity-induced charge carriers within the $SrTiO_3$ quantum wells of these heterostructures induces a host of unusual magnetotransport behaviors. Examples include metal to insulator transitions, pseudogap openings, and signatures of quantum critical transport that appear as the quantum wells are thinned and the corresponding carrier densities diverge. Here I will present two studies: The first shows that $SrTiO_3$ wells embedded within the ferrimagnetic Mott host $GdTiO_3$ acquire ferromagnetic order below a critical well thickness and that the onset of this ferromagnetism maps to the suppressed order parameter responsible for quantum critical behavior observed at this same thickness. The second study shows that $SrTiO_3$ wells embedded within the antiferromagnetic Mott host $SmTiO_3$ instead manifest incipient antiferromagnetism below a critical temperature. The onset of this quasistatic antiferromagnetism in $SrTiO_3/SmTiO_3$ heterostructures directly maps to the previous observation of a pseudogap opening in this system as well as the onset of quantum critical magnetotransport behavior. By identifying the onset of magnetic order/correlations in the quantum wells of each of these heterostructures, we provide a direct link between prior observations of anomalous electron transport across the interface-induced high density two dimensional electron gases and the coinciding symmetry breaking within the quantum wells themselves.

T7-02. Structural distortions and Oxygen vacancies enhance interfacial magnetism in $La_{0.7}Sr_{0.3}MnO_3/SrTiO_3$ heterostructures. J. Beltrán[1], J. Grandal[1], J. Tornos[1], C. León[1], J. Santamaria[1], M. Varela[1] and *C. Muñoz*[2] *1. GFMC, Física de Materiales, Universidad Complutense de Madrid, Madrid, Spain; 2. Instituto de Ciencia de Materiales de Madrid (ICMM), Consejo Superior de Investigaciones Científicas (CSIC), Madrid, Spain*

Interfacial coupling of lattice, charge, orbital and spin degrees of freedom in $La_{0.7}Sr_{0.3}MnO_3/SrTiO_3$ (LSMO/STO) heterostructures induces emergent phenomena with great potential technological relevance, although the presence of an elusive magnetic-dead-layer reduces their applicability. Here, we report on the mechanisms underlying interfacial magnetism controlled by local structural distortions and oxygen vacancies at LSMO/STO interfaces. We combine first-principles density functional theory (DFT) with advanced electron microscopy techniques, such as electron energy-loss spectroscopy in the aberration-corrected scanning transmission electron microscope, to study such local phenomena. LSMO is a polar ferromagnetic metal and holds full spin polarization, while STO is a non-polar, non-magnetic insulator. DFT calculations reveal that the ideal interface -without chemical disorder or defects- presents local structural distortions but no charge transfer to the STO. The out-of-plane lattice expands at the interface while oxygen vacancies effectively induce a partial occupancy of the Ti *d*-orbitals, see Fig 1. Atomic resolution images of LSMO/STO epitaxial interfaces grown by high-pressure O_2 sputtering, indeed exhibit an increase of the out-of-plane lattice parameter at the interface, pointing to a local structural reconstruction as the significant pathway to compensate the interface polar discontinuity. In addition, energy-loss magnetic chiral dichroism allows probing magnetic quantities with atomic resolution. The dichroic signal at both the Mn $L_{2,3}$ and the Ti $L_{2,3}$ edges is enhanced near the interface, revealing a local increase of both Mn and Ti magnetic moments in good agreement with the calculations. Aside from the lattice expansion and octahedral tilts deformations, calculations show a hole depletion at the Mn interface planes, enhancing interface magnetism. Our results indicate that promoting structural distortions at the interface is a promising approach to improve magnetism at LSMO/STO heterostructures.

T7-03. Magnetic Coupling in $SrRuO_3/La_{0.7}Ba_{0.3}MnO_3/SrRuO_3$ Trilayers Probed With X-Ray Magnetic Circular Dichroism. *C. Piamonteze*[1], F. Bern[2], S. Avula[1], M. Studniarek[1] and I. Lindfors-Vrejoiu[3] *1. Swiss Light Source, Paul Scherrer Institut, Villigen PSI, Switzerland; 2. Fakultät für Physik und Geowissenschaften, Abteilung Supraleitung und Magnetismus, Universität Leipzig, Leipzig, Germany; 3. II. Physikalisches Institut, Universität zu Köln, Köln, Germany*

The possibility of producing high quality ultra-thin films and heterostructures combining different complex oxides provides further degrees of freedom to tailor new electronic and magnetic properties. $La_{0.7}Sr_{0.3}MnO_3$ (LSMO) exhibits a large spin polarization and its use as a ferromagnetic

electrode in magnetic tunnel junctions has been exploited [1]. One important obstacle to its application is the finding of a large decrease in T_c when going to ultra-thin LSMO layers deposited on $SrTiO_3$, which is attributed to a magnetic dead layer [2]. $SrRuO_3$ (SRO) constitutes a rare example of an itinerant ferromagnetic oxide and it has been used as a conducting electrode in oxide electronics. Superlattices of LSMO/SRO have been shown to exhibit a strong antiferromagnetic exchange coupling through the interface [3,4]. On top of that, the magnetocrystalline anisotropy is such that LSMO has an in-plane easy axis, while SRO has out-of-plane easy axis. Therefore, these systems show a complex magnetic behavior as a function of field and temperature where the magnetocrystalline anisotropy and interface antiferromagnetic coupling compete with each other. Interestingly, in these systems LSMO holds its ferromagnetic coupling down to a thickness of 2 unit cells (u. c.) [5,6]. In this work, we have studied trilayers of $SrRuO_3$(3 u.c)/$La_{0.7}Ba_{0.3}MnO_3$(x u.c.)/$SrRuO_3$ (3 u.c.) with varying x [6] using x-ray magnetic circular dichroism (XMCD) at the Mn $L_{3,2}$-edges and Ru $M_{3,2}$-edges. Our XMCD results unquestionably show a remanent Mn moment for 3|2|3 above SRO T_c, as pointed out previously [5,6]. The element specific magnetization loops measured with XMCD allow disentangling the contribution of each ferromagnetic layer. For 3|1|3, SRO is parallel to the field both in-plane and out-of-plane while LBMO is antiferromagnetically coupled to it. On the other hand, for 3|3|3 the magnetocrystalline anisotropy of the single layers play an important role, with SRO being parallel to the applied field for out-of-plane magnetization, while for in-plane magnetization LBMO is parallel to the external field. Our results will be discussed based on the competition of the various coupling mechanisms present.

T7-04. Dependence of the Dzyaloshinskii-Moriya Interaction in Pt/Co/Oxide Trilayers on the Degree of Ferromagnet Oxidation. D. de Souza Chaves[1], V. Krizakova[1,2], *J. Vogel*[1] and S. Pizzini[1] *1. Institut Néel, CNRS, Grenoble, France; 2. Brno University of Technology, Brno, Czechia*

We have used magneto-optical Kerr microscopy to study domain wall (DW) dynamics and to address the strength of the Dzyaloshinskii-Moriya interaction (DMI) in Pt/Co/MOx samples (M=Al or Gd) with perpendicular magnetic anisotropy (PMA). Al and Gd layers were grown with a thickness gradient and consequently exposed to oxygen plasma, so that the top Co interface presents a gradient of oxidation along one sample direction. Two methods were used to obtain the DMI strength. The first consists in measuring the DW speed driven by an easy-axis field H_z, while an in-plane field H_x is applied in the direction perpendicular to the domain wall direction. The DW speed depends on the strength of H_x and presents a minimum at a field H_{DMI} which compensates the local effective DMI field. The strength of the DMI can be obtained from the value of H_{DMI} [1, 2]. The second method relies on the fact that in systems with DMI the field-driven DW velocity saturates after the Walker field, and the saturation velocity is proportional to D/M_s (D is the DMI energy density and M_s the spontaneous magnetization) [3]. The two methods were tested on reference samples giving similar results. We have measured the DMI strength at several positions of the wedged Pt/Co/MOx samples. In both Pt/Co/AlOx and Pt/Co/GdOx, the DMI strength strongly depends on the degree of oxidation of the Co/Al(Gd) interface. The DMI presents a maximum for the degree of oxidation giving rise to the maximum of the PMA. Since this maximum corresponds to the appearance of a significant density of Co–O bondings at the Co/AlOx interface [4] we deduce that the change of DMI has the same origin as the change of PMA and is directly related to the degree of oxidation of the top Co interface. This result is in agreement with recent *ab-initio* DFT calculations suggesting that the magnitude and the sign of the DMI can be controlled by tuning the oxygen coverage of the magnetic film [5].

Finding ways to control the spin-dependent properties of two-dimensional electron states at surfaces and interfaces is a major challenge for the elaboration of novel spin-based devices. We report here about ARPES investigations on layered RT_2Si_2 compounds (R = rare-earth, T = Co, Rh, Ir) with a tetragonal structure consisting of R layers separated by rigid bound Si-T-Si blocks. Due to this structure, respective single crystals may easily be cleaved between R and Si layers, resulting in R- or Si-terminated surfaces, which can be clearly distinguished in the spectra. The Si-terminated surfaces are characterized by a Shockley surface state at the M-point and a surface resonance in the form of a Dirac-cone at the Gamma-point. The Shockley state extends over the whole outermost Si-T-Si block and is subject to strong spin

orbit splitting and Rashba effect. Although the compounds order antiferromagnetically in the bulk by arranging the magnetic moments of the 4f states within the planes ferromagnetically, but antiferromagnetically between adjacent R-layers, the surface state (and to less extend also the Dirac-cone) show itinerant ferromagnetism. Respective Stoner-like spin-splittings are a result of exchange interaction with the 4f states of the R atoms in the fourth subsurface layer and reflect the spin orientation of the latter [1-3]. Thereby, a clear distinction can be made between in-plane, perpendicular to plane or inclined orientation of the 4f moments [3]. Interestingly, in $EuRh_2Si_2$ the Curie-temperature (T_C = 42 K) of the surface state exceeds by far the Neel-temperature of the bulk (T_N = 24,5 K) pointing to an enhanced stabilization of the magnetic order of the 4f moments due to the surface state [1]. The Yb-Ir-compound is a heavy Fermion system and behaves paramagnetically. Here, hybridization with the 4f-subsurface states leads to a reduced mobility of the electrons in the Rashba-split surface state close to the Fermi energy as reflected by kinks in the dispersion curves.

Many of Fe-based superconductors exhibit a "nematic" phase where four-fold symmetry of the lattice is spontaneously broken without magnetic order. Angle-resolved photoemission spectroscopy (ARPES) measurements of FeSe are able to give a unique insight into the evolution of the electronic structure in the nematic phase. ARPES measurements have revealed substantial shifts of both the electron and hole bands associated with the onset of the nematic order parameter, however the interpretation of these data has caused some controversy due to the formation of twin orthorhombic domains in samples. Our high-resolution ARPES results obtained on FeSe crystals "detwinned" by application of mechanical strain, reveal remarkable anisotropies hidden in the measurements of twinned samples. We find that the low temperature Fermi surface of FeSe consists of one elliptical hole pocket and only one orthogonally-oriented electron pocket. Finally, we find that in detwinned NaFeAs samples in nematic phase (below the structural transition at T_S= 54 K but above the antiferromagnetic transition at T_N= 43 K) spectral weight is also detected on only one elliptical electron pocket. This dramatic anisotropy is likely to arise because of coupling to a fluctuating antiferromagnetic order in the nematic phase. In the long-range ordered antiferromagnetic state below T_N, this single electron pocket is backfolded and hybridizes with the hole bands, leading to the reconstructed Fermi surface. By careful analysis of the kz variation, we show that the backfolding of spectral weight in the magnetic phase has a wave vector of (π,0,π), with the c-axis component being in agreement with the magnetic ordering in NaFeAs observed by neutron scattering. Our results clarify the origin of the tiny Fermi surfaces of NaFeAs at low temperatures and highlight the importance of the three-dimensional aspects of the electronic and magnetic properties of Fe-based superconductors.

Department of Advanced Materials Science, The University of Tokyo, Kashiwa, Japan*

The structure of the superconducting gap in unconventional superconductors holds a key to understand the momentum-dependent pairing interactions. In superconducting FeSe, there have been controversial results reporting nodal and nodeless gap structures, raising a fundamental issue of pairing mechanisms of iron-based superconductivity [1,2]. Here, by utilizing polarization-dependent laser-excited angle-resolved photoemission spectroscopy, we report a detailed momentum dependence of the gap of FeSe single crystals [3], which form unidirectional- (nematic-) twin domains below structural transition at 90 K. We succeeded in observation of multi-domain and single-domain regions due to small laser spot size. We confirm that the superconducting gap has a twofold in-plane anisotropy, associated with the nematicity of the normal state electronic structure [4]. In multi-domain regions, we clearly find finite gap minima near the vertices of the major axis of the elliptical zone-centered Fermi surface, indicating a nodeless state. In contrast, the single-domain gap drops steeply to zero in a narrow angle range, evidencing for nascent nodes. Such unusual node lifting in multi-domain regions can be explained by the nematicity-induced time-reversal symmetry breaking near the twin boundaries [5].

T8-03. FeSe under uniaxial strain: influence on structural and superconducting transitions. *A. Steppke*[1], J. Bartlett[1], S. Hosoi[2], T. Shibauchi[2], A. Mackenzie[1] and C. Hicks[1] *1. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 2. Department of Advanced Materials Science, The University of Tokyo, Tokyo, Japan*

FeSe is a model system for the iron-based superconductors. It undergoes a nematic transition at $T_S \approx 90$ K, before becoming superconducting at $T_c \approx 9$ K. In contrast to the related superconductors, long-range magnetic order does not appear beneath the nematic transition at ambient pressure, which raises questions on the origin of the nematic (and structural) transition in FeSe. Here, we report results of resistivity measurements of FeSe under applied uniaxial strain. We apply strain both along the Fe-Fe bond direction and at 45°; the former is a conjugate field to the nematic transition. We apply both compressive and tensile strains. We show that the response differs strongly between these two directions. For strain along the Fe-Fe bond direction, the T_S is supressed under both compression and tension. The dependence of T_c on applied strain is linear within our applied strain range, and in agreement with previous work using thermal expansion and heat capacity measurements.

Applied Physics, Stanford University, Stanford, CA, United States*

In most high-temperature Iron-based superconductors (SC), the transition temperature T_c reaches its maximum when a nematic and a magnetic phase are suppressed. Therefore, it is important to understand the impact of these two ordering phenomena on the electronic structure. In the 122 Iron-based SC, it is hard to disentangle the infuence of the nematic and magnetic ordering as they appear almost at the same temperature. Additionally, simple calculations are not able to reproduce the observed bandstructure in the ordered state. Here, we study the prototype parent compound $BaFe_2As_2$ in the ordered and the normal state using angle-resolved photoemission spectroscopy (ARPES). The high quality of the samples and the spectra enables us to identify the folded bandstructure of twinned crystals in the ordered state in high detail. In particular, we can extract the nematic splitting between bands dominated by d_{xz} and d_{yz} orbital character. Its strong momentum dependence does not correlate with the momentum dependence of the orbital character in each band. Additionally, we fnd the corresponding binding energy shift to be highly asymmetric compared to the normal state dispersion. The description of the nematic state in $BaFe_2As_2$ therefore requires models beyond an on-site energy splitting. Additionally, we fnd a renormalization of all observed bands inside the ordered state. Applying these changes to the experimentally determined bandstructure in the normal state, we can model the folded bandstructure in the ordered sate and fnd a very good agreement with the observed ARPES spectra.

T8-05. Tuning the interplay between nematicity and spin fluctuations in $Na_{1-x}Li_xFeAs$ superconductors. *S. Baek*[1], D. Bhoi[2], W. Nam[2], B. Lee[2], D. Efremov[1], B. Büchner[1] and K. Kim[2] *1. IFW Dresden, Dresden, Germany; 2. Seoul National University, Seoul, The Republic of Korea*

Strong interplay of spin and charge/orbital degrees of freedom is the fundamental characteristic of the iron-based superconductors (FeSCs), which leads to the emergence of a nematic state as a rule in the vicinity of the antiferromagnetic state. Despite intense debate for many years, however, the origin of the nematic state—whether it is driven by spin or charge/orbital degree of freedom—remains unsettled. To elucidate this issue, we investigate the doping-temperature phase diagram of $Na_{1-x}Li_xFeAs$ up to $x = 0.1$ which were successfully synthesized for the first time by overcoming intriguing difficulties in forming single phase materials. By use of transports, magnetization, and ^{75}As nuclear magnetic resonance (NMR) measurements, we observe a striking transformation of the relationship between nematicity and spin fluctuations (SFs) with doping; For $x < 0.03$, the nematic transition *promotes* SFs which diverges towards a static spin density wave (SDW) order. In contrast, for $x > 0.03$, the SDW transition vanishes, and the system undergoes a phase transition at a temperature T_0 into a new nematic state, which *suppresses* SFs. This implies that as x exceeds a critical doping $x \sim 0.03$ nematic fluctuations becomes strongly entangled with SFs, resulting in a distinct nematic state associated with charge/orbital order. Such a drastic change of the spin fluctuation spectrum associated with nematicity by small doping is highly unusual, and provides fresh insights into the origin and nature of nematicity in FeSCs.

Temperature-doping phase diagram for $Na_{1-x}Li_xFeAs$. T_{SDW}, T_{nem}, $T_c^ρ$, and $T_c^χ$ were obtained by our transport, magnetization, and NMR measurements which turn out to be consistent one another. The sharp transition between the spin-density-wave to bulk superconducting (SC) states is observed at the critical doping $x_c \sim 0.03$. The emerging phase at T_0 before entering the bulk SC state is seemingly connected to the nematic transition at lower dopings. The shade of green below T_c schematically represents the SC volume fraction.

T9-01. Fermi surface instabilites in Kondo lattices: Ce,Yb, and U. *G. Knebel*[1], A. Pourret[1], D. Aoki[2] and J. Flouquet[1] *1. CEA / INAC / Pheliqs, Univ. Grenoble Alpes, Grenoble, France; 2. IMR, Tohoku University, Oarai, Japan*

Fermi surface instabilities have regained interest very recently as they are strongly connected to the change of the ground state in strongly correlated electron systems as function of tuning parameters like pressure, doping, or magnetic field. Usually the electronic band structure is a rather robust property of the metallic state especially when applying magnetic field. However, in heavy fermion systems, the Fermi energy scale is significantly reduced and Zeeman splitting of the flat bands crossing the Fermi level can be so strong that spin split Fermi surface sheets can be continuously suppressed. Thus, the system can undergo a Lifshitz transition, which is a continuous quantum phase transition and referred in the literature as 2 1/2 order phase transitions using the Ehrenfest terminology. Here we will review Fermi surface instabilities in different heavy fermion Kondo lattice systems. In $CeRh_2Si_2$ the first order metamagnetic transition induced a drastic Fermi surface change due to the change of the localization of the 4f electrons [1]. In $YbRh_2Si_2$ a cascade of Lifshitz transitions appear due to the derenormalization of the quasiparticles under magnetic field [2]. Quantum oscillation experiments under magnetic field in UCoGe for a field along the easy magnetization axis show the occurrence of several Lifshitz transitions in the polarized phase [3]. Furthermore, details of the Fermi surface of URu_2Si_2 will be discussed. Fermi surface properties of heavy-fermion systems can be easily tuned by magnetic field. The Lifshitz transitions can be decoupled from intersite correlations and be driven only by changes in the local fluctuations induced by reaching a critical magnetic polarization.

Hochfeld-Magnetlabor Dresden, Dresden, Germany; 7. MPI Chemical Physics of Solids, Dresden, Germany*

The Kondo lattice material $CeRhIn_5$ can be tuned to a quantum critical point (QCP), either by applying pressure or high magnetic fields [1-3]. When pressure is applied, the Fermi surface changes upon crossing the QCP [4], but in high fields, there is a Fermi surface reconstruction within the antiferromagnetic state at $B^* = 30$ T, below the QCP at $B_{c0} = 50$ T [3]. Here we have probed the nature of the change of Fermi surface at B^* by measuring the magnetostriction, torque magnetometry, and the absolute specific heat in pulsed magnetic fields [5]. We reveal a field-induced itinerancy of the 4*f* electrons, where the Sommerfeld coefficient from the specific heat and spin dependent effective mass deduced from quantum oscillation experiments are significantly enhanced above $B_{onset} = 17$ T. Above this field, distinctly different behavior of the specific heat is also found in the magnetic state. These findings that the effective masses become heavier in the approach to B^*, together with the sudden appearance of new quantum oscillation frequencies, imply that this Fermi surface reconstruction is driven by the delocalization of the 4f electrons from a 'small' Fermi surface at low fields where the 4*f*-electrons are localized, to a 'large' Fermi surface at high fields where they are itinerant.

We show that magnetic moments in Ce- and Yb- based Kondo-lattice systems often align spontaneously along the magnetically hard axis of the crystalline electric field (CEF). This counterintuitive phenomenon was believed to be a rare case, but our comparative study suggests that this is rather the general case in these materials. We discuss and review the proposed theoretical scenarios for this kind of perpendicular order by analyzing differences and similarities between all these systems. Differences appear in properties such as Curie temperatures T_C, crystalline structures, size of the ordered moment and CEF ground state, while similarities lie in a usual Kondo temperature T_K of a few Kelvin, a comparable magnetic anisotropy and a non mean-field like transition in specific heat, hinting at an important role of fluctuations.

T9-04. $CeCu_5Mg$: a novel ternary member of the $CeCu_6$ family.
M. Giovannini[2], H. Michor[1], H. Ueda[3], N. Ackerl[1], K. Yoshimura[3] and *E. Bauer[1] 1. Insitute of Solid State Physics, Technische Universität Wien, Wien, Austria; 2. Department of Physics, University of Genova, Genova, Italy; 3. Department of Chemistry, Graduate School of Science, Kyoto University, Kyoto, Japan*

We report on the crystal chemistry and low temperature physical properties, i.e., magnetization, resistivity, magnetoresistance, and specific heat, of novel $CeCu_5Mg$, being crystallographically ordered in the solid solution $CeCu_{6-x}Mg_x$. The latter exhibits a discontinuity in the composition range $0.4<x<0.8$, i.e., tends to avoid the region of maximum disorder in between the two ordered structures $CeCu_6$ and $CeCu_5Mg$ (isotypic with $CeCu_5Au$). The electronic ground state of $CeCu_5Mg$ is a magnetically ordered Kondo lattice state with both, the onset temperature of long range magnetic order, T_M = 1.3 K, and the Kondo temperature, T_K ~ 2.3 K, being of comparable magnitude. The effective paramagnetic moment μ_{eff} = 2.46 mu_B is slightly reduced as compared to the Ce^{3+} free ion value.

T9-05. Skyrmion Defects and Competing Singlet Orders in a Half-filled Antiferromagnetic Kondo-Heisenberg Model on the Honeycomb Lattice.
C. Liu[1], P. Goswami[2] and Q. Si[3] *1. Physics, Rice University, Houston, TX, United States; 2. Department of Physics and Astronomy, Northwestern University, Evanston, IL, United States; 3. Rice University, Houston, TX, United States*

The global phase diagram of antiferromagnetic heavy fermions [1] raises the issue of how to access the paramagnetic spin singlet states from the antiferromagnetic order. Due to the interaction between the topological defects of the antiferromagnetic order parameter and underlying fermions, the defects can lead to the presence of the fluctuating competing orders inside the core of a topological defect [2]. In this regard, the interaction between fermions and skyrmion defects of an antiferromagnetic phase can have important consequences for understanding the global phase diagrams of heavy fermion material. Therefore, we studied the relation between fluctuating competing orders and skyrmion defect of the antiferromagnetic Kondo-Heisenberg model on a honeycomb lattice by starting from a non-linear sigma model representation of the local moments. By solving the exact eigenstates of underlying Dirac fermions in the presence of a single skyrmion configuration, we calculate the susceptibilities of different translational symmetry breaking charges, bond and current density wave orders, and translational symmetry preserving Kondo singlet formations. Based on the computed susceptibilities, we establish spin Peierls and Kondo singlets as dominant competing orders of antiferromagnetism, since their susceptibility gain huge enhancement due to the presence of skyrmion defect (Fig 1)[3]. The relative stability of these two orders is studied by varying the Kondo coupling (Fig 2) [3]. Once we increase the Kondo coupling, the skyrmion defects will eventually favor Kondo singlet order over the spin Peierls order, causing the transition from spin Peierls to Kondo phases. Our results provide new insight into the global phase diagram of the heavy fermion systems.

T10-01. Hidden order in hyper-honeycomb β-Li_2IrO_3. *J. Analytis*[1]
1. University of California, Berkeley, Berkeley, CA, United States

Magnetic honeycomb iridates are thought to show strongly spin-anisotropic exchange inter- actions which, when highly frustrated, lead to an exotic state of matter known as the Kitaev quantum spin liquid. However, in all known examples these materials magnetically order at finite temperatures, the scale of which may imply weak frustration. Here we show that the ap- plication of a relatively small magnetic field drives the three-dimensional magnet β-Li2IrO3 from its incommensurate ground state into a quantum correlated paramagnet. Interestingly, this paramagnetic state admixes a zig-zag spin mode analogous to the zig-zag order seen in other Mott-Kitaev compounds. The rapid onset of the field-induced correlated state implies the exchange interactions are delicately balanced, leading to strong frustration and a near degeneracy of different ground states.

T10-02. Novel quantum-entangled fully coherent phase in a 5d-electron insulating compound. *Z. Islam*[1], K. Willa[1], U. Welp[1], J. Ruff[1], Z. Diao[4], R. Das[1], A. Rydh[3], W. Kwok[1], H. Lee[2] and I.R. Fisher[2] *1. Argonne National Laboratory, Lemont, IL, United States; 2. Stanford University, Palo Alto, CA, United States; 3. Stockholm University, Stockholm, Sweden; 4. Halmstad University, Halmstad, Sweden*

Novel forms of magnetism are expected from exchange and spin-orbit interactions in double perovskites [1,2]. In particular, Ba_2NaOsO_6 (BNOO), a nominally cubic system, behaves as a ferromagnet (FM, T_c~6.8 K, ordered moment ~0.2 m_B per Os) with an unusual easy axis [3]. NMR/NQR studies have reported this ordered phase to be a novel canted FM (cFM) preceded by a local-symmetry breaking [4]. Using high-resolution x-ray scattering methods, we correlate lattice symmetry and magnetism in BNOO as a function of temperature and magnetic field. Even at 300K BNOO is tetragonal (T), undergoing a bulk global symmetry-breaking transition into a twinned orthorhombic (O) phase at low temperature. While there is some evidence of structural fluctuations in paramagnetic phase, calorimetric data [5], concurrently measured with diffraction, indicated T-to-O transition to occur just above T_c. In the phase below T_c, x-ray resonant scattering revealed a commensurate super-lattice peak of wave vector of q=(1,0,0) along orthorhombic a* (i.e. shortest axis of O phase) due to some staggered order. In a field normal to q, this staggered order saturates, indicating a coherent rotation of ordered domains as the FM component aligns with field, with some qualitative difference with M(H) data. Due to twins, bulk measurements are susceptible to effects of field applied along all three directions simultaneously, while scattering probes magnetic behavior of individual twins. This field-evolution of q satellite along with its angular, polarization, and azimuthal properties of x-ray scattering on resonance at Os L edge is indicative of an orbital-ordered phase with quantization (or principal) axis confined to the orthorhombic *bc* plane. Honeycomb-based iridates with strong spin-orbit (SO) coupling have taken central stage in condensed matter physics due to their potential to realize a Kitaev quantum spin liquid (QSL) state [1]. This non-trivial ground state, which has charge-less elementary excitations, emerges as a result of bond-directional exchange anisotropy rooted in the strong SO interaction at Ir sites and geometrical frustration inherent to the honeycomb lattice structure. While such novel ground state has not been realized, largely due to competing isotropic interactions (Heisenberg) that stabilize magnetic order and/or lattice distortions that relieve geometrical frustration, searches for Kitaev and related QSLs are ongoing. In this context, chemical doping and pressure studies on honeycomb iridates are being strongly pursued [2-7]. We have performed a thorough investigation of the electronic and structural response of β-Li_2IrO_3 to applied pressure with emphasis on understanding the drivers for a magnetically disordered state above P=1.5 GPa [3]. Using synchrotron x-ray and diamond anvil cell techniques we show that the suppression of net magnetization in applied field is accompanied by a sudden reconstruction of the electronic ground state (Fig. 1). The electronic reconstruction, which manifests a reduction in the effective spin-orbit coupling interaction in 5d orbitals, pushes β-Li_2IrO_3 further away from the pure J_{eff}=1/2 limit. Although lattice symmetry is preserved across the electronic transition, x-ray diffraction shows a highly anisotropic compression of the hyperhoneycomb lattice (Fig. 2), which affects the balance of bond-directional Ir-Ir exchange interactions driven by spin-orbit coupling at Ir sites. Evoking recent theoretical calculations [8] that use *precisely* this anisotropic Ir-Ir bond compression, an enhancement of symmetric anisotropic exchange over Kitaev and Heisenberg exchange interactions provide a possible route to realization of a QSL state in this hyperhoneycomb iridate at high pressures.

The metal-insulator transition in 5*d* transition metal oxide $NaOsO_3$ which occurs concomitantly with antiferromagnetic (T_{MIT}=T_N) has been proposed to be of Slater mechanism [1, 2, 3, 4]. However, there is no consensus and other mechanisms such as a Lifshitz transition have also been proposed. We employed non-resonant and resonant x-ray single crystal diffraction at the Os $L_{2,3}$ edges in order to obtain details of the Os electron density deformation across T_{MIT} and to determine the microscopic mechanism of the phase transition. In case of a Slater metal-insulator transition, there should be no change in the crystallographic symmetry and, indeed, our single crystal x-ray diffraction experiments find no evidence of crystallographic symmetry breaking across the metal-insulator transition. In addition, using an incident x-ray energy corresponding to the Os L_3 edge, we observe the emergence of a diffracted intensity at the (300) forbidden reflection at T_{MIT}=T_N for a specific energy E_A (see Fig. 1). The intensity of this space-group forbidden peak increases continuously with decreasing temperature and it is not of magnetic origin. Rather, we show that it is due to a change in the Os electron density which is associated with the onset of long range antiferromagnetic ordering. Thus, the main conclusions of our experimental results, namely the absence of crystallographic symmetry breaking and the presence of antiferromagnetic driven osmium electron density reconstruction, support the first realization of a Slater insulator, $NaOsO_3$.

Cornell University, Ithaca, NY, United States; 5. Microstructured Quantum Matter, MPI for Chemical Physics of Solids, Dresden, Germany; 6. National High Magnetic Field Laboratory, University of Florida, Tallahassee, FL, United States*

We present a detailed study of the magnetic anisotropy of $RuCl_3$ – a layered honeycomb structure of effective spin-1/2 moments. The strong spin-orbit coupling of ruthenium on this network leads to highly anisotropic and frustrated exchange interactions and an unconventional magnetic ground state. Recent neutron diffraction data reveal a continuum of excitations centered at the gamma point, suggesting the presence of emergent Majorana excitations associated with a Kitaev quantum spin liquid. It is still unclear, however, to which degree the magnetic exchange terms depart from the ideal Kitaev Hamiltonian and how this impacts the ground state. We use a newly developed technique, resonant torsion magnetometry, to explore the magnetic field and temperature evolution of the magnetic anisotropy of $RuCl_3$. The sensitivity of our technique allows us to measure a single structural domain, revealing the intrinsic anisotropy in the exchange interactions. At low temperatures, we observe a single magnetic transition into the zigzag-antiferromagnetically ordered phase. We map out the complex shape of the phase boundary as a function of field-orientation. With increasing field, long-range order is suppressed and a highly correlated state emerges. The high-field state is characterized by an unusual anisotropy that reflects the underlying Kitaev-like exchange interactions and persists to at least 50K—well above the Neel transition.

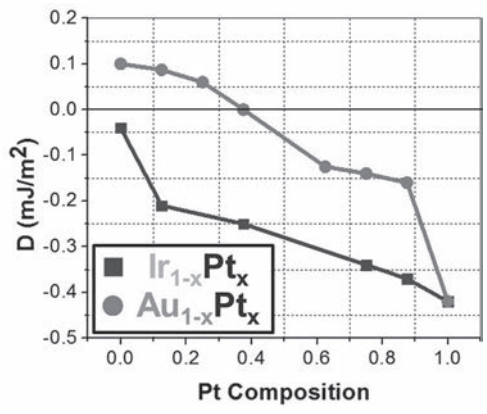
U1-01. Magnetic domain structure within kagome-compound $Co_3Sn_2S_2$. *A. Sugawara*[1], T. Akashi[1], M. Kassem[2], Y. Tabata[2], T. Waki[2] and H. Nakamura[2] *1. Center for Exploratory Research, Research and Development of Group, Hitachi Ltd., Hatoyama, Saitama, Japan; 2. Department of Materials Science and Engineering, Kyoto University, Kyoto, Japan*



Shandite-type $Co_3Sn_2S_2$ is a model kagome ferromagnet with uniaxial anisotropy. Our recent measurements on magnetization and susceptibility of single crystal specimens suggest presence of an unusual magnetic phase associated with slow spin relaxation below Curie temperature (T_c=174K) and under low external field[1)]. Recently skyrmionic bubble domain was reported for another frustrated kagome compound Fe_3Sn_2[2)]. The unusual phase may be related to such ordering. We report Lorentz microscopy observation of magnetic domain within $Co_3Sn_2S_2$ as a function of applied field and temperature. In order to obtain sufficient Lorentz deflection within the weak saturation magnetization flux density material (0.1T at 2K), we observed thick specimens (300-500 nm) using a 1MV field-emission transmission electron microscope equipped with a liquid-He cooling holder and a superconducting magnetizing stage. The domain wall (DW) motion is found to depend strongly on temperature. In the specimen rapidly cooled down below 30 K under zero field, maze domain pattern is observed. When the temperature is increased under the 500 Oe field, the DW's hardly move at low temperature, but begin to move at around 75K. The motion is activated with temperature, and the reversal complete at around 147K. The field required to the DW motion increases with decreasing the field. The large gap between field-cool and zero-field-cooled magnetization-temperature curves measured for bulk specimens can be explained in terms of DW depinning due to thermal activation. The domain formation on cooling through T_c is also examined. Formation of high-density bubble domains are observed at around 170K, and their reorganization on cooling according to shrink of individual small domains and also coalescence of the neighboring domains to form larger isolated bubble or elongated domains simultaneously. The spin configuration in individual bubble has not been determined, since the magnetic contrast is very weak slightly below Tc, and the dense bubble state is stable only in very narrow range of field and time. The domain configuration after cooling down to 160K is found to depend on cooling rate. The results suggest slow spin relaxation influence the domain reorganization.

U1-02. Effect of Seedlayer Composition on Interfacial DMI in Co/Ni Multilayers. *D.K. Lau*[1], J.P. Pellegren[1] and V.M. Sokalski[1] *1. Materials Science and Engineering, Carnegie Mellon University, Pittsburgh, PA, United States*

The interfacial Dzyaloshinskii-Moriya Interaction (DMI) in heavy metal/ferromagnet heterostructures has attracted significant attention in recent years because it stabilizes chiral magnetic features that are promising for next-generation spintronics. The heavy metal has predominantly been a pure element such as Pt, Ir, W, or Ta, but the range of possible alloy combinations for this seedlayer remain largely unexplored. The ability to tune DMI via composition without compromising other magnetic properties is critical for engineering future devices. In this study, we examine the impact of seedlayer composition alloying on DMI by studying asymmetric domain growth in Co/Ni multi-layers using Kerr Microscopy. Pt, Ir, and Au are known to have large spin-orbit interactions and exhibit significant DMI with reportedly different signs[1]. We explore the composition space between these three elements by sputtering film stacks grown on seedlayers of various compositions: TaN(3nm)/Pt(3.5nm)/Seedlayer(1.2nm)/[Co(0.2nm)/Ni(0.6nm)]2/Co(0.2nm) /Ta(0.8nm)/TaN(6nm). The seedlayers studied are composed of either PtxIr1-x or PtxAu1-x binary alloy systems (where x varies from 0 to 1) that showed little influence on magnetic properties such as anisotropy and coercivity. Based on recent reports for interpreting field driven domain wall velocity curves[2,3], we can infer the chirality and magnitude of the DMI in our layered systems. In our Pt/Ir system, we characterize a left handed chirality for the pure Pt seedlayer that monotonically decreases with Ir composition reversing sign around 75% Ir. We characterize a similar trend in the Pt/Au seedlayer system. (Figure 1) In addition to characterizing DMI in a thin film system, we also characterized domain wall behavior in current driven devices. Our findings are supported by current induced domain wall motion studies on the same systems to show that DMI magnitude can be directly influenced by seedlayer composition. As suggested in earlier works[4,5], the magnitude and direction of the DMI vector influences energy efficiency in domain wall devices. We have found that the efficiency of our domain wall devices decreases as a function of decreasing Pt composition and effectively, DMI. (Figure 2)

U1-03. Manipulating magnetic textures using dynamical strain.
A. Rushforth[1], R.P. Beardsley[1], R.M. Rowan-Robinson[1], S. Bowe[1], D. Parkes[1], R. Campion[1], K. Edmonds[1], C. Reardon[2], J. Zemen[1,3], S.A. Cavill[2] and B. Gallagher[1] *1. School of Physics & Astronomy, University of Nottingham, Nottingham, United Kingdom; 2. Department of Physics, University of York, York, United Kingdom; 3. Faculty of Electrical Engineering, Czech Technical University, Prague, Czechia*

Controlling magnetic anisotropy using strain, via the inverse magnetostriction effect, has emerged as a growing area of research and a promising route to ultra-low energy information storage and processing technologies. It has been shown that static strain can re-orientate the magnetisation vector in micron scale[1] and nanoscale devices[2], and that strain pulses can induce precession of the magnetisation[3]. Until recently, it has not been clear how strain can be used to manipulate magnetic textures, such as vortices and domain walls, deterministically. We will discuss recent work in which we have shown for the first time how dynamical strain profiles, varying on the timescale of the magnetisation dynamics, can induce deterministic switching of the chirality[4] and polarity[5] of vortex structures, and deterministic displacement of domain walls along nanowires[6]. Experimental measurements employing X-PEEM to image magnetic contrast are complemented by numerical and micromagnetic calculations to understand the underlying mechanisms. Potential ways to implement strain control of magnetic textures in information and communications technologies will be discussed.

U1-04. Symmetry Breaking in a Three-Dimensional (3D) Flux-Closure Domain Structure.
S. Lee[1], H. Han[1], N. Kim[1], M. Im[2], J. Hong[3] and K. Lee[1] *1. School of Materials Science and Engineering, Ulsan National Institute of Science and Technology, ULSAN, The Republic of Korea; 2. Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, United States; 3. Emerging Materials Science, Daegu Gyeongbuk Institute of Science and Technology, Daegu, The Republic of Korea*

In a submicron-scaled patterned ferromagnetic thin film, a flux-closure magnetization configuration along the pattern boundaries appears on the film plane to reduce the magnetostatic energy while compromising the exchange energy, e.g., a Landau domain structure in a square disk or a vortex structure in a circular disk [1]. As increasing the film thickness, a flux-closure configuration also forms along the thickness direction, resulting in a complex three-dimensional (3D) structure, asymmetric Bloch wall (ABW) with Néel caps [2, 3] as shown in Fig. 1(a). In this system, there are two degenerate states of ABWs whose rotating sense is clockwise (CW) or counter-clockwise (CCW) as shown in the insets of Fig. 1(a). By utilizing magnetic transmission soft X-ray microscopy (MTXM) [4], we observe that a simple Landau domain structure in a square disk transforms to an ABW structure as shown in Fig. 1(b). I.e., symmetric vortex core structure at the center of Landau domain is shifted along +y direction by an external in-plane magnetic field along +x direction and it abruptly transformed to the ABW structure. Surprisingly, we found the symmetry breaking in this transition; top and bottom vortex core structures are always separated to +x and –x directions, respectively. As a result, the rotation sense of the ABW is always CCW. In contrast, the opposite sense of ABW is formed when the magnetic field applied –x direction. From these results accompanying with micromagnetic simulations, we conclude that the energy states of ABW with opposite rotating sense are not the degenerate states anymore and energetically flavored orientation might be determined by the position of transformation.

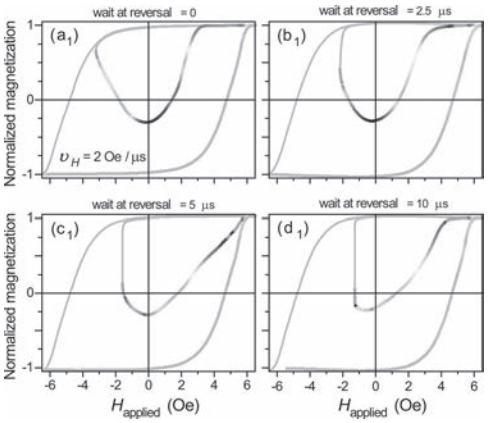
U1-05. Inverse generalized Preisach model of hysteresis. *P. Andrei*[1,2] and M. Dimian[3] *1. Electrical and Computer Engineering, Florida State University, Tallahassee, FL, United States; 2. Electrical and Computer Engineering, Florida A&M University, Tallahassee, FL, United States; 3. Department of Electrical Engineering and Computer Science, Stefan cel Mare University, Suceava, Romania*



The Preisach model describes the output of a hysteretic system in the form of a history-dependent double-integral of the Preisach distribution function [1]. Many efficient numerical implementations have been developed in the literature to compute the output as a function of input, however, inverting the Preisach operator (i.e. computing the input as a function of the output variable) remains a difficult task. Although the existence and continuity of the inverse of the Preisach operator has been theoretically demonstrated [2], the lack of efficient numerical algorithms to invert the operator has limited the area of applicability of the model and made it only sporadically used in the real-time control applications involving optimal design, sensors and actuators, and mechanical systems, where the hysteretic operator needs to be written in a differential form [3,4]. In this work we present an efficient numerical technique to invert the generalized Preisach model of hysteresis. The technique is based on defining the "up and down susceptibility" Preisach distributions and writing the model in the form of a differential equation that can be solved to compute the input variable as a function of the desired output. The computational cost of the inverted Preisach model is relatively low and is equal to the computational cost of the direct model. For this reason, the model can be used in real-time applications that required optimal control, design of systems with hysteresis, or sensors and actuators control. A more detailed discussion about the numerical implementation and overhead of the inverted model, and applications in smart materials will be presented at the meeting. We will also discuss about different ways to represent the susceptibility diagrams and about the numerical instabilities that arise when in inverting and integrating the model. Such instabilities are given by the fact that the inverse of the differential susceptibility vanishes for large positive and negative values of the input, which they are a direct consequence of the fact that not all output variations can be represented by the hysteretic system.

U1-06. Waiting time and relaxation effects on FORC-type measurement of magnetic wires. D. Cimpoesu[1], I. Dumitru[1], A. Domocos[1] and *A. Stancu*[1] *1. Department of Physics, Alexandru Ioan Cuza University of Iasi, Iasi, Romania*

Due to the popularity gained by the magnetic characterization of materials based on the measurement of the first-order reversal curves (FORC), the correct evaluation of the dynamic effects on the FORC diagram [1,2] is becoming important. The magnetic behavior of the sample in the starting point of the FORCs is a good way to evaluate the possible impact of the dynamic effects on the diagram. The negative susceptibility in the reversal points are a good indicator for that (for other hysteretic systems see [3,4]). In the figure we show a typical FORC behavior when the waiting time in the reversal field is increased in a dynamic FORC measurement of one magnetic wire with the technique presented in [2]. We see how each FORC is considerably changed only by this experimental parameter. One main point of this work is the evidence of the changes in the irreversible part of the FORC diagram with the value of the waiting time in the reversal points and with the measuring time in each point. The second point is to develop proper theoretical tools to understand these effects. On the theoretical side we have used two types of models. One is based on a very simple 1D chain of interacting Ising-Preisach hysterons with controlled interactions [5, 6]. The results give a good explanation for a typical FORC structure named usually as "boomerang shape" FORC diagram. This model evidences how the static diagram is losing its ability to give information about the components of a 1D chain of wires as the inter-wire interactions are increasing. Finally, we get a case in which the chain is controlled by an avalanche-type switching of the entire chain and the FORC distribution is collapsing towards one point. This is in fact what is observed in the switching of a long wire. In order to regain access to the distribution of the local sources of coercivity along an imperfect cylindrical wire we recommend the dynamic FORC technique and as a tool to simulate the results a Bouc-Wen-type model.

U1-07. Theory of Linear Spin Wave Emission from a Bloch Domain Wall. *N.J. Whitehead*[1], S.A. Horsley[1], T.G. Philbin[1], A.N. Kuchko[2] and V. Kruglyak[1] *1. Physics and Astronomy, University of Exeter, Exeter, United Kingdom; 2. Institute of Magnetism, Kiev, Ukraine*

The generation of small wavelength spin waves for future magnonic technologies will require nanometer-sized spin wave sources. Recent work has shown that pinned domain walls can generate spin waves when excited by a microwave external field [1-3] or spin-polarized current [4], even with wavelengths down to tens of nanometers. These results would benefit from a quantitative, theoretical explanation of the underpinning physics. We use analytical theory to demonstrate and explain the emission of exchange spin waves from a Bloch domain wall driven by a uniform microwave magnetic field directed perpendicular to the plane of the wall [5]. Crucially, we find that the spin wave emission (Fig. 1) is the result of a linear process, meaning that the spin wave frequency matches that of the excitation field. Furthermore, we explore the peculiar characteristics of the Pöschl-Teller potential well, which naturally represents the graded magnonic index due to the Bloch

domain wall in the Schrödinger-like linearized Landau-Lifshitz equation. This potential is known to allow 100% transmission of incident waves at any frequency, for certain parameters of the potential. We find that the domain wall is naturally sized not only to exhibit this property, but also to maximize its spin wave emission.

Using spin waves as information carriers in wave-based logic architectures is a promising approach to extend conventional charge-based circuitry with additional functionalities as well as to reduce energy losses connected to Joule heating [1,2]. For the realization of complex devices with high integration densities, efficient and flexible means have to be established to guide spin waves on the nanometer scale. Magnetic domain walls are highly versatile and reconfigurable, rendering them ideal candidates for building spin-wave channels that confine the information transport to nm-wide conduits [3-5]. Here, we investigate spin waves guided along Néel walls in microstructured thin-film elements made of Py and single crystalline Fe by μBLS and micromagnetic simulations [6]. In a first step, the spectral properties of the domain wall channel and surrounding domains are studied by recording the thermally excited spin waves. We then analyze the efficiency of excitation of channeled spin waves using microstructured antennas, in both the linear and non-linear regimes. For high pumping powers, we observe the generation of higher harmonic spin-wave modes that are localized to the edges of the domain wall channel. Additionally, we present first experimental observations of spin-wave transport along interconnected Néel walls in flux closure domain structures as well as along walls that suddenly change their direction at the edge of the microstructure (Fig. 1). Financial support from the Deutsche Forschungsgemeinschaft within programme SCHU 2922/1-1 is gratefully acknowledged. samples were prepared at the Nanofabrication Facilities (NanoFaRo) at the HZDR and the IPCMS [7].

U1-09. Correlation between compensation temperatures of magnetization and angular momentum in GdFeCo ferrimagnets. *Y. Hirata*[1], D. Kim[1], T. Okuno[1], T. Nishimura[1], D. Kim[2], Y. Futakawa[3], H. Yoshikawa[3], A. Tsukamoto[3], K. Kim[4], S. Choe[5] and T. Ono[1] *1. Institute for Chemical Research, Kyoto University, Uji-City, Japan; 2. Physics and Astronomy, Seoul National University, Seoul, The Republic of Korea; 3. Nihon University, Funabashi, Japan; 4. Department of Physics, Korea Advanced Institute of Science and Technology (KAIST), Daejeon, The Republic of Korea; 5. Seoul National University, Seoul, The Republic of Korea*

Determining the angular momentum compensation temperature of ferrimagnets is an important step towards ferrimagnetic spintronics, but is not generally easy to achieve experimentally [1, 2, 3]. We propose a way to estimate the angular momentum compensation temperature of ferrimagnets. We find a linear relation between the compensation temperatures of the magnetization and angular momentum in GdFeCo ferrimagnetic materials, which is proved by theoretically as well as experimentally. Figure 1 shows experimental result of correlation between magnetization compensation temperature (T_M) and angular momentum compensation temperature (T_A). The linearity comes from the power-law criticality and is governed by the Curie temperature and the Landé g factors of the elements composing the ferrimagnets. Therefore, measuring the magnetization compensation temperature and the Curie temperature, which are easily assessable experimentally, enables us to estimate the angular momentum compensation temperature of ferrimagnets.

U1-10. Magnetization Observation Using Near-field Scanning Optical Microscopy. *H. Yang*[1], J. Nath[1], I. Joumard[1], S. Auffret[1], G. Gaudin[1] and I. Miron[1] *1. SPINTEC (CEA/CNRS), Grenoble, France*

Magnetic structures can be detected by wide-field Kerr microscopy. However, the spatial resolution is limited by optical diffraction. Near-field scanning optical microscopy (NSOM), enabling the probing of light-matter interactions at the functionally relevant length scales, exhibits high space resolution and sensitivity [1-2]. We describe a NSOM imaging in perpendicular anisotropy ultra-thin magnetic films. Images exhibit a spatial resolution of < 100 nm. The visible laser (532 nm) was coupled into a metal coated fiber probes. The distance between the probe and surface, controlled by the piezo stage based on the detection of the shear force between the probe and the sample surface, was maintained constant at approximately 5 nm. Evanescent photons emitted from the aperture and transmitted through the glass-based substrate passed through the analyzer and were collected by the photon counter. The magneto-optical features (NSOM Image), along with the topological features (AFM Images) were re-constructed simultaneously. By selecting the same intensity symmetrically on the opposite sides of the extinction axis, shown in Fig.1(a), the magnetic information will change sign while the topographical information will stay the same. The near field magnetic optical images of the sample composed of a thin cobalt layer with strong perpendicular anisotropy and sandwiched with two symmetric platinum layers are shown in Fig.1(b) and (c). The results show that, out of plane magnetic information is collected by the NSOM images, indicating the spin up/down orientation illustrated in the figure. This technology could give us a new approach to investigate the ultra-tiny magnetic structure and domain wall motion behavior.

U1-11. Simulations of All-Optical Switching and Domain Wall Displacement in a Ferromagnetic material. *M. Menarini*[1], P. Scheid[2], R. Medapalli[3], Y. Quessab[2], S. Mangin[2] and V. Lomakin[1,3] *1. Electrical and Computer Engineering, University of California, San Diego, La Jolla, CA, United States; 2. Institut Jean Lamour, Université de Lorraine, Vandoeuvre-lès-Nancy, France; 3. Center for Magnetic Recording Research, University of California, San Diego, La Jolla, CA, United States*

The study of the effect of optical circularly polarized impulse on ferromagnetic material has been studied extensively in recent years. A helicity dependent all optical switching (HD-AOS) without any external field, has been observed in ferromagnetic materials such as FePtL10 media and Co/Pt multilayers [1,2] The mechanism behind these optical transitions is still a matter of study. Some partial explanations have been proposed using Magnetic Circular Dichroism (MCD) to explain the switching in ferromagnetic materials [3,4]. However MCD alone cannot explain the helicity dependent domain wall displacement (HD-DWD) observed experimentally at low fluencies [5,6]. We developed a model based on a three level lambda system where the optical effect is fue to spin-flip excitation followed by fast relaxation. The magnetization dynamic in absence of optical source follows the Landau-Lifshitz-Bloch dunamics. Using this Landau-Lifshitz-Lambda (LLL) model, we managed to reproduce HD-AOS in continuous media due to subpicosecond laser pulses (Fig. 1) as well as HD-DWD (Fig.2). Our results show how the combination of this optical excitation and the thermal demagnetization during the cooling down gives rise to an asymptotic switching value depending on the effectiveness of the optical process and the fluency intensity. Here we present our simulation results on a continuous 3nm thick FePtL10 thin film. We compare our results with the ones obtained using MCD and the experimental results.

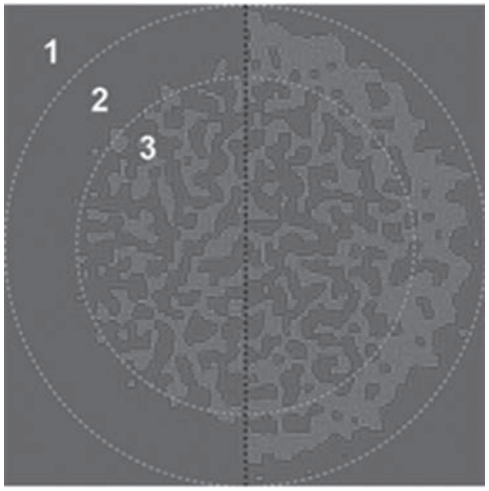

Fig. 1. Left side shows the effect of a linear polarized pulse on a continuous film, while the right side shows the effect of the optical reversal due to spin flip effect. At the center of the laser pulse the fluency is too high and only demagnetization is observed (3). When the fluency is too low no demagnetization or reversal is observed (1). It exist only a small ring for which the presence of an helicity-dependent optical effect is able to produce a magnetization reversal (2)

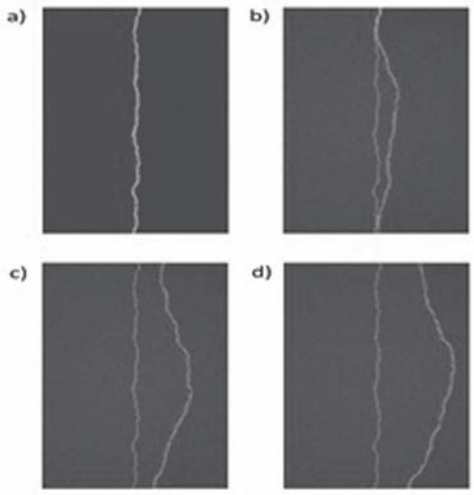

Fig. 2. A domain wall reversal is simulated using the LLL model. The picture shows the initial state of the system (a), and its evelution due to the optical source after 5 pulses(b), 20 pulses (c), and after reaching saturation (d).

U1-12. Temperature dependent domain wall width in ferrimagnets. *R. Moreno Ortega*[1], S. Khmelevskyi[4], R.F. Evans[1] and O. Chubykalo-Fesenko[3] *1. Physics, University of York, York, United Kingdom; 3. Insituto de Ciencia de Materiales de Madrid, Madrid, Spain; 4. 2 Center for Computational Materials Science, Vienna University of Technology, Vienna, Austria*

The study of the temperature dependence of the domain wall width is important for several reasons, e.g., it defines the domain wall velocity. For the specific case of ferrimagnetic materials, it has been shown that near the compensation point (T_M), the domain wall velocity sharply increases [1]. In our work, using atomistic spin dynamics simulations (Vampire code [2]), the temperature dependence of the domain wall width in ferrimagnets is studied. As a prototype, we use initially TbFe2 in a Laves phase C15 atomic structure. Firstly, the long-range exchange parameters are obtained from ab-initio calculations. Secondly, because with this parametrisation we don't observe any compensation point, we varied the intersublattice exchange (J_{AFM}). In the ground state (T=0K), both analytical and numerical results show that the width of domain walls is the same in transition and rare earth metals for JAFM values larger than 3% of the ab-initio value of JFe-Fe. Its value increases with J_{AFM}. Different domain widths in Fe and Tb are observed for small values of J_{AFM}. The domain wall width monotonically increases with temperature when the system does not present a compensation point. However, when T_M exists, an additional maximum is observed near the compensation point. The calculated domain wall width together with the temperature dependence of the macroscopic damping parameter allows us to analyse the domain wall velocity as a function of temperature in ferrimagnets.

U1-13. Power Frequency Domain Imaging on Goss-Textured Electrical Steel. *R. Schaefer*[1] and I. Soldatov[1] *1. IFW Dresden, Dresden, Germany*

Although the loss per cycle in Goss-textured FeSi steel has been steadily improved always in view of the magnetic domain structure [1], there is still a lack of knowledge about the dynamic magnetization process under power frequency conditions due to restrictions in magnetic imaging. Kerr microscopy, the mostly applied method for Goss steel, e.g. suffers from two drawbacks: (i) The insulation coating needs to be removed and the sheet surface must be polished. As the coating is stress-effective, the domains are expected to change after sample preparation. (ii) Time-resolved imaging can only be performed in the stroboscopic mode as the Kerr signal is too low to provide sufficient intensity in the single-shot mode. Stroboscopic imaging, however, relies on the averaging of many domain images which appear non-reproducibly from cycle to cycle thus leading to blurred averaged images. Using a magneto-optical indicator film with perpendicular anisotropy (PMOIF) for domain imaging solves these problems and adds further benefits. The PMOIF is simply placed on top of the sheet sample and the domains are imaged in a wide-field reflection polarization microscope [2]. Applying low resolution avoids the visibility of the intrinsic PMOIF domains, while at the same time the domains in the underlying sheet show up as areal contrast. The benefits are: (i) sample areas up to 30 mm can be captured in one image thus allowing to study grain neighborhoods, (ii) domains can be imaged in the presence of the insulation coating, and (iii) the contrast is based on the Faraday effect and thus much stronger than any Kerr contrast, allowing for single shot imaging of dynamic processes up to the 500 Hz frequency regime. For our experiments, Epstein sheets were placed in a single-sheet magnet, specially designed for domain observation [3] and the domain dynamics was imaged with a high-speed camera with a frame rate up to 8000 fps. Differences between quasistatic and dynamic processes are elaborated, revealing the mechanisms of domain refinement and showing the role of grain boundaries and mechanical stress on domain formation and flux propagation. As an example, three 50 Hz single-shot imaged at time delays as indicated are shown in the figure.

U2-01. Spin Wave Field Effect Transistor. *Y. Chen*[1], H. Lee[1], A.A. Jara[1], A. Khan[1], E. Yang[2], P.M. Braganca[2] and I. Krivorotov[1] *1. Physics and Astronomy, University of California, Irvine, Irvine, CA, United States; 2. HGST, a Western Digital Company, San Jose, CA, United States*

Spin waves (SWs) have been proposed as information carriers in novel logic devices [1-2]. Voltage-controlled magnetic anisotropy (VCMA) is a promising approach to generation [3] and control of spin waves [4] due to its high energy efficiency. We developed a spin wave field effect transistor (SW-FET), which can turn on and turn off SW propagation in a ferromagnetic nanowire with a gate voltage via the VCMA effect. We experimentally demonstrate a nanoscale SW-FET based on a Ta/CoFeB/MgO multilayer nanowire, as shown in Fig. 1. The device consists of a ferromagnetic nanowire magnetized perpendicular to the sample plane that serves as a channel for SW propagation and a voltage gate on top of the wire. Propagating SWs are excited on one side of the gate via application of a localized ac spin Hall torque at the SW resonance frequency. SW propagation to the other side of the gate is detected via anomalous Hall effect. Utilizing VCMA, a dc voltage applied to the gate adjusts perpendicular magnetic anisotropy (PMA) under the gate and transforms the spatially uniform magnetic energy landscape into a potential well or barrier for SW propagation depending on the gate voltage polarity. Fig. 2 shows variation of the AHE voltage measured at the SW detector region as a function of gate voltage and frequency of the ac current applied to the SW generator region. The data reveal suppression of the AHE signal at the propagating spin wave frequency for negative gate voltage. Since negative gate voltage gives rise to a magnetic anisotropy energy barrier in the gate region, the data in Fig. 2 reveal suppression of the propagating SW amplitude by the VCMA-induced barrier. For positive gate voltage that generates a magnetic potential well for propagating SWs, a weak AHE signal amplification is observed. This weak amplification results from increase of the SW group velocity in the potential well region. Our measurements pave the way towards energy-efficient SW control in nanoscale spin wave devices.

U2-02. Strain Mediated Current-induced Magnetization Switching in PMN-PT/Ta/Pt/Co/Pt Heterostructures. M. Wang[1], *X. Xu*[1], Y. Wu[1], K. Meng[1], J. Miao[1] and Y. Jiang[1] *1. School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China*

Current-induced spin-orbit torques (SOT) induced magnetization switching and electric filed controlled magnetism in ferroelectric materials are two interesting topics with potential application in spintronic devices [1-7]. However, the research of the strain mediated SOT switching on ferroelectric substrates is still limited. Therefore, it is important to clarify the mechanism of the strain mediated electric field induced SOT switching. In this work, we study strain mediated SOT induced magnetization switching in $PbMg_{1/3}Nb_{2/3}O_3$-$PbTiO_3$ (PMN-PT)/Ta (1)/Pt (3)/Co (1.3)/Pt (1) (thickness in nanometer) multilayers. The film was patterned into a Hall bar using EBL and an Ar ion milling technique. The multilayer takes on a perpendicular magnetic anisotropic state on the basis of the figure of the Hall resistance (R_H) as a function of the out-of-plane magnetic field. R_H-I curves under external in-plane magnetic field H_x=100 Oe are shown in Figure 1, the magnetic field is applied along the positive current direction. The changes of resistance ΔR of the clockwise switching loops can respond to the extent of the magnetization switching. Along the magnetic field direction, applying an electric field of E=10 kV/cm, the magnetization switching becomes close to full switching compared with E=0 kV/cm under H_x=100 Oe. Therefore, the effective magnetic anisotropy field can promote the magnetization switching under the external magnetic field. We can also observe the easy axis rotated in hysteresis loops before and after applying E=10 kV/cm in Figure 2. According to our experiments, strain modulation of interface magnetic anisotropy plays an essential role in manipulating the SOT induced magnetization switching. By applying the electric-filed E=10 kV/cm, the magnetization switching can be increased about 40%, which suggests that magnetization witching can be realized with lower external in-plane magnetic field or even zero field.

U2-03. Temperature dependence of I-V characteristics of Fe_3O_4/ Nb:$SrTiO_3$ heterostructures. *S. Ghimire*[1], Y. Lee[1] and J. Dho[1] *1. Physics, Kyungpook National University, Deagu, The Republic of Korea*

Epitaxial Fe_3O_4 films were prepared on 0.5wt% and 0.05wt% Nb-doped $SrTiO_3$ (Nb:STO) substrates by pulsed laser deposition. Ti, Al and Au electrodes were deposited by DC-sputtering to prepare ohmic contacts. X-ray diffraction data for Fe_3O_4 suggested a successful (1 0 0)-oriented epitaxial growth on (1 0 0) Nb:STO. Atomic force microscopy images showed that Fe_3O_4 films had a very smooth surface with the root-mean-square roughness of ~0.3 nm. The magneto-optic Kerr effect (MOKE) measurement revealed that the magnetic hysteresis loops of Fe_3O_4/Nb:STO were an erected-square shape for easy axis and had a four-fold symmetry within the plane. The temperature dependence of the I-V characteristics was measured from 10 K to 300 K by using a cryostat and a two-probe method. Both Fe_3O_4/Nb:STO heterostructures showed that the current flow is small in negative bias voltage while it significantly increases to a larger value in positive bias. At room temperature, the diode-like behavior of Fe_3O_4 on 0.05wt% Nd-doped Nb:STO was much more obvious than that on 0.5wt% doped Nb:STO. As the temperature decreased from room temperature to 10 k, the current in negative bias voltages decreased dramatically, but its change in positive bias regions was small. In addition, a hysteresis behavior in the cyclic I-V measurement was observed at low temperatures.

U2-04. Theoretical analysis of write error rate in bias-magnetic-field-free voltage-torque MRAM. *R. Matsumoto*[1], T. Nozaki[1], S. Yuasa[1] and H. Imamura[1] *1. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan*

Low write-error-rate (WER) magnetization switching at zero-bias magnetic field has become one of the key requirements in developing voltage-torque magnetoresistive random access memory (VT-MRAM) [1]. In the conventional VT-MRAM with a perpendicularly-magnetized free layer (p-FL) [2-5], the low WER on the order of 10^{-5}, which enables practical WER with a single error-correction process, has been experimentally demonstrated at room temperature [5]. In this case, however, the magnetization of p-FL requires a bias magnetic field having in-plane component for the switching. In the conically-magnetized free layer (c-FL) [6, 7] with elliptic cylinder shape (inset of Fig. 1), voltage-torque switching at zero-bias magnetic field has been theoretically demonstrated, but the analysis was done at 0 K [8]. Analysis at finite temperature is necessary to further extend the development of VT-MRAM having c-FL with low WER. In this work, we numerically calculated the WER of a VT-MRAM with c-FL at zero-bias magnetic field using the Langevin equation. In the calculation, following parameters were assumed: the temperature of 300 K, the saturation magnetization of 1400 kA/m, the Gilbert damping constant of 0.005, the volume of the free layer of $48\times20\times\pi\times1.1$ nm^3, the first- and second order anisotropy constants after the subtraction of the demagnetization energy $K_{1,\mathrm{eff}} = -300$ kJ/m^3, $K_{u2} = 300$ kJ/m^3, and thermal stability factor $\Delta = 60$ at zero-bias voltage. Because of the competition between $K_{1,\mathrm{eff}}$ and K_{u2}, the magnetization is tilted at 45°. By the application of voltage, the anisotropy constants became $K_{1,\mathrm{eff}} = -139$ kJ/m^3 and $K_{u2} = 60$ kJ/m^3, and precessional motion of the magnetization was induced. The voltage-pulse width (τ_p) dependence of the calculated WER is shown Fig. 1. By adjusting τ_p to 0.5 ns, the WER was reduced to 1×10^{-6}. The results provide a practical guide to design a reliable bias-magnetic-field-free VT-MRAM, which simplifies the device structure and reduces the fabrication cost. This work was partly supported by the ImPACT Program of the Council for Science, Technology and Innovation and JSPS KAKENHI Grant Number 16K17509.

U2-05. Theory of ferromagnetic resonance driven by the combined action of spin-transfer torque and voltage controlled magnetic anisotropy. *C.A. Gonzalez-Fuentes*[1] *1. Physics, UTFSM, Valparaiso, Chile*

We present an analytical study of the spectral line shape of ferromagnetic resonance (FMR) detected the by spin rectification effect and driven by the combined action of spin-transfer torque (STT) and voltage-controlled magnetic anisotropy (VCMA). The system under consideration consists of a magnetic tunnel junction (MTJ), where an oscillating

electric current is injected into the structure simultaneously inducing both VCMA and STT effects. We obtain that the lineshape function is given by $L(\omega) = [A((\omega/\omega_r)^2-1)+S(\lambda/\omega_r)(\omega/\omega_r)2]/[((\omega/\omega_r)^2-1)^2+(\lambda/\omega_r)^2(\omega/\omega r)^2]$, where ω is the frequency, ω_r is its resonant value and λ is the linewidth. S and A are dimensionless parameters that describe qualitatively L(ω) function (see Figure 1), and their magnitudes are determined by the physical mechanisms that induce magnetization precession: STT and VCMA. Explicit expressions for S and A are derived, where the role of the VCMA, in-plane STT and field-like STT are clearly identified and discussed. A full angular dependence is presented and typical configurations are particularly analyzed and rigorously compared with experimental results [1-4]. The results are summarized in Table 1. Our theory establishes a general analytical framework that is useful to quantify and distinguish between the spin transfer torque and voltage controlled magnetic anisotropy effects on MTJs.

U2-07. Voltage control of RKKY exchange coupling in magnetoelectric heterostructures. *X. Wang*[1], H. Chen[1], C. Dong[1], H. Lin[1], X. Liang[1] and N. Sun[1] *1. ECE, Northeastern University, Boston, MA, United States*

Control of magnetism in a fast, compact and energy efficient manner remains a key challenge for future spintronic memories and logic devices, tunable RF/microwave magnetic devices, etc.[1-6] Conventional magnetoelectric (ME) coupling in magnetic/ferroelectric bilayer heterostructures only leads to the voltage controlled 90° magnetization switching. However, magnetic information storage such as MRAM and MERAM all required voltage controlled 180° magnetization switching, which remains elusive. Here we reveal a new magnetoelectric (ME) coupling mechanism for potentially achieving a voltage controlled 180° magnetization switching, *i.e.* voltage control of Ruderman–Kittel–Kasuya–Yosida (RKKY) exchange coupling which plays a key role in Spintronics. We fabricated FeCoB/Ru/FeCoB/PMN-PT (lead magnesium niobate-lead titanate) ME heterostructures, in which the RKKY interaction between two ferromagnetic FeCoB layers was manipulated by voltages applied onto the ferroelectric PMN-PT layer. Magnetic states can be potentially switched between "antiferromagnetic" and "ferromagnetic" states through E-field induced exchange coupling constant change, leading to the magnetization switching, represented by measured magnetic hysteresis loops under different applied voltages, shown in Figure 1. This demonstrated new ME coupling mechanism of voltage control of RKKY exchange coupling in ME heterostructures provides a new means for achieving highly efficient ME random access memory (MERAM) and other applications such as RF/microwave devices and spintronics.

U2-08. Zero-field magnetization switching by an acoustic wave. I. Camara[1], L. Becerra[1], A. Lemaître[2], J. Duquesne[1], C. Gourdon[1] and *L. Thevenard*[1] *1. CNRS,UPMC, Institut des Nanosciences de Paris, Paris, France; 2. Centre de Nanosciences et de Nanotechnologies, Marcoussis, France*

In precessional switching, a pulsed field or current triggers highly non-linear, large amplitude magnetization dynamics. Switching off the excitation at the right moment can lead to a final opposite magnetization, potentially within only fractions of nanoseconds and deterministically. It was recently shown that this can be done using the effective field generated by inverse magnetostriction upon the passage of a surface acoustic wave (SAW) on a magnetic

layer [1,2,3]. For this, the field must be adjusted for the precession frequency to resonate with that of the lattice excitations. As when driving the switching with fields or current, it clearly appears that even minute misalignments of the field with the hard axis can hugely favor switching from e.g. +M to –M, preventing a deterministic toggling between both states [2]. A potential remedy is to achieve SAW switching in zero field. Working on in-plane magnetized layers of GaMnAs, we exploit the fact that the resonance field decreases strongly with increasing temperature (Fig.c). Close to the Curie temperature, at 100K, the coupling between SAW and magnetization was indeed strong enough in zero field to achieve clear magnetization switching after a 250ns SAW burst (Fig.a). Applying over twenty bursts in a row moreover showed that close to the transducer, a deterministic switching could be obtained (Fig. b). Far from the transducer, consecutive pulses made the domain walls propagate at speeds of the order of 70m/s, evidencing a SAW-driven mechanism competing with precessional switching. This confirms the relevance of using resonant magnetoacoustic interactions to control magnetic devices, from switching magnetic data bits, to propagating magnetic domain walls.

U2-09. Spin-current-less spin Hall effect in magnetic insulators.

H. Chen[1,2], Q. Niu[3] and A.H. MacDonald[3] *1. Physics, Colorado State University, Fort Collins, CO, United States; 2. School of Advanced Materials Discovery, Colorado State University, Fort Collins, CO, United States; 3. Physics, The University of Texas at Austin, Austin, TX, United States*

The spin Hall effect (SHE) in a nonmagnetic conductor is conventionally described as a transverse spin current induced by a longitudinal electric field or voltage, which in turn leads to accumulations of opposite spin at opposite transverse boundaries. Despite its conceptual attractiveness, this definition of the SHE suffers from fundamental difficulties related to the lack of spin conservation, especially in the strongly spin-orbit-coupled systems where the SHE becomes more prominent. In this work we propose an alternative view of SHE phenomena by relating them to the polarization of spin density, in analogy to the charge polarization, induced by an electric field. The spin density polarization can be conveniently defined in insulating systems, and a counterpart of the conventional SHE can be present if there is a transverse response of it to an electric field. A constraint on this response from time reversal implies that in insulating systems it is non-zero only if the systems are magnetic. We use some toy models to illustrate the physical consequences of this magnetic spin Hall effect.

U3-01. Critical magnetization curves in NiFe/FeMn(*t*) bilayers with noncollinear anisotropies. *D.J. Adams*[1], P.R. Kern[2], M. Carara[2] and L. Spinu[1] *1. AMRI/Physics, University of New Orleans, New Orleans, LA, United States; 2. Física, Universidade Federal de Santa Maria, Santa Maria, Brazil*

Exchange bias is an interfacial effect occurring between ferromagnetic (FM) and antiferromagnetic (AF) materials with spin structures at the interface playing a critical role [1]. This interfacial coupling is most notably observed as a shift in the major hysteresis loop (MHL) of the sample, although other, more subtle features may also be expressed including an enhanced coercivity and often noncollinear uniaxial and unidirectional anisotropies. In this work, we explore avenues to characterize these anisotropies through different techniques. Bilayer samples of $Ni_{81}Fe_{19}$(50 nm)/$Fe_{50}Mn_{50}$(*t*) were prepared on Si (100) substrates through magnetron sputtering with a magnetic field of approximately 1 kOe applied in the sample plane in order to define a pinning direction. Five samples were studied with the thickness of the AF varied within the range 3 nm ≤ *t* ≤ 15 nm, and the thickness of the FM material held constant. The noncollinearity of the anisotropies in these samples manifests itself in the angular evolution of the MHL, but this can also be characterized through angular-dependent ferromagnetic resonance (FMR). To probe this, vector network analyze FMR was measured for selected microwave frequencies in the plane of the sample by recording the S_{21} transmission coefficient at every increment of the applied magnetic field at. This was repeated at different angles for a full 360° characterization. The results of these investigations are displayed in polar contour charts, constructed under critical curve formalism introduced by Slonczewski [2]. The measured values of exchange bias in these samples at any measured frequency are consistent with the values obtained through the MHL and angular-dependent cavity FMR for X-band frequency.

U3-02. Electrical modulation of unidirectional anisotropy in the exchange biased AFM/FM bilayers mediated by piezoelectric strains. *H. Kim*[1] and J. Hong[1,2] *1. Emerging Materials Science, Daegu Gyeongbuk Institute of Science & Technology (DGIST), Daegu, The Republic of Korea; 2. Global Center for Bio Convergence Spin Systems, DGIST, Daegu, The Republic of Korea*

Controlled manipulation of magnetic anisotropy has a practical potential in many applications involving magnetic films. The modulation of unidirectional anisotropy in exchange coupled structure by mechanical strains through the piezoelectric substrate is considered in the present study with the fabrication of ferromagnetic (FM)/antiferromagnetic (AFM)/ferroelectric (FE) substrate. FM $Co_{60}Fe_{20}B_{20}$/AFM $Co_{0.7}Ni_{0.3}O$ bilayers were deposited by magnetron sputtering on the piezoelectric substrate of $Pb(Mg_{1/3}Nb_{2/3})O_3$-Pb-ZrO_3-$PbTiO_3$ (PMN-PZT) with (011) plane. Subsequently, the samples were field-cooled from 390K to 300K under +5 T magnetic field applied along the [100] or [0-11] axis of PMN-PZT to set the pinned direction (P.D.) of AFM. Exchange bias field (H_E) and coercivity (H_C) at various azimuthal angles ranging from 0° to 180° with a step 10° were obtained from the measurements of magnetic hysteresis loops employing vibrating sample magnetometer (VSM) at room temperature under various applied electric fields, as shown in figure 1. The piezoelectric strain induced an appreciable change in the exchange bias field (H_E) and the coercivity (H_C) of the exchange-biased bilayers, thus the unidirectional anisotropy can be controlled accordingly. Based on the study by Haiwen Xi et al., the azimuthal angle Φ_C (called a 'critical angle') where maximum H_E and minimum H_C is achieved simultaneously is determined by the ratio of uniaxial anisotropy (K_U) and unidirectional anisotropy (K_E). With the electrical modulation of the substrate, it was demonstrated that the variation of critical angle can be achieved in a single specimen. Azimuthal dependences of anisotropy were analyzed by assuming the cosine series, $H_E(\Phi)=\sum A_n\cos(n\Phi+\alpha)$ and variations of the coefficient by the piezoelectric strains. Coefficients A_n's of odd orders changed by significant amounts indicating the control of unidirectional anisotropy, and variation of α reflected the change in the anisotropy direction. Therefore, a strain mediated electrical control of both direction and magnitude of the anisotropy in the AFM is demonstrated.

U3-03. Exchange Bias Effect in the Multiphase FM and AFM Mixture. *M. Jung*[1,3], M. Im[2,4] and J. Hong[1,3] *1. Emerging Materials Science, DGIST, Daegu, The Republic of Korea; 2. Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, United States; 3. Global Center for Bio Convergence Spin Systems, Daegu, The Republic of Korea; 4. Research Center for Emerging Materials, Daegu, The Republic of Korea*

Spin coupling at the interface between ferromagnet (FM) and antiferromagnet (AFM) mediated by uncompensated spins is known to causes the shift of hysteresis loops of FM layer along the field axis breaking the symmetry of the hysteresis behavior of the film. With more than a half century of research, understanding of the exchange bias effect in FM/AFM bilayers has progressed considerably driven not only by the academic curiosity but also by the industrial interests resulting in wide use in various spin valve devices. In general, the amount of shift, referred as the exchange bias field (H_E), is formulated to be, where is the magnetization of FM material and is thickness of the FM film [1]. In the present study, we employ nano-granular mixtures of FM and AFM phase instead of singe FM phase material to improve the exchange bias effect. Based on the previous study [2], the mixture phase film has been shown to exhibit strong exchange bias effect by itself due to the maximized internal interface density with its 3-dimensional spatial arrangement of FM and AFM phases. We confirmed noticeable enhancement of exchange bias effect by using the phase mixture coupled with AFM layer compared with conventional FM/AFM bilayers. Films were fabricated in the Si(100) /AFM $Co_{0.7}Ni_{0.3}O$, (20 nm)/FM (t nm) or multi-phase mixture (t' nm)/SiO_2 (3 nm) structures where the thickness t and t' were controlled in order to compare the EB effects. Permalloy ($Fe_{0.2}Ni_{0.8}$) was used as the FM material with the thickness (t) of 2, 3, 5 and 10 nm, and phase mixture of metallic $Co_{0.7}Ni_{0.3}$ and metal-oxide $Co_{0.7}Ni_{0.3}O$ was used with t' of 3, 5, 7, and 13 nm's, that were adjusted to have magnetizations of corresponding permalloy layers. Bilayers films with phase mixture in FM layer exhibits significantly greater exchange bias field (H_E) compared to the bilayers with permalloy film of the same thickness over the entire temperature range. Furthermore, multiphase mixture coupled with AFM shows unusual thickness dependence as well as the opportunity for exchange bias along the both in-plane and out-of-plane directions suppressing the inherent shape anisotropy of the ferromagnetic film structure.

U3-04. Exchange bias in antiferromagnetic $NaNiF_3$ thin films. *S.A. Morley*[1], H. Marquez[1], A. KC[1] and D. Lederman[1] *1. Department of Physics, University of California, Santa Cruz, Santa Cruz, CA, United States*

Fluoro-perovskites have been proposed as an alternative candidate to the oxide perovskites for magneto-electric applications [1]. It is therefore desirable to create thin film samples to integrate into devices. $NaNiF_3$ (NNF) is an antiferromagnet which has a distorted perovskite crystal structure that sustains weak ferromagnetism. In bulk form, NNF the transition temperature is T_N = 156 K [2] and has a Pnma space group symmetry with bulk values for the lattice constants reported as a = 5.361 Å, b = 7.688 Å and c = 5.524 Å [3]. We have grown NNF via molecular beam epitaxy on $SrTiO_3$ [100] to produce high quality epitaxial films in the thickness range of 5 – 50 nm. The structure of the films was confirmed by x-ray diffraction (XRD), reflection high energy electron diffraction, and atomic force microscopy. XRD confirmed that the films had the expected the Pnma structure and were oriented along the [101] direction. The SQUID magnetometry displayed a temperature-dependent magnetization consistent with weak ferromagnetism and a $T_N \approx 152$ K. Co thin films were grown on the epitaxial NNF layers in-situ using electron beam evaporation with in and out-of-plane anisotropy. Exchange bias was observed with the field applied in the out-of-plane direction, manifested by a shift in the Co hysteresis loops. The temperature dependence of the exchange bias field showed a strong suppression as the temperature was increased towards the Néel temperature of the NNF. The potential for enhancement of the effect using the anisotropy, Co layer thickness, and strain as tuning parameters will be discussed.

U3-05. The Azimuthal Dependence of Exchange Bias Effect and Its Analyses by Spin Glass Model in $Ni_{0.8}Fe_{0.2}/Co_xNi_{1-x}O$ Bilayers. W. Yoo[1], K. Lee[2], C. You[3], J. Hong[3] and *M. Jung*[1] *1. Department of Physics, Sogang University, Seoul, The Republic of Korea; 2. Johannes Gutenberg University Mainz, Mainz, Germany; 3. Emerging Materials Science, Daegu Gyeongbuk Institute of Science and Technology, Daegu, The Republic of Korea*

The exchange bias (EB) effect has been vigorously researched for many years due to its possible applications in information storage and spintronics, especially in spin valves for magnetic recording devices. Even though many models have been expounded to this day, they do not prove convincingly the origins of EB effect. Meiklejohn and Bean model (M-B model) [1] accounted for the magnitude of EB field, assuming that the ferromagnetic (F) layer is magnetically rigid and antiferromagnetic (AF) layer is not reversed during the magnetic reversal of F layer. Mauri model [2] took a domain wall developing the AF spins into consideration to reduce the EB field computed by M-B model. EB effect resulting from Mauri model, however, continuously decreased for the variation of AF anisotropy constant and the interfacial exchange interaction energy, while EB field computed by M-B model steeply decreased. Therefore, to overcome this problem, spin glass model [3] assumed the spin-glass like system in the interface between F and AF layer. This model is highly probable with respect to analysis of asymmetry of hysteresis loop and azimuthal dependence of coercivity. We attempts to establish the azimuthal dependence of EB effect with respect to varying composition of AF layer and temperature, even if it is a topic which is difficult to explore because we should consider many variables. In this report, we deposited the bilayer thin films of $Ni_{0.8}Fe_{0.2}/Co_xNi_{1-x}O$ with x varying from 0.4 to 0.8 by magnetron sputtering, and studied the variation of exchange bias field and coercivity measured by using the new approach to anisotropic magnetoresistance. The EB effect was investigated for various external parameters such as temperature, the composition of AF layers, and the direction of magnetic field on the base of the Mauri model and the spin glass model. The comparison showed good consistency with the spin glass model, suggesting the validity of spin glass model to understand the origin of exchange bias effect in the permalloy/Co-Ni-O bilayers. This new approach is useful because of the difficulty to measure the azimuthal dependence of magnetization by vibrating sample magnetometer or magneto-optical Kerr effect.

U3-06. Exchange Bias in CoO/Fe(110) Bilayers: a Ferromagnet Drives an Antiferromagnet. *M. Slezak*[1], T. Slezak[1], P. Drozdz[1], K. Matlak[1], B. Matlak[1] and J. Korecki[1,2] *1. Faculty of Physics and Applied Computer Science, AGH University of Science and Technology, Cracow, Poland; 2. Jerzy Haber Institute of Catalysis and Surface Chemistry PAS, Krakow, Poland*

The AFM/FM bilayers that display the exchange bias (EB) effect are subjected to intensive material research. In a commonly accepted picture, the AFM, considered as rigid due to its high anisotropy and magnetic hardness, controls the magnetic properties of the FM. We show that this AFM-FM master-slave hierarchy is not generally valid, and that the influence of the FM to the magnetic anisotropy (MA) of neighboring AFM must be considered. Our computer simulation and experimental studies of EB in epitaxial CoO/Fe(110) bilayer show that the FM layer with strong uniaxial magnetic anisotropy decides on the interfacial spin orientations of the neighboring AFM layer and rotates their easy axis. This effect has strong feedback on the EB effect experienced by the FM layer. The EB in the CoO/Fe(110) system was studied using *in situ* MOKE microscope, as a function of the Fe thickness. In Fig. 1 we present $H_{EB}(d_{Fe})$ dependence (squares) as extracted from MOKE data. Two uncommon features in the presented $H_{EB}(d_{Fe})$ dependence are to be noted. First, the $H_{EB}(d_{Fe})$ dependence definitely does not follow the $1/d_{Fe}$ dependence. Second, the H_{EB} value is significantly enhanced for d_{Fe} in the 100 – 150 Å range and a drastic drop of H_{EB} at d_{Fe} ~ 150 Å is observed. The $H_{EB}(d_{Fe})$ dependence is nicely reproduced basing on the coherent rotation model of magnetization reversal (Fig. 1 open symbols). The major conclusions from simulations are briefly summarized in Fig. 2. With increasing d_{Fe} the effective MA of Fe layer evolves and its easy axis reorients from [1-10] to bulk-like [001]. Simultaneously with this SRT in FM another spin reorientation takes place, namely AFM spin axis in CoO rotates away from [1-10] towards [001] in plane direction. This work was partially financed by the Faculty of Physics and Applied Computer Science AGH UST statutory tasks within subsidy of Ministry of Science and Higher Education.

The recent rare-earth element price crisis has prompted intensive research in the development of rare-earth free permanent magnets for the European and US industry [1]. Since 1989, when the exchange coupling effect between the soft and hard magnetic phases was first observed, much work has been done to produce hard/soft exchange-spring magnets using various preparation techniques. M-type barium hexaferrites (BaM) are a type of technologically important permanent magnets with the coercivity of 2-3.2 kOe and highly resistive to oxidation and corrosion [3]. Due to their low cost and impressive magnetic and microwave properties in numerous electronic devices, many researchers have been motivated to develop high-performance BaM based exchange-coupled magnets in recent years [4-6]. The present investigation explores the exchange-coupling mechanism and shows the correlation between the structural, compositional and microstructural changes, and magnetic properties of BaM hexaferrite and Fe_3O_4 nanocomposites. $BaM@Fe_3O_4$ core-shell nanocomposite with magnetic exchange

interactions between the hard and soft phase, were prepared by coating magnetite nanoparticles using a hydrothermal method on as-prepared flake-like BaM particles via sol-gel auto-combustion method. The exchange-spring mechanism was then explored and optimized via the control of composite phase fractions and heat treatment conditions. Electron microscopy results show that 10 nm sized magnetite nanoparticles were developed as the shell of ultra-thin BaM nanoparticles. We observed the exchange coupling between the hard and the soft magnetic phases after post heat treatments. The obtained flake-like BaM@Fe_3O_4 nanocomposite exhibits a saturation magnetization of 83 emu/g and a coercivity of ~ 4 kOe at room temperature for the sample with BaM to magnetite weight ratio of 9:1 annealed at 500°C for 2h. Our results improve the magnetic properties of commercial BaM and previous studies and recent reports [4, 5].

U3-08. Unexpected new insights to the nature of exchange bias in Co/FeMn using detailed XMCD. *E.J. Goering*[1], P. Audehm[1], M. Schmidt[1] and G.A. Schütz[1] *1. Modern Magnetic Systems, Max-Planck-Institute for Intelligent Systems, Stuttgart, Germany*

The Co/FeMn exchange Bias system is a widely studied bilayer system. In order to understand the origin of Exchange Bias (EB) in this system we have performed earlier XMCD (x-ray magnetic circular dichroism) on the Fe $L_{2,3}$ edges [1], where we extracted spin- and orbital moments at the interface separated for uncompensated pinned and rotatable magnetic moments. Unexpectedly, we found that the pinned magnetic moments were of nearly pure orbital character [1]. This finding allowed us to identify an unexpected new contribution to the EB unidirectional anisotropy originated by a local "spin orbit coupling loaded spring". We used our own dedicated "ERNSt" endstation at BESSY II, which is by purpose a reflectometer and therefore capable of very precise angle dependent measurements, necessary to precisely separate rotatable from non-rotatable magnetic moments [1,2,3]. Here we present new results on the Mn $L_{2,3}$ edges as shown in Fig. 1a. Similar to the Fe results the pinned moments Mn XMCD spectra again reveal nearly pure orbital character, visible in the same sign for the L_2 and the L_3 spectra. In strong contrast to the previous Fe XMCD results [1] we also found a change of sign in the Mn pinned moment XMCD (Fig.1a). By a further analysis of the effective electron escape length in Total Electron Yield mode, we were able to extract for the first time a quantitative model of the temperature dependent pinned moment Mn and Fe profiles as sketched in Fig.1b, where the pinned Mn moments are parallel aligned close to the interface to Co and reversed in a deeper region. This new observation allows a new and deep understanding of the EB phenomena, combining pinned orbital moments and the AFM anisotropy energy.

U3-10. Training effect of exchange bias in Co/CoO core-shell nanowire films. *J. Mohapatra*[1], M. Xing[1] and P. Liu[2] *1. Physics, University of Texas at Arlington, Arlington, TX, United States; 2. University of Texas-Arlington, Arlington, TX, United States*

Assemblies of vertically aligned Co nanowire arrays (forests) have been synthesized on Pt coated glass substrates and then exposed to oxygen-containing atmosphere that leads to natural oxidation of their surface. The exchange bias field (H_{EB}), training effect (TE) and blocking behavior of the resulted Co/CoO core-shell nanowire films are systematically investigated. Field cooling (FC) magnetic hysteresis loops measured at low temperatures show the significant exchange-bias shift originated from the coupling between the ferromagnetic (FM) Co core and the antiferromagnetic (AFM) CoO shell. Below the blocking temperature (T_B = 200 K), H_{EB} increases from 50 Oe to 1.4 kOe with decreasing temperature (from 150 to 10 K) due to pinning of the AFM phase to the FM phase. The TE of the H_{EB} measured at 10 K, shows a decreasing trend in the coercivity H_C and H_{EB} with the magnetic hysteresis cycles. A large decrease of the TE of ~ 90% from the

first to the second cycles is observed, while for the subsequent cycles the TE only drops ~2-1%. The temperature-dependent exchange bias, training effect are attributed to spin-glass like behavior of the uncompensated spins at the interface of Co/CoO core-shell.

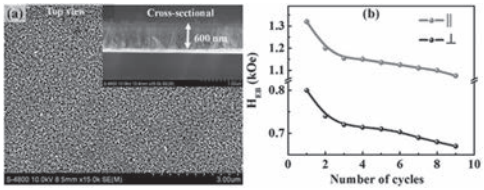

Figure 1 (a) SEM images of Co/CoO NWs array film prepared via hydrothermal decomposition of cobalt carboxylate and inset shows the cross-section view of the nanowire array film. (b) Dependence of H_{EB} on the number of magnetic hysteresis cycles, measured at 10 K after field cooling in 50 kOe, by applying the magnetic field parallel (∥) and perpendicular (⊥) to the NW axis.

U4-01. Mallinson-Halbach effect in chiral thin-film magnetic structures. *M.A. Marioni*[1], M. Penedo[1], M. Bacani[1] and H.J. Hug[1,2] *1. Empa - Swiss Federal Labs for Materials Science and Technology, Duebendorf, Switzerland; 2. Physics, University of Basel, Basel, Switzerland*

Skyrmion-supporting thin film multilayers exploit interfacial Dzyaloshinkii-Moriya interactions (DMI), with different materials on either side of the magnetic layer, so that the net DMI does not vanish [1]. The DMI defines a specific chirality of the magnetization structures, which typically feature Néel-type walls between domains. Such is the case, for example, in $Si/Pt/[Ir_{1nm}/Co_{0.6nm}/Pt_{1nm}]_{\times 5}/Pt$ and other material systems which we analyze in detail by magnetic force microscopy (MFM). Because the equilibrium domain widths in these films are of the order of 100 nm, and can easily be imaged by MFM, it is possible to obtain the magnitude of the DMI coefficient from a condition of minimum energy configuration assessed from the images. However, the sign of the DMI coefficient cannot be determined by this method. And yet, the sign of the DMI determines a relative amplification or attenuation of the stray field of the sample at a given distance on either side from the interface. We can understand this effect as a form of the Mallinson-Halbach effect [2,3], which is a direct consequence of the existence of volume magnetic charges in the domain walls, arranged symmetrically on either side of a through-thickness magnetic domain, as dictated by the chirality of the walls. We can utilize this knowledge to find the sign of the DMI coefficient from quantitative measurements of the magnetic field amplitude on either side of the film. In so doing, we characterize Halbach array-like structures of the smallest size reported to-date [4]. An extreme example is the skyrmion, which we show to funnel the stray field toward the top side for negative DMI and toward the bottom side for positive DMI [5]. This insight will be useful e.g. when designing stacked, integrated elements with chiral magnetic structures.

An exciting field in spintronics is the design of nanodevices whose operation is based on the movement and excitation of magnetic domain walls (DWs) without the application of magnetic fields, through the so-called Spin Transfer Torque (STT) effect [1]. The STT is based in the force that is created by applying an electric current to a ferromagnet, as the force drives the DWs along the direction of the electron movement. However, since this effect is weak, it has limited applications in technology. To overcome this problem, the use of the Spin Hall Effect (SHE) has been proposed. The SHE provokes a spin accumulation at the edges of a current-carrying non-magnetic material that exerts a torque on the magnetization of a neighboring magnetic layer [2], reducing the current densities needed. However, the torque induced by the SHE depends on the chirality of the DW and, as most ferromagnetic materials lack a well-defined chirality, the applications are limited. A suitable way to lift the left-right degeneracy is to exploit the Dzyaloshinskii–Moriya interaction (DMI), present in systems without point-inversion symmetry [3]. Our goal in this work is to determine how to induce and stabilize DW chirality in a magnetic layer whose domain walls are non-chiral. To this end, we have used the SPLEEM instrument at the Lawrence Berkeley National Laboratory to study the interface between a Cu(111) substrate and a non-chiral magnetic layer. The SPLEEM microscope can map independently and in real space the three cartesian components of the spin structures [4]. The experiments were done in a (Ni/Co) multilayer grown on Cu(111). Magnetic films grown on Cu(111) do not present homo-chiral DWs [5], because the DMI at the interface is negligible. We have found that this behavior can be substantially modified by introducing a thin heavy-metal layer (suitable to induce a high DMI) between the Cu substrate and the magnetic layer. In this case, relevant changes in the chirality of the DWs of the magnetic layer are observed. Our results demonstrate that the buffer layer influences the spin texture, which evolves from non-chiral Bloch to homo-chiral Néel DWs. The experimental results are rationalized based on theoretical calculations.

U4-03. Shape magnetic anisotropy from spin density in nanoscale slab systems. *T. Oda*[1,2], I. Pardede[3], T. Kanagawa[3], N. Ikhsan[3] and M. Obata[1,3] *1. Institute of Science and Engineering, Kanazawa University, Kanazawa, Japan; 2. Center for Spintronics Research Network (CSRN), Osaka University, Toyonaka, Japan; 3. Graduate School of Natural Science and Technology, Kanazawa University, Kanazawa, Japan*

The magnetic anisotropy at the surface/interface plays an important role of magnetic properties in nanoscale slab systems. The contribution of magnetic dipole-dipole couplings among electron spins cannot be neglected as well as that of spin-orbit couplings in band electrons. We have developed the computational method which enables us to estimate the magnetic dipole energy of slab materials [1]. In the present work, the magnetic anisotropy energy (MAE) from magnetic dipole interaction (shape anisotropy energy, SAE) has been estimated for slabs using the spin-density obtained from the density functional approach. For examples, in the slabs of Fe/MgO interfaces, the quadruple component of atomlike spin density was found to suppress the SAE in addition to the conventional suppression appearing as magnetic surface. Such quadruple contribution is only observed at the interface layer, not at the Fe atoms inside the Fe-layer. The origin of quadruple spin density is based on the electron occupation of angular dependent 3d orbitals. The prolate (oblate) type of atomlike spin density disfavors (favors) the in-plane shape anisotropy. The results of SAE were discussed in comparison with those of obtained by the continuum magnetic moment approach and separated magnetic moment approach. The computational method developed in our works on magnetic anisotropy is not only for ferromagnetic

layers, but also for the layers of other magnetic configurations, such as antiferromagnetic and ferrimagnetic configurations. We discuss the SAEs of the magnetic slab systems with various magnetic configurations. This work was partially supported by ImPACT Program of Council for Science, Technology and Innovation (Cabinet Office, Japan Government).

In this paper the results of the manipulation of the magnetic properties and magnetic structure in ultrathin Ru/Co/W/Ru films with the interfacial Dzyaloshinkii-Moriya interaction (iDMI) are presented. We use a focused ion beam (FIB) for the spatially resolved irradiation of the films by Ga+ ions. The polycrystalline Ru (10)/Co(1)/W(0.25)/Ru(2) films (all thicknesses in nm) were prepared by UHV magnetrons sputtering. The films have perpendicular magnetic anisotropy and dendritic domain structure [1]. The iDMI value was measured by Brillouin Light Scattering (BLS) Spectroscopy: D_{eff} = -3.1 erg/cm^2. We irradiated the films by FIB in two regimes using focused and defocused ion beams. The doses were varied from 4.0x10^{11} up to 4.0x10^{12} ions/cm^2. Decreasing of the coercive force from 16 down to 1 Oe at high doses was observed. There is also decrease of the remnant magnetization during remagnetization in a field applied perpendicularly to the film's plane from 1 to 0.2. The observation of the magnetic structure by a magneto-optical Kerr microscope showed the formation of arrays of skyrmion-like bubbles, which sizes reduced with the increasing dose. These results can be used for creations of artificial neuromorphic devises and skyrmions-based logics using gradients of PMA and/or iDMI. Moreover, the FIB modification can be used for formation of narrow magnetic tracks with desired properties for skyrmions propagation and operation. This work was supported by the Russian Foundation for Basic Research (grant 17-52-50060) and by the Russian Ministry of Education and Science under the state task (3.5178.2017/8.9 and 3.4956.2017).

Simultaneous manipulation of perpendicular magnetic anisotropy (PMA) and the interfacial Dzyaloshinskii–Moriya interaction (iDMI) is realized in thin films combining a ultrathin ferromagnet (Co, Fe, CoFeB) sandwiched between a heavy metal buffer (e.g. Pt, W, Ru, Pd) and an oxide capping (MgO, Al_2O_3) [1, 2]. This composition is essential for the nucleation of the chiral spin textures such as Néel domain walls and skyrmions [3]. Despite of the numerous research efforts the contribution of the oxide capping layer into the net iDMI induced at the both interfaces is rather elusive. In this work, we study the effect of the MgO layer's thickness on magnetic properties and iDMI of a Ta/Pt/CoFeSiB/MgO system [4]. The series of Ta(3)/Pt(5)/CoFeSiB(t_{FM})/MgO(t_{MgO})/Ta(t_{Ta}) samples (thickness in nm) were produced by magnetron sputtering. The as-deposited samples Ta(3)/Pt(5)/CoFeSiB(1.5)/MgO(t_{MgO}) have robust PMA for t_{MgO} = 0.25 and 0.5 nm. At the thicker MgO capping magnetic anisotropy transforms to in-plane one. The 3-nm Ta coverage does not widen the t_{MgO} range where PMA exists. The magnitude and sign of iDMI were measured with Brillouin Light Scattering (BLS) Spectroscopy [5]. The most interesting is the behavior of iDMI with the increasing t_{MgO}. The peak value of iDMI (D_{eff} = -1.25 erg/cm^2) was observed at t_{MgO} = 0.25 nm. The increased thickness of MgO promotes the sharp decrease of D_{eff} down to -0.65 erg/cm^2 at t_{MgO}=0.5 nm with the following small increase up to -0.8 erg/cm^2 at t_{MgO} = 0.75 nm and saturation at the higher thicknesses. The found effect of the MgO capping on iDMI can be explain by the degree of hybridization between magnetic atoms and oxygen [6]. The coverage of the MgO capping by Ta leads to a twice decrease of iDMI attributed to the prevention of the oxygen penetration into the top interface. Our findings reveal that the ultrathin MgO capping layer ($t_{MgO} \leq$0.5 nm) helps to simultaneously control PMA and iDMI for further development of the spin-orbitronic devices. One of the most intriguing outcomes of symmetry breaking and spin-obit interactions in magnetic systems is the possibility to create non-collinear and chiral spin textures. The Dzyaloshinskii-Moriya interaction (DMI) results from strong spin-orbit coupling and broken inversion symmetry to generate magnetization rotations with fixed chirality. Significant efforts have been aimed at understanding how to precisely control the sign and magnitude of DMI induced by inversion symmetry breaking at an interface between a magnetic layer and a layer with strong spin-orbit coupling as a means to create chiral magnetism [1]. Promising results have been achieved in multi-layer thin films of metals that combine cooperative DMI from multiple interfaces [2]; however transition metal oxides, in particular those containing heavy 5*d* elements, also possess the requisite materials parameters necessary to alter artificially the spin textures through interface-induced DMI. We examined the physical properties of a series of high quality epitaxially grown $[(SrIrO_3)_n/(LaMnO_3)_n]_m$ superlattices that combine the large spin-orbit coupled $SrIrO_3$ and the strongly correlated magnetic $LaMnO_3$ with inversion symmetry breaking at the interface. We observed a large topological Hall effect, which results from the interaction between charge carriers and the chirality of the underlying spin texture [3]. We observed the topological Hall effect occurring even in fields up to 14 T that we applied, pointing towards a remarkable stability of the spin texture in this system. In this talk, we will describe how changes to the interface symmetry, layer ordering, and the termination at the $LaMnO_3/SrIrO_3$ interfaces result in a strong variation in the magnitude of topological Hall resistance and hence the underlying chiral magnetism in this system. These results will also be compared with magnetometry measurements and element specific magnetism from Mn XMCD, which provide comparison of the bulk and interface magnetization, and the chiral magnetism. This work will describe the key role of interface symmetry to control the effective DMI and thereby the chiral spin structures in oxide superlattices.

Over the past decade, complex oxide heterostructures have shown a diverse spectrum of phenomena. The most studied of these systems, LaAlO3/SrTiO3, shows the outstanding characteristic of a high mobility 2D electron gas (2DEG) at the interface. The additional presence of interface superconductivity, magnetism and large spin-orbit coupling suggests that strong correlations play an important role in the electronic properties of this system, in contrast to conventional semiconductor 2DEGs. This has prompted a major research effort to look into the new physics of complex oxides, and engineer advanced devices with novel functionalities. Precise control of device characteristics requires understanding of the electronic bandstructure, and the interdependence of conduction electron density and properties. However, despite the large number of studies in this direction, significant sample to sample variation - influenced by sample quality, growth conditions and heterostructure configuration - has meant that there is a wide spectrum of results, leading to an unclear picture, not just of the bandstructure itself, but of which aspects of the bandstructure are especially important in determining the characteristics properties of the 2DEG. Further effort is required to resolve this problem. We present new results of low temperature, magnetotransport measurements in a high mobility LaAlO3/SrTiO3-based heterostructure. We have explored a range of sample orientations, and observe a complex pattern of Shubnikov de-Haas oscillations determined by the field normal to the interface plane, alongside distinct effects of an in-plane field. We employed magnetic fields of up to 70 T in an attempt to reach the quantum limit. By application of an electric field in the back gate geometry, we tune the Fermi level, and are able to follow the evolution of the multiple conduction subbands. Combining these new results with recent theoretical work [1], and previous high field magnetotransport measurements on similar samples, we are able to disentangle the complex bandstructure and quantify aspects such as Rashba spin-splitting, mixing of orbital character and interband scattering, which heavily impact the conduction electron properties.

Perpendicular magnetic anisotropy (PMA) at interfaces between the magnetic and nonmagnetic thin films has attracted much attention in the spintronics applications. In particular the mechanism of the PMA is important for enhancing the perpendicular magnetic anisotropy in the device structures [1]. Okabayashi *et al.* have reported the enhancement of anisotropic orbital magnetic moments in Fe at the MgO/Fe interface measured by x-ray magnetic circular dichroism (XMCD) of the Fe 2*p* core-level absorption spectroscopy [2]. They concluded that this enhancement can be mainly explained by the hybridization between the Fe 3*d* and O 2*p* states at the interface. Although XMCD is powerful tool to determine the spin and orbital magnetic moments through the magneto-optical sum rule analysis [3], XMCD spectra do not give us direct information on electronic structures. In order to directly investigate the electronic structures near the interfaces, we have performed hard x-ray photoelectron spectroscopy (HAXPES) [4] to probe the valence band electronic states of the buried Fe layer for the MgO(2 nm) capped Fe(1.5 and 20 nm) films on MgO(001) substrates. The magnetic states of the films were measured by core-level MCD-HAXPES [5]. We confirmed that the perpendicular magnetization of the 1.5-nm-thick Fe film from MCD-HAXPES under a magnetic field of 1.0 kOe. The valence band HAXPES spectrum for the 20-nm-thick Fe film was almost identical to that for bulk Fe, while the large difference between the valence band spectra for the 1.5- and 20-nm-thick Fe films was found. This result directly shows the lifting of degeneracy of the Fe 3*d* states in the MgO(2 nm)/Fe(1.5 nm)/MgO(001) structure. By comparing the experimental valence band spectra with the theoretical density of states obtained by the density functional theory calculations, we found that the Fe 3*d*- O 2*p* hybridization, the tetragonal distribution, and the lifting of degeneracy of Fe 3*d* states at the interface of Fe/MgO play important roles in the interface magnetic anisotropy.

CoFeB/MgO is one of the promising candidates for future spintronic devices due to very high tunnel magnetoresistance (TMR) [1] and perpendicular magnetic anisotropy (PMA) [2]. In order to have coherent tunneling of electrons across the interface, which is essential for achieving high TMR ratio, it is necessary that magnetic electrode has a crystalline bcc structure. This is achieved by post deposition annealing of the CoFeB based TMR multilayer in the temperature range 300 – 450^{o}C, leading to form bcc CoFe phase with (001) out-of-plane texturing, which results in improvement of TMR by several orders of magnitude [3]. However, there are some unresolved issues like contradictory results have been obtained in literature regarding diffusion of Boron. Therefore, In present work diffusion of boron has been studied in Si/$[CoFeB/MgO]_{x10}$ multilayer as a function of temperature with the help of polarized neutron reflectivity (PNR) and soft x-ray reflectivity (SoXR) measurements. SoXR measurements were done across the k absorption edge of boron, to enhence the sensitivity. With thermal annealing there are three possibilities (i) Boride and bcc (CoFe) phase both are intermixed in a single layer (ii) Boron diffuses in MgO (iii) Boride phase form at center of CoFeB. Since height of Bragg peak in PNR and SoXR changes with thermal annealing, so it rules out the first approximation. Moreover, if Boron would have diffused in MgO, it results in crystallization of CoFeB to CoFe with increase in magnetic moment. But in actual we found very less magnetic moment after fitting of PNR data. This suggests that Boron was not diffused in MgO. Best fit of PNR and SoXR data was obtained considering (iii) approximation. Applying conservation of mass, three layers of CoFeB were considered CoFe layer at the interface (2.3 μB) and a layer of Boride phase at center (1.3 μB). Therefore combined analysis of PNR and SoXR suggests that with thermal annealing Boron is not diffusing in MgO instead it diffuses in the bulk of CoFeB layer forming a layer of Boride phase at center.

U4-10. Wire width dependence of ferromagnetic resonance in Ni wires on ferroelectric $LiNbO_3$ substrate for studying heterojenction-induced magnetic characteristics. *A. Yamaguchi*[1], A. Nakao[2], T. Saiki[3], Y. Utsumi[1], T. Ogasawara[4] and K. Yamada[5] *1. Laboratory of Advanced Science and Technology for Industry, University of Hyogo, Ako-gun, Japan; 2. RIKEN, Wako, Japan; 3. Hyogo Prefectural Institute of Technology, Kobe, Japan; 4. National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; 5. Gifu University, Gifu, Japan*

Recently, the introduction of the heterojeunction between ferromagnetic and ferroelectric materials has demonstrated to control or modulate the magnetic characteristics. One of the special behaviors issues that the zebra-stripe domain structure spontaneously forms near the absence of an external magnetic field due to the competition between the shape and additional magnetic anisotropies. [1, 2] In this study, we investigated ferromagnetic resonance of Ni wires with magnetic anisotropy induced by the heterojunction between the Ni layer and ferroelectric single crystalline $LiNbO_3$ substrate using the rectifying effect. [3] In particular, we focused on the wire width dependence of ferromagnetic resonance of the Ni wires to understand the magnetization dynamics under the additional magnetic anisotropy competing with the shape and crystalline magnetic anisotropy. We fabricated 30-nm Ni wires with various widths of 0.5, 1.0, 2.0, 3.0, and 5.0 μm onto a single crystalline Y-cut $LiNbO_3$ substrate by means of electron beam lithography and lift-off method using magnetron sputtering. Figure 1 shows a schematic of the system and measurement circuit. Figure 2 displays typical wire width dependence of rectifying spectra of Ni wires under the application of an external magnetic field along the longitudinal axis of wire in plane. In this magnetic field range, the zebra-stripe domain structures are formed in the Ni wires. As shown in Fig. 2, the ferromagnetic resonance frequency increases with decreasing the wire width. This result indicates that the ferromagnetic resonance frequency is modulated by the magnetic shape anisotropy because the additional magnetic anisotropy induced by the heterojunction makes same contribution to ferromagnetic resonance. Consequently, this shape magnetic anisotropy dependence of ferromagnetic resonance allows the estimation of the additional magnetic anisotropy derived from the heterojunction.

U5-01. Observation of changes in static domain structures of thin-film magnetoimpedance element with dc bias current. *H. Kikuchi*[1] and C. Sumida[1] *1. Iwate University, Morioka, Japan*

We clarified the dc bias current on thin-film magnetoimpedance (MI) elements enhances a sensitivity and induces asymmetric impedance profiles [1]. Though asymmetric profile is partially explained by the shape of element [2], further investigation to interpret the properties still requires. Since MI properties depend on domain structures, domain observation gives beneficial information about MI profiles. Thus, we observed static domain changes of thin-film elements by a Kerr-effect microscope when the dc bias current and external field is applied to the elements. The amorphous thin-film elements having an easy axis with parallel to the width direction were prepared for the observation. Fig. 1 shows the changes in domain structures owing to applied field with/without a dc bias current. All cases in Fig. 1 show 180° domain (multi domain) around zero field whereas we confirmed no multi domain appears with the dc bias of –2 mA. When the field was swept from a positive to negative field, the multi domain appears around 1.5 or 1 Oe and disappears at –3 to –4.5 Oe. As the dc bias current generates additional bias field within the element, the field where domains translate between multi and single domain slightly shifts, while the field range where multi domain appears does not change so much with changing dc bias current. The impedance changes at 100 MHz exhibited no hysteresis and almost reversible curves against the field [2], even though the changes in domain do not correspond between the behaviors when the field sweeps forward and backward. From the results mentioned above, the dc bias current affects the behaviors of static domain structures whereas its contribution to impedance profiles at higher frequency range (e.g. 100 MHz) is not remarkable: the magnetization rotation plays main role in magnetization process. Meanwhile, the domain configuration changes due to applied field may influence impedance profiles at relatively lower frequency where domain walls can move. The results obtained are contributed to understand the acts in MI properties with dc bias current.

U5-02. Superparamagnetic Tunnel Junctions for Probabilistic Computing. *B. Parks*[1], M. Bapna[1] and S. Majetich[1] *1. Physics, Carnegie Mellon University, Pittsburgh, PA, United States*

For invertible logic gates based on superparamagnetic tunnel junctions (SP-MTJs), the device should be tunable between the parallel (P) and anti-parallel (AP) states with either a current or voltage [1]. Here we demonstrate such a device using spin transfer torque (STT) for current control. The magnetic tunnel junction film stack is Ta(5 nm)/ PtMn(20 nm)/CoFe(2 nm)/ Ru(0.8 nm)/CoFe(3 nm)/MgO(1 nm)/CoFeB(2.5 nm)/Ta(10 nm)/Pt(5 nm), and was patterned using e-beam lithography and Ar ion milling. The elliptical patterns had their easy axes along the magnetization direction of the fixed layer. Transport measurements were done using a conductive atomic force microscope (C-AFM). Tunnel magnetoresistance (TMR) on a 20 x 60 nm ellipse shows a preference for the P state due to orange peel coupling a H = 0. The corresponding resistance as a function of voltage for the same device is shown in Figure 1, showing competition between the fixed strength of the Néel dipolar orange-peel coupling field favoring the P state and the variable STT effect favoring the AP state. Resistance versus time traces were measured at different bias voltages (Figure 2). We analyzed the effect of STT current on the time-averaged magnetization of the free layer [2]. This prototype demonstration shows that low thermal stability MTJs have the necessary characteristics for future computing applications that require stochasticity and true randomness, including tunability, speed, and room temperature voltage-controlled operation. The STT control of $\langle m \rangle_t$ scheme shown in this paper is also advantageous because the sign of the bias need not be changed and thus the voltage or current control of $\langle m \rangle_t$ is unipolar in nature, requiring only the built-in coupling field and *no* external field. Such a device can be integrated in a two- or three-terminal setup and control over $\langle m \rangle_t$ can be achieved using a spin current generated by SOT instead of STT.

U5-03. Recording resolution of granular exchange-coupled composite media for microwave-assisted magnetic recording. *T. Tanaka*[1], Y. Kanai[2] and K. Matsuyama[3] *1. Faculty of Information Science and Electrical Engineering, Kyushu University, Fukuoka, Japan; 2. IEE, Niigata Institute of Technology, Kashiwazaki, Japan; 3. Dept. of Electronics, Kyushu Univ., Fukuoka, Japan*

Microwave-assisted magnetic recording (MAMR)[1] has potential application in future recording. In this study, read/write characteristics of MAMR for exchange-coupled composite (ECC) granular media were numerically simulated, and then signal-to-noise ratio (SNR) and resolution was characterized regarding the anisotropy fields for the media. 30-nm-wide recording head and spin torque oscillator designed for shingled MAMR were assumed. A 14-nm-wide MR reader with 15 nm reading gap was also assumed in reading process. ECC granular media consists of 2 layers with the soft (6 nm) and hard (6 nm) materials were modeled by discrete Voronoi grains with 4.6-nm-average-diameter. The M_s of the ECC media was 800 emu/cm^3. In the present study, various anisotropy fields were taken into consideration for comparison of the recording characteristics, where the average of the anisotropy fields for the ECC grain were constant to be 40 kOe. Recording process was simulated by numerically solving the LLG equation. The damping constant was 0.05. Significant SNR gains due to microwave assistants were obtained at the optimum microwave frequency for the media with the anisotropy fields ($H_{k,soft}/H_{k,hard}$) = (30 kOe/50 kOe), (25 kOe/55 kOe), and (20 kOe/60kOe). Figure 1 shows the SNRs and the resolutions for these media as a function of the distance (d) from the trailing edge of the main pole and leading edge of STO. The resolution is defined by the amplitude ratio of the output signal for the low (200 kbpi) and the high (1600 kbpi) density recorded tracks. SNR for the media with higher H_k gradient is tolerant of the distance. Similar tendency is also observed for the resolution. The SNR and resolution for the low gradient medium (30 kOe/50 kOe) are sensitively decrease with increase in d because of the reduction of the MAMR effects. The slight increase of the resolution for the media with (20 kOe/60 kOe) may come from optimization of microwave field angle applied to ECC grain underneath the main pole. The effect of the optimization is also observed slightly increased reproduced signal power.

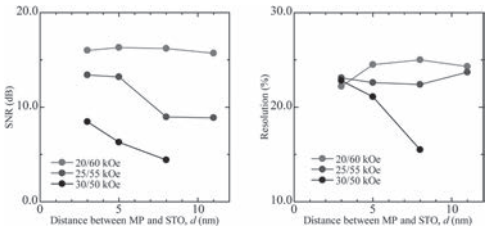

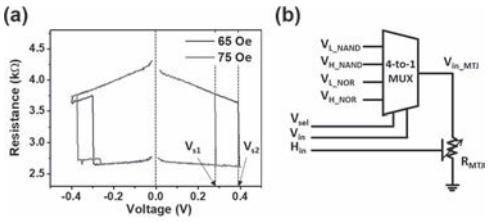

Fig. 1 SNR and recording resolution for granular exchange-coupled composite media as a function of the distance between MP and STO.

U5-04. Reconfigurable logic using a single magnetic tunnel junction. *G. Bae*[1], Y. Hwang[1] and W. Park[3] *1. Electronic Engineering, Hanyang University, Seoul, The Republic of Korea; 3. Electronics Engineering, Hanyang University, Seoul, The Republic of Korea*

Reconfigurable logic is an attractive candidate for low-power computing systems to achieve multi-functionality in a single architecture. However, the current CMOS reconfigurable logic still requires static and standby power due to the volatile characteristics of the memory component. High hardware costs and unfavorable area efficiency also limit the usability and functional expandability for newly proposed low-power computing systems within this architecture. As emerging reconfigurable logic, a magnetic tunnel junction (MTJ) has been introduced as an alternative for memory, but these approaches only performs the memory function by simple replacement of CMOS memory. This work proposes a method for reconfigurable logic that implements a universal logic function with a single MTJ logic gate where the MTJ not only works as a memory element, but it also performs computations. We construct the Boolean logic gate with a three-terminal configuration of a single MTJ where the two inputs are independently set with the Amperian and the spin-torque transfer (STT) current correlated with the field assistant switching effect [1,2]. The three-terminal MTJ becomes a programmable logic element whose multi-functional operation is performed at the single logic gate. By selecting the input ranges for logical low and high inputs, it is possible to generate multiple logic functions within an identical circuit configuration. The universality of the reconfigurable logic function is demonstrated through the 1-bit full adder by adopting the programmable gate of an MTJ. This work gives a benefit for reduction of the number of devices for reconcilable logic architecture by implementing logic and memory with the same MTJ.

U5-05. Spintronic memristor in chained MTJs. *E. Raymenants*[1,2], A. Vaysset[2], D. Wan[2], S. Couet[2], J. Swerts[2], M. Manfrini[2], O. Zografos[1,2], D. Mocuta[2], I.P. Radu[2], M. Heyns[1,2] and T. Devolder[3] *1. KU Leuven, Leuven, Belgium; 2. Imec, Leuven, Belgium; 3. IEF, Orsay, France*

In the context of neuromorphic computation, spintronic memristors are investigated for their use as synaptic weights [1]. Here, we propose and demonstrate a scalable synaptic device based on 10 magnetic tunnel junctions (MTJs) connected in series (Fig. 1(a)). Our device allows for multi-level switching, showing a large number of resistance states. This coincides well with the desired analog-like behavior in ideal memristors. When driving the magnetization reversal with magnetic field, this device can reach 10 resistance levels, switching the MTJs consecutively as shown in Fig. 1(b). For spin-transfer torque (STT)-driven reversal with positive voltage pulses, half of MTJs switch from parallel (P) state to anti-parallel (AP) while the other half switches from AP to P. However, by applying bipolar voltage pulses and by selecting the appropriate external magnetic field, we can

intentionally decrease (Fig. 1(c)) or increase (Fig. 1(d)) the resistance of the chain. In the ideal case, a total of 2^N resistance levels could be accessible when connecting N MTJs in series [2]. Here, we show experimentally that we can distinguish at least 14 levels in our memristor (Fig. 2). These levels are obtained by sweeping the external magnetic field and adding a bipolar voltage pulse at every field step. We performed this experiment a dozen times and could access at least 14 discrete synaptic weights. This device shows promise as a scalable synapse in neuromorphic hardware.

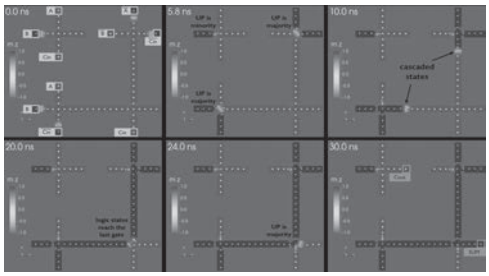
U5-06. Demonstration of Pavlov associative memory using magnetic tunnel junctions. *Y. Hwang*[1] *1. Department of Electronic Engineering, Hanyang University, Seoul, The Republic of Korea*



Attaining the functional abilities of the human brain is one of breakthroughs for the advanced modern electronics. An example of the biological functions, associative memory, which performs remembrance by learning and forgetting through the relationship between unrelated events, requires a distinct architecture differing from the standard CMOS-based electronics since the non-declarative memory recalls information by habituation, sensitization, and classical conditioning [1]. Mimicking neuron-synapse system with electronic devices has been attracted as appropriate method for realizing the functions of the associative memory [2]. In this work, we propose artificial neuron-synapse system based on magnetic tunnel junction (MTJ) for the function of associative memory. Artificial neurons generating spike trains are implemented with stochastic oscillation of MTJ by telegraphic switching, which can bring simplicity than conventional CMOS neuron circuit [3]. The rate of generated spike is a function of current and magnetic field applied to MTJ in artificial neuron. Artificial synapse is constructed by using memristive switching characteristics of MgO layer in MTJ and represents a synaptic weight with its conductance. Spike-rate-dependent-plasticity (SRDP) which is one of biological learning rules is adopted to control the weight of synapse with the difference of spike rates between pre-neuron and post-neuron. Using the proposed architecture, we present an associative memory demonstrating full functions of the Pavlov's representative experiment describing learning, memorizing, and forgetting.

U5-07. Optimization of Spin-Torque Majority Gate shape via domain-wall pinning. A. Vaysset[1], O. Zografos[1,2], M. Manfrini[1], *E. Raymenants*[1,2] and I.P. Radu[1] *1. Imec, Leuven, Belgium; 2. KU Leuven, Leuven, Belgium*

As scaling of CMOS transistors is approaching fundamental limits [1], research on future generations of beyond-CMOS logic devices is becoming very active. In this respect, spintronics offers unique properties such as intrinsic non-volatility and the possibility to write, propagate and detect information via current. New paradigms combining logic and memory are thus considered for next digital circuits [2]. New logic gates can also be designed instead of the standard NAND and NOR gates. This is the case of the Spin Torque Majority Gate (STMG) [3-7] that can lead to very compact circuits [8]. In STMG, logic levels '1' and '0' are represented by magnetization orientation up and down. They can be written by Spin-Transfer Torque and detected by Tunnel Magneto-Resistance. Previous work [7] has shown that STMG can rely on current-driven domain wall (DW) motion for information propagation between inputs and outputs. Here, with micromagnetic simulations, we investigate different designs and shapes of the STMG to show the impact of different pinning sites on device functionality. The DW motion is studied in various complex cross-like shapes with non-uniform current distribution along the x- and y-axes. After thorough investigation of single devices, we demonstrate that they can be connected to each other to form large circuits. In particular, a one-bit full is demonstrated by micromagnetic simulations using only 4 majority gates. Fig.1 illustrates the operation of this DW-based circuit. While the minority domains are pinned at the gate, the majority domains propagate to the next gate, allowing functional circuit.

Micromagnetic simulation of a one-bit full adder. This circuit computes the sum of A=0 ('down') and B=1 ('up') with a carry-in Cin=0. After about 6ns, the input domains have reached the center of the gates thanks to current-driven DW motion. Only the majority domain propagate to the output branch of STMG. After passing the first gates, the DWs propagate to the last majority gate where 1 (i.e. 'up') is majority and propagate to the output of the circuit. The final result of the operation is 1 with carry-out Cout=0.

U5-08. Modulation of Voltage-Controlled Magnetic Anisotropy through Interface Engineering Alloying in FeCo/MgO Heterostructures. *M.a. Jackson*[1], N. Kioussis[1] and F. Mahfouzi[1] *1. Physics & Astronomy, California State University, Northridge, Los Angeles, CA, United States*

Recent experiments have reported a large modulation of voltage-controlled magnetic anisotropy in Cr/Fe/MgO interfaces which arises from the presence of Cr atoms in the proximity of the Fe/MgO interface. Using ab initio density-functional theory calculations we investigate the modulation of magnetic anisotropy in FeCo/MgO interfaces through controlled doping of Cr into the FeCo-MgO interface. The calculations reveal Cr prefers an antiferromagnetic (AFM) ordering with nearest neighbors. We show that increasing the Cr concentration at the FeCo surface leads to a reduction in the MCA value, which is consistent with experimental observations in Ref [1].

U5-09. Non-Volatile Spin Logic-Memory Device. *X. Zhang*[1] and Z. Luo[1] *1. School of Materials Science and Engineering, Tsinghua University, Beijing, China*

Conventional computers based on CMOS logic suffer from the von Neumann performance bottleneck due to its hardware architecture that non-volatile magnetic memory and semiconductor based logic are separated. The necessary processes of information reading, processing and writing, information transformation and transfer between two units are required and would consume a huge amount of time and energy. In addition, because the information during processing is volatile and needs to be refreshed frequently, it also consumes a great deal of energy and has the risk of information loss when suddenly powered down. Our purpose is to solve this problem by synthesizing the complementary features of magnetic materials and semiconductors. We invented Si based magnetic logic device which can perform reconfigurable four basic Boolean logic operations including AND, NAND, OR and NOR [1]. We also proposed an alternative way to realize magnetic logic by coupling spin-dependent transport effect in magnetic material and nonlinear transport effect in semiconductor material. All four Boolean logic operations could be performed [2]. Furthermore, we proposed a spin logic-memory device by coupling anomalous Hall Effect and negative differential resistance phenomena (Fig.1) [3]. All four basic Boolean logic operations could be programmed by magnetic bit at room temperature with high output ratio (> 1000 %) and low magnetic field (~5 mT). In the same clock cycle of reconfigurable logic operation, logic outputs could be directly written into magnetic bits by spin-orbit-torque switching effect, demonstrating non-volatile information reading, processing and writing realized in one step and one device (Fig.2). Hence, logic and non-volatile memory could be closely integrated in one chip. The time and energy used in the processes of information transformation and transfer could be saved. The information during processing was non-volatile, leading to the feature of zero quiescent power and 'instant-on' performance. Our device might break through the Von Neumann performance bottleneck and make computer more energy efficiency and higher performance.

Heat assisted magnetic recording (HAMR) is a new technology which uses temporary near field heating of the media during write to increase hard disk drive storage density. By using a plasmonic antenna embedded in the write head, an extremely high thermal gradient is created in the recording media (up to 10K/nm). State of the art HAMR media consists of grains of $L1_0$-FePt exhibiting high perpendicular anisotropy separated by 1 to 2 nm thick carbon segregant. Next to the plasmonic antenna, the difference of temperature between two nanosized FePt grains in the media can reach 80K across the 2 nm thick grain boundary. This represents a gigantic local thermal gradient of 40K/nm across a carbon tunnel barrier. In the field of spincaloritronics, much weaker thermal gradients of ~1K/nm were shown to cause a thermal spin-transfer torque capable of inducing magnetization switching in magnetic tunnel junctions. Considering that the thermal gradients in HAMR are one to two orders of magnitude larger than those used in conventional spincaloritronic experiments, one may expect a strong impact from these thermal spin-transfer torques on magnetization switching dynamics in HAMR recording. This study addresses this problem. It combines theory, experiments aiming at determining the polarization of tunneling electrons across the media grain boundaries and micromagnetic simulations of recording process taking into account these thermal gradients. It is shown that the thermal in-plane torque can have a detrimental impact on the recording performances by favoring antiparallel magnetic alignment between neighboring grains during the media cooling. Implications on media design are discussed in order to overcome the influence of these thermal torques. Suggestions of spincaloritronic experiments taking advantage of these huge thermal gradients produced by plasmonic antenna will also be given.

U6-01. Mutual Inductance Calculation Method of Multiple Coils at an Arbitrary Spatial Posture. *J. Zhao*[1,2] *1. Nanyang Institute of Technology, Nanyang, China; 2. Xuji Power Co. Ltd., Xuchang, China*

The mutual inductance as a fundamental electrical engineering parameter in numerous electrical applications is the principal parameter between primary and secondary. Today, with the availability of powerful and general numerical methods, such as finite element method and boundary element method, it is possible to calculate accurately and rapidly the mutual inductance of almost any practical 3-D geometric arrangement of conductors. However, in many circumstances, there is still an interest to address this problem using analytic and semi-analytic methods, as they considerably simplify the mathematical procedures, and often lead to a significant reduction of the computational effort. The mutual inductance calculation between coaxial circular filaments has been thoroughly treated by a number of authors since the time of Maxwell [1]–[5]. A formula for two circles whose axes intersect was first given by Maxwell [1]. Formulas for circular loops with parallel axes have later been derived by [1, 2], and for movable planar coils on parallel surfaces also have been derived by [3]. However, these formulas are slowly convergent and are applicable only within a restricted range of parameters. In this paper, Mutual inductance calculation method of multiple coils arranged in space is derived at an arbitrary spatial point with an arbitrary angle. First, we use the approach of the magnetic vector potential to calculate the mutual inductance of two circular loops arbitrarily positioned with respect to each other. We treated this problem in its most general form, by considering plane equations for representing the positions of the loops. In the final form of our equations, the mutual inductance is obtained by sequentially evaluating a few elementary expressions and solving numerically a single, well behaved integral. Its unlimited range validity therefore makes it an ideal choice in any of the above-mentioned application fields. Second, relative positional relationship of multiple coils in space can be obtained by using coordinate transformation of space rigid body motion. Then mutual inductance value of multiple coils can be gotten according to inductance calculation method derived above.

U6-02. Research on Transient Electric Field of Converter Transformer Based On Insulation Material Properties. *Q. Wang*[2], B. Bai[1,2], D. Chen[2] and X. He[2] *1. Shenyang University of Technology, Shenyang, China; 2. School of Electrical Engineering, Shenyang University of Technology, Shenyang, China*

1. Introduction The insulation of converter transformer windings is not only influenced by DC voltage, but also by polarity reversal voltage [1]. The analysis of the electric field of the converter transformer is beneficial to improve the stability of the HVDC transmission. The transient electric field distribution is determined by the dielectric properties of the insulation material, which is affected by temperature and frequency [2]. Therefore, the dielectric parameters of vegetable oils, mineral oils, and insulating papers were measured at different frequencies and temperatures, firstly. Then, a 500 kV converter transformer winding model was established. The influence of polarity reversal time and properties of insulating materials on the electric field distribution of transformer windings was analyzed. The results show that the characteristics of the insulating material are related to temperature and frequency, and the effect of the insulation material type on the transient polarity reversal electric field distribution is significant. 2. Insulation material parameter measurement The relative permittivity and conductivity of oil-immersed paper, vegetable oils and mineral oils were measured at different temperature, from 1 kHz- 10 MHz. The dielectric parameters of vegetable oils are shown in Fig. 1, and more results will be shown in the full paper. 3. Calculation and analysis The valve winding is applied 118 kV voltage, and the regulating winding is applied 303 kV voltage. The transient electric field distribution of converter transformer under polarity reversal voltage was obtained. The electric field of converter transformer with (a) vegetable oils and (b) mineral oils before and after polar inverse are shown in Fig. 2, and more results and analysis will be shown in the full paper. 4. Conclusion The maximum electric field strength of converter transformer with vegetable oils is 59.2 kV/m, and that with mineral oils is 57.9 kV/m. The electric field intensity in the oil-immersed insulation paper is slightly higher than that between the oil gaps.

U6-03. Simulation and Validation by Experiment of 3kW, 100,000rpm High-speed Motor for Electric Turbo Charger Considering Response Time. *D. Hong*[1,2], T. Lee[2] and Y. Jeong[1] *1. Korea Electrotechnology Research Institute, Changwon, The Republic of Korea; 2. Department of Energy Conversion, University of Science and Technology, Changwon, The Republic of Korea*

Centrifugal supercharger motor also known as e-booster, e-charger or electric blower. The electric motors run at speeds in excess of 100,000rpm. We can drive the compressor of an independent supercharger to create steady boost (and power) mostly during startup, transient and low-speed operation. The motor can be turned on and off as needed. This technology also virtually eliminates turbo lag and enables engine downsizing without compromising engine performance. The ETC (Electric Turbo Charger) consists by a high speed permanent magnet synchronous motor (PMSM), ball or air foil bearings, impeller, controller and power stack and so on. KERI (Korea Electrotechnology Research Institute) is developing a high speed surface permanent magnet (SPM) type of synchronous motor and a PWM-driven inverter in Fig. 1. This system operates at a power density of 3kW at 100,000rpm and is intended to fit the 1,600cc diesel vehicles to reduce turbo-lag within 0.5sec. The change in the ratio of the diameter to the length of the rotor affects the moment of inertia of the rotor and the response time varies with the moment of inertia. Also, as the diameter of the rotor decreases and the length increases, it also affects critical speed of rotor, which is an important factor in designing the motor. Because the voltage and torque characteristics vary according to the diameter and length of the rotor, the design of experiment is applied so that it can be predicted. Air gap, stator outer diameter, the conductor occupying rate and winding specifications were applied as the same conditions. Deciding what materials to use in the motor application is important, especially when it comes to permanent magnets, hard magnetic materials, such as samarium cobalt (SmCo) and neodymium iron boron (NdFeB) and core materials such as 0.2t, 0.35t 0.025t. SmCo and 0.2t core were more suitable for high speed. In this paper, the analysis result is in good agreement with the experimental result, with a maximum error of 2.5% considering the mechanical loss, as shown in Table I [1-2]. The detailed comparison between experiment and simulation results will be dealt with in final paper.

U6-06. First experimental evidence of magnetic structure variations in FeCr alloys damaged by self-ions under an external magnetic field. *I. Garcia-Cortes*[1], A. Moroño[1], F.J. Sanchez[1], P. Muñoz[1] and J.F. Cuñado[2,3] *1. Laboratorio Nacional de Fusion. CIEMAT, Madrid, Spain; 2. IMDEA Nanociencia, Madrid, Spain; 3. Universidad Autónoma de Madrid, Madrid, Spain*

The research on structural materials for future fusion reactors has been mainly focused on the evolution of mechanical properties with irradiation dose, temperature, etc. However the performance of materials from the point of view of its magnetism remains unclear, although this aspect is critical, as vacuum vessels and structural materials in magnetically confined fusion reactors need to withstand an intense and hazardous radiation environment under the presence of strong magnetic fields. FeCr alloys are promising candidates for different parts of a fusion reactor but irradiation is known to change Cr distribution on them [1,2]. Changes in Cr concentration can be detected by many techniques. For instance by looking at changes in the magnetic domain structure, as already shown on pristine FeCr alloys with well-defined stoichiometric relation [3]. Series of experiments have been carried out to investigate the damage on FeCr alloys by using self-ions irradiation (trying to simulate the neutrons effect) [2]. On these experiments, we have use Fe^{+}@1MeV ions up to a dose of 15 dpa (displacement per atom) for each sample. The samples were irradiated in couples (with/without an external magnetic field, 0.4 T) and at different temperatures. A shadow mask covering half the specimen is used during irradiation to compare magnetic domain structure between irradiated and non-irradiated zones. The analysis was carried out using Kerr Microscopy for imaging the magnetic domain structure, and SEM-EDX to correlate the underlying structural changes. Preliminary results confirm different magnetic domain structure as we move from non-irradiated to irradiated regions. This is (in general) compatible with lower Cr concentration in the irradiated zone (see Fig. 1), having different effect depending on the temperature and the exposition to an external magnetic field during irradiation. SEM-EDX confirms structural changes between both regions.

Magnetic domains (in remanence) at the frontier between irradiated and non_irradiated regions

U6-07. Magneto-viscosity of Ba-Sr ferrite based ferrofluids in different colloids. *N. Gautam*[1] and R. Singh[1] *1. School of Physics, University of Hyderabad, Hyderabad, India*

The Ba-Sr ferrite (BSF) nanoparticles of Ba0.8Sr0.2Fe2O4 were synthesized by hydrothermal process. The BSF nanoparticles were coated with DBSA (4-Dodecylbenzenesulfonic acid) and oleic acid to prevent the agglomeration and cluster formation and dispersed in water and silicone oil to prepare the water and silicone oil based ferrofluids (FF) respectively [1]. The transmission electron micrographs (TEM) show the hexagonal structure of the nanoparticle. The magnetization vs magnetic fied, M(H) and magnetization vs temperature M(T) plots under zero field cooled (ZFC) and field cooled (FC) modes with applied field of 100 Oe show ferromagnetic behaviour of the nanoparticles. The magneto-viscosity plots were recorded using a rheometer (Anton-Paar MCR501) equipped with magnetic setup. Different hysteresis behavior is observed in the magneto-viscosity plots (fig 2) at 1 s-1 shear rate for water based and silicone oil based ferrofluids. This is due to the different relaxation rates of the formed chains in the ferrofluids when the fluids is subjected to magnetic field [2]. The silicone oil based FF showed slower relaxation with higher viscosity compared to water based FF due to the strongly coupled magnetic particles in chains. The magnetic hysteresis of water based FF is found to be more compared to the silicone based oil FF. In the silicone oil based FF, the magnetic particles are strongly coupled in the field direction and form chains. On removing the field particles relax and form closed hysteresis loop. Whereas in water based FF after removing the field the particles do not return to the original orientation and give rise to open hysteresis loop. These results show that surfactant and colloids affect the magneto-viscosity behavior of the ferrofluid. The silicone oil based FF is more stable compared to water based FF. The flow curves at different magnetic fields show power law behavior.

U6-08. Dual Resonant Mode Magnetic Composite Energy Harvester. *M. Khan*[1] and J. Kosel[2] *1. CEMSE, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 2. CEMSE, King Abdullah University of Science and Technology (KAUST), Thuwal, Saudi Arabia*

A multitude of always on and interconnected sensing, actuating and computing systems can enable numerous applications in medical diagnostics, navigation and remote sensing ushering in the internet of things era. However, such electronic systems are not capable of truly autonomous operation as they are still powered by the electrical grid either directly or via a rechargeable battery. Thereby, it makes sense to power these devices by harvesting ambient vibrations from various sources such as air conditioners, human movement, sounds, etc., which can enable a reliable, pervasive and ubiquitous sensing and computing environment [1]. While ambient vibrations exist throughout the sub 100 Hz frequency region, most vibration harvesters are resonant systems, limiting their usability to a very narrow range of frequencies within this band. Herein, we present a wide band, low-frequency energy harvester, comprising of a magnetic composite proof mass supported by a high aspect ratio magnetic composite cilia array, fabricated on top of a microfabricated planar coil (fig. 1). The frequency response of this magnetic composite structure consists of two closely spaced resonant peaks with overlapping pass bands, which results in a large continuous band of operating frequencies. The planar coil has 40 turns and occupies an area of 1 cm^2. Permanent magnetic NdFeB micropowder is dispersed in polydimethylsiloxane (PDMS) to form a magnetic composite elastomer [2]. This composite is molded to form a 1.15 cm^3 proof mass atop a 10x10 array of cilia, each of which is 2 mm long and 200 μm wide. This highly flexible structure readily responds to ambient vibrations efficiently converting the mechanical energy into an oscillating magnetic field. This oscillating magnetic field is transformed into an oscillating electrical potential by the planar coil, thereby converting mechanical vibrations into electrical energy. When excited by a vibration of 3.0g amplitude, this harvester exhibits resonant peaks at 52 Hz and 61 Hz with a peak open circuit r.m.s voltage of 614 μV, and a 3 dB bandwidth of 19.2 Hz centered around 58.14 Hz (fig. 2).

U6-09. Optimal Design of an IPMSM in Railway with Independently Rotating Wheel-Sets. H. Liu[1], Y. Oh[1] and *H. Lee[2] 1. Hanyang University, Seoul, The Republic of Korea; 2. Electric Automatisation, Busan Institute of Science & Technology, Seoul, The Republic of Korea*

The railway vehicle is required to have the ability to automatically restore to center when the wheel is offset to one side of the rail. If there is no restoration capability, there will be a large friction between the wheel and the rail during driving, which can increase the noise and vibration and cause the derailment in case of serious. In the railway industry, the wheel system is divided into solid axle wheel-set (SAWS) and independently rotating wheel-set (IRWS),. Different with SAWS, the IRWS can run on rush curve section rails. but cannot generate restoring force due to no shaft connection of the motor, requiring additional restoring force when controlled by a separate motor. As shown in Fig. 1, the IRWs need to be exactly opposite the additional torque, eventually repeated collision on the track to get the final recovery. Therefore, the minimum torque ripple for the motor design is required to reduce the effect on the additional restoring torque. However, for railway traction motors that require a large starting torque density, in order to obtain a greater current density, the stator of the motor is generally designed as an open slot and a flat coil to increase the coil fill factor. In the past studies[1]-[2], the design of the open slot will bring a lot of cogging torque, which will lead to large torque fluctuations. In this paper, in order to reduce the torque ripple of the design motor and improve the control performance of IRWs, this paper adopts different pole/slots combinations, winding methods, and PM shape design, Fig.2 shown the IPMSM, and after optimization, the design parameters are obtained, as presented in Table I. Finally, it effectively reduces the torque ripple of the (interior permanent magnet synchronous motor)IPMSM with open slots. In final paper, the simulation results will be verified through experiments

U7-01. Magnetic shape-memory effect in $SrRuO_3$. *D. Brüning*[1], S. Kunkemöller[1], A. Stunault[3], A. Nugroho[2], M. Braden[1] and T. Lorenz[1]
1. II. Physikalisches Institut, University of Cologne, Cologne, Germany; 2. Faculty of Mathematics and Natural Science, Institut Teknologi Bandung, Bandung, Indonesia; 3. Institut Laue Langevin, Grenoble, France

The discovery of type-II multiferroics initiated strong interest in the control of magnetism by electric fields as well as the control of a structural distortion by magnetic fields. This effect is not restricted to polar distortions. We show that an antiferrodistortive structral distortion, namely an oxygen octahedron rotation, can be driven by weak magnetic fields in $SrRuO_3$. As most perovskites, $SrRuO_3$ exhibits structural phase transitions associated with rotations of the RuO_6 octahedra. From a high temperature cubic phase it becomes tetragonal at 975 K and orthorhombic at 800 K resulting in six possible domains. Furthermore, $SrRuO_3$ orders ferromagnetically at T_c = 160 K with easy-axis anisotropy due to spin orbit coupling. Our neutron diffraction and macroscopic measurements unambiguously show that moderate magnetic fields rearrange structural domains, although the ferromagnetic order occurs at six times lower temperature than the structural distortion. For the field along a cubic $[110]_c$ direction, a fully detwinned crystal is obtained by applying fields of the order of 2 T. The magnetic field control of structural domains arises from the large magnetic anisotropy due to strong spin-orbit coupling. Subsequent heating above T_c causes a magnetic shape-memory effect, where the initial structural domains recover, which is remarkably different from Heusler alloys, which have to be heated above the structural phase transition T_S. Our results have to be taken into account when analyzing the magnetic field dependence of any physical property in single-crystalline or thin-film $SrRuO_3$.

U7-02. Exchange bias and spin-phonon coupling in complex glassy layered perovskite $SrLaMn_{0.5}Ni_{0.5}O_4$. *R. Das*[1], P. Neenu Lekshmi[1] and P. Santhosh[1] *1. Department of Physics, Indian Institute of Technology Madras, Chennai, India*

Oxide perovskites have been intensively studied, and they also exhibit an enormous variety of structural modifications and variants. Among them layered perovskite of Ruddlesden Popper (RP) 214 compounds [1] corresponding to the general formula $A_{2n}B_nO_{3n+1}$, (n = 1, 2, ...), consisting of alternated ABO_3 and AO layers, also shows interesting properties such as superconductivity [2], ferroelectricity [3-4], colossal magnetoresistance [5] etc. In the present work, a single-layered Ruddlesden-Popper oxide, $SrLaMn_{0.5}Ni_{0.5}O_4$ (SLMNO) have been synthesized and characterized. The crystallographic structure obtained from X-ray diffraction and Raman spectroscopy revealed a tetragonal crystal structure with lattice parameters of a = 3.8388(4) Å and c = 12.5593(2) Å. dc magnetization shows the presence of multiple magnetic phase transitions which have been analyzed in detail with magnetic memory and isothermal measurements. Our results show that this oxide undergoes a weak ferromagnetic ordering below 150 K and enters into spin glass regime around 15 K, thereby characterizing this material as a complex glassy layered magnetic material. The prime novelty regarding the present work is the observation of Exchange Bias (EB) as well as a spin-phonon coupling in a single-layered Ruddlesden-Popper phase. SLMNO exhibits EB at 5 K, ~0.075 kOe at an applied cooling field of 50 kOe, and the EB value decreases with increasing temperatures. The temperature variation of Raman spectra shows the existence of spin-phonon coupling, softening of symmetric mode (682 cm^{-1}), near and below the first magnetic transition temperature. The evidence of EB, as well as spin-phonon coupling in Ruddlesden-Popper phase, will definitely motivate for further novel innovations in the field of functional oxides.

U7-03. Forbidden coherent transfer observed between two realizations of quasi-harmonic spin systems. *S. Bertaina*[1] and I. Chiorescu[2,3] *1. Magnetism, IM2NP - CNRS, Marseille, France; 2. Physics, NHMFL, Tallahassee, FL, United States; 3. Physics, FSU, Tallahassee, FL, United States*

Using a multi-level quantum system, we demonstrate Rabi oscillations between states belonging to different realizations of quasi-harmonic oscillators. The Mn^{2+} ions diluted in a MgO matrix have tunable equally-spaced Sz spin states. The hyperfine field is large enough to separate sets of states {Iz,Sz=–5/2…+5/2} of consecutive Iz values. Due to the combined action of the hyperfine and crystal-field operators, such sets are coupled. If this coupling is strong enough and the coherence times of the electro-nuclear states are large enough, a level repulsion of corresponding dressed states is to be observed. Experimentally, we have been able to implement a two-tone technique allowing us to excite the multi-level system at any detuning, and then read it with a resonant pulse. This technique allows us to achieve a strong coupling regime when a splitting between Rabi oscillations of the electro-nuclear states is observable, although the states belong to different Iz

values. We have developped a numerical model which describes with a high accuracy all the Rabi frequency modes. This demonstrates the possibility of including long-lived nuclear states as a degree of freedom in quantum computing based on multi-level systems

U7-04. Ab Initio Investigation of Fe Substitution Effect on Magnetostructural Transition of CoMnGe. *Y. Okubo*[1], S. Eto[1], Y. Mitsui[1], K. Koyama[1] and S. Fujii[1] *1. Kagoshima University, Kagoshima-shi, Japan*

In CoMnGe alloy, the structural transformation from the Ni_2In-type hexagonal structure to the TiNiSi-type orthorhombic structure at 375~620 K (T_m) is followed by the magnetic transformation from a paramagnetic state to a ferromagnetic state at 327~355 K (T_C). When the structure changes from hexagonal to orthorhombic, there is a large volume change (approximately 4%) and a large increase in magnetic moment. If lowering the T_m below the T_C, two, structural and magnetic, transitions can occur simultaneously. For this purpose, there are several experimental studies such as introducing the vacancy, the fourth elements in CoMnGe. Recently, several experimental studies of (Co,Fe)MnGe and Co(Mn,Fe)Ge show the Fe substitution brings the decrease of the T_m below the T_C. Thus, these materials have a possibility of a magnetic functional material used as a magnetic-field-driven actuator or a magnetic refrigeration material. We have carried out first-principles calculations for the systems (Co,Fe)MnGe and Co(Mn,Fe)Ge to clarify the effects of Fe substitution for Co or Mn on the hexagonal-structure stabilization from the point of view of an atomic scale or an electronic scale.

U7-05. Confinement Effects on the Metamagnetic Behavior of Mesoscale FeRh Structures. *J. Arregi*[1], M. Horký[1], E.E. Fullerton[2] and V. Uhlir[1,3] *1. CEITEC BUT, Brno University of Technology, Brno, Czechia; 2. UC San Diego, La Jolla, CA, United States; 3. Institute of Physical Engineering, Brno University of Technology, Brno, Czechia*

The FeRh alloy undergoes a first-order metamagnetic phase transition from antiferromagnetic (AF) to ferromagnetic (FM) order at 370 K, presenting a thermal hysteresis of 10 K between the cooling and heating cycles. The transition is also characterized by a volume increase and a reduction in resistivity, thus possessing interconnected structural, magnetic and electronic order parameters [1,2]. This specific feature of FeRh allows controlling the phase transition via several types of external driving forces, such as temperature, magnetic field, strain, electrical currents or optical pulses. Unlike bulk crystals, thin films of FeRh present a relatively broad phase transition due to structural defects and local stoichiometry variations. However, we recently found by tracking the resistance of mesoscale FeRh stripes that an avalance-like abrupt FM-to-AF transition occurs during cooling, whereas the reverse AF-to-FM transition remains broad [3]. We attributed the origin of this asymmetry to the different role of FM and AF interactions in the presence of disorder. Here, the effects of mesoscale confinement on the metamagnetic behavior of patterned FeRh structures are investigated via Kerr microscopy [4]. The temperature-dependent magnetization reversal behavior of individual FeRh structures provides specific phase-transition characteristics of single mesoscale objects. Our study reveals that confining FeRh films into sub-micron lateral sizes reduces the transition temperature by about 20 K, which is a result of strain relaxation caused by patterning. We also observe that for stripe widths below 500 nm, the transition during cooling becomes very abrupt for the magnetization order parameter (Fig. 1), similarly to resistance [3]. This recovery of the abrupt transition in nanostructures could lead to more efficient routes to control the phase transition. We discuss that the study of FeRh under lateral confinement provides an interesting platform to explore emergent metamagnetic phenomena arising from the interplay of the structural, magnetic and electronic degrees of freedom at the mesoscopic length scale.

U7-06. Magnetic properties of Bis-Lanthanoates. K. Esien[1], E. McCourt[2], P. Nockemann[2] and *S. Felton*[1] *1. School of Mathematics and Physics, Queen's University Belfast, Belfast, United Kingdom; 2. School of Chemistry and Chemical Engineering, Queen's University Belfast, Belfast, United Kingdom*

Magnetic ionic liquids (MILs) are a class of ionic liquid incorporating one or more magnetic atoms into the anion or cation of the ionic liquid, endowing the ionic liquid with magnetic properties alongside the existing properties of ionic liquids. MILs have applications in e.g. fluid-fluid separations, electrochemistry, and polymer chemistry. In this study three different types of bis-lanthanoates, that exist in different phases, have been synthesised and characterised (Ln = lanthanide): 1) imidazolium lanthanide acetate – [C4Mim]2[Ln2(OAc)8] – forms a crystalline solid at room temperature, 2) phosphonium lanthanide acetate – [P666 14]2[Ln2(OAc)8] – is in a solid glassy state, and 3) phosphonium lanthanide octanoate – [P666 14]2[Ln2(Oct)8] – is an ionic liquid. X-ray diffraction of the crystalline solid 1) confirm that the Ln(III) ions form dimers, bridged by carboxyl groups, but cannot yield information about samples 2) and 3) since these lack long-range order. SQUID magnetometry studies of samples where the lanthanide is dysprosium, show that all three samples have effective magnetic moments consistent with non-interacting Ln(III) ions at room temperature, but deviate from this behaviour in the same way below 50 K, see figure. The experimentally determined magnetic susceptibility has been compared to a simple model for a system with two Dy(III) ions; the implications from these fits for the magnetic interactions and the structure of the ionic liquid and glass will be discussed.

U7-07. Eddy Current Loss Analysis of Underwater Wireless Power Transfer Systems with Misalignments. *Z. Yan*[1], Y. Zhang[2], K. Zhang[1], H. Wen[1], Z. Mao[1] and B. Song[1] *1. School of Marine Science and Technology, Northwestern Polytechnical University, Xi'an, China; 2. Department of Electrical and Computer Engineering, San Diego State University, San Diego, CA, United States*

Underwater Wireless Power Transfer (WPT) has gained a lot of popularity in recent years. In the seawater environment, the electrical conductivity is non-negligible compared with that in the air. Therefore, the eddy current loss is generated by the high-frequency alternating currents in the coils. The eddy current loss of the aligned coils has been analyzed while the eddy current loss of the misaligned coils has not been explored yet. In this paper, an analytical model for the eddy current loss of a coreless WPT system in seawater with misalignments is established with Maxwell's equations. The theoretical expressions of the electric field intensity and the eddy current loss are derived. Then the eddy current loss is analyzed under different misalignments and frequencies. Finite element analysis (FEA) simulations are conducted in Comsol Multiphysics. The electric field is analyzed and the eddy current loss is calculated, which is consistent with the analytical model. An underwater WPT prototype is set up and the simulations and the experiments have verified the theoretical analysis.

U7-08. Magnetoelectric Spin Glass Transition(s) in Pure and Disordered $BiFeO_3$. *A. Kumar*[1] and D. Pandey[1] *1. School of Materials Science and Technology, Indian Institute of Technology (BHU), Varanasi, India*

For disordered Heisenberg systems with small single-ion anisotropy (D), two spin-glass transitions below the long-range ordered (LRO) phase transition temperature (T_c) have been predicted theoretically for compositions close to the percolation threshold. Experimental verification of these predictions is still controversial for conventional spin glasses. We show that multiferroic spin-glass systems can provide a unique platform for verifying these theoretical predictions via a study of change in magnetoelastic and magnetoelectric couplings, obtained from an analysis of diffraction data, at the spin-glass transition temperatures. Results of macroscopic and microscopic measurements are presented on disordered $BiFeO_3$, a canonical Heisenberg system with small D, which reveal appearance of two spin-glass phases SG1 and SG2 in coexistence with the LRO phase below the Almeida-Thouless and Gabay-Toulouse lines. It is shown that the temperature dependence of integrated intensity of antiferromagnetic (AFM) peak shows dips with respect to the Brillouin function behaviour around the SG1 and SG2 transition temperatures. The temperature dependence of the unit-cell volume departs from the Debye-Grüneisen behaviour below the SG1 transition and the magnitude of departure increases significantly with decreasing temperature upto the electromagnon driven transition temperature below which a small change of slope occurs followed by another similar change of slope at the SG2 transition temperature. The ferroelectric polarization also changes significantly at the two spin-glass transition temperatures. Our results, clearly demonstrate that the SG1 and SG2 transitions occur on the same magnetic sublattice and are intrinsic to the system. We also construct a phase diagram showing all the magnetic phases in BF-xBT system. While our results on the two spin-glass transitions support the theoretical predictions, it also raises several open questions which need to be addressed by revisiting the existing theories of spin-glass transitions after taking into account the effect of magnetoelastic and magnetoelectric couplings as well as electromagnons.

U7-09. Relaxation Mechanisms in the Néel Skyrmion Lattice Host GaV_4S_8 Probed by AC Magnetic Response. *E. Clements*[1], R. Das[1], G. Pokharel[3], D. Mandrus[3,4], M. Osofsky[2], H. Srikanth[1] and M. Phan[1]
1. Department of Physics, University of South Florida, Tampa, FL, United States; 2. Naval Research Laboratory, Washington, DC, United States; 3. Department of Physics & Astronomy, University of Tennessee, Knoxville, TN, United States; 4. Materials Science and Technology Division, Oak Ridge National Laboratory, Oak Ridge, TN, United States

The multiferroic lacunar spinel, GaV_4S_8, realizes a Néel skyrmion lattice (SkL) phase below the ferromagnetic Curie temperature, T_C = 13 K. Due to a cubic to rhombohedral structural transition [1] at T_{JT} = 42 K (JT = Jahn-Teller), the magnetic easy axis is oriented in the direction of rhombohedral distortion along one of four equivalent <111> directions. Unlike the chiral SkL that exists in the well-studied cubic helimagnets, the Néel SkL can be described as a superposition of spin cycloids. Furthermore, the vortex cores are fixed along the magnetic easy axis. [2] The propagation direction of the incommensurate spin cycloid and SkL is confined within the lamellar ferroelectric domains. Thus, the relaxation dynamics observed in this system are complicated by coexisting magnetic orders and the termination of the spatially-modulated magnetic states at the structural domain boundaries. [3] In this study, we investigate the relaxation mechanisms across the magnetic phase diagram of GaV_4S_8 as a function of temperature and magnetic field. Ac susceptibility measurements are performed for frequencies f = 11 – 10,000 Hz, which allow the detection of relaxation phenomena on time-scales ranging from the response of the magnetic superlattice to the moments of the magnetic domains. Particularly, our results allow the refinement of the dynamic response as the magnetic phases evolve from high temperature-information which is typically lost in measurements confined to longer time windows. At low temperature, we investigate the transition between the zero-field spin cycloid and the ferromagnetic ground state. In this regime, the higher harmonic components of the ac magnetic response support the picture of a harmonically-modulated cycloid spin structure which becomes distorted on approaching the ferromagnetic regime. The dynamic results are discussed within the context of canonical chiral magnetic systems.

U7-10. Magnetic properties of mixed sodium-lithium iron fluorophosphate $NaLiFePO_4F$ cathode material. *J. Seo*[1], H. Choi[1] and C. Kim[1]
1. Department of Physics, Kookmin University, Seoul, The Republic of Korea

The mixed sodium-lithium iron fluorophosphates $NaLiFePO_4F$ have been synthesized by solid-state route. The crystal and magnetic properties were investigated by x-ray diffraction (XRD), vibrating sample magnetometer (VSM), and Mössbauer spectroscopy. Structure refinement of $NaLiFePO_4F$ was analyzed using Fullprof program. The $NaLiFePO_4F$ was measured by X-ray diffraction (XRD) and was found that the structure of sample was orthorhombic with space group of *Pnma*. Cell parameters of $NaLiFePO_4F$ are as follows: a_0 = 10.9720 Å, b_0 = 6.3616 Å, c_0 = 11.4267 Å, and V = 797.5837 Å^3. In $NaLiFePO_4F$, *8d* positions are occupied by Na ions only, while *4c* sites are occupied both by Na and Li ions. Also, a six-coordinated Fe^{2+} environment is observed in $NaLiFePO_4F$ with distances ranging from 2.079 to 2.173 Å and an average distance of 2.1052 and 2.1266 Å for Fe1 and Fe2, respectively. Temperature dependence of zero-field-cooled (ZFC) and field-cooled (FC) curves was obtained by VSM under 100 Oe from 4.2 to 295 K. We were confirmed the magnetic Néel temperature. Mössbauer spectra of $NaLiFePO_4F$ have been taken at various temperatures ranging from 4.2 to 295 K. The Mössbauer spectra of $NaLiFePO_4F$ compound exhibits doublets with typical for Fe^{2+} in octahedral sites in fluorophosphates.

U7-11. Investigation of spin-orientation in antiferromagnetic ordering for $LiFe_{1-x}Zn_xPO_4$ with Mössbauer spectroscopy. *H. Choi*[1], M. Kim[1] and C. Kim[1]
1. Department of Physics, Kookmin University, Seoul, The Republic of Korea

Zn-doped $LiFe_{1-x}Zn_xPO_4$ (x=0.1, 0.2, 0.3, and 0.5) samples were prepared by using the solid-state reaction method. The XRD patterns of samples were analyzed using Fullprof program by Rietveld refinement method. The crystal structure of $LiZn_xFe_{1-x}PO_4$ were determined to be orthorhombic with space group *Pnma* up to x=0.3. The $LiZn_xFe_{1-x}PO_4$ compounds with x=0.5 is a two-phase mixture of the orthorhombic and monoclinic phase. According to the temperature dependence of magnetic susceptibility of $LiFe_{1-x}Zn_xPO_4$, all samples show antiferromagnetic behaviors. The Néel temperature (T_N) and spin-reorientation temperature (T_S) decrease from 48 K, 14 K at x=0.1 to 36 K, 8 K at x=0.5 with Zn concentrations. This is due to the Fe-O-Fe superexchange interaction being larger than that of the Fe-O-Mg link. In order to investigate the hyperfine interaction of Fe^{2+} ions in FeO_6 octahedral sites, Mössbauer spectra of $LiFe_{1-x}Zn_xPO_4$ have been taken at various temperatures from 4.2 to 295 K. The Mössbauer spectra at temperatures below T_N were fitted with eight Lorentzians by diagonalizing the 4x4 magnetic and quadrupole Hamiltonian. The magnetic hyperfine field (H_{hf}) and electric quadrupole splitting (ΔE_Q) values of $LiFe_{0.7}Zn_{0.3}PO_4$ at 4.2 K were determined to be H_{hf} = 122.93 kOe, and ΔE_Q = 2.75 mm/s. The isomer shift (δ) values of the $LiZn_xFe_{1-x}PO_4$ were between 1.10 and 1.25 mm/s, indicating the ferrous(Fe^{2+}) at all temperatures. We have found that Zn ions in $LiFe_{0.7}Zn_{0.3}PO_4$ induce an asymmetric charge density due to the presence of Zn^{2+} ions at the FeO_6 octahedral sites.

Mössbauer spectra of $LiFe_{0.7}Zn_{0.3}PO_4$ at various temperatures

U8-01. Multiferroic behavior of Tb_2BaCoO_5, with an exceptionally large magneto-dielectric coupling. S.K. Upadhyay[1] and *E. Sampathkumaran[1] 1. Tata Institute of Fundamental Research, Mumbai, India*

The spin-chain compounds, R_2BaNiO_5, crystallizing in *Immm* space group (orthorhombic) and considered to be the prototype for Haldane spin-chain magnetism (with S=1 for Ni), have been subjected to exhaustive investigations by us for magnetoelectric behavior, reporting many new features [1]. We consider it important to study the Co analogues in order to explore how the modifications of the spin value at the transition metal site influences multiferroic and magnetodielectric features. We have therefore studied the isostructural compound, Tb_2BaCoO_5, hitherto not investigated in detail in the literature [2]. The present work (in the range 2-300 K) through magnetization, heat-capacity, dielectric constant, magnetocapacitance and bias pyrocurrent measurements establish the following: (i) This compound exhibits only one magnetic transition at (T_N= 18.8K) without glassy features. (ii) Below T_N, there is a spin reorientation (or metamagnetic transition) beyond 40 kOe. (iii) There is a strong peak in the plot of dielectric constant at T_N, responding to the application of magnetic-field, thereby establishing the existence of magnetodielectric coupling. (iv) Pyrocurrent studies reveal the onset of ferroelectricity at T_N. These results conclusively establish that Tb_2BaCoO_5 is a new multiferroic compound and that Haldane spin-chain behavior is not a necessary criterion to observe multiferroicity in this structure. The most fascinating finding which we would like to emphasize is that the observed value of magneto-dielectric effect beyond the metamagnetic transition field is the largest (close to 55%, below 10 K, for H= ~100 kOe) ever reported (to our knowledge) among polycrystalline materials.

U8-02. Magnetic Field in Triangular Ising System $LuFe_2O_{4+\delta}$. *L. Ding*[1], F. Orlandi[1], P. Manuel[1], D. Khalyavin[1], A. Boothroyd[2], D. Prabhakaran[2] and G. Balakrishnan[3] *1. ISIS Facility, Rutherford Appleton Laboratory, Science and Technology Facilities Council, Oxford, United Kingdom; 2. University of Oxford, Oxford, United Kingdom; 3. University of Warwick, Coventry, United Kingdom*

We present a study of the magnetic-field effect on spin correlations in the charge ordered triangular Ising system $LuFe_2O_{4+\delta}$ (see figure 1) through single crystal neutron diffraction [1]. In the absence of a magnetic field, the strong diffuse neutron scattering observed below the Neel temperature (T_N = 240 K) indicates that $LuFe_2O_{4+\delta}$ shows short-range, two-dimensional (2D) correlations in the FeO_5 triangular layers, characterized by the development of a magnetic scattering rod along the 1/3 1/3 L direction, persisting down to 5 K. We also found that on top of the 2D correlations, a long range ferromagnetic component associated with the propagation vector k_1 = 0 sets in at around 240 K. On the other hand, an external magnetic field applied along the c-axis effectively favours a three-dimensional (3D) spin correlation between the FeO_5 bilayers evidenced by the increase of the intensity of satellite reflections with propagation vector k_2 = (1/3, 1/3, 3/2). This magnetic modulation is identical to the charge ordered superstructure, highlighting the field-promoted coupling between the spin and charge degrees of freedom. Formation of the 3D spin correlations suppresses both the rod-type diffuse scattering and the k_1 component. Simple symmetry-based arguments provide a natural explanation of the observed phenomenon and put forward a possible charge redistribution in the applied magnetic field. Such a striking effect of the magnetic field on the magnetic structure brings new insights into the complex magnetic field vs temperature phase diagram as well as the understanding of multiferroicity in this compound.

U8-03. Fabrication of highly qualified $(Bi_{1-x}Ba_x)FeO_3$ multiferroic thin films by using a pulsed DC reactive sputtering method and demonstration of magnetization reversal by electric field. *S. Yoshimura*[1,2] and M. Kuppan[3] *1. Research Center for Engineering Science, Akita University, Akita, Japan; 2. JST-PRESTO, Saitama, Japan; 3. Regional Innovation Center, Akita University, Akita, Japan*

Magnetization reversal by electric field is a prospective technology for future magnetic devices due to its lower power consumption. Multiferroic materials with ferromagnetism and ferroelectricity [1,2] have garnered attention as candidate materials in electric-field driving magnetic devices. In previous study, we fabricated (001)-oriented $Bi_{0.6}Ba_{0.4}FeO_3$ film which exhibited hysteresis curves indicating ferromagnetic and ferroelectric behavior by using an RF sputtering method [3]. However, the M_s was not sufficient for magnetic device application. In the present study, a pulsed DC reactive sputtering technique which is useful fabrication method of oxide films from the point of view of high sputtering voltage and free arcs [4] was used for fabrication of highly qualified $(Bi_{1-x}Ba_x)FeO_3$ thin films. The sputtering parameters such as frequency and duty ratio of the pulsed DC were optimized. Fig. 1 shows the dependence of the M_s on the Ba concentration in

the Bi-Ba-Fe-O films. In the case of $(Bi_{0.5}Ba_{0.5})FeO_3$ film fabricated by the pulsed DC reactive sputtering method, a very high M_s of 90 emu/cm^3 which is 1.5 times larger than the case fabricated by the RF sputtering method was obtained. Figs. 2 (a), (b), (c), and (d) show topographic, MFM (tip end: N), and EFM (tip end: +1 V), and EFM (tip end: -1 V) images, respectively, of the $(Bi_{0.5}Ba_{0.5})FeO_3$ film with the M_s of 90 emu/cm^3 after the application of a DC voltage of -10 V with 2 μm square to the film. In the MFM image (b), the magnetization direction was downward toward film surface in the ferromagnetic domain structure. In the EFM image (c) and (d), a positive electric charge was observed in the ferroelectric domain structure. Therefore, it can be concluded that micrometer-scale magnetization was achieved by applying a local electric field, and the proposed multiferroic film is useful in novel magnetic devices driven by electric field.

U8-04. Magnetization curves in magnetoelectric layered structures.

M. Auslender[1] *1. Electrical and Computer Engineering, Ben-Gurion University of the Negev, Beer Sheba, Israel*

The structures comprising intermittently bonded magnetostrictive and piezoelectric layers attract a keen interest in sensor applications since they exhibit strong strain-mediated magnetoelectric (ME) coupling [1]. The bonding compliance exerts hidden stresses that cause changes in magnetic properties of magnetostrictive layers at *no* mechanical load. We termed the first effect *implicit inverse effect of magnetostriction* (IIEM), similarly to apparent inverse effect of magnetostriction in single-pase ferromagnets [2]. We studied IIEM for a laterally wide bi/tri-layer ME structure. Our theory is based on minimization of the total energy including bare elastic [3], magnetic-anisotropy and magneto-elastic energies [4] under strains matching and zero-mean traction conditions at the layers interfaces and facets, respectively. Unlike the previous theories [4, 5], we consider also the *shear* strain and traction. In this presentation, we report on the calculation of magnetization curves in initial and saturation magnetizing ranges. We predicted IIEM in: (i) a latent-stress induced magnetic anisotropy unnoted previously [5, 6]; (ii) a decrease of the ME coupling coefficient [5] *below* the values obtained previously [5, 6], which may make a slipping correction factor [6] unnecessary. Our materials are Alfa Aesar 99.95% purity polycrystalline Ni foil and APC-844 ceramic lead zinc titanate (PZT). Two 20x20mm^2 area samples with 0.5 mm thick Ni and 0.83 mm thick laminates were used for the magnetostriction measurements, and a pair of 5x2 mm^2 area samples with 0.25 mm thick Ni and 0.58 mm thick laminates, for the magnetization measurements. The room temperature magnetization curves were obtained with a Physical Properties Measurement System (PPMS) machine. The magnetostriction was measured with Vishay Micro-Measurements two-axis SR-4 strain gauges. The type (i) IIEM is seen in Fig.1 that shows the magnetization curves. A notable decrease of the initial susceptibility and magnetic saturation lag in the laminate, compared to the bare Ni layer is observed in Fig.1. The above noted predictions of our theory agree well with the experimental data.

U8-05. Giant magnetic Kerr effect of $(Bi_{1-x}La_x)(Fe_{0.75}Co_{0.25})O_3$ multiferroic thin films with perpendicular magnetic anistropy fabricated by a pulsed DC reactive sputtering technique. *M. Kuppan*[1] and S. Yoshimura[2,3] *1. Regional Innovation Center, Akita University, Akita, Japan; 2. Research Center for Engineering Science, Akita University, Akita, Japan; 3. JST-PRESTO, Saitama, Japan*

Magnetic reversal using an electric field is a promising and future technology for multifunctional devices due to its lower power consumption. Multiferroic materials with magneto-electric effect, which simultaneously exhibit spontaneous polarization and magnetization, have been receiving greater attention. In these days, we succeeded to fabricate the highly qualified $(Bi_{1-x}Ba_x)FeO_3$ (BBFO) films with ferromagnetism and ferroelectricity by using a pulsed DC reactive sputtering technique[1)], and also we succeeded to demonstrate the magnetization reversal by electric field[2,3)]. However, the perpendicular magnetic anisotropy and the coercivity of the films were not sufficient for high performance magnetic device application. In this study, we aimed to produce highly qualified La-doped $BiFeO_3$[4)] films with perpendicular magnetic anisotropy by using reactive pulsed DC sputtering method. Fig. 1 show the dependence of saturation magnetization M_s and coercivity H_c (in-plane and out-of-plane) on La concentration for $(Bi_{1-x}La_x)(Fe_{1-y}Co_y)O_3$ (BLFCO) films. By increasing the La concentration up to x=0.65, the M_s increases with maintaing high H_c of 4 kOe. Fig. 2 shows the magnetization curves (*M-H and* θ_k-*H*) of $(Bi_{0.4}La_{0.6})(Fe_{0.75}Co_{0.25})O_3$ film. The squareness S (= remanent magnetization M_r / M_s) and H_c of the film in perpendicular to film plane are 0.65 and 4.0 kOe, which are larger than the case of the film in parallel to film plane (0.50 and 2.5 kOe) and than the case of the BBFO film in perpendicular to film plane (0.40 and 2.0 kOe). These indicate that the BLFCO films has perpendicular magnetic anisotropy with large H_c compared with the case of BBFO films. The Kerr effect of the $(Bi_{0.4}La_{0.6})(Fe_{0.75}Co_{0.25})O_3$ film is very large which is simlar to the magneto-optical materials. Therefore, it can be concluded that the proposed multiferroic films are expected to be useful in novel magnetic recording and optical devices driven by electric field.

U8-06. A New Type II Multiferroic $HoFeWO_6$. *M. Adnani*[1], N. Poudel[1], M.J. Gooch[1], Z. Wu[1], L. Deng[1] and C. Chu[1,2] *1. Texas Center for Superconductivity and Department of Physics, University of Houston, Houston, TX, United States; 2. Lawrence Berkeley National Laboratory, Berkeley, CA, United States*

The search for new multiferroic materials is a continued subject of interest for engineers as well as scientists. From technological point of view, such materials provide a mean to control magnetism with electric field or vice versa. They are also of fundamental importance as they provide an ongoing research for materials that exhibit two coexisting ferroic orders. Recently Ghara *et al.* published their work on $RFeWO_6$ (where *R=Dy, Eu, Tb and Y*) that is refined to a polar structure of $Pna2_1$ and they suggest that this new class of materials are type II multiferroics [1]. In this work, we employed magnetic, dielectric, pyroelectric current and heat capacity measurements to study the multiferroic properties of $HoFeWO_6$ as a new member of this family of materials. Polycrystalline samples were synthesized using solid state reaction technique and X-ray diffraction (XRD) measurements were completed for phase identification of the final product. Samples crystalize in a polar orthorhombic structure ($Pna2_1$) and were phase pure within the resolution of the XRD measurement. From temperature dependent magnetization measurements, it can be seen that $HoFeWO_6$ orders antiferromagnetically (AFM) with a $T_N \sim 17\ K$, above which the inverse molar susceptibility (χ_{mol}^{-1}) follows the Curie-Weiss law. Heat capacity measurements also confirm the AFM, which is seen as a sharp lambda anomaly. A ferroelectric transition is observed in both the dielectric as well as the polarization measurements at ~ *17 K*. By applying an external magnetic field, we see a decrease in the polarization as well as the dielectric constant. Polarization is suppressed with 1 T; however, the dielectric constant is still observable at 5 T. All of these findings give strong evidence that $HoFeWO_6$ is a new type II multiferroic.

U8-07. Magnetodielectric effect in Eu^{2+} doped $BaTiO_3$. K. Rubi[1] and *R. Mahendiran*[1] *1. Physics Dept, National University of Singapore, West Singapore*

$EuTiO_3$ has attracted much of attention recently because of the large magetoelectric coupling exhibited by this sample at and below the antiferromagnetic transition (T_N = 5.6 K) although $EuTiO_3$ is not a proper ferroelectric[1,2]. Solid solution of $Ba_{1-x}Eu_xTiO_3$ can be prepared in single phase over a wide composition ($0 < x < 1$) [3] and this series exhibit a giant magnetocaloric effect that is related to spin entropy of Eu^{2+}:$4f^7$ ions[2]. The substitution of Eu^{2+} for Ba^{2+} is expected to lower the ferroelectric transition of $BaTiO_3$ to room temperature or below and also induce magnetism. There has been no

report on the effect of magnetic field on dielectric constant in $Ba_{1-x}Eu_xTiO_3$ series for x £ 0.7. We have investigated magnetization and dielectric properties of the insulating ferroelectric $Ba_{0.6}Eu_{0.4}TiO_3$ in response to external magnetic field. It is found that this compound exhibits remarkable positive magnetodielectric effect where in the dielectric constant increases by 7.6% in a magnetic field of 7 Tesla. The existence of magnetodielectric effect in such a paramagnetic but ferroelectric compound is quite interesting and we will describe possible mechanisms of the observed effect.

U8-08. Multiferroic Characterization of Single Crystal Samples of Quadruple Perovskite Manganite $LaMn_3Mn_4O_{12}$. *V. Pascotto Gastaldo*[1,2], F. Milton[1], A. Gualdi[2,1], D. Garcia[1], A. Gauzzi[2] and A.J. de Oliveira[1] *1. Physics Department, Federal University of São Carlos, São Carlos, Brazil; 2. Institut de Minéralogie, de Physique des Matériaux et de Cosmochimie, Université Pierre et Marie Curie, Paris, France*

There is a pressing demand for materials that can be tailored to perform multiple functions. Specifically, materials that can produce multiple response from a single input. Multiferroic materials are proposed as viable alternative to fill that niche, especially those who present magnetic and electrical order. If there is robust coupling between these orders, several technological applications, from memory to spintronic devices, might become viable [1,2]. Several instances of multiferroicity were found in manganites with quadruple perovskite structures ($AA'_3B_4O_{12}$, where A'=B=Mn). For instance, $CaMn_7O_{12}$, $BiMn_7O_{12}$, $NaMn_7O_{12}$ e $LaMn_7O_{12}$ [3,4,5] have been shown to be multiferroic, the last one showing high values of polarizations. Besides that, the achievement of strong magnetoelectric coupling remains a challenge. $LaMn_3Mn_4O_{12}$ is a quadruple perovskite manganite that has two antiferromagnetic lattices, A' and B sites, that order respectively at 21K and 78 K [6]. Its ferroelectric transition coincides with the ordering of the B site as shown in figure 1 [5]. Still, experimental difficulties regarding the crystal sizes make the electrical characterization of single crystals very difficult, which also hinders the search for magnetoelectric coupling. This work shows advances in characterizing a single crystal of $LaMn_7O_{12}$. Due to small crystal sizes, samples were enclosed in resin and polished to 50 μm. Mica linings were applied to avoid the application of Schottky barriers. The characterization consists of magnetization measurements under electrical fields up to 20 KV/cm from 300 K to 5 K and magnetic fields up to 7 T. Pyroelectric current measurements under magnetic fields and direct magnetoelectric coupling measurements were also performed. Results show the coincidence of ferroelectric and antiferromagnetic ordering temperatures and magnetization measurements exhibit a small difference between sample with/without electrical field bias.

U8-09. Magnetodielectric response and dielectric relaxation mechanism in $LiNiO_2$ cathode. *S. Dash*[1], M. Pradhan[1] and L. Tangi[1] *1. Dept. of Physics and Astronomy, National Institute of Technology, Rourkela, Rourkela, India*

Layered lithium metal oxides $LiNiO_2$ (LNO) has been of great interest as cathode materials for secondary lithium batteries. Presently this material has been intensely investigated because of its comparatively low cost, less toxicity, lower price, large reversible capacity and environmental advantages over others[1-2]. Though the magnetic ordering in this system is complex, a few studies are also carried out to know the exact magnetic state [3]. The random and order phases along with orbital ordering in the material control the magnetic behaviour. Furthermore, the dielectric property of the doped LNO is remarkably affected by concentration of Li [4]. Since LNO posses both magnetic as well as dielectric ordering, one would expect a coupling between them as in the case of most of the multiferroics, however, to the best of our knowledge, studies related to the magnetic field dependent dielectric behaviour is rare. With this aim, LNO is prepared by the solid-state route using high purity NiO black and Li_2CO_3, calcined and sintered at 700 ^oC. The phase compositions were determined by XRD, FESEM etc. The field dependent dielectric measurement was performed using PPMS below room temperature. As shown in Fig.1, the temperature dependent dielectric permittivity (e) and loss tangent (tan d) is measured at various frequencies at constant field of 1 Tesla. The sharp increase of dielectric permitivity differing from maxima in tan d rules out an intrinsic dipole response in this material [5]. The tan d peak which varies with frequency is falls around the same temperature of the AC- ki peak of the similar material reported otherwise [6]. Moreover, a strong field dependent of both parameters is shown in Fig.2, which shows a strong coupling between the dielectric and magnetic ordering in this material. The conduction process has been further probed through complex impedance studies in different temperature ranges and it is found that this material undergoes kinetic transfer and diffusion like mechanism.

U9-01. Enhanced field sensitivity by the strong mutual coupling and magneto-induction in amorphous film/planar coil multilayers. F. Song[1], *Y. Wen*[1], P. Li[1], Y. Wang[1], T. Han[1] and X. Ji[1] *1. School of Electronic Information and Electric Engineering, Shanghai Jiaotong University, Shanghai, China*

GMI devices have ultra-high field sensitivity as the magneto-impedances vary a considerably large amount under fields. The variation ratio can reach a percentage of several hundreds [1]. Based on the significant large impedance variation pT-sensitivity at room temperature has been achieved [2-3]. In sensor applications, the current flowing through or the voltage across a GMI device is detected. This way, the variation ratio of the output quantity is not compared to the impedance ratio but usually much less. This fact constrains the final sensitivity of a GMI sensor. Here we propose an amorphous film/planar coil multilayer structure. Three laminated planar coils are sandwiched by amorphous films, so their inductances are magnetically sensitive. One coil is used as the exciting input port and the other two are serially connected as the output port. The schematic illustration of the multilayers is in Fig1. Since the mutual coupling between coils, the structure actually functions as a field-dependent transformer under AC electrical excitation: both its input/output impedance vary with external fields. While the three coils are of identical self-inductances L, due to the strong mutual coupling of closely laminated planar coils, i.e. the coupling coefficient approaches one, the output voltage is proportional to the input current by a factor of 2ωL if the coils'ohmic resistances are ignorable. In this way, the inductance variation is fully reflected in the output voltage with 2-fold amplification. A prototype of the proposed structure is fabricated with FeNiMo amorphous films of 18mm*6mm*0.022mm and planar coils of 5mm*5mm*0.086mm. The self-inductance of a coil is ~16μH (@ 0Oe), the maximum variation rate is 4.68%/Oe (4-20Oe). Being excited by a 20 mA AC current at 500kHz, the output vs. external field is shown in Fig.2. The maximum voltage variation rate is 5.11%/Oe corresponding to a field sensitivity of 70mV/Oe. Obviously, the output voltage variation is greater than the inductance variation and more beneficial to the field sensitivity. And the sensitivity can be further enhanced by increasing the output coil laminates.

U9-02. Electrical Transport Signature of Skyrmions in Pt/Co/Ir Multilayer Disc. *K. Zeissler*[1], S. Finizio[2], K. Shahbazi[1], J. Massey[1], F. Al Ma'Mari[3], J. Raabe[2], M. Rosamond[4], E. Linfield[4], T.A. Moore[1], G. Burnell[1] and C.H. Marrows[1] *1. School of Physics and Astronomy, University of Leeds, Leeds, United Kingdom; 2. SYN, Paul Scherrer Institut, Villigen PSI, Switzerland; 3. Department of Physics, Sultan Qaboos University, Muscat, Oman; 4. School of Electronic and Electrical Engineering, University of Leeds, Leeds, United Kingdom*

Magnetic skyrmions are quasi-particles which are of importance for novel magnetic information storage designs. In ultrathin multilayer systems skyrmions are stabilized by the interfacial Dzyaloshinskii-Moriya interaction (1). This interaction occurs due to broken inversion symmetry at the interface between a ferromagnet and a heavy metal. Their tunability and room temperature stability is of interest for new applications (2-5). Active focal areas are electrical skyrmion detection and manipulation. In the experiment outlined here individual skyrmions in a Ta (3.5 nm)/Pt (3.8 nm)/[Co (0.5 nm)/Ir (0.5 nm)/Pt (1.0 nm)]x10 Pt (3.2 nm) multilayer nanodisc were imaged using the PolLux scanning transmission X-ray microscopy as a function of out-of-plane magnetic field. The Hall resistance was measured *in situ*. The circular polarized X-rays were tuned to L_3 cobalt edge and were transmitted perpendicular to the sample plane. By directly correlating the measured Hall resistance to the magnetic state obtained from the imaging (A-C), a magnetization independent resistance contribution to the Hall resistance was identified (E). This contribution was observed to be proportional

to the number of skyrmions present in the disc. This work was funded by Horizon 2020 MagicSky.

U9-03. Tailoring the magnetostriction of sustainable Fe-Al thin films by ternary alloying. *W.K. Huettenes*[1], M. Cialone[2,3], M. Coisson[2], P. Tiberto[2], P. Rizzi[3], L.A. Greer[1] and Z.H. Barber[1] *1. Materials Science and Metallurgy, University of Cambridge, Cambridge, United Kingdom; 2. Nanoscience and materials, Istituto Nazionale di Ricerca Metrologica, Torino, Italy; 3. Chemistry Department and NIS, University of Torino, Torino, Italy*

Broad application of magnetostrictive (MS) thin films ranging from micro-actuators to sensitive magnetoelectric sensors foster persistent scientific interest in these materials. Intensive research has, thus, been dedicated to materials with high MS coefficients such as Terfenol-D [$Tb_xDy_{1-x}Fe_2$ $x\approx0.3$] or Galfenol [Fe-Ga] with bulk coefficients of ~2000 ppm (parts per million) and ~350 ppm, respectively [1]. Containing critical raw materials such as rare-earth metals and gallium, however, their future availability is threatened and drives the search for sustainable alternatives. The Fe-Al system could serve as such: At a composition of $Fe_{81}Al_{19}$ it exhibits MS properties on the same order of magnitude as the Fe-Ga system [2] at a fraction of its cost. While partial substitutions of gallium with aluminium in Galfenol have already been attempted [3], the potential of Fe-Al thin films as a functional material and in MEMS devices is yet to be explored in more detail. In this work we seek to tailor the functional properties of magnetron sputtered Fe-Al thin film alloys. Small additions of niobium, boron or carbon serve as a substitute for aluminium atoms (see Fig. 1) or fill interstitial sites in the crystal lattice. Such ternary alloying directly influences the magnetic coercivity and susceptibility of Fe-Al and, thus, the MS properties. The presence of metastable solid solutions in as-deposited thin films enables further tailoring. Measurements have been conducted with a newly developed, simple setup for the direct static measurement of the magnetostriction of very thin films <70 nm employing a commercial atomic force microscope and its tips as micro cantilevers (see Fig. 2). After a presentation of new insights into the MS properties of binary and ternary Fe-Al thin films, an outlook on their implementation in MEMS devices will be given.

U9-04. Toward single pulse All Optical - Helicity dependent switching in Co/Pt multilayer systems. *G. Kichin*[1], M. Hehn[1], G. Malinowski[1] and S. Mangin[1] *1. Institut Jean Lamour, Nancy, France*

All-optical methods for magnetization manipulation in materials are promising for future technical applications. A promising materials for such studies are thin films with a high perpendicular magnetic anisotropy. Initially magnetization switching by optical irradiation was discovered in ferrimagnetic GdFeCo alloy thin films [1]. Later It was demonstrated that a single ultrashort laser pulse could be used to change the state of the magnetization. Later, all-optical switching was also be observed for separate classes of materials (ferrimagnets, ferromagnets, granular film ferromagnetic structures [2][3]). Despite the similarity of these processes there is still an unfinished discussion about the switching mechanism in these cases. We present a study of the laser induced magnetization manipulation in Co/Pt multilayer samples with perpendicular magnetic anisotropy. We performed multiple-shot and single-shot experiments to analyze the changes in magnetization state using magneto-optical approach and electrical measurements. We studied how the magnetization reversal is affected by the experimental conditions. Experiments reveal that the duration of laser pulses plays an important role in the magnetization reversal. The magnetization manipulation was easier to observe for trains of picosecond-scale laser pulses then for femtosecond scale pulses. We have shown that with an increase of the pulse duration the switching process take place easier. With respect to previous studies in which without laser sweeping only a μm lateral extended ring was reversed, the switching over the spot size is observed without the laser sweep. We will show that the size and the final structure of the domains are critically controlled by the magnitude and duration of the laser pulses. Special attention was paid to the study of the displacement of the DW and its dependence on the helicity of the laser pulses. This finding thus indicates a difference in the mechanisms of magnetization reversal in ferromagnetic and in GdFeCo ferrimagnetic materials.

Nowadays, giant magnetoresistance (GMR) devices are used in various biomedical applications [1-3]. Compared to GMR sensors, magnetic tunnel junction (MTJ) sensors have higher magnetoresistive (MR) ratios and better prospects for miniaturization [4-6]. In this paper, we present a biosensor platform based on an array of MTJ sensors for detecting the flow of magnetically labeled cells. The proposed MTJ sensor is shown in Fig. 1(a) and consists of one MTJ and a PDMS micro-channel. The target cells are HEK 293. The cells were incubated with 2.8 um magnetic beads for around 10 minutes and then injected into the microchannel. The magnetic beads are magnetized by passing current through a gold strip. The signals from the MTJ sensor array is obtained using a lock-in amplifier SR 850 to reduce the signal-to-noise ratio. We designed and fabricated MTJ sensors presented in Fig. 1(a). Each sensor consists of 10 elliptic pillars (16x8 um2) in series. The MTJ multilayer stack (shown in Fig. 1(b)) was deposited using magnetron sputtering system (Singulus) and annealed for 2 hours at 360 °C and 8 kOe. The stack was patterned using standard optical lithography and ion milling. A 150-nm-thick gold layer was deposited over the junction area. Figure 1(c) shows the transfer curve of the MTJ drndot, which has a high sensitivity of 3.25 Ω.Oe-1. A linear response is obtained in the range [-10 Oe, 10 Oe]. As shown in Fig. 2(a), when a labeled cell passes over the MTJ, a change in the output voltage occurs. Each sharp signal change indicates a single labeled cell that passed by the sensor. Figure 2(b) shows a zoomed-in view of the largest signal detected. To evaluate the background noise, the same experiment was performed with unlabeled cells. Figure 2(c) shows that no signal is detected in this case. In this work, we have developed MTJ-based cytometer and demonstrated its functionality for detecting magnetically labeled cells.

U9-06. Stabilizing skyrmion lattices in multilayered magnetic stacks. W. Legrand[1], D. Maccariello[1], J. Chauleau[1,3], N. Reyren[1], S. Collin[1], K. Bouzehouane[1], N. Jaouen[2], *V. Cros*[1] and A. Fert[1] *1. Unité Mixte de Physique CNRS/Thales, Palaiseau, France; 2. Experimental division, Synchrotron SOLEIL, Gif sur Yvette, France; 3. SEXTANTS, Synchrotron SOLEIL, Gif sur Yvette, France*

Magnetic skyrmions are topological magnetic textures holding a lot of promise for applications as well as of fundamental interest [1]. Initially observed under the form of skyrmion lattices at low temperature and under large magnetic fields in a few bulk non-centrosymmetric compounds e.g. MnSi or FeCoSi [2] and one monolayer of Fe on Ir(111) [3], there has been a huge research effort in the last couple of years to stabilize them at room temperature in magnetic multilayers [4-7]. In these systems, skyrmions are up to now most often observed as individual skyrmions, but seem to form skyrmion lattices only in very particular systems having a relatively large thicknesses [8,9]. Here we explore experimentally the presence of a skyrmion lattice phase in multilayered stacks which all exhibit significant DM interaction due to the lack of inversion symmetry of the repeated layers. We report the magnetic characterization of skyrmion based configurations with various elemental compositions, tailored anisotropies and multilayer repetition number. The imaging of the magnetic configuration in these different systems (skyrmion size and lattice parameter) is performed using Magnetic Force Microscopy under various external fields. Compared to non-centrosymmetric compounds, the magnetic properties of the multilayered asymmetric stacks can be easily and precisely adjusted by varying the thicknesses of the ferromagnetic, heavy-metal, and non-magnetic metal or oxide layers, which allows us to quantify some parameters resulting in the room temperature stabilization of a skyrmion lattice phase. We strive to explain the formation of lattices as well as to characterize the regularity of the lattice under the influence of these magnetic properties, in order to allow obtaining the skyrmion lattice phases in technologically compatible, small-thickness stacks for their applications as shift register memories or reconfigurable skyrmion based devices [1]. U9-08. Two fold characteristics of Swift Heavy Ion irradiation on magnetic nanocomposites. *A. Mishra*[1] and T. Mohanty[1] *1. School of Physical Sciences, Jawaharlal Nehru University, New Delhi, India*

This work presents the dual role exhibited by swift heavy ion irradiation (SHI) on magnetic - reduced graphene oxide (RGO) nanocomposites presented as decoration of magnetic nanoparticles on RGO nanosheets. On one hand SHI becomes successful in delinking the attached functional groups from RGO this driving towards its purification. Raman spectra of irradiated samples confirm this result, where, exponential decrease of intensity ratio of D and G peaks of RGO with fluence occurs. On the other hand, SHI generates extended defects in the form of latent tracks in decorated magnetic nanoparticles, thus modifying the magnetic and surface electronic properties of these nanocomposites. Results obtained from magnetization studies using SQUID magnetometer and surface electronic response from scanning Kelvin probe support the fact.

Session U10
NEW MAGNETIC MEASUREMENT METHODS
(Poster Session)

Gonzalo Vallejo-Fernandez, Chair
The University of York, York, United Kingdom

U10-01. Development of sensitive 3D vector VSM on a cryo-free low temperature and high field platform. *J. Lu*[1], C. Guo[1], L. Meng[1] and B. Shen[1] *1. State Key Laboratory of Magnetism, Institute of Physics, CAS, Beijing, China*

In most cases of magnetic measurement, magnetic moment could be taken as a scalar quantity, when only one component of vector magnetic moment is sufficient since the direction of the measured has been predetermined. Whereas, some magnetic researches require full components of vector magnetic moment or direction of magnetic moment is unknown, when the macro magnetic moment is not directly stimulated by pure magnetic field, but rather influenced by other kind of fields such as stress, heat or radiation. Unfortunately, no commercial instrument has function of simultaneously full vector measurement. Therefore, 3^d vector vibration sample magnetometer (VSM) has been designed and developed for advanced magnetic investigations. To get the three components of magnetic moment simultaneously, we have designed a sophisticated coil set, where well-pairing coil array can measure three components independently, with high sensitivity and low cross talking among each component. Furthermore, a multichannel precision lock-in amplifier (LIA) has also been developed for detection of three-component signals of magnetic moment with high efficiency. Preliminary result shows that developed vector VSM has sensitivity below 1e-7 emu and angle resolution below 1 degree. To enhance the convenience of various physical research, our vector VSM measurement system has been connected and integrated to a cryo-free low temperature and high field platform. We expect wider cooperation with magnetic researchers around the world.

U10-02. doFORC tool for calculating first-order reversal curve diagrams of noisy scattered data. *D. Cimpoesu*[1], I. Dumitru[1] and A. Stancu[1] *1. Physics, Alexandru Ioan Cuza University of Iasi, Iasi, Romania*

In the last years one of the most popular experimental methods for characterization of the hysteretic phenomena is the first-order reversal curves (FORC) diagram method [1,2]. The FORC diagram is defined as the mixed second derivative of the set of FORCs with respect to the applied and reversal fields, taken with negative sign. The main problem in numerical calculation of FORC diagrams is that the second-order derivative of a function for which only discrete noise-contaminated scattered data values are available magnifies the noise that is inevitably present in measurements. In this paper we present doFORC tool for calculating FORC diagrams of noise scattered data. It can also provide both a smooth approximation of the measured magnetization and all its partial derivatives. doFORC is a free, portable application working on various operating systems, with a easy to use graphical interface. Input data may have various formats. A comprehensive description can be found at [3]. In the full paper we will present a comparison with similar existing tools [4-5]. doFORC implements four nonparametric methods for regression: LOESS and three modified Shepard methods [6-7] (quadratic polynomial, cubic polynomial, and cosine series). The motivation is to enable researchers to experiment with different algorithms using their data and select one that is best suited to their needs. In all methods the problem is addressed as first obtaining a smooth approximation of the data which may then be differentiated to obtain approximations for derivatives. In order to perform the diagnostics and goodness of fit doFORC computes residuals to characterize the difference between observed and predicted values, generalized cross-validation to measure the predictive performance of the model, two information criteria to quantify the information that is lost by using an approximate model, and three degrees of freedom to compare different amounts of smoothing being performed by different smoothing methods. Based on these doFORC can perform automatic smoothing parameter selection. The methods were tested for accuracy on artificial data sets constructed with different test functions. We also present results associated with some experimental data sets.

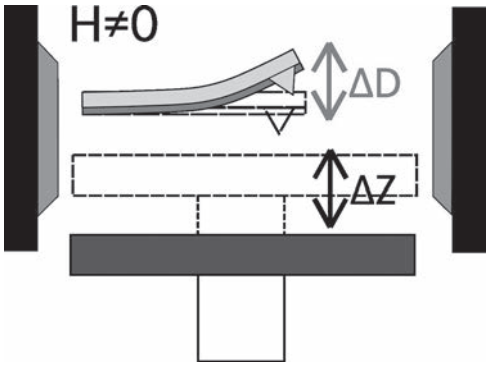
U10-03. Magneto-Optical Characterization of Super-Paramagnetic Nanoparticles in AC Magnetic Fields using Multi-Harmonic Analysis. *M. Syed*[1] and C. Patterson[1,2] *1. Physics & Optical Eng, Rose-Hulman Institute of Technology, Terre Haute, IN, United States; 2. Applied Physics, University of Michigan, Ann Arbor, MI, United States*



Superparamagnetic nanoparticles (SNPs) are widely used in biomedical applications. Characterizing dilute suspensions of SNPs in bio-relevant media is particularly valuable for magnetic particle imaging, magnetic hyperthermia, drug delivery, etc. [1-2]. We present a continuation of our study of dilute aqueous suspensions of single-domain magnetite nanoparticles using an AC Faraday rotation (FR) setup [3]. The setup employs a stabilized He-Ne lase (633 nm) along with an AC magnetic field that enables lock-in detection. We use magnetite nanoparticles with α–olefin sulphonic acid. The primary and hydrodynamic diameters are 11 ± 3 nm and 52 ± 15 nm respectively. Our previous results focused on analyzing the first and higher harmonics of the magnetic field frequency (800 Hz) using the Fourier components of the theoretical signal determined by a nonlinear, Langevin-like magnetization. With this procedure, we determined the particle magnetic moment *m*, particle number density *n*, and Verdet constant of the sample. We employ the same procedure to investigate data that is also multi-harmonic in nature but is collected using a more viscous sample with different field excitation frequencies. The motivation for doing this is to investigate relaxation properties of SNPs and SNP clusters. Moreover we hope to show that the formation dynamics of clusters are a keen function of magnetic field excitation frequency. This data helps extend our analysis to such viscous samples where Brownian relaxation times are different, by design. Finally, in all these samples, the analysis is predicated on the presence of odd harmonics only. Our data does contain a 2f signal. Moreover, this signal appears to not depend on the polarization state of the incident light. The evidence of clustering/chain formation along with the geometric shadowing effect can perhaps explain the presence of a second-harmonic signal not predicted by the theory. We plan to share our analysis of the causes that we think lead to this response. Using this powerful and self-consistent analysis procedure, future studies are aimed at further refining the clustering mechanisms in this AC system and characterizing SNP suspensions at additional frequencies and viscosities [4].

U10-04. Innovative technique for thin films magnetostriction measurements by scanning probe microscopy. M. Coisson[1], *M. Cialone*[1,2], W.K. Huettenes[3], G. Barrera[1], F. Celegato[1], Z.H. Barber[3], P. Rizzi[2] and P. Tiberto[1] *1. Nanoscience and Materials, Istituto Nazionale di Ricerca Metrologica, Torino, Italy; 2. Chemistry and NIS, Università degli studi di Torino, Torino, Italy; 3. Materials Science and Metallurgy, University of Cambridge, Cambridge, United Kingdom*

Magnetostriction is an intrinsic property of ferromagnetic materials, determined by the spin orbit coupling, which causes a change in the overall dimensions of the system when an external magnetic field is applied. The order of magnitude of this change ranges from a few parts per millions up to 0.1% for rare-earth based alloys. Given their capability to couple electromagnetic and mechanical energy, magnetostrictive materials can be considered a basic building block for transducers and wireless control actuators. When scaling down towards the nano scale, the reduced dimensionality introduces several challenges for the direct measurement of the magnetostriction, since the change in dimension is in the nanometer scale. Indeed, there is the need for subnanometer precision in the measurements, and amplification of the deformation. While the latter is successfully accomplished by a cantilever deflection design with a non-magnetic substrate [1] (see Fig.1), standard capacitive [2] or optical [3] methods for measurement lack precision for very thin films and require cost-intensive, dedicated setups. The working principle is based on the expansion or compression of the ferromagnetic film, resulting from application of an external magnetic field, inducing a stress on the cantilever that bends upward or downward, according to the direction of the magnetostriction. Exploiting the sub-nanometer precision of a standard atomic force microscope, the vertical deflection of the cantilever is measured. The vertical displacement of the cantilever is shown in Fig.2 alongside the magnetic hysteresis loop. We were able to measure the deflection induced by polycrystalline $Fe_{81}Al_{19}$ (at.%) films as thin as 70 nm. The strength of the technique is also in the versatility. Indeed, given the metallic nature of the cantilevers the ferromagnetic films can be deposited with a wide range of techniques. Moreover, the technique uses a standard setup, with a commercially available cantilever, hence guaranteeing easy application and reproducibility, without the need for dedicated experimental setup.

U10-05. DC Drift Error Mitigation Method for Three-Phase Current Reconstruction with Single Hall Current Sensor. *H. Yan*[1], Y. Xu[2], H. Zhang[1], W. Zhao[1] and C. Gerada[1] *1. International Academy of the Marine Economy and Technology, University of Nottingham Ningbo China, Ningbo, China; 2. Department of Electrical Engineering, Harbin Institute of Technology, Harbin, China*

I. INTRODUCTION Magnetic field sensors are widely used in various industrial applications. Their primary use was in direction finding or navigation. Today, these sensors are still dominating means in navigation, but many more uses have emerged [1]. Permanent-magnet Synchronous Motors (PMSMs) drive system is a heavy user of magnetic field sensors in applications such as electric vehicles, position control for industrial servo systems, current measurement of motor close-loop control systems, etc. Conventionally, PMSM drive requires Hall current sensors to measure motor phase currents and then implement the space vector control. In the market of magnetic sensors, Hall sensors are integrated with electronics and allow contactless operation [2]. Contactless current measurement uses the magnetic field induced around a current carrier. As shown in Fig. 1, where the system measures the current I_P, the magnetic core directs a magnetic field from the primary carrier I_P onto the ASIC containing the Hall sensor with surrounding electronics. In this paper, a PMSM control method with single Hall current sensor to implement the phase current reconstruction is introduced. Moreover, a novel DC drift error mitigation method is proposed to increase the measurement accuracy. At last, the proposed method is verified by simulation. II. PROPOSED DC DRIFT ERROR MITIGATION METHOD Fig. 2 shows the block diagram of proposed DC drift error mitigation method. The sampled current value through the ADC i_{sam_in} which includes an DC drift component i_{off} is written as $i_{sam_in} = i_{sam} + i_{off}$ (1) For the phase current reconstruction method, the current isam_new which is represented as (2) is utilized $i_{sam_new} = i_{sam_in} - i_{off_est}$ (2) where i_{off_est} is the estimated current offset. The main idea of the offset compensation algorithm is to estimate i_{off_est}. In this method, a notch filter whose cutoff frequency is identical to the fundamental frequency ω_r is applied to v_β' to extract the dc drift error. At last, the proposed DC drift error mitigation method has been verified by the simulation results.

U10-06. Development of triple-axis-spectrometer devices in HANARO – Numerical simulation results on mirror-type collimators. *J. Lee*[1], H. Hiraka[1] and S. Cho[1] *1. Neutron Science Center, Korea Atomic Energy Research Institute, Daejeon, The Republic of Korea*

Jisung Lee, Haruhiro Hiraka, and Sangjin Cho Neutron Science Center, Korea Atomic Energy Research Institute (KAERI), Daejeon 34057, Korea Triple-axis neutron spectroscopy is still powerful for dynamic studies on spin and lattice degrees of freedoms in materials. In the research reactor HANARO of KAERI, Korea, two triple-axis neutron spectrometers (TASs) are installed: one is Thermal-TAS in the reactor hall, and the other is Cold-TAS in the guided hall. As a renovation program of neutron devices for TASs, we newly started to fabricate a total-reflection combining collimator (RC) at in-house. In parallel, we examined the performance of the RC using a Monte Carlo simulation program, McStas. The divergence-angle (θ) dependence of the emerging beam from the RC shows a rectangular cap shape for $|\theta| \le \theta_c$, where θ_c is the total-reflection critical angle. We propose that the standard deviation (σ_{std}) of the θ profile is a suitable parameter for specifying the characteristic angular divergence, rather than the full width at half maximum. It is found that, for a given condition, the RC has the potential to increase the transmission rate by ~20% while keeping σ_{std} constant. Such the mirror-type RC might be useful for measurements on TASs, for which RCs are set up in the beam stream in series.

U10-07. Study on Broadband Impedance Matching for Three-Dimensional Magnetic Properties Testing. *B. Qu*[1,2], Q. Yang[3], Y. Li[1] and C. Zhang[1] *1. Hebei University of Technology, Zibo, China; 2. Shandong University of Technology, Zibo, China; 3. Tianjin Polytechnic University, Tianjin, China*

Abstract-This paper adopts the combination of genetic algorithm and least square method to design broadband impedance matching network (EIMN) for three-dimensional (3-D) magnetic tester. The optimal topology and element parameters of the network can be searched simultaneously by properly coding. The improved control method of thyristor switched capacitor (TSC) is used for high-capacity segment reactive compensation. Simulation results show that the matching network with better electronic capability satisfies the application of wide-range excitation frequency. By using the 3-D magnetic tester, samples of non-oriented silicon sheet steel are measured with different frequencies and the results are more reliable than those obtained by experiments without optimized. It is necessary to accurately measure the 3-D magnetic properties of silicon steel laminations at different frequencies (10Hz-2kHz). The key technical issue is the winding impedance design and impedance matching problems at different frequencies[1]. Unreasonable impedance matching will cause sample materials unable to reach magnetic saturation state, consequently the precise measurement to theirs magnetic properties cannot be achieved. This paper uses TSC, which is consisted of multi-groups binary-coded capacitors(0.5μF~200μF), for large-capacity compensation of reactive power step by step. And then design EIMN to compensate small-capacity reactive power[2][3]. First, the 3-D magnetic tester is modeled by the voltage and flux linkage equations, as shown in Fig.1. Second, the new TSC control method not only calculates the switching combination of TSC, but also determines whether the load reactive power change is in transient process. Third, genetic algorithm is used to search initial value for impedance matching optimization, and then the final value is calculated by least square method. Finally, detailed simulations are used to verify the performance of this new algorithm and compare the performance differences between these algorithms, as shown in Fig.2 Tests were performed with non-oriented silicon sheet steel, and the rotational magnetic properties at 10Hz-2kHz are measured by 3D magnetic tester. Result show that it is more reliable.

U10-08. Research on the squeeze flow effect of the Foil-type Excitation windings in high frequency. Y. Li[2,4], M. Yang[1,4], *C. Zhang*[4,2] and Q. Yang[3,4] *1. School of Electrical Engineering, Hebei University of Technology, Tianjin, China; 2. Hebei University of Technology, Tianjin, China; 3. Tianjin Key Laboratory of AEEET, Tianjin, China; 4. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China*

Combined with the design of three-dimensional rotational magnetic properties measurement structure, as shown in Fig.1, the traditional copper stranded wire coil winding reduces the equipment available space to limit the improvement of measuring equipment and the winding has many turns leading to an increase in inductance [1]. Therefore, in this paper a new winding design method is proposed to improve the magnetic properties testing device in order to decrease the inductance of windings and the volume of windings. The excitation windings will be in foil structure. But the current density distribution of foil winding is more complex under the influence of the skin effect and the squeeze flow effect. The existence of

the radial component of the magnetic flux density B between each layer of the foil winding makes the current density on the copper foil unevenly distributed [3]. As the frequency increases, the skin effect will become more pronounced [4]. Impact of two kinds of effects of excitation winding current density distribution on copper foil in the 10kHz is shown in Fig.2, and we can see B vector in the existence of radial component between each layer winding. Some methods are to add ferromagnetic ring plates at both ends of the winding [5]. But these methods have yet to consider various factors under the comprehensive impact. In this paper, four conclusions are drawn. First, a soft magnetic ferrite is used to make a ring plate. Second, increasing the distance between the magnetic field and the core of the main magnetic circuit. Third, reducing the distance between the ferromagnetic plate and the core of the main magnetic circuit. Finally, foil windings are properly segmented to reduce the squeeze flow effect. By adopting the above methods, it works well to eliminate the squeeze flow effect of foil winding and the skin effect in high frequency, and it can also decrease the inductance of windings to increase the excitation current.

U10-09. A Improved Method of Feedback Control Based on Perception Neural Network for Three Dimensional Magnetic Properties Testing.

B. Qu[1,2], Q. Yang[3], Y. Li[1] and C. Zhang[1] *1. Hebei University of Technology, Zibo, China; 2. Shandong University of Technology, Zibo, China; 3. Tianjin Polytechnic University, Tianjin, China*

Abstract—An improved method that is based on the perception neural network is developed to eliminate the effects of harmonics on three Dimensional(3D) magnetic properties measurement. First, the excitation model of 3D magnetic properties tester is built, in which considers the mutual inductance of excitation system and the magnetic saturation of the magnetic circuit. Second, improved digital lock-in technique is used to extract weak magnetic induction signals under the background of complex noises. Finally, the 3D magnetic properties of the non-oriented silicon sheet are measured by the 3D magnetic tester using the new method. Because of the requirements for the flux density shape and strong nonlinearity of a magnetic material there is a necessity to use additional systems to control the magnetizing process[1]. Moreover, it is necessary to establish arbitrary waveform of flux density or magnetic field strength. An adaptive digital feedback method for 1D and 2D magnetic measurements is designed with multi-variable inputs and outputs[2]. However, 3D magnetic testing show a stronger self and mutual inductances, the excitation circuit of 3D magnetic testing is more complex, and the traditional control method cannot be directly extended to the 3D magnetic properties measurement simultaneously. First, modeling of 3-D magnetic properties testing system is built, As shown in Fig.1. Second, A dynamic multi-frequency digital lock-in technique is proposed to obtain the magnetic sensing signal composed of the fundamental and the harmonics, and solve the problem of frequency drift by rectifying the reference frequency dynamically. Third, the oversampling method is used to increase the resolution of the ADC in order to distinguish weak signals from strong background noise. Finally, the Design of Feedback Control Based on Perception Neural Network for 3D Magnetic Tester, as shown in Fig.2. Tests were performed with non-oriented silicon sheet, and the rotational magnetic properties at 10Hz-200Hz are measured by 3D magnetic properties testing. Result show that the new method works the most effectively with enabled low pass digital filters. For example, the magnetizing time is shorter and stability of algorithm is better.

U10-10. ELF stimulations Reveals Definite Subliminal Effects to Visual Perceptions: Human Reliability Measurements on ELF-Inducing Flickering Light Sensation. *H. Nakagawa*[1] and S. Ueno[2] *1. Department of Electrical and Electronic Engineering, Tokyo Denki University, Adachi-ku, Japan; 2. Department of Applied Quantum Physics, Kyushu University, Fukuoka, Japan*

Introduction: A flickering light sensation caused by the extremely low-frequency (ELF) stimulation to retina is known as the one and only phenomenon that the human body can articulately perceive with a biological effect with the use of very weak magnetic fields [1]–[5]. The flicker sensation can be made visible by direct stimulation to retina [6]–[8]; therefore, considerations for details in the retinal receptivity of the sensation are of great importance. Our previous trial using ELF stimulations provided a valuable finding about sub/supraliminal effects with the flicker on prefrontal hemodynamics [9]. As further research, we attempted at the verification of human reliabilities during the stimulations. Here we will report on several flows of retinal activities with the ELF-Inducing flicker sensation, employing functional near-infrared spectroscopy (fNIRS) analyses. Materials and Methods: Eight volunteers (five volunteers in their 20s, one volunteer in his 30s, and two volunteers in their 40s) participated in our experiments. The contrast between the usual visual recognitions and those with the flicker sensations was estimated by measuring the realized detections of the appearance of the spots at irregular intervals in the retinal region, and fNIRS measurements during the ELF-stimulation experiment. Results and Discussion: In the results of our fNIRS measurements, although no significant difference in the responses for the volunteers' ages could be detected, the prefrontal hemodynamics corresponding to the detection were enhanced gradually when compared with a control experiment ($P < 0.05$). On the other hand, the error rates in the correct directions at the threshold for the flicker sensation were significantly poorer in almost all the volunteers. The error rates at 80% of the threshold were decreased in no more than five among the eight volunteers; of particular note is, the rates at 70% of the threshold were maintained in two of them. Conclusion: Our experimental results support the fact that ELF stimulations can reveal definite subliminal effects to the human visual perceptions.

Tumor destruction with magnetic nanoparticles (MNPs) in an AC magnetic field is a promising cancer therapy called magnetic fluid hyperthermia (MFH). The specific absorption rate (SAR) value, defined as the power transformed into heat per unit of mass of MNPs, is one of the most relevant parameters for the treatment. It is demonstrated that *SAR* is proportional to the area of AC hysteresis loops of MNPs. Electromagnetic applicators (EMAs) are the devices that generate the alternating magnetic fields suitable for magnetic hyperthermia. Current EMAs create fields that only permit to measure minor AC hysteresis loops of the sample [1-3]. The aim of our work is to create magnetic fields high enough to overcome the anisotropy field of the MNPs and measure the hysteresis loops as close as possible to the saturation. With this device, we will be able to obtain precise value of *SAR* and more important, study theoretical models of the dynamic response of MNPs. We simulate, implement and characterize a multifrequency EMA based on a variable parallel LCC resonant circuit fed by a linear power amplifier (figure1). Theoretical simulations of the *z*-component of magnetic field inside the driving coil were carried out with different coils geometries and its resonant frequencies were calculated. The EMA was assembled and the impedance of the coil and LCC resonant circuit were measured with a network analyzer. Ten frequencies between (130-920kHz) were selected as working frequencies. By proper selection of the resonant circuit, maximum transference of power was achieved at these frequencies. The magnetic field was measured along z-axis of the driving coil in steps of 3.5 mm at 3 different frequencies (130, 515 and 920 kHz) by using a home-made 3-turns search coil (figure2). Taking these data into account and using an amplifier of 1000W, our EMA is able to generate magnetic fields up to 80kA.m^{-1} that is strong enough to saturate most of currently used iron oxides nanoparticles.

U10-12. Studying nanoscale magnetic systems with polarization analysis on the small-angle neutron scattering diffractometer KWS-1. *L. Barnsley*[1], A. Feoktystov[1], E. Babcock[1], Z. Salhi[1] and H. Frielinghaus[1] *1. Jülich Centre for Neutron Science, Forschungszentrum Jülich GmbH, Garching, Germany*

The KWS-1 small-angle neutron scattering instrument is operated by the Jülich Centre for Neutron Science (JCNS) and located at the research reactor FRM II of the Heinz Maier-Leibnitz Zentrum (MLZ) in Garching, Germany. The instrument covers a Q-range from 0.0007 to 0.5 Å^{-1}, with a selectable wavelength span from 4.7 to 20 Å and a high resolution owing to its neutron selector with an optional double-disc chopper to reduce the wavelength spread down to $\Delta\lambda/\lambda = 1\%$ [1]. This allows study of feature sizes from 10 to 9000 Å. The maximum neutron flux on the sample is 1×10^8 cm^{-2} s^{-1}, making it one of the most intense SANS instruments in the world. This is a highly flexible instrument with many possibilities and options available for users. A suite of sample environments is available to allow users to study magnetic systems down to cryogenic temperatures and in horizontal or vertical fields

up to 5 T. A custom-designed, non-magnetic hexapod at the sample position can carry up to 550 kg of useful load, and can allow flexible positioning and orientation of heavy sample environments for measurements either in transmission or grazing-incidence small-angle neutron scattering (GISANS) geometries. All magnetic sample environments are compatible with the available option for polarization-analysis, which can be used to clearly separate the magnetic and nuclear scattering contributions. The field-dependence of the magnetic scattering from 10, 15 and 27 nm diameter iron oxide nanoparticles was investigated with polarization-analysis and applied fields up to 3 T, demonstrating the capability of KWS-1 to probe magnetic structures on the nanoscale.

U11-01. Anisotropic *H-T* quadrupole phase diagrams $PrTi_2Al_{20}$: Al-NMR and Magnetization studies. *T. Taniguchi*[1,2], H. Takeda[2], M. Takigawa[2], S. Nakamura[2], T. Sakakibara[2], K. Hattori[3], M. Tsujimoto[2], Y. Matsumoto[2], A. Sakai[2] and S. Nakatsuji[2] *1. Science, Kyoto University, Kyoto, Japan; 2. The University of Tokyo, Kashiwa, Japan; 3. Tokyo Metropolitan University, Hachioji, Japan*

The cubic compound $PrTi_2Al_{20}$ has the non-magnetic ground states of crystal field (Gamma3). The Gamma3 doublet have two pure electric quadrupoles of the G_3-type, O_{20} ($3z^2$-r^2) and O_{22} (x^2-y^2), and magnetic octupole of Gamma2-type, T_{xyz}=xyz [1, 2]. The various measurements, such as specific heat, ultrasonic, neutron and NMR, reported that the ferro-quadrupole transition occurs near 2 K in this compound [3-6]. In this presentation, we will discuss the *H-T* phase diagrams from ^{27}Al-NMR and magnetization measurements in a single crystal of $PrTi_2Al_{20}$. When a magnetic field is applied along the <111> direction above 0.5 T, certain lines of the NMR spectrum split upon entering into the ordered phase, indicating breaking of the C_3 symmetry due to field induced magnetic dipole moment perpendicular to the field. This provides the first evidence for symmetry-breaking ferro-quadrupole order of O_{20} type[6]. Recently, we observed the clear anomaly for the field-induced transition (the first transition) associated with the quadrupole moments near 2 T and 1.5 T for $H \parallel$ <100> and <110> from NMR spectra and magnetization [7]. However, for $H \parallel$ <111>, the absence of an anomaly occurs between 0.5 T and 11 T, suggesting the phase diagram has single ordered phase[6, 7]. The origin of anisotropic field induced transition is the competition between Zeeman interaction and ferro-quadrupole interaction coupled with the magnetic field. We will then present the detail of these experimental results and our calculation of Free energy for this system with mean field theory.

U11-02. Simultaneous suppression of the antiferroquadrupolar and superconducting transitions in $PrIr_2Zn_{20}$ by non-hydrostatic pressure. *M. Adachi*[1], K. Umeo[3], K. Matsumoto[2], T. Onimaru[1] and T. Takabatake[1] *1. Graduate School of Advanced Sciences of Matter, Hiroshima University, Higashi-Hiroshima, Japan; 2. Graduate School of Science and Engineering, Ehime University, Matsuyama, Japan; 3. N-BARD, Hiroshima University, Higashi-Hiroshima, Japan*

Praseodymium-based compounds are attracting much attention because of a variety of interesting phenomena such as non-Fermi liquid (NFL) behavior, multipole order, and heavy-fermion superconductivity [1]. $PrIr_2Zn_{20}$ with the Γ_3 doublet ground state of Pr^{3+} ions undergoes an antiferroquadrupolar (AFQ) order at T_Q = 0.11 K and a superconducting transition at T_c = 0.05 K [2]. It was proposed that the superconducting paring is mediated by the quadrupole fluctuations. Moreover, at $T > T_Q$, the magnetic specific heat C_m and the electrical resistivity ρ exhibit NFL behavior: $C_m/T \propto -\ln T$ and an upward curvature in $\rho(T)$, both of which are characteristics of a quadrupole Kondo lattice [3,4]. In order to investigate the interplay between the superconductivity, AFQ order, and NFL behavior in $PrIr_2Zn_{20}$, we have measured $\rho(T)$ down to 0.04 K under pressures up to P = 10.6 GPa using two pressure transmitting media: argon maintaining highly hydrostatic pressure and glycerol which solidifies above 5 GPa. When argon is used, T_c hardly changes, while T_Q monotonically increases from 0.11 K to 0.23 K for P = 10.6 GPa, indicating stabilization of the AFQ order. We found that the upward curvature of $\rho(T)$ is reproduced by a theoretical formula for a quadrupole Kondo lattice model with a characteristic temperature T_0 [4]. The scaling of $\Delta\rho(T)$ by T_0 suggests that the quadrupole Kondo lattice is maintained under hydrostatic pressures. With increasing P up to 4.9 GPa using glycerol as pressure transmitting midium, T_Q rises and T_c remains unchanged as similar in the case of argon. At P = 6.3 GPa, however, both T_Q and T_c simultaneously go down below 0.04 K. The solidification of glycerol should give rise to non-hydrostatic pressure, which could lower the cubic symmetry of the Pr site. As a result, the Γ_3 doublet splits at random, quenching the quadrupolar degrees of freedom. The simultaneous disappearance of T_Q and T_c indicates that the active quadrupole is indispensable not only for the AFQ order but also for the superconductivity in this compound.
