The quasi-two-dimensional bismuth layer-like $AMnBi_2$ (A = alkaline as well as rare earth atom) lately advanced as an arena for the investigation of low-energy quasiparticle excitations in topological materials. We describe optical reflectivity measurements from the far-infrared up to the ultraviolet range and as a function of temperature of $Ca_{1-x}Na_xMnBi_2$, also discussed in connection with their dc transport properties. This is the prerequisite for reliable Kramers-Kronig transformation, giving access to the optical conductivity. Besides observing a vestigial linear frequency dependent behaviour of the optical conductivity, which is ascribed to electronic interband transitions involving Dirac bands, the asset of our work consists in experimentally revealing an incipient Fermi surface (FS) gapping, which strengthens with Na doping and turns out to pair with the anomaly in the dc transport properties, generally ascribed to the onset of a spin reorientation. We conjecture that this latter (spin-canting) transition could be associated with a density-wave order directly affecting the electronic structure at the Dirac cones. Our findings may generally underline the proneness towards FS instabilities in topological materials, driven by an incipient symmetry breaking magnetic ordering.

GD-08. Interlayer Dzyaloshinskii-Moriya Interactions. *E.Y. Vedmedenko*[1] *1. Physics, University of Hamburg, Hamburg, Germany*

The magnetic interfacial Dzyaloshinskii-Moriya interaction (DMI) in multi-layered thin films can lead to exotic chiral spin states, of paramount importance for future spintronic technologies [1]. Interfacial DMI is normally manifested as an intralayer interaction defining a rotational sense for the magnetization within two-dimensional films. Recently, we have shown theoretically that in addition to the interfacial DMI, magnetic layers can interact by means of a so-far neglected interlayer DM coupling across a spacer [2]. In contrast to the interfacial DMI, this interaction leads to the formation of three-dimensional spin spirals with unique rotational sense within as well as between the interfaces and, hence, combines intra- and inter-plane chiralities. Direct evidence of the interlayer-DMI at room temperature has recently been observed in synthetic magnetic heterostructures resulting in chiral exchange-biased hysteretic loops [3]. Schematics of the interlayer-DMI in synthetic magnetic heterostructures is shown in Fig.1. The realization of systems integrating interlayer magnetic chiral interactions paves the way for the creation of unprecedented magnetic effects in the emerging field of three-dimensional nanomagnetism and spintronics.

GD-09. Majorana States in Atomic-Scale Magnet-Superconductor Hybrid Systems. H. Kim[1], A. Palacio-Morales[1] and *R. Wiesendanger*[1] *1. Dept. of Physics, University of Hamburg, Hamburg, Germany*

Majorana states in atomic-scale magnet-superconductor hybrid systems have recently become of great interest because they can encode topological qubits and ultimately provide a new direction in topological quantum computation [1,2]. First, it will be demonstrated how well defined 1D atomic chains of magnetic adatoms on superconducting substrates with high spin-orbit coupling can be artificially fabricated using STM-based atom-manipulation techniques. Spin-polarized STM measurements [3] allow revealing the presence of non-collinear spin textures, i.e. spin spiral ground states, stabilized by interfacial Dzyaloshinskii-Moriya interactions [4,5]. Simultaneously performed scanning tunneling spectroscopy on the magnetic atom chains on the superconductor substrate reveal the evolution of the spatially and energetically resolved local density of states as well as the emergence of zero-energy bound states at the chain ends above a critical chain length. Based on the exact knowledge of the geometrical, electronic, and spin structure of the magnetic chain – superconductor hybrid system, the experimental results can be compared rigorously with ab-initio and model-type tight-binding calculations supporting the interpretation of the spectroscopic signatures at the ends of the chains as Majorana bound states [6]. More recently, the atomic-scale design of more complex network structures for Majorana state manipulation, including braiding operations, has been in the focus of our research. In a second part, experimental and theoretical studies of monolayer topological superconductivity and chiral Majorana edge modes in model-type 2D magnetic islands on elemental superconductors will be presented [7]. In particular, it will be demonstrated that interface engineering by an atomically thin oxide layer is crucial for driving the studied hybrid system

into a topologically non-trivial state as confirmed by theoretical calculations of the topological invariant, the Chern number. Finally, the prospects for studies of Majorana states in skyrmion – superconductor hybrid systems [8] will be discussed.

GD-10. Spin-orbit coupling-driven superconducting spintronics.
N. Banerjee[1], M. Blamire[2], J. Linder[3] and A.T. N'Diaye[4] *1. Physics, Loughborough University, Loughborough, United Kingdom; 2. University of Cambridge, Cambridge, United Kingdom; 3. Physics, Norwegian University of Science and Technology, Trondheim, Norway; 4. Lawrence Berkeley National Laboratories, Berkeley, CA, United States*

Recently, we have demonstrated the crucial role spin-orbit coupling plays in generating and controlling triplet Cooper pairs [1] confirming theoretical predictions of this phenomenon [2,3]. This provides a radically novel way to generate and control triplet Cooper pairs which is significantly simpler than the traditional conversion of singlet Cooper pairs into triplet Cooper pairs in the presence of inhomogeneous magnetic fields [4-6]. In this talk, I will discuss our results on proximity-coupling Pt/Co/Pt trilayer to a Nb thin-film superconductor to generate and control triplet Cooper pairs. The results demonstrate the generation and control of triplets using a single homogeneous ferromagnet instead of complex magnetic inhomogeneties. I will highlight our recent progress in this direction to better understand the origin of spin-orbit coupling in these heavy-metal/ferromagnet heterostructures using x-ray magnetic circular dichrosism and also briefly focus on some recent theoretical progress we have made in understanding the effect of superconductivity on magnetism in spin-orbit coupled structures [7]. Our experiments combine superconductivity, ferromagnetism and spin-orbit coupling into a new platform for spin-orbit coupling-driven superconducting spintronics.

GD-11. Superchiral spin waves.
F. Torres[1,2] *1. Departamento de Física, Universidad de Chile, Santiago, Chile; 2. Centro para el desarrollo de la Nanociencia y Nanotecnología Cedenna, Santiago, Chile*

The interference of two electromagnetic waves of opposite chirality leads to a locally enhanced chiral asymmetry (or superchiral fields) [1-3], due to the suppression of the electric dipole transitions [2]. This, in turn, produces an asymmetry in the absorption rate of chiral molecules [2, 3]. We demonstrate that an analogous field configuration arises from the superposition of two spin waves with opposite chirality, see Fig.[1]. We consider a ferromagnetic spin chain with an effective magnetic anisotropy at ends induced by the symmetry breaking and the Dzyaloshinskii-Moriya interaction. The magnetic moments located at the ends of the chain experience an additional torque, because of the boundary conditions, tilting away from the rest of the magnetic moments of the chain in the opposite directions. This model describes the dynamics and magnetic properties of superchiral spin waves, and shown an enhanced chiral asymmetry along the chain, that can be used, for instance, to manipulate the chiral magnetic coupling at the atomic scale. Further potential applications for spintronics also are discussed.

Recent advances in the studies of the spin-orbit torque (SOT) opened novel perspectives for nano-spintronics and magnonics by enabling utilization in spintronic devices of insulating magnetic materials such as Yttrium Iron Garnet (YIG), which is famous for its unprecedented small magnetic damping. In particular, SOT was shown to enable highly efficient compensation of the decay of propagating spin waves and excitation of localized coherent magnetization auto-oscillations in YIG. However, for a long time, it was not possible to achieve generation of propagating spin waves by insulator-based SOT oscillators, which is of particular importance for implementation of efficient magnonic nano-devices and circuits. Here, by using the space- and time-resolved micro-focus Brillouin light scattering (BLS) spectroscopy, we experimentally demonstrate an approach, which allows one to achieve an efficient emission of SOT-excited coherent spin waves into an extended magnetic-insulator film. We show that this can be accomplished by utilizing nanometer-thick Bi-substituted YIG films exhibiting large perpendicular magnetic anisotropy (PMA). The effects of PMA result in a compensation of the in-plane shape anisotropy of the film. Due to this compensation, the nonlinear frequency shift vanishes leading to the current-independent frequency of the auto-oscillations. As the result, the auto-oscillations do not experience nonlinear self-localization and can emit propagating spin waves with the wavelength of about 300 nm. We emphasize that, in our devices, the excitation of microwave-frequency spin waves requires dc current only, i.e. they incorporate an internal microwave source. Since microwave generation is performed directly in the device, the proposed approach is free from difficulties associated with the coupling and transmission of microwave-frequency electric currents in nano-scale circuits.

Macroscopic quantum states---Bose-Einstein condensates (BECs) can be created in overpopulated gases of bosonic quasiparticles as excitons, polaritons or magnons [1]. However, interactions between quasiparticles of a different nature, for example, between magnons and phonons in a magnetic medium, can significantly alter the properties of these gases and thus modify the condensation scenarios. Recently, we reported on the discovery of a novel condensation phenomenon mediated by the magnon-phonon interaction: an accumulation of hybrid magneto-elastic bosons [2]. Unlike a BEC, the accumulated magneto-elastic bosons possess a nonzero group velocity, making them promising data carriers in prospective magnon spintronic circuits. Here, we present the results of two-dimensional transport measurements of magneto-elastic bosons in a single-crystal Yttrium Iron Garnet film. Due to the strong magnetically induced anisotropy the curvature of the magnon-phonon spectrum is changed in the hybridization area (see Fig. 1) and therefore we observe several spatially localized beams with different group velocities for the magnon-phonon hybrid states. The observed behavior can be explained trough precise modeling of the avoided crossing region in wavevector space. This work is supported by the European Research Council within the ERC Advanced Grant “Supercurrents of Magnon Condensates for Advanced Magnonics”.

Yttrium iron garnet (YIG) is a unique material with the lowest known spin wave damping. It is therefore well suited for the investigation of fundamental spin wave dynamics and a promising candidate for the application in spin wave based circuits and logic devices [1, 2]. In this work, we study the impact of nanostructuring by means of electron beam lithography and successive ion milling on the spin wave propagation in individual spin wave waveguides. These structures are fabricated from a 44 nm thin high-quality YIG film grown by liquid phase epitaxy (LPE) [3] and their width varies from a few microns down to 40 nm (Fig. 1.a) [4]. By exciting the magnetization dynamics with a coplanar waveguide antenna and performing spatially resolved Brillouin Light Scattering (BLS) microscopy measurements, the propagation of spin waves in such nanostructures could be measured directly. In addition, the decay length of the spin waves in these conduits was investigated as a function of the conduit width. It is shown that for the smallest conduit width of 40 nm, the decay length decreases from 15.5 μm to 1.8 μm (Fig. 1.b). However, this decrease is mainly due to a change in the dispersion resulting in a significant decrease in the spin wave group velocity. This was confirmed by the measurement of the group velocity of the spin waves generated by pulse excitation and the temporal tracking of the spin wave packet using BLS microscopy. In addition, the spin wave mode spectra were extracted using thermal BLS measurements from which the effective exchange constant was derived. No significant dependence on the conduit width is found, which allows the conclusion that the impact of the nanostructuring process on the quality of YIG is minor. These findings pave the way for magnon-based data processing in nanoscale magnonic circuits. This research has been supported by ERC Starting Grant 678309 MagnonCircuits, DFG Grant DU 1427/2-1 and the Graduate School Material Science in Mainz (MAINZ).

GE-04. Reconfigurable Magnonic Crystals Based on YIG thin films and Co/Pt Bar-Magnets with Perpendicular Magnetic Anisotropy. *M. Kiechle*[1], A. Papp[1,2], M. Golibrzuch[1], S. Mendisch[1], V. Ahrens[1] and M. Becherer[1] *1. Department of Electrical and Computer Engineering, Technical University of Munich, Munich, Germany; 2. Pazmany Peter Catholic University, Budapest, Hungary*

This work presents an experimental demonstration of reconfigurable magnonic crystals (MC) based on periodic magnetic field profiles applied on YIG by nano-imprinted Co/Pt bar-magnets. The dipole fields of the hard-magnetic Co/Pt bars fabricated on top of YIG influence the propagation of spin waves (SWs) locally. In contrast to previously demonstrated MCs [1-3], reconfigurability is hereby achieved through the reversible magnetization of the Co/Pt stripes, resulting in the formation of magnonic bandgaps dependent on their magnetization direction. This concept promises additional degrees of freedom for bandgap engineering by simply switching nanomagnets in a global field and furthermore provides significant advantages in fabrication, since nano-patterning of Co/Pt is by far less challenging compared to that of YIG itself. The Co/Pt nanomagnets have perpendicular magnetic anisotropy (PMA), hence their magnetization is switchable from up to down and vice versa. Their coercivity is significantly higher than the required out-of-plane bias field for YIG, thus keeping their magnetization state in the experiment. An established method of engineering the coercivity in PMA magnets is inducing local defects via focused ion beam (FIB) irradiation. Switching the magnetization in FIB manipulated Co/Pt requires lower bias fields, facilitating altering dipole field directions by inverting selected magnets only; e.g. an antiferromagnetic field map by switching every second bar-magnet. The magnonic crystal is characterized by all-electrical metrology, i.e. measuring the transmission between two short-circuited coplanar waveguides (Fig. 1), as well as by means of trMOKE microscopy. Until now, we are able to excite wavelengths down to 2 μm and visualize the dispersion in the first Brillouin zone. Complementary, the SW dispersion in the MC is modelled in micromagnetic simulations in Mumax3. With varying field configurations of the bar-magnets, magnonic band gaps of variable size can be obtained. (Fig. 2).

GE-06. Experimental Demonstration of a Spin-Wave-Based Spectrum Analyzer Using FIB Patterning of YIG. A. Papp[1,2], *M. Kiechle*[1], S. Mendisch[1], V. Ahrens[1], G. Csaba[2], W. Porod[3] and M. Becherer[1] *1. TU Munich, München, Germany; 2. Pazmany Peter Catholic University, Budapest, Hungary; 3. University of Notre Dame, Notre Dame, IN, United States*

We present a new method for locally altering the magnetization of YIG (yttrium iron garnet), and using this technique we demonstrate a spin-wave-based spectrum analyzer proposed in [1]. YIG is an attractive candidate for magnonic applications due to its very low damping, but precise nanoscale patterning of YIG is challenging. We demonstrate the use of FIB (focused ion beam) irradiation to achieve magnetically inactive regions in YIG with nanoscale precision. This way, instead of patterning YIG by removing material, we only 'switch off' its magnetization in the irradiated regions, which results in similar behavior for guiding spin waves. We used a high-dose irradiation (10^{15} ions/cm^2) to achieve a binary magnetization landscape, however, we are also investigating the use of lower doses for smooth changes in magnetization, which could be useful for gradient index spin-wave optics or phase-shifter plates for magnonic computing. Film level ion irradiation of YIG was recently investigated in [2]. To demonstrate the utility of this technique, we present an experimental demonstration of the spin-wave-based microwave spectrum analyzer proposed in [1]. This device requires a concave grating, which can act as a source of spin waves driven by a nearby microwave antenna. In the original design, this was achieved by patterning YIG by removing material. Here, we demonstrate that this is also possible using FIB irradiation in the required pattern. Fig. 1 shows a proof-of-concept experimental result, where the resulting diffraction peaks are clearly visible (zero order and first order peaks). The irradiated region does not allow the propagation of spin waves, and the edge of the irradiated region acts as the source of new spin waves, which are excited by the magnetic field of the neighboring CPW (coplanar waveguide), at the same frequencies as the microwave signal in the CPW.

GE-07. Brillouin Light Scattering (BLS) Measurements of Spin Waves Excited by Surface Acoustic Waves (SAWs). *K.E. Nygren*[1], J.D. Schneider[2], Q. Wang[2], D. Labanowski[3], S. Salahuddin[3], G. Carman[2] and K. Buchanan[1] *1. Department of Physics, Colorado State University, Fort Collins, CO, United States; 2. Department of Mechanical and Aerospace Engineering, University of California Los Angeles, Los Angeles, CA, United States; 3. Deparment of Electrical Engineering and Computer Science, University of California Berkeley, Berkeley, CA, United States*

Propagation distances for surface acoustic waves (SAWs) are much longer than most spin waves in metals. However, spin waves may travel farther with propagation distances similar to that of SAWs if they can be coupled to these SAWs. Acoustic waves have recently garnered interest as an efficient means to drive magnetic oscillations. Indirect measurements have shown acoustic power absorption by magnetic materials attributed to the creation of spin waves, but few measurements have been done to directly measure coupled spin waves [1-3]. Here, we have used an interdigital transducer (IDT) on a piezoelectric substrate to convert an electrical signal into surface acoustic waves that can then propagate along the substrate surface. When a thin magnetic film is deposited on top of the substrate, the mechanical ripple of the SAW strains the thin magnetic layer [4]. We have made Brillouin light scattering (BLS) measurements on a 25 nm thick nickel pad, while driving the IDT at 1.8 GHz (a sample schematic is shown in Fig. 1a). For higher external magnetic fields, a BLS signal at the 1.8 GHz driving frequency is detected. At lower fields where the driving frequency overlaps the spin wave manifold, we see a BLS signal at 1.8 GHz (Fig. 1b) as well as at 3.6 GHz (Fig. 1c), twice the driving frequency, attributed to a non-linear magnetic process. Measurements at multiple locations across the 300 x 300 µm^2 square nickel pad provide a means to determine how the coupled spin waves decay with distance. We will also discuss the power dependence of the non-linear magnetic signal. This work is supported by NSF EFMA 1741666, NSF DEEC 1160504, and NSF EFRI NewLaw Award no. 1641128.

In analogy to conventional space crystals in condensed matter and atomic physics, Wilczek proposed the theory of spontaneous breaking of time symmetry and the emergence of Time Crystals [1]. Furthermore, a simultaneous crystalline formation in space permits the emergence of discrete space-time crystals (STC). Experiments confirmed the existence in abstract quantum systems [2, 3]. Here, we directly observe lattice scattering on a driven STC within a magnonic Py waveguide. Due to the generated periodicity in space and time, a band structure is formed and mode folding at the first Brillouin has to be taken into account. Therefore, magnons can scatter at the driven STC into higher spatial frequencies, which are forbidden in the conventional dispersion relation theory for the same structure (*cf.* Fig. 2). These scattering processes are observed and imaged in real space by scanning transmission x-ray microscopy (STXM) with magnetic contrast that features the necessary spatial (< 20 nm) and temporal (< 40 ps) resolution. The initial formation of the driven STC is caused by a continuous wave (CW) global radio frequency field, which leads to spin wave emission from the left and right edge of the waveguide [4]. Consequently, a standing spin wave pattern arises revealing oscillation in space and time (*cf.* Fig. 1). With the realization of a driven space-time crystal in magnonic waveguides, we take the abstract idea of space-time crystalline structures to the next level and reveal new phenomena in the field of non-linear wave physics. These fundamental findings could pave the way for reconfigurable magnonic crystals without nanoscale patterning and for a new generation of spin wave emitter at ultra short length scales.

Institute of Microengineering, Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland*

Coherent emission and phase-resolved detection of exchange-dominated magnons with wavelengths of λ = 100 nm and below is one of the biggest challenges of the emerging field of nanomagnonics. A promising approach is the magnonic grating coupler (GC) effect [1], in which a periodic lattice of nanomagnets (periodicity *p*) is integrated on a magnetic thin film to modulate the electromagnetic near field of a conventional coplanar waveguide (CPW). In Ref. [2] GC-excited SWs were consistent with a wavelength of λ = 50 nm [2]. However, λ was not measured directly, but estimated from theoretically predicted dispersion relations assuming a reciprocal lattice vector $G = 2\pi/p$ of the GC. Using time resolved scanning transmission x-ray microscopy (TR-STXM) we investigated the GC effect in real space. We prepared periodic gratings with p = 200 nm (p = 400 nm) consisting of 100 nm (200 nm) wide and 20 nm thick Permalloy (Py) stripes underneath a CPW on a 100 nm thick Yttrium iron garnet (YIG) film. We imaged the first and second GC mode of the p = 200 nm grating by TR-STXM. In the latter case, plane-wave SWs with λ = 100 nm were induced underneath the GC and emitted into the bare YIG, where the wavelength amounted to λ = 104 nm. The emitted plane-wave SWs were still detected 10 µm away from the CPW. Preferential emission of SWs to one side of the antenna was observed. Also the p = 400 nm GC showed emission of SWs with λ = 100 nm. Their wave vector corresponded to 4G. At 8.7 GHz and fields around 24 mT, the so-called resonant grating coupler effect was apparent in that magnetization oscillations with the periodicity of the Py lattice were superimposed on 100 nm SWs in the YIG film underneath the GC. When arranging 100-nm-wide Py stripes in an aperiodic 1D Fibonacci sequence [3] we observed additional high frequency SW branches compared to the periodic lattices reports above. From broadband spectroscopy based on a vector network analyzer we estimated wavelengths down to below 100 nm for the additional branches. The aperiodic Fibonacci sequence hence allowed us to excite more wave vectors compared to a periodic grating. The work is funded by SNF 163016. We thank HZB, Germany for the allocation of synchrotron radiation beamtime.

GE-10. Wavelength-Selective Optical Detection of Spin Waves Beyond the Diffraction Limit. *M. Peeters*[1], J. Lucassen[1], C. Schippers[1], R. Duine[1,2], H. Swagten[1], B. Koopmans[1] and R. Lavrijsen[1] *1. Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands; 2. Institute for Theoretical Physics, Utrecht University, Utrecht, Netherlands*

The introduction of spin waves in next-generation computing devices is expected to lead to several advantages, such as the ability for wave computing or chargeless information transport [1]. However, its introduction is hampered by an inability to efficiently excite and detect these spin waves. One of the more interesting ways to do this is optically, although here we run into the limitation of accessible length scales (wavelength of the spin-waves) set by the optical diffraction limit. In this work, we demonstrate optical detection of spin waves beyond the diffraction limit by nanostructuring light reflecting elements (a grating) on top of a magnetic strip (Fig. 1). We electrically excite spin waves in this strip using a spin wave antenna, and detect them by focusing a pulsed fs-laser onto the grating. The grating will modify the spatial intensity profile of the laser spot, leading to a non-vanishing magneto-optical Kerr effect if the grating matches the spin wave wavelength. Experimentally, we demonstrate that the grating allows us to detect spin waves with a wavelength of 700 nm using a spot with a full width at half maximum (FWHM) of 12 µm (Fig. 2). Additionally, we see that the spatial filtering of the grating makes these measurements extremely wavelength selective. Our current efforts are aimed at unravelling the measured spectra, which is done using an analytical model that describes the excited spin waves based on Fourier analysis. The resulting behavior is qualitatively similar to the measurements (such as the one in Fig. 2). We expect that this technique can provide a new non-invasive and artefact free way of measuring spin waves as a function of position and help integrate the field of optics with nanoscale magnetism.

GE-11. Exploration of modified density of states and multi-directional emission of spin-waves in artificial magnetic quasicrystals.
S. Watanabe[1], V.S. Bhat[1], K. Baumgaertl[1] and D. Grundler[1,2] *1. Institute of Materials, Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland; 2. Institute of Microengineering, Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland*

A quasicrystal possesses a long range order but no translational invariance. Penrose tiling [1] is known as a 2D analogue of a natural quasicrystal. Photonic artificial quasicrystals based on Penrose tiling, i.e., nanostructures engineered to create quasicrystalline properties, exhibit a complete band gap for light due to their manifold rotational symmetry [2]. Artificial magnetic quasicrystals (AMQs) provide further interesting features in that collective spin excitations (spin waves) exhibit anisotropic dispersion relations and depend on the inhomogeneity of the internal field and rotational symmetry [3, 4]. We fabricated AMQs based on 100 nm thick yttrium iron garnet (YIG) thin films. Nanotroughs with a depth of 18 nm and a diameter of 330 nm were structured at the vertices of a Penrose P3 tiling whose characteristic length amounted to 900 nm. The AMQs covered 52.8 x 50.2 μm^2. Two coplanar waveguides were integrated on top of the samples to excite spin waves (SWs). Here we report SW properties explored by broadband SW spectroscopy and Brillouin light scattering (BLS). Angular-dependent SW spectroscopy showed broad frequency bands of excited spin waves which contained narrow regime of forbidden frequency gaps. We attribute this observation to the formation of a pseudo Brilloun zone (p-BZ) [2] and modified density of state for SW in the AMQ. SW transmission spectra indicated that the wave vector of the SW was modified by the basic reciprocal vector of the AMQ [5]. SW imaging via BLS technique with phase and time resolution evidenced irregular SW phase fronts, which are not observed in periodic structures. Our experimental results suggest that aperiodically arranged nanogratings [5] allow one to emit spin waves with a manifold of propagation directions and wavelengths. This work was supported by Swiss National Science Foundation via Grant No. 163016.

Helmholtz-Zentrum Berlin, Berlin, Germany*

Magnonic quasicrystals exceed the possibilities of spin wave (SW) manipulation offered by regular magnonic crystals, because of their more complex SW spectra with fractal characteristics. Here, we report a combined X-ray microscopic and Brillouin Light Scattering observation of propagating SWs in a magnonic quasicrystal, consisting of dipolar coupled permalloy nanowires arranged in a one-dimensional Fibonacci sequence. SWs from the first and second band as well as evanescent waves from the band gap between them are imaged (cf. Figure). Moreover, additional mini-band gaps in the spectrum are demonstrated, directly indicating an influence of the quasiperiodicity of the system. Finally, the localization of SW modes within the Fibonacci crystal is shown. The experimental results are interpreted using numerical calculations and we deduce a simple model to estimate the frequency position of the magnonic gaps in quasiperiodic structures. The demonstrated features of SW spectra in one-dimensional magnonic quasicrystals allows utilizing this class of metamaterials for magnonics and makes them an ideal basis for future applications. We confirm the existence of collective spin waves propagating through the structure as well as dispersionless modes; the reprogammability of the resonance frequencies, dependent on the magnetization order; and dynamic spin wave interactions. With the fundamental understanding of these properties, we lay a foundation for the scalable and advanced design of spin wave band structures for spintronic, microwave and magnonic applications.

We demonstrate that the spin waves can be strongly coupled to coherent shear waves that have very long characteristic decay length and propagate ballistically over millimetric distances. In our spin valve structure, which consists of two insulating magnetic layers (YIG) deposited on both sides of a dielectric GGG substrate, the standing acoustic waves couple to the magnetization oscillations in both layers. The coupling signifies a change of sign between the acoustic modes with even or odd indices, which results in a contrast between two tones separated by half a wavelength. We measure the contrast at different polar angles via inverse spin Hall effect using a thin Pt wire deposited on one side of the YIG layer. In our sample the two YIG layers resonate at slightly different frequencies. The change in

the polar angle allows to detune their resonances and make them cross, which leads to a peak of the contrast at the crossing point. We show that the observed behavior is in agreement with theoretical prediction. This long range coherent coupling by phononic angular momentum currents adds new functionalities to insulator spintronic circuits and devices.

GE-14. Coupling between acoustic and optic magnons in synthetic antiferromagnets. *Y. Shiota*[1], T. Taniguchi[2], M. Ishibashi[1], T. Moriyama[1] and T. Ono[1] *1. Institute for Chemical Research, Kyoto University, Uji, Japan; 2. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan*

Synthetic antiferromagnets consist of two or more ferromagnetic layers separated by nonmagnetic layers. When the magnetizations are coupled antiferromagnetically through the interlayer exchange coupling, this enables us to investigate the antiferromagnetic resonance modes; an acoustic mode (in-phase precession) and an optic mode (out-of-phase precession). Recently, an anti-crossing gap of ferromagnetic resonance (k = 0 μm^{-1}) between acoustic and optic modes, so-called magnon-magnon coupling, was reported in the layered antiferromagnet of $CrCl_3$[1]. In this study, we observed the anti-crossing gap of spin wave resonance ($k \neq 0$ μm^{-1}) between acoustic and optic modes in synthetic antiferromagnet of FeCoB/Ru/FeCoB. The films were prepared by sputter deposition on a thermally oxidized Si wafer: Ta(3)/Ru(3)/$Fe_{60}Co_{20}B_{20}$(15)/Ru(0.6)/$Fe_{60}Co_{20}B_{20}$(15)/Ru(3) (thickness in nm). The two in-plane magnetized FeCoB layers separated by a Ru layer with a thickness of 0.6 nm were antiferromagnetically coupled through the interlayer exchange coupling. The films were micro-fabricated to spin wave devices, as shown in inset of Fig. 1. The efficiently excited spin wave wavenumber k was determined by the design of coplanar waveguides (CPWs). The scattering parameter S_{11} for reflection was measured by a vector network analyzer connected to the CPWs. The external magnetic field was applied at an angle φ_H with respect to the spin wave propagation direction. Figure 1 shows the Re[S_{11}] spectra as a function of magnetic field. When φ_H = 0, 90 deg. (Fig. 1(a)(c)), spin wave resonance frequencies of acoustic and optic modes are degeneracy at their crossing point and there is no anti-crossing gap. On the other hand, when φ_H = 45 deg. (Fig. 1(b)), two resonant modes are hybridized and the anti-crossing gap is generated. This is due to the interaction between two ferromagnetic layers through the magnetostatic dipole fields generated by spin waves. In the presentation, we will discuss more detail about φ_H and k dependence of anti-crossing gap, and provide a quantitative description of coupling strength.

GE-15. Nonlinear magnon scattering mechanism for microwave pumping in magnetic films. *T. Qu*[1,2], A. Venugopal[1], J.M. Etheridge[2], W. Peria[2], P.A. Crowell[2] and R. Victora[1] *1. Department of Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States; 2. School of Physics and Astronomy, University of Minnesota, Minneapolis, MN, United States*

The nonlinear properties of magnons have been a focus both as a prototypical nonlinear system [1,2] and for their potential applications. Nonlinear microwave devices, such as Signal to Noise Enhancers and Frequency Selective Limiters are known to provide useful manipulation of microwave signals without the need for power-hungry (and fragile) electronic circuitry, exploiting nonlinear magnon properties. However, the underlying physical processes are poorly understood, making efficient device design impossible. Here we examine this nonlinearity from the perspectives of micromagnetic simulation and experiment, for the perpendicular-pumping configuration, a common device arrangement. Parallel computing on graphical processing (GPUs) is used to overcome the barriers of long time and length scales, and thus predict steady state phenomena. We use a 2D simulation model to quantitatively identify magnon scattering regimes, in the light of magnon-band structure. The experimental nonlinearity is measured as a function of microwave power using heterodyne ferromagnetic resonance. A strong agreement is shown between the two approaches (shown in Fig. 1), with a clear theoretical demonstration that the complex experimentally observed phenomena are caused by magnon scattering, consistent with the predicted magnon dispersion curve (in Fig. 2). For the same sample, the power threshold indicating the nonlinear region, increases for higher microwave frequency. For fixed microwave frequency, the power threshold is very sensitive to the film thickness in varying samples. These results yield fundamental insights, as well as direct application to the design of microwave devices. This work was supported by the DARPA M3IC program, the Center for Micromagnetics and Information Technologies (MINT), and SMART a SRC NCore center sponsored by NIST.

The magnetic skyrmion lattice (SkL) is an example of a state protected by a topological energy barrier [1]. This barrier arises from the inability to continuously transform between spin structures with different topological charge; it can only be overcome by large discontinuous deformations, such as those caused by thermal fluctuations. In bulk materials, skyrmions typically exist in a narrow range of magnetic field and temperature, just below the Curie temperature, T_c [2,3]. However, metastable skyrmions have recently been observed, achieved by cooling the sample under an applied field, allowing the skyrmions to survive to low temperatures [4]. Fig. 1. displays a magnetic phase diagram showing the metastable SkL region as measured in Cu_2OSeO_3, a multiferroic skyrmion material [5], and the subject of the current work. These metastable skyrmions decay to the competing conical phase with a finite lifetime which is temperature dependent [6]. Close to T_c, the metastable SkL state therefore has a short lifetime, necessitating a rapid cooling rate to ensure a significant population of metastable skyrmions survives to low temperature [7]. In our study, we demonstrate that the introduction of non magnetic Zn ions into the underlying crystal lattice of Cu_2OSeO_3 dramatically increases the lifetime of the metastable SkL state – by a factor of 50 at just 2.5% Zn doping, as shown in Fig. 2. In turn, this reduces the required cooling rate to produce a substantial metastable SkL population. Our time-resolved AC susceptibility measurements suggest that this is not due to a change in the energy barrier protecting the metastable skyrmion state, but due to an increased pinning site density because of the included Zn ions. We expect that this effect can be exploited to engineer and control the metastable skyrmion lifetime in other doped skyrmion-hosting systems.

GF-02. Room temperature skyrmions in B20 Fe-rich $Fe_{1.2}Ge$ films. *T. Liu*[1], R. Bennett[1], S. Cheng[1], A. Ahmed[1] and R. Kawakami[1]
1. Department of Physics, The Ohio State University, Columbus, OH, United States

The topological stability, small size, and the ability to be very energy efficiently written, read and manipulated, put magnetic Skyrmions at the forefront of candidates for next-generation storage technology. Current skyrmion research is focused on metallic multilayers and B20 crystals. However, none of them can achieve skyrmions at room temperature with size smaller than

10 nm, which has already become a major bottleneck of their development. For metallic multilayers, they have small Dzyaloshinskii-Moriya interaction (DMI) arising from surface inversion symmetry breaking and consequently large skyrmions. On the contrary, B20 crystals have a large bulk DMI and nanoscale skyrmions with sizes down to 3 nm but have not achieved room temperature operation. The closest B20 material is FeGe which has a Curie temperature of ~280 K. In this work, we successfully synthesized Fe-rich $Fe_{1.2}Ge$ films by non-equilibrium alternating layer molecular beam epitaxy at room temperature to incorporate additional Fe atoms within the B20 FeGe structure. The cross-sectional TEM indicates that the $Fe_{1.2}Ge$ film maintains the B20 structure. XRD exhibits a peak corresponding to the B20 FeGe structure but with a shift in peak position to a lower angle indicating an expanded lattice constant. This peak shift and the absence of additional XRD peaks as well as the lack of visible clusters in the TEM images suggests the absence of phase separation and macroscopic secondary phases. Rather, the structural characterization is more consistent with the incorporation of Fe into interstitial sites with possible formation of atom-scale Fe aggregates (e.g. dimers, trimers, etc.). Magnetic characterization result shows that the Curie temperature of the $Fe_{1.2}Ge$ film is above room temperature (RT). More interestingly, we observe topological Hall resistance above room temperature with a maximum value around H ~1.5 kOe, which provides strong evidence for the skyrmion formation above room temperature.

Magnetic compounds with the noncentrosymmetric cubic B20 structure such as MnSi are potential spin-electronics materials due to skyrmion spin structures associated with non-zero Dzyaloshinskii-Moriya (DM) interactions [1, 2]. However, a disadvantage of existing B20 compounds is their low magnetic-ordering temperatures T_c < 300 K and some are not even ordered at zero temperature, including CoSi and FeSi. Furthermore, T_c improvements in these compounds are normally accompanied by unfavorable increase in helical periodicity and skyrmion size [1]. This study reports a non-equilibrium fabrication of B20-ordered $Co_{1+x}Si_{1-x}$ with $0 \le x \le 0.043$ (Figs. 1a and 1b), which exhibit a T_c = 328 K for x = 0.043, the highest among all B20-type magnets. DFT calculations show a transition from Pauli paramagnetism to a magnetically ordered state above a critical excess Co concentration x_c = 0.028 (Fig. 1c) and explain that the onset of magnetism has the character of a quantum phase transition (QPT), similar to that observed in disordered alloys [3]. The chirality of the crystals supports spin spirals caused by DM interactions, and we estimate a helical periodicity λ of about 17 nm from magnetic measurements, which also reveal skyrmionic spin structures around room temperature as depicted in a temperature-field magnetic phase diagram (Fig. 1d). A unique combination of high T_c and relatively small λ achieved in $Co_{1+x}Si_{1-x}$ will be explained in terms of QPT, where spin-polarized excess-Co atoms are coupled through the host matrix. This research is primarily supported by NSF-DMREF: SusChEM (award no. 1729288, fabrication and characterization) and the U.S. DOE (award no. DE-FG02-04ER46152, theory).

Skyrmion-hosting materials, and in particular the archetype cubic chiral magnets, show the same generic behaviour, which was so far assumed to be universal. Recent experiments on the insulator Cu_2OSeO_3, however, show remarkable deviations from this universal behavior, with far-reaching implications. A new phase occurs when it is the least expected, at low temperatures and high magnetic fields, but only when the field is applied along the [001] easy crystallographic axis [1]. Furthermore, extremely robust skyrmionic states, can be produced in large areas of the magnetic phase diagram [2, 3]. Nascent and disappearing spiral states near critical lines catalyze topological charge changing processes, leading to the formation and destruction of skyrmionic states at low temperatures, which are thermodynamically stable or metastable depending on the orientation and strength of the magnetic field. The metastable low temperature skyrmions are surprisingly resilient to high magnetic fields and their memory persists in the field polarized state, even when the skyrmion lattice signal has disappeared [3]. These results hint to novel routes for skyrmion nucleation [4] and highlight the paramount role of magnetic anisotropies in stabilizing exotic chiral magnetic states.

Recently, there has been appreciable interest in the physics of magnetic skyrmions due to their potential use in spintronic devices [1]. Magnetic skyrmions are topological magnetic spin structures originally identified in the B20 class of materials, but have more recently been found in other non-centrosymmetric materials [2]. Bulk Cu_2OSeO_3 is a multiferroic insulator that crystallises in the $P2_13$ space group and has been shown to host a Bloch-type skyrmion lattice. The magnetoelectric coupling in Cu_2OSeO_3 means that skyrmions can be manipulated by electric fields, a useful property for spintronic devices. The skyrmion lattice in Cu_2OSeO_3 has a magnetic modulation period of ~ 62 nm in the skyrmion phase, situated just below the T_c of ~ 59 K [3]. The understanding of confinement and isolation of single skyrmions is vital for applications [4]. Previously a large increase in the temperature and magnetic field stability region of skyrmions has been observed in thinned bulk crystal samples of Cu_2OSeO_3 using Lorentz TEM, showing that confinement of one spatial dimension plays an important role in the stabilisation of skyrmions. We have produced Cu_2OSeO_3 nanoparticles with sizes ranging from 20 to 250 nm using a modified hydrothermal method (Fig. 1). This has enabled us to investigate the effect of confinement on the formation of skyrmions and probe the magnetism within these nanoparticles, with close attention being paid to studying the effects when the size of the nanoparticles is made comparable to the size of the skyrmions expected in this system (Fig. 2). Here, we present the results of our investigation of the dependence of their magnetic properties on the particle size by using x-ray diffraction, *dc* and *ac* magnetic susceptibility measurements, and microscopy techniques.

Skyrmions, topologically protected particle-like vortices in the magnetization, hold potential as an energy efficient, high-density magnetic storage media due to their nanometric size and the low driving current densities [1]. The widely-studied B20 skyrmion materials (chiral cubic $P2_13$ space group) present a bottleneck to technological applications due to their below room-temperature transition [2]. However, CoZn alloys are known to host a β-Mn phase [3], creating a structurally chiral cubic magnet which breaks spatial inversion symmetry. Such alloys can host Dzyaloshinkii-Moriya interaction (DMI) stabilised skyrmions at and above room temperature [4], making them a candidate for developing skyrmion technologies. To date these materials have primarily been studied as bulk crystals, but to realise technological applications it is necessary to produce thin films on planar substrates from which devices can be fabricated. We present the results of work to address this gap by growing thin films by co-sputtering of CoZn alloys from elemental targets. The films were grown on Si/SiO_2 substrates at room-temperature. In their as-deposited form they are amorphous or nanocrystalline, lacking Bragg peaks in XRD or showing weak contributions from constituents' crystalline phases. After annealing at 400 °C for 48 hours, crystallites with the β-Mn structure form, as shown by the presence of Bragg reflections in XRD and further confirmed by TEM imaging (Fig. 1b). Typical lateral crystallite sizes are of the order of 40-50 nm, with exceptional cases of around 100 nm. Annealed samples also show an above room-temperature transition around 380 K (Fig. 1a), with as-grown samples showing an emergent transition in the M(T) down-sweep. These thin film alloys present with the β-Mn phase ($P4_132/P4_332$ space group), and thus possess an appropriate point group symmetry to give rise to a bulk DMI and are potential candidates for an above room-temperature thin film skyrmion material. This work was supported in part by the STFC ISIS Neutron and Muon Source.

Magnetic skyrmions are nanoscale, particle-like entities made up of a swirling, topologically protected spin texture which exist in chiral magnetic systems. These skyrmions are promising candidates for novel memory technologies and spintronic devices due to the potential to encode information as the presence or absence of skyrmions, allowing for a racetrack memory system [1]. Techniques to manipulate the skyrmions in such a system are key to development of such devices. Here we present a novel method to manipulate skyrmion motion using magnetic field gradients (Fig. 1) [2]. Cu_2OSeO_3 is a well-established skyrmion system in which individual skyrmions assemble into a closed-packed hexagonally ordered magnetic lattice [3,4]. The magnetic lattice constant is relatively large ~(60 nm), allowing for the observation of skyrmions using resonant elastic x-ray scattering (REXS). This technique is ideally suited to studying slow dynamics in situ and uses polarized soft x-rays only available at synchrotrons. Our REXS experiments on beamline I10 at the Diamond Light Source show that the skyrmion lattice structures in single-crystal Cu_2OSeO_3 are highly mobile in a radial field gradient. The skyrmions rotate collectively in a shell-like structure following a given velocity-radius relationship. The direction of the field can be used to control the sense of rotation of the lattice. These results show that field gradients provide an effective mechanism for fine control of skyrmion motion. In this scheme, no local electric currents are needed, thus providing an alternative, lower energy approach to shift-register-type operations based on spin-transfer torque. Our findings open the door to a new way to manipulate and engineer the skyrmion state which will enable applications in the future.

GF-08. Skyrmion ratchet for single-electrode skyrmion transport.
W. Gan[1], C.C. Ang[1], X. Wang[2] and W. Lew[1] *1. Nanyang Technological University, Singapore; 2. Lanzhou University of Technology, Lanzhou City, China*

The use of voltage-controlled magnetic anisotropy gradients to drive skyrmions promises highly efficient skyrmion transport.[1] However, their complicated designs thus far have eluded experimental realization.[2] In this work, we demonstrate a new type of skyrmion transport mechanism, the skyrmion ratchet, which uses a single gate electrode to drive any number of skyrmions. To achieve the feat, a transverse driving force was used instead of a longitudinal type previously proposed. The driving mechanism relies on the skyrmion Hall effect for the forward propagation force. In doing so, the speed limit is no longer limited by skyrmion annihilation by the skyrmion Hall effect. As the transverse driving scheme is a self-restoring, an array of engineered potential wells was constructed to serve as a ratchet for unidirectional skyrmion motion. A succinct advantage of the skyrmion ratchet lies in its ability to move the skyrmion very closely to the centerline of the nanowire, thus allowing for predictable behavior and high transport velocities. Finally, we demonstrate that, despite the unidirectional operation, the skyrmion ratchet can recirculate the skyrmions in a closed loop and achieving high data densities

GF-09. Beyond Skyrmions - Utilizing alternative magnetic quasiparticles for spintronics devices. *B. Göbel*[1], A.F. Schäffer[2], A. Mook[2], J. Henk[2], J. Berakdar[2], O. Tretiakov[3,4], S.S.P. Parkin[1] and I. Mertig[2,1] *1. Max Planck Institute of Microstructure Physics, Halle (Saale), Germany; 2. Martin Luther University Halle Wittenberg, Halle (Saale), Germany; 3. School of Physics, The University of New South Wales, Sydney, NSW, Australia; 4. Institute for Materials Research and Center for Science and Innovation in Spintronics, Tohoku University, Sendai, Japan*

Over the last 10 years the field of skyrmionics has attracted an enormous research interest, as skyrmions (small, whirl-like spin textures) possess strong stability, characterized by an integer topological invariant $N_{Sk} = \pm 1$. Due to their non-trivial real-space topology, skyrmions offer a topological contribution to the Hall effect, commonly measured in skyrmion crystals, and can be stabilized as individual quasiparticles in collinear ferromagnets. They can be driven by currents in thin films allowing for spintronics applicability for example as carriers of information in racetrack storage devices. However, one issue which is hindering the utilization of skyrmions in applications is the skyrmion Hall effect: A skyrmion does not move parallel to an applied spin-polarized current but is pushed towards the edge of the sample [1]. In this talk, I discuss magnetic quasiparticles that are related to skyrmions and exhibit either effects that are interesting from a fundamental point of view, or are attractive application-wise. After giving a general overview over different observed or proposed quasiparticles, I focus on the antiferromagnetic skyrmion (topological charge $N_{Sk} = 0$), the skyrmionium ($N_{Sk} = 0$), the biskyrmion ($N_{Sk} = 2$), and the bimeron ($N_{Sk} = 1$); cf. Fig. 1. All of these objects can be understood as the combination of two smaller topologically non-trivial quasiparticles, what brings about different properties compared to conventional skyrmions. The most remarkable results are that antiferromagnetic skyrmions [2,3] and skyrmioniums [4] do not exhibit a skyrmion Hall effect when driven by currents, that the bimeron [5,6] (the topological equivalent of a skyrmion in in-plane magnetized samples) exhibits a pure version of the topological Hall effect, and that biskyrmions [7,8] can be generated in centrosymmetric materials without the chiral Dzyaloshinskii-Moriya interaction.

Nanoscale Semiconductor Engineering, Hanyang University, Seoul, The Republic of Korea*

The skyrmions which are the topological chiral spin textures, have drawn significant interests because of their novel topological phenomena including emergent electromagnetism, the topological Hall effect and the skyrmion Hall effect (SkHE) [1]. In addition, magnetic skyrmions have become one of the most promising candidates as robust information carriers in the next-generation spintronic devices. However, the current-driven motion of skyrmions is deflected from the direction of the current by SkHE [2,3]. Therefore, it is essential to understand and manipulate SkHE not for only unveiling the underlying physics but also for making the best use of skyrmions in spintronics applications. Here, we address a novel method to control the skyrmion Hall angle (SkHA), the angle between the skyrmion motion and the current direction, using both out-of-plane and in-plane external magnetic fields, and an efficient way to achieve the straight motion of magnetic skyrmions by completely suppressing the SkHE. Manipulation of the SkHA via the external magnetic fields is experimentally confirmed by studying chiral stripe shooting with the half-skyrmion end as shown in Fig.1. The observed field dependence of the SkHA is explained by generalizing the existing theory for the elongated chiral bubbles [4] to the cases with the simultaneous presence of external magnetic fields and spin-orbit torques. Finally, based on the demonstrated precise control of the SkHA, skyrmion multiplexer (S-MUX) devices are fabricated where the direction of the current-induced elongation of skyrmions is determined by the external magnetic field.

GF-11. Thermodynamic concept for current-induced skyrmion dynamics at Pt/Co interfaces. *S. Sugimoto*[1], S. Kasai[1] and Y. Takahashi[1]
1. Research Center for Magnetic and Spintronic Materials, National Institute for Materials Science, Tsukuba, Japan

Magnetic skyrmions are topological defects in magnetization mostly induced by the chiral interaction [1,2]. Interfacial skyrmions hosted at heterostructures of ferromagnets and heavy metals can be stabilized at room-temperature [3], and attract great interest for device applications [3]. One of the excellent characteristics of skyrmions is the ultralow threshold current density for driving [4], and their current-induced dynamics are usually described by the Thiele equation [5] as kinds of steady particle motions. We here report observations of different types of current-induced dynamics between (i) CoFeB/MgO and (ii) Pt/Co interfaces, where the latter can be described with the thermodynamic concept beyond the scope of particle nature. Figure 1 shows responses to current injections at (i) W/CoFeB/MgO and (ii) Pt/Co/Ir interfaces, respectively. For (i) W/CoFeB/MgO interfaces (Fig. 1(a)), skyrmion's trajectories can be described by the Thiele equation with spin-orbit torque terms [5]: skyrmions are driven along the charge flow with finite skyrmion Hall angle (SkHA), and increase in current leads to increase in SkHA [6,7]. On the contrary, dynamics at (ii) Pt/Co/Ir interfaces in Fig. 1(b) appear different from Thiele's descriptions: skyrmions show accumulation phenomena along the Hall (y) direction prior to threshold current for longitudinal driving (~4.0×10^{10} A/m^2) [6]. The distribution of skyrmion shows linear profiles along the direction, which can be described by a phenomenological diffusion model with assumption of macroscopic intensive property, i.e., chemical potential. Such thermodynamic concept can be applicable over ten of micrometers even where current is absent. We've demonstrated large scale of skyrmion pumping by tuning the chemical at nonlocal devices designed as analogies of "canal gates" of water control, where skyrmions are transferred between different canals though narrow junctions following profile of the chemical potential. This work provides a new methodologies of handling distributions of skyrmions over several tens of micrometers only by switching local currents.

GF-12. Voltage-driven high speed skyrmion motion in Skyrmion shift device. *N. Lei*[1] *1. Beihang University, Beijing, China*

Magnetic skyrmions are topological protected chiral spin textures, which are promising for memory and logic applications. Low energy cost of skyrmion manipulation is crucial, especially for skyrmion motion. Large driving current is required to achieve high-speed skyrmion motion, which results in significant Joule heating and instability of devices. Here, we propose a voltage-driven skyrmion motion approach in a skyrmion shift device made of magnetic nanowires. As the figure shown below, a simple structure with equidistant identical electrodes on a uniform-thickness nanowire, which allows voltage-driven high-speed skyrmion motion with low power. To demonstrate its feasibility, numerical calculations have been done by standard micromagnetic simulator. This work provides a new scope to fill in the gap of studies on skyrmion nanodevices [1].

A key problem for probabilistic computing is that cascading gates propagate undesired correlations and thus vitiate the functionality of the logic device. Therefore, in order to implement probabilistic computing, one needs to reshuffle the signals to keep them uncorrelated. While for many non-conventional computing approaches non-magnetic implementations have been identified as promising, for building a reshuffler device, skyrmions [1,2] might be ideally suited due to the low footprint and low power compared to e.g. CMOS implementations [3]. We develop a low pinning material, where we can stabilize skyrmions and controllably nucleate and displace them by current injection due to spin-orbit torques [4]. We find topologically non-trivial N=1 skyrmions that exhibit strong motion also at zero applied current, which we ascribe to thermally activated skyrmion dynamics [4]. By tracking the trajectories of skyrmions, we can identify motion by pure diffusion and obtain the diffusion constant that shows a surprisingly strong temperature dependence [4]. We then employ thermal skyrmion motion in a reshuffler device. We evaluate its performance for the decorrelation of the input signal and find an uncorrelated output signal while keeping the stream's mean value with high fidelity showing the applicability of skyrmions for information processing in stochastic computing approaches. Finally by lowing the temperature, we can crystallize skyrmions into a lattice. We measure the time-resolved crystallization dynamics and from the pair correlation function quantify the interaction potential.

Complex oxides possess a wide range of technologically relevant functional properties including ferromagnetism, ferroelectricity, and superconductivity. Furthermore, their interfaces exhibit unexpected functional properties not found in the constituent materials due to structural and chemical changes as well as electronic and magnetic interactions occurring over nanometer length scales. These unique interfacial effects lead to fundamental differences compared to analogous metallic systems. For example, spin-flop coupling is observed at ferromagnetic (FM) $La_{0.7}Sr_{0.3}MnO_3$ / antiferromagnetic (AF) $La_{0.7}Sr_{0.3}FeO_3$ interfaces where the AF spin are oriented perpendicular to the magnetization of the FM layer.[1] Moreover, FM/FM interfaces consisting of magnetically hard $La_{0.7}Sr_{0.3}CoO_3$ and soft $La_{0.7}Sr_{0.3}MnO_3$ display exchange-spring behavior where the magnetically hard layer pins the FM moments of the soft layer, however, the hard/soft magnetic interface does not coincide with the chemical interface.[2] Rather, an interfacial $La_{0.7}Sr_{0.3}CoO_3$ layer forms that is characterized by magnetically active Co^{2+} ions which couple to the soft $La_{0.7}Sr_{0.3}MnO_3$ layer. The full characterization of the magnetic and structural properties of this $La_{0.7}Sr_{0.3}CoO_3$/$La_{0.7}Sr_{0.3}MnO_3$ bilayer system required the combined results of synchrotron-radiation and neutron-scattering based techniques as well as high resolution electron microscopy. We found that the proportion of the Co^{2+} ion-rich $La_{0.7}Sr_{0.3}CoO_3$ layer and the magnitude of the exchange bias shift of the hysteresis loops depended sensitively on parameters such as the individual layer thicknesses, the BO_6 octahedral tilt pattern of the underlying substrate, and the stacking order of the layers.[3] These results demonstrate how the competing interactions in complex oxides enable intriguing opportunities to tailor functional properties for new, versatile, and energy efficient spintronic devices. We are grateful to the support by NSF (DMR 1411250 and 1745450), SRC (No. 2309.001), UC MRPI (No. MR-15-328528), and the DOE SCGSR program. This research utilized DOE user facilities including ALS at LBNL, SSRL at SLAC, SNS at ORNL, and EMSL at PNNL.

Multiferroic materials have been proposed for an array of applications due to their binary or ternary co-existing magnetic spin, electric dipole, and ferroelastic properties. While many researchers are interested in optimizing these single-phase compounds, creating a strain-coupled multiferroic to mimic two or three types of ordering is a more tunable and less expensive option for device components. In strain-coupled multiferroics, a magnetostrictive/magnetoelastic thin film is grown on a piezoelectric substrate to control the desirable multiferroic ordering. Previous work on magnetostrictive Galfenol (400 ppm) coupled with permalloy (NiFe) to reduce the energy required to flip the magnetization, indicated that the magnetization rotates coherently in-plane with magnetic field and with an applied voltage.[1] In this work, the reversal mechanisms of amorphous Tb_xFe_{1-x} ($0.1<x<0.45$) was studied when exchange-coupled with NiFe to create a system with a unique switching mechanism during magnetic reversal.[3] Amorphous Tb_xFe_{1-x} has a large magnetostriction close to 1000 ppm,[2] perpendicular magnetic anisotropy[3] and a lower magnetic coercivity than its crystalline counterparts. It was coupled to soft NiFe which will switch its magnetization faster than TbFe. This work reports on the magnetic and structural profiles that were studied at multiple field conditions to characterize the depth profile of the vector magnetization through the Tb_xFe_{1-x}/NiFe layers by using polarized neutron reflectometry (PNR) at several fields. Fig. 1(a) illustrates the saturation PNR fits for the compound system on a silicon substrate with respect to the applied magnetic field in-plane. The resulting nuclear and magnetic scattering profile can be seen in Fig. 1(b). After magnetic reversal, the spin flip scattering, shown in Fig. 1(b) reveals a unique reversal state where the NiFe magnetization is canted away from the in-plane field direction at intermediate fields. A full analysis for several field states to uncover the unique reversal mechanisms and MOKE microscopy will be discussed in this presentation. The reversal mechanisms of exchange coupled Tb_xFe_{1-x}/NiFe provide insight on how to best utilize this compound system in future devices.

GG-03. Unveiling the high temperature properties of ε-Fe_2O_3.
A. Romaguera[1], Z. Ma[1], J. Garcia-Muñoz[1], F. Fauth[2], J. Nogués[3,4] and *M. Gich*[1] *1. ICMAB-CSIC, Bellaterra, Spain; 2. ALBA Synchrotron Light Source, Cerdanyola del Vallès, Spain; 3. Catalan Institute of Nanoscience and Nanotechnology, Bellaterra, Spain; 4. The Barcelona Institute of Science and Technology, Barcelona, Spain*

ε-Fe_2O_3 displays remarkable properties such as huge coercivity (20 kOe at room temperature)[1], magnetoelectric coupling, multiferroicity at room temperature in film form.[2] The difficulties related to its complex preparation make ε-Fe_2O_3 the less studied of all the iron (III) oxide polymorphs. Indeed, obtaining extremely pure sample has been a challenge necessary to achieve a thorough structural study using synchrotron diffraction of the fine structural evolution above ambient temperature and across the transition associated to the disappearance of the hard ferrimagnetic phase. This system presents a complex non-centrosymmetric *Pna2₁* frustrated structure isomorphous to the multiferroic $GaFeO_3$ with four non-equivalent Fe^{3+} sites, three octahedral and one tetrahedral environments, from which a rich physics arise, in part associated to the existence of a substantial spin-orbit coupling.[3] Our studies have been extended to a series of Cr doped ε-Fe_2O_3, in which the *Pna2₁* structure is rather robust against the substitution of Fe by Cr., being so a way of modifying the spin-lattice coupling. Upon heating from room temperature, the saturation magnetization of ε-Fe_2O_3 nanoparticles undergoes a monotonic decrease while the coercivity and remanence sharply drop, virtually vanishing around ~500 K. However, above that temperature the hysteresis loops present a non-linear response with finite coercivity, evidencing signs of ferrimagnetic order up to temperatures as high as 850 K (T_{N1}).[4] Interestingly, this transition from superhard to soft ferrimagnetism involves changes in the magnetic state and magnetostructural effects that are relevant for a better understanding of the origin of spin-lattice coupling in ε-Fe_2O_3. With the aim of refuting previous belief that the magnetic ordering temperature of ε-Fe_2O_3 is well below that of other iron oxides such as hematite, magnetite or maghemite, and to shed light on the structural evolution across the hard-soft transition and the physical origin of the high temperature properties, we present temperature-dependent studies combining magnetic, x-ray and neutron diffraction measurements to understand different anomalies present in the interval 300K-900K.

GG-04. Metamagnetism and kinetic arrest in a long-range ferromagnetically ordered multicaloric double perovskite Y_2CoMnO_6.
R. Pokharel Madhogaria[1], E. Clements[1], V. Kalappattil[1], N. Dang[2], R. Das[1,3], N. Bingham[4], D. Kozlenko[5], M. Phan[1] and H. Srikanth[1] *1. Joint Institute of Nuclear Research, Dubna, Russian Federation*

Among double perovskite oxides ($A_2BB'O_6$), Y_2CoMnO_6 (YCMO) emerges as a multifunctional system for device applications, as it has shown multiferroicity and a multicaloric effect [1]. However, the exact nature of the magnetic ground state and its association with the magnetocaloric, magnetoelectric and electrocaloric effect remains to be investigated [2]. To address this important issue, we have performed a systematic magnetic study of the monoclinic $P2_1/n$ phase of YCMO, synthesized using a *sol-gel* method. Neutron diffraction (ND) measurements evidence the onset of long-range ferromagnetic (FM) ordering at T_C = 76 K, which persists down to 4 K. The absence of any E-type structure peaks in the ND data indicates that YCMO is a centrosymmetric system in nature. The presence of 25% antisite disorder, estimated from the ND data, leads to the appearance of short-range antiferromagnetic interactions, giving rise to an exchange bias effect at temperatures below 10 K. The pinning of magnetic domains at the antiphase boundaries resulted in a metamagnetic-like behavior. The kinetic arrest of the high temperature FM state at low temperature (< 35 K) in YCMO is also evident from magnetization versus magnetic field/temperature measurements. In full agreement with the ND data, a detailed analysis of critical exponents near the paramagnetic-FM phase transition also confirms YCMO as a long-range interacting mean-field system. A careful examination of temperature- and field-dependent magnetic entropy change yields a better understanding of coexisting ordered and disordered phases in the system from high to low temperature. The occurrence of the different magnetic phases in the system causes the exotic effects observed in this class of double perovskites.

National High Magnetic Field Laboratory, Florida State University, Tallahassee, FL, United States*

Multiferroics are fascinating materials in which ferroelectric and magnetic orders coexist and spatial-inversion and time-reversal symmetries are simultaneously broken. Outstanding challenges that currently prevent widespread application in memory and logic devices as well as neuromorphic computing

include requirements for (i) a large coupling coefficient and (ii) room temperature operation. The development of a homologous series of superlattices with formula $(LuFeO_3)_m$:$(LuFe_2O_4)_n$ offers a path forward, although questions still exist about the microscopic origin of the high temperature magnetism and the nature of the charge ordering pattern. In order to resolve these issues and provide additional insight into how external stimuli like high magnetic fields can control behavior, we combined optical spectroscopy, magnetic circular dichroism, and first principles calculations to reveal the response of the $(LuFeO_3)_3$:$(LuFe_2O_4)_1$ superlattice. Importantly, the dichroic response is proportional to magnetization in a chemically-specific, site-selective manner. Analysis of the optical hysteresis loops demonstrates that the unique magnetic behavior of the (3, 1) material emanates primarily from the $Fe^{2+} \rightarrow Fe^{3+}$ charge transfer excitations the $LuFe_2O_4$ layer. In addition to illustrating how control of composition and local strain (which is modulated by Lu ion positions) enables high-temperature properties to emerge, we discuss how the two-component nature of these superlattices (in the form of $LuFeO_3$ and $LuFe_2O_4$ end members) interact at the interface. These techniques open the door to the microscopic analysis of engineered materials with multiple metal centers and strong charge, spin, orbital, and lattice entanglement.

GG-06. Creating Long Range Magnetic Order in a Configurationally Disordered Single Crystal Perovskite. *T.Z. Ward*[1], Y. Sharma[1], E. Skoropata[1] and A.R. Mazza[1] *1. Oak Ridge National Laboratory, Oak Ridge, TN, United States*

The ABO_3 perovskite and its derivatives are broadly important to a range of fundamental and applied magnetic interests. Modification of the A and B sites through substitutional doping allows for a wide variety of distortions and charge states to be tuned. Local distortions arising from cation size variance are balanced by internal changes to Jahn-Teller distortions and octahedral tilts and rotations which are often used to design functionality. In strongly correlated systems, these shifts to local environment are often central to the emergence of important macroscopic functionalities such as complex magnetic textures and phases. We will describe our recent work using entropy stabilization [1] to synthesize single crystal ABO_3 perovskite films possessing 6 or more cations to understand how microscopic disorder might be used to generate unexpected long range and highly tunable ordering responses. We will discuss how the element specific magnetic and charge states of the cations in $La(Cr_{0.2}Mn_{0.2}Fe_{0.2}Co_{0.2}Ni_{0.2})O_3$ films are impacted by the presence of site-to-site disorder. Experimental results from STEM-EELs, XRD, XMCD, neutron diffraction, and SQUID magnetometry demonstrate that the extreme cation disorder present in $La(5B)O_3$ films generates long range magnetic order. Epitaxy driven strain studies on these single crystal films also point to an acute sensitivity to lattice anisotropy. Both strain and cation radii may be used to finely tune metastability and functionality.

GG-07. Role of rare-earth size on the structural, electronic, and magnetic properties of doubly ordered R_2NiMnO_6 perovskites. *M. Nasir*[1], M. Khan[2] and S. Sen[1] *1. Physics, IIT Indore, Indore, India; 2. Physics, Miami University, Oxford, OH, United States*

The R_2NiMnO_6 (R = La, Pr, Nd, Sm, Gd, Tb, Dy, Y, and Ho) double perovskites, prepared by sol-gel assisted combustion route, have been systematically investigated using powder x-ray diffraction, Raman spectroscopy, ultraviolet–visible spectroscopy, magnetization, and synchrotron based x-ray absorption spectroscopy measurements. All compounds in the family crystallize in the monoclinic structure ($P2_1/n$ space group) and the monoclinic distortion enhances with decreasing R^{3+} radii. The magnetic ordering temperature (T_C) decreases from 270 K for La_2NiMnO_6 to 80 K for Ho_2NiMnO_6 as the R^{3+} radii ($r_R{}^{3+}$) decrease from 1.16 Å (La^{3+}) to 1.02 Å (Ho^{3+}). An additional anomaly is observed in Nd_2NiMnO_6, Sm_2NiMnO_6, Tb_2NiMnO_6, and Dy_2NiMnO_6 at lower temperatures, which originates from the 3*d*-4*f* coupling between Mn-Ni and $Nd^{3+}/Sm^{3+}/Tb^{3+}/Dy^{3+}$ magnetic moments. Further, high saturation magnetization is achieved for all samples indicating that they are atomically ordered and have less antisite disorders. Upon decreasing the size of R^{3+}, the local structure shows an expansion of NiO_6 octahedra and almost unchanged MnO_6 octahedra. X-ray-absorption near-edge spectroscopy reveals that majority of Ni and Mn ions are in +2 and +4 valence states in all the samples. Raman spectra of RNMO show a softening of phonon modes resulting in the elongation of Ni/Mn-O bond length. Finally, a correlation between lattice parameters, structural distortion, octahedral tilting, superexchange angle, and electronic band gap, Curie temperature, and the rare-earth ionic radius is established.

GG-08. Magnetic and thermoelectric properties of Bi, Cu double-substituted $La_{1-x}Sr_xCoO_3$ at room temperature. *D.P. Dubey*[1] and R. Chatterjee[1] *1. Physics Department, Indian Institute of Technology- Delhi, New Delhi, India*

Recycling of waste heat and the search for renewable energy sources is a contemporary issue of the interest for the world in general *[1-3]*. Oxides thermoelectric materials (TEs) have an advantage over other well-known alloy based TEs, due to their chemical and thermal robustness, high thermal stability and excellent oxidation resistance *[4]*. Among all oxides, the perovskite transition metal oxides like cobaltite, exhibit rich physical properties for a good thermoelectric figure of merit. In this work, a detailed magnetic and thermoelectric properties are investigated for Bi, Cu co-doped cobaltite sample. The polycrystalline samples of $La_{0.95-x}Bi_xSr_{0.05}Co_{0.5}Cu_{0.5}O_3$,

have been synthesized through Solid State Reaction route. The X-ray diffraction (XRD) data shows a distorted rhombohedral phase (space group) with lattice parameters $a=b=$ 5.46Å, c= 13.160Å and 90^0, 120^0. A monotonic decrease of lattice constants was noted with increasing x for all samples. The scanning electron microscopy (SEM) data on bulk shows optimal grain growth with grain size ~1-3μm. The electron dispersive analysis of X-ray (EDAX) with elemental mapping, confirms the existence of stoichiometric and homogeneous compositions for all prepared samples. The ZFC-FC and (M-H) plots show the spin glass behavior at low (~10K) and paramagnetic nature of the system at room temperature. The specific heat capacity C_p measurement was carried out on PPMS, where an anomaly observed around room temperature. The data of specific heat used to calculate the thermal conductivity from the values of thermal diffusivity by Discovery DXF-900. The electrical conductivity and Seebeck measurement performed by ZEM-3 Advanced Riko Inc. It was found that, with increasing the Bi-substitution for samples, the thermal conductivity (κ) decreases, while the Seebeck voltage (S) increases. The decrease of κ and increase of S, is desirable for good thermoelectric properties. The power factor (PF) and ZT values were extracted from the derived parameters and the results (ZT~ 0.016, PF~ 80μW/mK²) shows the co-doping system of $La_{0.95-x}Bi_xSr_{0.05}Co_{0.5}Cu_{0.5}O_3$ have enough potential for efficient thermoelectric performance.

GG-09. Spin and Dipole Ordering in Flexoelectrical Coupled Strain Gradient Garnet Ferrite Thin Films. *H. Tabata*[1] *1. School of Engineering, The University of Tokyo, Tokyo, Japan*

Rare-earth iron garnets (RIGs) are ferrimagnetic insulators whose chemical formula is $Re_3Fe_5O_{12}$ (R : rare-earth elements). They have been industrially available for optical devices such as optical isolators since they show large magneto-optical effects. On the other hand, they are unlikely to show remnant po-larization character in bulk phase, due to their centrosymmetric crystal structure. If remnant magnetiza-tion and dielectric polarization co-exist in RIGs, multiferroic behaviors and magneto-electric correlation (ME-effect) are expected, which is promising materials design for the future application on spintronics devices. In this research, $Re_3Fe_5O_{12}$ (Re=Sm,Lu,Y; SmIG, LuIG, YIG) films are formed on $Gd_3Ga_5O_{12}$ (GGG) substrates by a pulsed laser deposition. The lattice mismatch between SmIG and GGG is −1.2%, so that the critical thickness where misfit dislocation occurs is estimated to be around 60 nm [1]. TEM observations suggest that SmIG films grown on GGG show three regions of tetragonal, strain-gradient, and cubic structure from the interface to the surface caused by the epitaxial strain and the lattice relaxation as shown in Figure 1. Especially, in the strain-gradient region, the inhomogeneous strain can generate flexoelectric polarization, P(flexoelectricity) = μ(∂u/∂x), where μ and (∂u/∂x) are flexoelectric tensor and strain-gradient, respectively. The inhomogeneous atomic displacement and the presence of dielectric polarization in the strain-gradient region are confirmed by a scanning nonlinear dielectric microscopy (SNDM) [2]. Moreover, as shown in Fig. 2, coercive magnetic fields are dramatically enhanced (from 0.08T to 0.4T) in the strain gradient region. Simultaneous ordering of spin and dielectric polarization is observed in these strain-gradient SmIG films. The strain gradient (flexoelectric) engineering is one of the promising techniques to create novel multi-functional materials.

GG-10. Tuning the Perpendicular Magnetic Anisotropy and the Dzyaloshinskii-Moriya Interaction by Ferroelectric Polarization at BeO/Co Interfaces. *F. Ibrahim*[1], A. Hallal[1] and M. Chshiev[1] *1. Univ. Grenoble Alpes, CEA, CNRS, Grenoble INP, IRIG-SPINTEC, Grenoble, France*

Spin-orbit coupling (SOC) at material interfaces leads to the emergence of a wealth of phenomena such as perpendicular magnetic anisotropy (PMA) and Dzyaloshinskii–Moriya interaction (DMI). Interestingly, PMA and DMI were reported even at interfaces with weak SOC such as Co/graphene [1,2]. However, the efficient control of these phenomena by low-consumption means, e.g. electric fields, is a key gradient towards potential applications in memory and logic devices [3,4,5]. We demonstrate by first-principles calculations the possibility of tuning both PMA and DMI by the ferroelectric polarization (P) in wurtzite w-BeO at the w-BeO/Co interface. The calculated potential shows a typical double well between two polar states (P_+ and P_-) with an estimated P switching barrier of 0.1 eV/atom. The magnetic anisotropy energy MAE per Co layer shows a favorable PMA for ferroelectric (P_- and P_+) and paraelectric states [Fig. 1]. The remarkable PMA value (~ 3 erg/cm²) is highly dependent on the BeO polar state and

changes by 70% upon *P* switching. The total DMI coefficient calculated for polar w-BeO/Co heterostructure, comprising both P_+ and P_- interfaces, is d^{tot} = -0.62 meV whereas it vanishes in paraelectric case. This is due to the breaking of inversion symmetry by *P* while the inversion geometry of the stacking in the paraelectric case is preserved. The layer resolved SOC energy difference ΔE_{soc} associated with DMI between clockwise and anticlockwise spin spirals reveals the asymmetry imposed by *P*; an effect that extends beyond the interface [Fig. 2]. We also note opposite DMI chiralites for P_+ and P_- interfaces which provides the ability of controlling the DMI of Co by switching *P* in the adjacent w-BeO layers.

GG-11. Correlation of Hyperfine Field Distribution and Isomer Shifts with Magnetoelectric Properties in Mo-substituted Z-type Barium Hexaferrites. *M. Przybylski*[1], J. Zukrowski[1], K. Latka[2], Z. Su[3,4], P. Kukil[3], Z. Celinski[5] and V. Harris[3] *1. Academic Centre for Materials and Nanotechnology, AGH University of Science and Technology, Kraków, Poland; 2. Department of Physics, Jagiellonian University, Kraków, Poland; 3. Electrical and Computer Engineering, Northeastern University, Boston, MA, United States; 4. EE, Princeton University, New York, NY, United States; 5. Physics, University of Colorado, Colorado Springs, CO, United States*

Barium hexaferrites are important for technological applications, in particular, in data storage and microwave communications [1]. Among them, Z-type barium hexaferrites can exhibit magnetoelectric properties. The electrical polarization partly stems from transverse conical spin configurations and strongly depends upon an external magnetic field and temperature. Moreover, since the Fe atoms are ferro- or antiferromagnetically coupled to the Fe atoms occupying other sublattices, a preferential substitution of iron in one of them can result in a drastic change of the magnetization. Mössbauer spectroscopy is the optimal tool for such studies since the spectra of barium hexaferrites consist of several well-separated components corresponding to the sublattices occupied by Fe atoms. We prepared series of single phase $Ba_3Co_{2+x}Mo_xFe2_{4-2x}O_{41}$ samples. We measured magnetic properties using VSM, and the Mössbauer spectra (MS) of these samples as functions of their composition, temperature (4.2 – 700 K), and external magnetic field. Such measurements, in combination with analysis of MS reveal presents of collinear ferrimagnetic between 500 K and Curie temperatures. For temperatures smaller than 500 K the transverse conical spin structure is present in measured samples. Despite the fact that there are ten inequivalent crystallographic sites of Fe, the spectra were almost perfectly fitted with three components which correspond to the groups of the crystallographic sites showing similar hyperfine parameters [2]. Two of these are spin-up and the other one spin-down sites. However, only by applying magnetic field the components of different spin can be separated and therefore their relative contributions to the total spectrum can be deducted. Figure 1 shows examples of Mössbauer spectra for x=2 measured at 4.2 K with and without external magnetic field. We conclude that the competition between the uniaxial and planar magnetic anisotropies may produce either an easy magnetization axis, cone, or plane. This eventually depends on the types and amounts of the substitutional cations in the unit cell.

GH-01. Synthesis and Electromagnetic Properties of Fe-based Nanocrystalline Powders with High M_s. *Y. Li*[1], C. Zhang[1] and W. Zhang[1]
1. Dalian University of Technology, Dalian, China

With the rise of the new generation of wireless communication technology, plenty of electronic devices have been applied in GHz frequency range, and the ensuing electromagnetic (EM) interference and EM pollution are also increasing seriously. Therefore, it is of great significance to explore and develop new EM wave absorbing/shielding materials for the GHz frequency range. Ferrites have been widely used as EM wave absorbers in the frequency below 1 GHz but not suitable for higher frequency applications due to the Snoek's limit. Compared with ferrites and other traditional magnetic materials, Fe-based soft magnetic nanocrystalline alloys with a composite structure of bcc-Fe nano grains homogeneously dispersing in amorphous matrix exhibit superior soft magnetic properties, especially high saturation magnetization (M_s) and permeability at higher frequency. Combined with their high resistivity, the Fe-based nanocrystalline alloys might be good candidates for EM wave absorption materials. Considering that non-magnetic elements would lower the M_s, nanocrystalline alloys containing higher Fe contents may exhibit superior absorption performance. Accordingly, a FeSiBCu alloy with Fe content of over 80 at.% has been designed for developing new nanocrystalline EM wave absorbers in this work. We investigated the evolutions of structure and morphology of the alloy powders by ball-milling for different milling time, and studied the effects of structure and morphology on the magnetic and EM properties as well as EM wave absorption performance. The as-milled powders can form a bcc-Fe/amorphous composite structure with the bcc-Fe grain size of around 10 nm, and exhibit large M_s, high permeability, and matchable permittivity in the GHz range. The absorption samples with a thickness of around 2 mm exhibit large reflection loss (RL) of -39.1−-50.5 dB with effective absorption bandwidth (RL < -10 dB) of 4.5−5.0 GHz covering the X-band (8−12 GHz).

GH-02. FeBNbP Nanocrystalline Alloy Powder with High Amorphous Forming Ability and High B_s for Magnetic Core. *A. Hasegawa*[1], H. Kumaoka[1], K. Yoshiki[1], M. Hosono[1], K. Yoshidome[1], S. Mori[1], K. Horino[1] and H. Matsumoto[1] *1. Material Development Center, TDK Corporation, Narita, Japan*

The effect of additional P with Fe-B-Nb type nanocrystalline alloy already researched to improve amorphous forming ability using a thin film method [1]. The influence of P content on amorphous forming ability and the magnetic properties were investigated in the Fe-B-Nb-P nanocrystalline alloys using a metallic ribbon. The $Fe_{84-x}B_9Nb_7P_x$(x=0-3) nanocrystalline alloy metallic ribbons prepared by a single-roller melt-spinning method. The $Fe_{84-x}B_9Nb_7P_x$(x=0-3) nanocrystalline alloys annealed at 873-923 K consist of stable α-Fe grain formed in a residual amorphous phase, and the average α-Fe grain diameter showed nanocrystal of 6.3 to 7.7 nm. Critical thickness of ribbon indicating amorphous forming ability was increased from 20 μm (x=0) to maximum 68.7 μm with $Fe_{81}B_9Nb_7P_3$ by increasing P content. Especially, $Fe_{81}B_9Nb_7P_3$ alloy also exhibited high saturation magnetic flux density (B_s) of 1.51 T. In addition, $Fe_{81}B_9Nb_7P_3$ alloy indicated a good magnetic softness of low coercivity (H_c) of 4.8 A/m and high permeability of approximately 33000 at 1kHz-20A/m. From the above results, the possibility of producing a powder up to 60 μm was explained in Fe-B-Nb-P alloys. Although FeBNb type alloys has not been realized as powders due to difficulty of obtaining high amorphous formation ability for producing powder, $Fe_{80}B_{10}Nb_7P_3$ alloy increasing B content succeeded to obtain the powder with precursor of a single amorphous phase by rapid quenching gas atomization method. $Fe_{80}B_{10}Nb_7P_3$ annealed alloy powder at 873 K exhibited nanocrystalline structure withα-Fe grain of average diameter 8.1 nm and high B_s of 1.46 T. Therefore, the $Fe_{80}B_{10}Nb_7P_3$ nanocrystalline alloy powder can acquire a large advantage due to miniaturization of magnetic core for power device by 20 % higher B_s compared with commercialized composition of $Fe_{73.5}Si_{13.5}B_9Nb_3Cu_1$ (B_s=1.24 T) [2].

GH-03. Magnetic and structural properties of $(Fe,Ni)_{86}B_{14}$ nanocrystalline soft magnetic alloys prepared by ultra-rapid annealing.
Z. Li[2], R. Parsons[2], B. Zang[2], J. Karel[2], H. Kishimoto[1], T. Shoji[1], A. Kato[1] and K. Suzuki[2] *1. Toyota Motor Corporation, Susono, Japan; 2. Material Science and Engineering, Monash University - Engineering Faculty, Melbourne, VIC, Australia*

Nanocrystalline soft magnetic materials consist of nano-sized grains embedded within an amorphous matrix. The nanocrystalline structure in early reports [1] was achieved through the use of non-magnetic additives such as Cu and Nb. However, the recently developed rapid annealing technique has allowed for the production of nano-scale grains even in an Fe-B binary system without addition of these non-magnetic elements. With a low concentration of non-magnetic elements, a higher saturation magnetization (J_s) up to 1.92 T has been obtained for the ultra-rapidly annealed (URA) $Fe_{87}B_{13}$ [2]. Although, an addition of 2 at.% Ni to this binary alloy resulted in a reduction of the coercivity from 6.4 to 3.8 A/m [2], the effect of larger amount of Ni in the URA Fe-B alloys remains unknown. In this study, the magnetic and structural properties of nanocrystalline $(Fe_{1-x}Ni_x)_{86}B_{14}$ (x = 0, 0.1, 0.2 and 0.3) were investigated. A low coercivity of 2.6 A/m was obtained for $(Fe_{0.9}Ni_{0.1})_{86}B_{14}$, while maintaining a high J_s of 1.7 T. This low coercivity is suggested to be the result of a reduction in the magnetocrystalline anisotropy brought about by the addition of Ni. Furthermore, apart from bcc nanocrystallites as normally observed in most Fe-rich nanocrystalline systems, the formation of fcc phase was also found with extremely small grain size of < 5 nm for x > 0.2.

GH-04. Iron loss characteristics of a high-temperature amorphous ring under PWM inverter excitation.
A. Yao[1] and T. Hatakeyama[1] *1. Department of Electrical and Computer Engineering, Toyama Prefectural University, Imizu, Japan*

Several researchers have recently focused on high-temperature (HT) and high speed (HS) motor drive systems in HT environments[1~5]. In these HT and HS motor systems, pulse width modulation (PWM) inverters are generally used to control the rotational speed[4~8]. The iron loss of magnetic cores under PWM inverter excitation increases compared to case of sinusoidal input[4~8]. To realize low loss HT and HS motor systems, it is important to understand iron loss characteristics of amorphous magnetic materials (AMM) at HT fed by PWM inverter. However, there has been no report on AMM properties at HT under PWM inverter excitation. In this study, the iron losses of AMM as a function of carrier frequency under inverter excitation are experimentally and numerically examined at RT and HT (300°C). Fig. 1 shows a schematic of the ring test at RT and HT under PWM inverter excitation. The ring specimen is made of AMM and is exposed to HT variations in the oven. Here, the iron loss W is calculated by $W = \int H dB/T\rho$, where T is the period, ρ is the density, H is the magnetic field intensity, and B is the magnetic flux density. The fundamental frequency and the maximum magnetic flux density of the ring are set to 50 Hz and 0.8 T, respectively. See Refs. 4,5) for details of the measurements and numerical methods. Figs. 2 (a) and (b) show experimental and numerical B-H curves at RT and HT under PWM inverter excitation. The area of the minor loop at RT is larger than that at 300°C. Here, it is found that the temperature dependency of iron loss properties depends not only on major loop but also on minor loops. Fig. 2(c) and (d) show the iron and eddy current losses with respect to carrier frequency under inverter excitation at RT and 300°C. The iron loss under PWM inverter excitations decreases with an increase in temperature. In addition, we for the first time found that the ratio of the eddy current losses under PWM inverter excitation depended strongly on the temperature. These results open the way to further research in HT and HS motor system based on studies of magnetic properties.

GH-05. Influence of Circular Magnetic Field and Combined Mechanical Stress on Spiral Domain Structures in Magnetic Microwires. *A. Chizhik*[1], J. Gonzalez[1], A. Zhukov[1,2], P. Corte-Leon[1], V. Zhukova[1], P. Gawronski[4] and A. Stupakiewicz[3] *1. Departamento de Fisica de Materiales, Universidad del Pais Vasco, UPV/EHU, San Sebastian, Spain; 2. Ikerbasque, Basque Foundation for Science, San Sebastian, Spain; 3. University of Bialystok, Bialystok, Poland; 4. AGH University of Science and Technology, Krakow, Poland*

The experimental observation of the spiral domain structure has opened a new possibility of the fine control of the domain structure with different magnetization states in magnetic microwires which are the base elements of the magnetic sensors [1]. Here we demonstrate that the tuning of magnetic domain structures in Fe-rich amorphous microwires can be engineered by the circular magnetic field and the combination of tension and torsion mechanical stresses. The application of the circular field rotates the domain structure towards the axial direction (Fig.1). The axial direction could not be reached in the present experiments because of the limit of the circular field. It is determined in turn by the limit value of the electric current producing the circular field, related to the heating limit. Here we also present the results of the micromagnetic simulations of the influence of the circular magnetic field created by the electric current passing through the microwire on the modification of a spiral domain structure during the magnetization reversal process (Fig.2). In the presence of the tension stress only rotation of the magnetization takes place. Torsion stress stabilized the helical structure – helical bistability becomes more pronounced with the torsion increase. The addition of tension to the torsion does not cause the extinction of the helical bistability. The effect of the stress combination increases the switching field and decreases the value of the remanent magnetization. The main reason of the observed transformation is the induced change of the helical outer shell. Competing action of torsion and tension permits found the structure with predictable angle of magnetic helicity which is important for GMI effect and establishes the switching in wide range of the magnetic field which is important for bistability based sensors.

GH-06. Prediction of Good Glass Forming Ability in Amorphous Soft Magnetic Alloys by Thermocalc Simulation and Experimental Validation. *Y. Krimer*[1], N. Aronhime[2], P. Ohodnicki[3] and M. McHenry[1] *1. Materials Science, Carnegie Mellon University, Pittsburgh, PA, United States; 2. Research and Development, Carpenter Technologies, Reading, PA, United States; 3. National Energy Technology Laboratory, Pittsburgh, PA, United States*

Advances in Metal Amorphous Nanocomposite (MANC) alloys where the amorphous phase has excellent glass forming ability (GFA) may impact formability in hot stamping motor laminates. [1-2]. Thermocalc software was used to simulate liquidus temperatures and solidification ranges of $(Fe_{70}Ni_{30})_{80}$(B-Si-Nb)$_{20}$ alloys, with varying proportions of glass forming elements, to identify regions with good GFA. A region with excellent GFA was identified at 14-18% B and 0-7% Si with the balance Nb, showing minima in both liquidus and solidification range. GFA was ranked using differential scanning calorimetry (DSC), using the GFA parameters T_{rg}, ΔT_{xg}, and γ_m. DSC data showed liquidus results to be in good agreement with simulation, and that GFA correlates well with predictions. DSC was used to determine Curie temperatures, T_c's, of the alloys, and these results were confirmed by PPMS magnetometry measurements. It was found that T_c decreases with increasing Nb content and increases with increasing B. Si content has little effect on Curie temperature. T_c's are plotted vs. B/Nb, where B and Nb are the atomic fractions of these glass forming elements. T_c's increase with increasing B/Nb, from 294 to 422 °C at B/Nb=10, and then saturate. The role of B in increasing T_c in Fe-based amorphous alloys is known [3]. Nb virtual bound states (VBS) decrease induction and T_c and increase resistivity [2]

Thin magnetically soft wires exhibiting Giant magnetoimpedance (GMI) effect and fast domain wall (DW) dynamics attracted growing attention owing to promising industrial applications [1,2]. It was demonstrated that properly prepared and processed glass-coated microwires prepared using Taylor-Ulitovsky technique can exhibit excellent magnetic softness, GMI effect and fast DW dynamics [1]. DW propagation observed in thin (mostly planar) magnetic wires has been proposed for applications in data storage devices (magnetic random memory devices, logic devices)[3]. Most of studies have been reported for Fe-Ni-rich permalloy-like nanowires [3]. Generally cast glass-coated microwires present one order higher DW velocities, however most of results have been obtained in Fe-Co- based materials. Fe-Ni-rich permalloy-like microwires have been studied in only a few papers [1,4]. Consequently, we present our last experimental results on effect of annealing on magnetic properties and DW dynamics of Fe-Ni based glass-coated microwires. We studied the effect of annealing on hysteresis loops and DW dynamics of $Fe_{62}Ni_{15.5}Si_{7.5}B_{15}$ and $Fe_{49.6}Ni_{27.9}Si_{7.5}B_{15}$ microwires with metallic nucleus diameters of about 14 μm. We found that as-prepared and annealed (at 410 °C) microwires present perfectly rectangular hysteresis loops. Generally as-prepared samples present soft properties with switching field of about 100 A/m (see Fig). After annealing we observed increase of the switching field up to about 200 A/m. In both samples we observed linear dependence of domain wall velocity, v, on applied magnetic field, H, and maximum v-values up to 1000 m/s. Upon annealing we achieved quite fast domain wall propagation in $Fe_{62}Ni_{15.5}Si_{7.5}B_{15}$ sample where maximum v-values up to 2500 m/s have been observed. In $Fe_{49.6}Ni_{27.9}Si_{7.5}B_{15}$ microwire we observed moderate increase of v-values up to 1200 m/s. We attributed these changes to the stress relaxation after annealing. Consequently, appropriate annealing is the effective method for engineering of the DW dynamics in Fe-Ni-based glass-coated microwires.

GH-08. Effect of latent heat during primary crystallization on nanostructural formation process in nanocrystalline soft magnetic materials. R. Parsons[1], H. Kishimoto[2], T. Shoji[2], A. Kato[2] and *K. Suzuki*[1] *1. Monash University, Clayton, VIC, Australia; 2. Toyota Motor Corp., Mishuku, Japan*

Nanocrystalline soft magnetic materials are known to be prepared by primary crystallization of Fe-based amorphous precursors. Since the crystallization reaction is exothermic, the amorphous precursor may experience a temporary rise in its temperature relative to its surroundings during the process of nanocrystallization. Given the typical latent heat of crystallization (~ 10 kJ/mol), this temperature rise may exceed hundreds of degrees if not adequately controlled and thus, lead to the formation of unwanted magnetically hard compounds. Recently, an ultra-rapid annealing (URA) process realized by a pair of preheated Cu blocks (heating rate of ~10^4 K/s, annealing time of 0.5 s) has been shown to be effective for grain refinement [1] and in the production of nanocrystalline soft magnetic materials with a saturation magnetisation greater than 2 T [2]. However, despite the use of very high heating rates, the resultant microstructures are free of magnetically hard compounds. In this study, the effect of latent heat during crystallization on nanostructural formation process is investigated at a range of heating rates by in-situ observation of temperature with a fine 20-mm thick thermocouple and also by finite element analysis. Figure 1 shows the change in sample temperature of an amorphous $Fe_{86}B_{14}$ precursor which was rapidly annealed by a pair of preheated Cu blocks both with and without a single layer of polyimide tape. Indications of an overheating effect are only observed in the sample annealed with the insulating polyimide tape layer. It is found that the high thermal conductivity of the junction between the sample and the Cu block allows for the heat produced during crystallisation to be effectively removed. This limits any significant overheating effect during crystallisation and allows for the use of high heating rates without the formation of magnetically hard phases. As a result, a small coercivity < 8 A/m is realized for URA $Fe_{86}B_{14}$. Contrarily, a significant overheating effect (> 100 K) was seen when a conventional infrared lamp furnace is used even at a moderate heating rate of ~ 10 K/s. Annealing by preheated Cu blocks is ideal for preventing the detrimental effect of latent heat.

GH-09. Role of heavy metal interface in controlling the structural and magnetic properties of amorphous FeCoB film. *J. Dwivedi*[1], M. Gupta[2], V. Reddy[2], D. Mishra[1], P. Pandit[3] and A. Gupta[4] *1. School of Physics, Devi Ahilya University, Indore, India; 2. UGC DAE Consortium for Scientific Research, Indore, India; 3. Deutsches Elektronen-Synchrotron (DESY), Hamburg, Germany; 4. Amity Center for Spintronic Materials, Amity University, Noida, India*

Thin films of FeCoB are the best candidates for magnetic electrodes in MgO based magnetic tunnel junctions. Buffer layer of heavy metals like Mo, has been used to tailor magnetic anisotropy in this system. Post deposition annealing results in crystallization of amorphous FeCoB film into bcc-FeCo phase and plays an important role in enhancing tunnel magnetoresistance. Film having structure; substrate/Mo(30nm)/ FeCoB(70nm)/Mo(2nm) was deposited using dc-magnetron sputtering (dc-MS). The hysteresis loops were taken by magneto-optical Kerr microscope, in UGC-DAE CSR, Indore. The transition from amorphous to crystalline phase of FeCoB was confirmed by wide angle x-ray scattering (WAXS) at P03 Beamline, PETRA III, DESY, Hamburg, Germany. Anomalous behaviour of magnetic anisotropy in FeCoB film (70nm) sandwiched between Mo layers using has been studied as a function of thermal annealing at different temperatures. In general assumption, the anisotropy should vanish after crystallization of FeCoB. In contrast, MOKE measurement reveals that magnetic anisotropy remained in the film after appearance of bcc-FeCo phase. We find an anomalous magnetization reversal behaviour that occurs for partially disordered, but still anisotropic samples in the vicinity of the HA, at 350°C and 400°C annealed sample. The anomaly of the occurrence of non-uniform magnetization near hard axis can be explained by two-grain Stoner-Wohlfarth model [1].

GH-10. Magnetic domains in Pt/Co(Fe)B/Ir multilayers grown on ferroelectric substrates. *K.N. Alshammari*[1], L. Benito[1], R.C. Temple[1], M. Alyami[1], M. Ali[1], T.R. Forrest[2], F. Maccherozzi[2], S.S. Dhesi[2], S. Cavill[3] and T. Moore[1] *1. University of Leeds, Leeds, United Kingdom; 2. Diamond Light Source, Harwell, United Kingdom; 3. University of York, York, United Kingdom*

At the interface of a 5d metal and a thin film 3d ferromagnet such as Pt/Co, the interfacial Dzyaloshinskii-Moriya interaction (DMI) leads to domain walls with a defined chirality and skyrmion bubbles in the ferromagnet that are promising for low power magnetic memory devices [1]. Furthermore, the strain control of thin film magnetism promises power-reduction in nanomagnetic devices [2]. Recently we have measured the effect of out-of-plane strain on DMI and domain walls in Pt/Co thin films [3,4]. In this work we study the effect of strain on magnetic properties by depositing Pt/Co(Fe)B/Ir thin films directly onto ferroelectric substrates. In the first study, Ta(5)/[Pt(2.3)/$Co_{68}B_{32}$(0.8)/Ir(0.5)]$_n$/Pt(2.3) multilayers (nominal thicknesses in nm) were deposited by dc magnetron sputtering onto a $BaTiO_3$ (BTO) substrate. X-ray magnetic circular dichroism - photoemission electron microscopy (XMCD-PEEM) was used to obtain high resolution magnetic images in the remanent state. Strain was generated by varying the temperature from -150 to 35 C° to change the BTO crystal structure. It was found that the domain period increases as the temperature increases as shown in Fig.1.(a). In the second study, Ta(5)/[Pt(2.3)/$Co_{68}Fe_{22}B_{10}$(0.7)/Ir(0.5)]$_n$/Pt(2.3) multilayers (nominal thicknesses in nm) were deposited by dc magnetron sputtering onto polished PMN-PT(011) substrates. Local changes of the position and shape of the domains were evident in XMCD-PEEM images as the voltage was varied from 0-250-0V, as shown in Fig.1.(b). This can be attributed to the movement of ferroelectric grain boundaries and the strain. As the voltage is varied from 0-180 V, a U-shaped domain in the middle of the image has moved by ~1um^2 and slightly elongated. While there are other localised changes in the domain pattern, when averaging over a larger number of domains, the characteristic domain size does not change (520±3 nm) as a function of the strain.

GH-11. Tuning of magnetic and structural properties of Fe-rich ferromagnetic microwires. *I. Baraban*[1], V. Kolesnikova[1], A. Bazlov[2], N. Andreev[2], S. Evstigneeva[2], A. Morchenko[2], L. Panina[2,1] and V. Rodionova[1,2] *1. Laboratory of Novel Magnetic Materials, Immanuel Kant Baltic Federal University, Kaliningrad, Russian Federation; 2. National University of Science and Technology (MISIS), Moscow, Russian Federation*

Amorphous ferromagnetic microwires with Fe-rich nucleus present outstanding magnetic properties, such as magnetic bistability [1] and high velocity of the domain wall propagation [2]. Magnetization reversal process occurs through the fast propagation of the domain wall. Therefore, these properties can be used for the creation of modern high-speed mass storage devices with a high recording density and logic elements [3]. In this work, we have demonstrated that the change in critical parameters of microwire fabrication, namely, the drawing velocity, offers the opportunity to optimize the structural and magnetic properties of FeCo-based glass-coated microwires. During the fabrication process of microwires by the Ulitovsky Taylor method, one can control magnetic properties by varying the geometric parameters of the microwires: d, a diameter of the nucleus, and the diameter ratio of the microwire, d/D. In its turn, d is associated with solidification stress, d/D – with stress arising due to the difference of thermal expansion coefficient for metal and glass during the manufacturing process. The decreasing of these stresses will dramatically change the magnetic properties of microwires. Changing the manufacturing conditions as a slower drawing velocity and air cooling make it possible to produce microwires in a complex state (amorphous/nanocrystalline). For different compositions and manufacturing conditions, the structural features were studied by Mossbauer and XRD spectroscopy and HRTEM imaging. In Fe-based microwires, the

amorphous state prevails but for very low velocities crystalline microregions were observed. In FeCo- microwires the centers of crystallization appeared in an amorphous matrix and the size of crystalline grains increases with reducing the drawing velocity. The possibilities of phase transformations were studied by DSC technique. Two stages of the crystallization processes were detected and the activation energy of crystallization was calculated. Identifying the inflection point on the DSC curve, the Curie temperature was also deduced.

GH-12. Improvement of Soft Magnetic Properties in $Fe_{81}Sn_7B_{12}$ Nanocrystalline Alloys Upon Rapid Annealing. *I. Skorvanek*[1], B. Kunca[1], I. Janotova[2], J. Skoviera[2], J. Marcin[1] and P. Svec[2] *1. Institute of Experimental Physics SAS, Kosice, Slovakia; 2. Institute of Physics SAS, Bratislava, Slovakia*

The continuing interest in Fe-based nanocrystalline alloys is motivated mainly due to their high saturation magnetic flux density combined with relatively low coercivity. An improvement of magnetic performance in these alloys is possible by using a compositional tuning as well as by employing special processing techniques resulting in optimal phase content and reduced grain sizes. Ternary Fe-M-B type alloys (M = Zr, Nb, Hf, …) belong to the most frequently investigated compositions of this material family [1]. On the other hand, only few reports are available in scientific literature on rapidly quenched Fe–Sn–B ribbons [2,3]. In this work, formation of amorphous and nanocrystalline phases has been investigated in $Fe_{81}Sn_7B_{12}$ alloy system. Short ribbon-shaped samples were prepared by planar flow casting and subsequently annealed in the regions of phase transformation determined by differential scanning calorimetry. Structure analysis has been performed on as-quenched and annealed samples using X-ray diffraction and transmission electron microscopy. The results show a dependence of lattice parameter of primary bcc-Fe phase with proceeding nanocrystallization and indicate supersaturation of this phase with Sn. The size evolution of nanocrystalline grains is correlated with observed magnetic behavior. We show that a significant improvement of the soft magnetic properties can be achieved by employing of rapid annealing technique that utilizes a pair of pre-heated Cu blocks [4]. A high heating rate and much lower processing time (10 seconds at 480°C) as compared to conventional annealing (30 minutes at 400°C) results in formation of markedly smaller nanocrystalline grains. An observed grain refinement induced by rapid annealing is accompanied by a strong reduction of the coercivity to 7.3 A/m, which is superior value for Fe–Sn–B alloys. This work was supported by the projects APVV-15-0621, VEGA 2/0171/19 and JRP SAS-TUBITAK MAGSAT.

GH-14. Nanoclusters formation and their influence on the superferromagnetic behavior of glassy Fe-Cr-Nb-B magnetic particles. H. Chiriac[1], M. Lostun[1], M. Grigoras[1], G. Ababei[1], G. Stoian[1], T.A. Ovari[1] and *N. Lupu*[1] *1. Magnetic Materials and Devices, National Institute of Research and Development for Technical Physics, Iasi, Romania*

Magnetite particles (MPs), magnetic-vortex NiFe microdiscs, ultrathin perpendicularly magnetized MPs, synthetic antiferromagnetic and ferrimagnetic microdiscs with no magnetic remanence, nanowires with various compositions obtained by electrodeposition in aluminum membranes were studied at large for use in different cancer treatment applications. In this work we present our recent results on the microstructure, nanoclusters formation and specific magnetic behavior of $Fe_{79.7-x}Cr_xNb_{0.3}B_{20}$ (x = 11.5÷13 at.%) magnetic particles (MPs) obtained by high-energy ball milling the superferromagnetic rapidly solidified melt-spun ribbons precursors. By controlling the process, we can downsize the particles to 10-200 nm. The MPs have non-zero coercivity at room temperature, exhibit large magnetization, large magnetic susceptibility and low Curie temperature of about 47°C. High resolution imaging and electron diffraction confirm that in the as-milled state the structure is completely amorphous, independent of the Cr content. Clear indications have been found of Fe and Cr clusters varying from approximately 1-2 nm to 7-8 nm in size with the increase of Cr content from 11.5 to 13 at.%. The Fe and Cr atoms clearly segregate the atomic scale to form nanometer sized clusters, influencing strongly the macroscopic magnetic behavior. The magnetization curves were analyzed with a model based on superferromagnetism. The Curie transition temperature of the system, T_C^{system}, confirmed by the plot of inverse susceptibility versus temperature, gives the strength of the magnetic interactions between clusters. The inter-cluster interactions are much stronger for lower contents of Cr, the microstructure is less uniform and T_C^{system} increases from 290 K for 13% at. Cr to 330 K for 11.5 at.% Cr. The whole system transforms to a ferromagnetic state through interactions between the clusters. Zero-field cooling and field cooling curves confirm the cluster behavior. GH-15. Stress- induced Magnetic Anisotropy Enabling Engineering of Magnetic Softness and GMI effect of Fe-rich Amorphous Microwires.
P. Corte-Leon[1,2], V. Zhukova[1,2], M. Ipatov[1,2], J. Blanco[2], J. Gonzalez[1] and *A. Zhukov*[1,3] *1. Dept. Phys. Mater., Univ. Basque Country, UPV/EHU, San Sebastian, Spain; 2. Dpto. Física Aplicada, EIG, Univ. Basque Country, UPV/EHU, San Sebastian, Spain; 3. Basque Foundation for Science, Ikerbasque, Bilbao, Spain*

Giant magnetoimpedance (GMI) effect exhibited by soft magnetic materials allows achievement of extremely high sensitivity (up to 10 %/A/m) to applied magnetic field, *H,* reported for magnetic wires [1]. Therefore, GMI effect is considered as one of the most promising phenomena for creation of magnetic sensors and magnetometers. The value of GMI effect and the magnetic field dependence are determined by the type of magnetic anisotropy: for achievement of high GMI ratio the high circumferential magnetic permeability is essentially important [1]. Studies on GMI effect have been focused mainly to develop extremely soft magnetic materials opening a new branch of research in soft magnets. Obviously, the different geometry leads to some differences in the GMI response like the frequency range or the magnetic field dependence of the impedance with single or double-peaks behavior etc. Modifications of the circular magnetic permeability can be reached by stress annealing of amorphous microwires allowing development of the magnetic anisotropy with the magnetization easy axis circumferentially oriented to the longitudinal direction of the microwire [2]. In this work we report a study on the GMI response in a stress-annealed Fe-rich glass-coated microwire (metallic diameter of about 15 μm). Stress-annealing of $Fe_{75}B_9Si_{12}C_4$ glass-coated microwire (300 ^oC, 1 hour) allows induction of macroscopic transverse magnetic anisotropy with the anisotropy field of around 750 A/m. The magnetization curve of the stress-annealed sample shows almost unhysteretic behavior. This anisotropy very significantly improves the GMI effect with respect to the observed in the as-prepared microwire. A resolved double-peaks behavior (symmetrical with respect to *H*) emerges as increasing the frequency. The values of anisotropy field obtained from frequency dependence of GMI effect are very different to those obtained from the hysteresis loops The analysis of the GMI response as a function of the frequency (10 – 1000 MHz) opens new lights to understand the distribution of the magnetic anisotropy inside the glass-coated microwire.

GI-01. Magneto-structural characterization and micromagnetic modeling of Co nanowire arrays for microwave applications up to 30 GHz. *M. Pasquale*[1], D. Gonzales Trabada[2], E.S. Olivetti[1], C.P. Sasso[1], M. Coisson[1], A. Magni[1], F. Garcia-Sanchez[1,3] and M. Vázquez[2] *1. INRIM, Torino, Italy; 2. Instituto de Ciencia de Materiales, CSIC, Madrid, Spain; 3. Applied Physics, Universidad de Salamanca, Salamanca, Spain*

In order to develop novel microwave circuits operating above 10 GHz [1], metallic magnetic systems possessing a combination of high permeability, high saturation magnetization, and high electrical resistivity are desirable. At these frequencies, eddy currents reduce the effective permeability and the simplest method to limit their presence goes through the reduction of the sample cross-section. Unfortunately, a generalized approach to producing tunable high-frequency magnetic materials of sub-micron size with a high density, and a high magnetic anisotropy has yet to be found [2,3]. To this end, ten Co nanowire array samples were grown by electrochemical route in solutions with a pH ranging from 2 to 6.5 using anodic alumina membranes with ~50 nm nanowire diameter and ~100 nm interwire distance (hexagonal lattice) and with a wire length ranging from 1 to 15 um [4]. The samples were analyzed by X-ray diffraction, Scanning Electron Microscopy, vector Vibrating Sample Magnetometry and field swept Ferromagnetic Resonance absorption. The analysis of the frequency vs. applied magnetic field behavior of the arrays was performed using a microwave source with an amplitude-modulated signal (100 kHz-40 GHz), a microwave detector (0.01-50 GHz) and a lock-in amplifier. Each sample was set on a wideband coplanar waveguide positioned in the gap of an electromagnet, and the DC bias field was swept from -1 T to + 1 T along the wire axis, while measuring the microwave absorption at each frequency value in the 1 GHz-40 GHz range. Using the magneto-structural data obtained by XRD and vector VSM as input parameters of the Mumax3 micromagnetic simulation program [5] we were able to successfully reproduce both the static magnetic behavior parallel/perpendicular to the wire axis and the respective microwave absorption spectra. This work shows that by a proper selection of the preparation conditions of Co nanowire arrays (e.g.,pH electroplating), the direction of the anisotropy can be engineered from perpendicular to given angles to the wire axis so that the tuning of the ferromagnetic resonance absorption frequency at zero applied field can be achieved in the 1-30 GHz range, allowing for the development of novel microwave applications.

GI-02. Superparamagnetic, Partially-Inverted Ni-ferrite and NiZn-ferrite Thin Film: Promising Material for On-chip RF Inductor Core. *R. Sai*[1], R. Kahmei[1], S. Arackal[1], N. Bhat[1], M. Yamaguchi[2] and S.A. Shivashankar[1] *1. Centre for Nano Science and Engineering, Indian Institute of Science, Bengaluru, India; 2. Dept. of Electrical Engineering, Tohoku University, Sendai, Japan*

The advent of 5G cellular communication escalates the demand for on-chip RF inductor with self-resonating frequency >10 GHz [1]. Continued miniaturization of such passive devices necessitates a magnetic-film core having ferromagnetic resonance (FMR) frequency > 10 GHz. Very few on-chip magnetic-core inductors in and around C-band (6-8 GHz) have been realized and published, excepting those with the core made of thin (t≈500 nm) zinc ferrite (ZF) and manganese-zinc ferrite (MZF) films with FMR at ~26 GHz and ~12 GHz respectively [2, 3]. However, owing to their low μ_r', inductance enhancement only up to 13% could be achieved. Thus, a superior magnetic material and a thicker (>1 μm) film is needed. In this paper, we explore nanocrystalline and superparamagnetic nickel ferrite (NF) and nickel-zinc ferrite (NZF) thick films, expecting superior high-frequency performance to ZF and MZF. Nanocrystalline NF and NZF films with various thicknesses (0.2~1.2 μm) were deposited on Si (100) and Si-CMOS foundry-fabricated inductors by a solution-based, low-temperature (<200 °C), microwave-assisted solvothermal (MAS) process [2]. The deposition rate was high – about 30 nm/min for both compositions. The structure and composition of the films were characterized by XRD, SEM, AFM, XPS, and Raman spectroscopy. The magnetic hysteresis loop was traced by SQUID magnetometry, whereas the frequency dispersion of complex permeability up to 22 GHz was measured by the all-shielded and shorted microstrip line-based technique [4]. Partial inversion in the crystal structure of both NF and NZF was evidenced by Raman spectroscopy (Fig. 1), unlike in bulk NF and NZF. The NF film surface is smooth and uniform (Fig. 1 inset). Both films are in-plane isotropic, with NF showing lower coercivity (25 Oe) than NZF (35 Oe). The μ_r' at C-band is larger in NF than in NZF (Fig. 2) and is 1.4 times more than our reported [3] value in MZF. The FMR frequency in both NF and NZF nanocrystalline thin films is beyond the upper limit of the measurement (22 GHz) - the highest ever reported.

GI-03. Giant Magnetoimpedance effect at GHz frequencies in amorphous microwires. V. Zhukova[1,2], M. Ipatov[1,2], P. Corte-Leon[1,2], J. Blanco[2] and *A. Zhukov*[1,3] *1. Dept. Phys. Mater., Univ. Basque Country, UPV/EHU, San Sebastian, Spain; 2. Dpto. Física Aplicada, EIG, Univ. Basque Country, UPV/EHU, San Sebastian, Spain; 3. Basque Foundation for Science, Ikerbasque, Bilbao, Spain*

Studies of Giant Magnetoimpedance (GMI) effect have attracted considerable attention considering various technological applications [1,2]. One of the main tasks in this field is the achievement of the highest GMI effect that will allow improvement of the sensitivity of the magnetic sensors and devices utilizing GMI effect. Additionally, small size and high magnetic field resolution are the features of magnetic field sensors made from magnetically soft microwires [1]. Furthermore, high frequency GMI effect is suitable for development of smart composites with tunable magnetic permittivity [2,3] It must be underlined that the diameter reduction must be associated with the increasing of the optimal GMI frequency range: a tradeoff between dimension and frequency is required in order to obtain a maximum effect [2, 4]. Additionally the GMI effect at microwave frequencies has been described considering analogy between the GMI and the ferromagnetic resonance [4]. Consequently development of thin soft magnetic materials required for miniaturization of the sensors and devices requires an extension of the frequency range for the impedance toward the higher frequencies (GHz range). Accordingly, the purpose of this paper is to study the GMI effect in thin amorphous magnetically soft microwires extending the frequency range up to GHz band. Studies of magnetic properties and GMI effect of amorphous Co-Fe rich microwires reveals that they present GMI effect at GHz frequencies. Magnetic field dependences of GMI effect are affected by the microwires composition, post-processing conditions and geometry. In particularly stress-annealing at certain conditions (time and temperature) allows achievement of better magnetic softness and higher GMI ratio. We observed that in both Co-rich and Fe-rich microwires maximum value of the GMI ratio, $\Delta Z/Z_m$, and the optimal frequency for GMI effect observation have been improved by stress annealing (see Fig.). We discussed observed experimental dependences considering both different magnetic structure and the anisotropy in the bulk and near the surface and close analogy between giant magnetoimpedance and ferromagnetic resonance.

GI-04. Ferromagnetic FeCo and Co nanowired substrates based integrated tunable microwave isolator with ultra-wideband application. S. Aslam[2,1], M. Khanna[2] and *B.K. Kuanr*[1] *1. Special Centre for Nanoscience, Jawaharlal Nehru University, New Delhi, India; 2. Department of Electronic Science, University of Delhi, New Delhi, India*

Rapid growth in wireless technology seen a fast evolution in communication systems from 1G to futuristic 5G, which is expected in 2020s. However, it is quite challenging to move to millimeter-wave based 5G technology from the existing devices[1]. Keeping this in mind, we have synthesized 1-D metamaterial in the form of magnetic nanowires(NWs) of FeCo and Co in alumina matrix and designed coplanar waveguide (CPW) based microwave isolators. Prior to isolator design, NWs were characterized by vibrating sample magnetometry:Fig(A). For an ideal isolator, the circularly polarized EM wave should have full transmission in forward direction and full attenuation in reverse direction. The basic principle of the isolator is its *asymmetrical loading* in the CPW:Fig.(B). The present scheme of experiment exhibit non-reciprocal behavior of EM-wave both experimentally and theoretically. In a CPW with NWs (length=30μm) in alumina matrix placed in one-side gap between signal and ground generate circular polarization of RF magnetic field[2]. With a dc magnetic bias (H) parallel to the NWs and perpendicular to propagation direction, the transmission direction of left-hand circular

polarization (LHCP) and right-hand circular polarization (RHCP) are opposite. In this investigation, non-reciprocity was found where $(M_i h_{rf}) \perp k$, as whole magnetic volume of the sample interacts with h_{rf}. We have observed maximum isolation of 9.0 dB with an insertion loss of ~2.0 dB at 27.0 GHz at H=6.0 kOe. Further, we tune the frequency of the device from 21.0 GHz to 37.0 GHz with H from 3 to 10 kOe. Isolation has been demonstrated in a broad frequency range. Using a micromagnetics [3] approach the simulated h_{rf} distribution for forward (+k) and reverse (-k) wave propagation exhibit non-reciprocity. We have model an NWs-alumina matrix of thickness 30 μm, and length and breadth of 3 mm each in one side of the CPW. The matrix is partitioned into a grid with μm size cells through the thickness, length and breadth. While these are large cells, this is sufficient for looking at the transmission parameters (S_{21}, S_{12}). The proposed schemes are potentially helpful to identify the essential requirements of a planar two-port isolator useful for 5G frequency.

GI-05. 400MHz MEMS Antenna Based on Magnetoelectric Coupling Effect. *H. Chen*[1], X. Liang[1], N. Sun[1], H. Lin[2], Y. Gao[2] and N.X. Sun[1,2] *1. Northeastern University, Boston, MA, United States; 2. Winchester Technologies, LLC, Burlington, MA, United States*

Abstract – 400MHz frequency band is the most commonly used band for Medical Implant Communications Service (MICS). However, most of recent antenna researches for this application are based on electromagnetic wave resonance, which lead to a comparable size to the wavelength [1, 2]. To solve this problem, a new antenna design based on the magnetoelectric coupling is introduced by our group [3], which is a thin-film bulk acoustic resonance (FBAR) antenna for 2.5GHz applications, based on the AlN resonator and magnetoelectric coupling. Since acoustic wave has smaller wavelength than electromagnetic wave, the antenna size can be easily scaled down by more than 100 times. However, for most AlN resonator designs, impedance matching is a problem because of the high electric impedance. Hence, a parallel antenna array structure is applied to reduce the impedance and increase the antenna gain [4]. In this work, nano-plate resonance (NPR) antenna arrays for 400MHz application are designed, fabricated and tested. This antenna is based on the magnetoelectric coupling between AlN thin film and FeGaB/SiO_2 multilayer. The antenna array structure is shown in Fig. 1 (a) with 8um width and array numbers of 1,4, 8 and 16. This strip structure resonates at in-plane mode, and this resonance is limited in width direction by the strip. The measured S-parameters are shown in Fig. 1 (b), with operating frequency of 371MHz, and 10dB-bandwidth of 3.875MHz. A radiation peak of S_{21} is observed clearly at the resonant frequency, and a peak antenna gain of -54.82dBi is achieved. This radiation peak is from the vibration and domain rotation of magnetic film. The measured S_{11} and calculated Z_{11} are shown in Fig. 2. For fewer array numbers, the impedance is higher, and the related return loss is also higher, so the radiation peak is cover by the baseline. For this reason, array structure with more than 16 strips is necessary for impedance matching and high antenna gain.

GI-06. Design and Fabrication of ZnO-Based SMR Magnetoelectric Antennas for High-Gain Applications. *X. Liang*[1], H. Chen[1], N. Sun[1], Y. Gao[2], H. Lin[2] and N. Sun[1] *1. Northeastern University, Boston, MA, United States; 2. Winchester Technologies, LLC, Burlington, MA, United States*

Magnetoelectric (ME) antennas based on the suspended ME circular disk consisting of FeGaB/AlN thin-film have been demonstrated recently [1]. However, the FBAR devices are very fragile and delicate due to the releasing structure, although the complicated packaging process [2]is able to solve this problem. From the device point of view, the solid mounted resonator (SMR) with Bragg reflector has attracted much attention as a promising technology for the film bulk acoustic wave resonator (FBAR) devices [3]. Typically, the SMR devices are formed of a piezoelectric film, such as ZnO that is sandwiched between top and bottom metal electrodes, on top of a Bragg reflector. A resonance is created when a radio frequency (RF) signal is applied across the FBAR device. There are a variety of products such as filters [4], duplexers [4], and voltage controlled oscillators (VCOs) [5] based on SMR designs have been developed in past years. In this work, we designed, fabricated and tested ZnO-based SMR ME antennas that operate at GHz with high gain performance. As shown in Fig. 1, the Bragg reflector consisting of three pairs of SiO_2/W layers was sputter deposited in one run with RF reactive magnetron sputtering for $SiO_2$and DC sputtering for W. The piezoelectric ZnO layer was sputter deposited by RF reactive sputtering with Zn target and high-purity Oxygen gas. The XRD curves and rocking

curves for ZnO films under different temperature were measured and exhibited in Fig. 2. In order to grow high quality ZnO films, it is vital to have sufficient ion bombardment during deposition. Therefore, high temperature of 450 degrees Celsius is preferred here with rocking curve FWHM of 2.25 degrees. After optimizing the performance of Bragg reflector and piezoelectric ZnO films, we fabricated and tested the SMR ME antennas. A gain enhancement of 12 dB was achieved in this novel design for robust ME antennas. Therefore, it is very promising in practical applications.

GI-07. Electrically Small Multiferroic Antenna Enhanced by Energy Reelecting Components. *J. Hu*[1,2], W. Yan[1], G. Carman[1] and A. Sepulveda[1,2] *1. Mechanical & Aerospace Engineering Department, UCLA, Los Angeles, CA, United States; 2. Vilya Nanotechnologies, Inc, Los Angeles, CA, United States*

Conventionally, antennas such as dipoles and loops rely on an electromagnetic (EM) wave resonance, therefore the sizes of such antennas are within the same order of free space wavelength. Electrically small antennas (i.e. size < λ/10) at ultra-high frequency hold promises for reducing the antenna system's size, weight and volume, yet state-of-the-art electrically small antennas confront a daunting challenge. So far, electrically small antennas radiate poorly when placed near a conducting surface because of platform effects. Recently, induced strain-mediated multiferroic composites interconvert between alternating magnetization and mechanical strain wave with ultra-high energy efficiency due to negligible current and Ohmic loss. Several reports of such devices, modified from thin-film bulk acoustic resonator (FBAR), have demonstrated a new concept on electrically small antenna[1-4]. However, until now, fabrication challenges hindered attempts at forming large scale antenna arrays to improve the signal strength. This work demonstrates a new strain-mediated multiferroic antenna that relies on lamb wave resonance of piezoelectrical substrate such as Aluminum Nitride (AlN). Oscillation of Ni micro elements excited by free space EM wave is detected by comb-shaped arrays of metallic electrodes through out-of-plane electrical field. Surrounding the Ni micro elements and comb-shaped electrodes there are acoustic gratings and Bragg acoustic mirror to reflect the acoustic energy to form a standing wave and prevent energy dissipation[5]. At least -40dBm radiation power is expected according for a 10dBm's energy be input to a 2cm*2cm antenna in the numerical finite element model. Based on the model and Monte-Carlo optimization on the structure, we designed the system and we plan to fabricate a device and made preliminary tests on it. This work demonstrates the feasibility of shear mode strain-mediated multiferroic antenna, which shows promising potential for the next-generation electrically small antenna at ultra-high frequency.

GI-08. Tunable Properties of Microwave Absorber and FMR Relaxation for GO Doped $MnFe_2O_4$ Nanoparticles. *A. Mishra*[1] and B.K. Kuanr[2] *1. School of Physical Sciences, Jawaharlal Nehru University, New Delhi, India; 2. Special Center for Nanoscience, Jawaharlal Nehru University, New Delhi, India*

In the present investigation, the reduced manganese ferrite/ graphene oxide ($MnFe_2O_4$/rGO) nanocomposites with different weight amounts of GO sheets have been synthesized using a simple and efficient one-step hydrothermal method. The crystallinity, morphology and magnetic studies were conducted using X-ray diffraction (XRD), confocal Raman imaging and vibrating sample magnetometry (VSM). The electromagnetic and microwave power absorption properties were examined in a broad frequency range of 5-30 GHz using a Keysight vector network analyzer. The largest ferromagnetic resonance (FMR) absorption of 27.5 dB of electromagnetic power was observed when the weight of GO sheets in maximum in the nanocomposites at the 22GHz frequency. The FMR relaxation and damping

parameters can be tuned by adding of GO sheets in $MnFe_2O_4$/rGO nanocomposites at specific frequency. It is observed that the damping parameters decreases if the weight amount of GO sheets increases in the nanocomposites. The micromagnetic model was used to calculate FMR linewidth as well as both intrinsic and extrinsic damping parameters of the $MnFe_2O_4$/rGO nanocomposites. Therefore, due to above properties $MnFe_2O_4$/rGO nanocomposites have various applications in the field of microwave absorber as well as in high speed microwave monolithic devices and amount circuits.

GI-09. High-gain Wideband Miniature Axial-mode Helical Antenna with Multi-layer Ferrite and Dielectric Structure. *H. Won*[1], Y. Hong[1,3], W. Lee[1,2] and M. Choi[1] *1. Department of Electrical and Computer Engineering and Center for Advanced Vehicle Technologies, The University of Alabama, Tuscaloosa, AL, United States; 2. RF Product Development Group, Samsung Electro-Mechanics, Suwon-si, The Republic of Korea; 3. Alabama Transportation Institute, Tuscaloosa, AL, United States*

For many advantages, the axial-mode helical antenna (AM-HA) received much attention for satellite communications. For the conventional AM-HA, either air (AC) or dielectric-core is employed but results in large antenna volume (*V*). A lossy ferrite-core/dielectric-shell (FD) structure was used for AM-HA to reduce the *V* without sacrificing gain, but with the expense of 400 MHz of axial ratio at boresight below 3 dB (AR_{3dB}), compared to that of air-core [1]. To address this issue, we propose high-gain wideband miniaturized N-layer FD-AM-HA (N-FD-AM-HA), where N is equal to 1, 2, and 3. All antennas were simulated for antenna performance using ANSYS HFSS. The specifications and designs of AC- and N-FD-AM-HAs are summarized in Fig. 1. To realize the *V* reduction by N-FD loading, the AC-AM-HA of 55 cm^3 was designed and compared with the N-FD-AM-HAs of 40 cm^3 for antenna performance. For accurate comparison between N-FD-AM-HAs, same ferrite-core (permeability (μ_r)=2, permittivity (ε_r)=7, dielectric/magnetic loss tangent ($\tan\delta_e/\tan\delta_u$)=0.01/0.1, and *V*=10.6 cm^3) and dielectric-shell (μ_r=1, ε_r=2.3, $\tan\delta_e/\tan\delta_u$=0.01/0, and *V*=15.6 cm^3) are used [1]. Fig. 2 shows the simulated antenna performances. From Fig. 2, all antennas resonate at 2.25 GHz, show 8.85 dBic of the peak realized gain (RG), and start AR_{3dB} at 2.83 GHz, indicating 27% *V* reduction without sacrificing RG from lossy FD loading. However, as Fig. 2 (b) and (c) show, low RG of 4.7 - 6.5 dBic above 3.2 GHz and narrow AR_{3dB} of 1.18 GHz were observed for the 1-FD-AM-HA. These issues were solved by adopting a multi-layer structure. The 2- and 3-FD-AM-HA show not only 0.8 - 0.9 dBic and 1.1 - 1.5 dBic higher RG but also 270 and 310 MHz higher AR_{3dB}, respectively, than those of the 1-FD-AM-HA. Further, the 2- and 3-FD-AM-HA show similar RG and AR_{3dB} compared to that of AC-AM-HA. Thus, multi-layer FD loading not only can effectively miniaturize antenna but also improve antenna performance. This work was supported in part by the NSF-I/UCRC for EV-STS under Grant number 1650564.

GI-10. Efficient Adjustment of Finite Graphene Scattering Properties via Magnetic-bias Control for Advanced Beam Manipulation. S. Amanatiadis[1], T. Ohtani[2], *Y. Kanai*[3] and N. Kantartzis[1] *1. Electrical and Computer Engineering, Aristotle University of Thessaloniki, Thessaloniki, Greece; 2. 1-17-134 Omachi, Asahikawa, Japan; 3. Niigata Institute of Technology, Kashiwazaki, Japan*

In the present work, the scattering of an incident plane wave due to magnetically-biased graphene patches is thoroughly investigated at millimeter-wave and THz bands. Graphene is placed perpendicular to the propagation of the incident wave, as depicted in Fig. 1 along with the 3D radar cross-section and static bias fields are applied to control its surface conductivity. Especially, magnetostatic bias is activating anisotropic effects due to the Lorentz forces on electrons, thus revealing various interesting phenomena, such as gyrotropy, non-reciprocity and magnetoplasmon propagation [1]. It is evident that bias control is able to tune the scattering properties and this is confirmed in Fig. 2, where the radar cross-section at a plane normal to graphene is illustrated. Specifically, as the strength of bias decreases, the transmitted wave is lower at the direction of propagation, namely 0^o, compared to a slight angle of approximately $\pm 10^o$. This effect is justified due to the magnetoplasmon surface wave that is propagating on graphene. The excitation of magnetostatic bias is implemented effectively via circular loops since the dimensions of graphene patches are in the micrometric order and relatively strong fields can be induced using coils of small radius. Moreover, the efficient adjustment of the bias field is achieved utilizing high-speed electronics that activate the desired number of active loops. It is worth to mention, that this kind of excitation is considered in the full-wave simulations to investigate the possible influence of the loops on the plane wave propagation. Finally, the extracted results from the previous analysis are

evaluated appropriately to design an array of graphene patches, of different magnetic-bias fields, to investigate the potential of advanced beam manipulation. All numerical results are extracted via an accurate modification of the popular Finite-Difference Time-Domain scheme [2].

GI-11. Near-Field Probing of the Effective Electromagnetic Shielding Using CoZrTaB Thin Films. *P. Miller*[1], Y. Wu[1] and H. Yu[1] *1. Arizona State University, Tempe, AZ, United States*

With rapidly decreasing electronic size and increasing multi-functionality that oftentimes mixing RF and digital circuit close to each other, it is critical to provide sufficient electromagnetic shielding between functional circuits to prevent electromagnetic noise interference. The unique resistivity and magnetic properties documented for the material indicate that it may well-suited to provide effective shielding, and is particularly applicable for Internet-of-Things (IoT) devices and others operating in the 5G spectrum. This work focuses on analyzing the variance in shielding effectiveness and electromagnetic field effects of a thin film of Cobalt-Zirconium-Tantalum-Boron (CoZrTaB) in the band of frequencies most likely to require innovative solutions to long-standing problems of noise and interference [1,2]. The CoZrTaB films were sputter-deposited onto silicon or polyimide substrate, with film thickness varying in the range of several hundreds nanometer to demonstrate the thickness effect, as well as multi-layered structure magnetic film and compared with Cu film of thickness on the order of a few micrometers. The measurements were performed using a commercial probing system that include Near H-Field attenuation and field effects, Far Field shielding, and Backscatter, with sample placed on microwave stripline (Fig.1) Minor variances in the thickness and layering of sputter deposition can have significant changes electromagnetic signature of devices which radiate energy through the material, as shown in Fig. 2. The material properties presented in this research are H-Field attenuation, H-Field Flux Orientation, Far-Field Approximation, E Field Vector Directivity, H Field Vector Directivity, and Backscatter Magnitude. The results demonstrated the effective shielding of thin CoZrTaB magnetic film compared to much thicker Cu film, across broad frequency range between 1.25-5.75 GHz, with average shielding effectiveness across all samples and frequencies over 13.9 dBm.

GI-12. Tunable Band-Stop Frequency Selective Surface by Permeability Control of Ferromagnetic Material. *J. Ge*[1] and G. Wang[1] *1. Electrical Engineering, University of South Carolina, Columbia, SC, United States*

Tunable frequency-selective surfaces (FSSs) attracted great interest in recent years as tunable filters for reconfigurable antenna systems, for tunable radar absorbers, or to provide a varying transmission window in radomes [1]. Traditional magnetically tunable FSSs are implemented by using a ferrite substrate with controllable permeability. This type of FSSs suffers from several disadvantages, i.e., low tuning speed and small tuning range [2]. To overcome these problems, in this paper, a ferromagnetic layer controlled by the biasing circuit is employed to cover the metal layer of FSS. The ferromagnetic layer can change the effective permeability of FSS by different inputs of the biasing circuit, leading to the variable resonant frequencies. A simple FSS using the square loop as a unit cell is employed in this paper to verify the proposed concept [3]. This FSS shows a band-stop filtering response since it strongly reflects an incident plane wave at the resonant frequency. The equivalent circuit of this FSS is given as a series LC network, which means the equivalent inductance is critical to the resonant frequency.

Meanwhile, the inductance can be changed by variable effective permeability caused by the ferromagnetic layer. In addition, permalloy ($Ni_{80}Fe_{20}$) is employed to form the ferromagnetic layer. Then, a tunable FSS can be achieved by permeability control of the ferromagnetic layer with the biasing circuit. Fig 1 shows the simulated results of the proposed FSS with different effective permeability. The results exhibit a frequency tuning range from 4.8GHz to 6.4GHz with peak attenuation greater than -41dB. Compared with traditional magnetically tunable FSSs, the proposed design shows a wider tuning range and a higher tuning speed.

GI-13. Hexagonal Nano-ferrites used on a V-band Self-bias On-chip Circulator for CMOS. *M.N. Afsar*[1], V. Koomson[1] and W. Quam[1] *1. ECE, Tufts University, Medford, MA, United States*

Hexagonal ferrite materials such as BaFe12O19 and SrFe12O19 have strong anisotropic magnetic field and strong remnant magnetism. These properties enable the working frequency of devices such as phase shifter, isolator and circulator, move up to tens of GHz without a strong external bias field and even achieve self-biasing. The advantage of ferrite devices such as passive circulators are their low insertion loss, high isolation, broad bandwidth and high power handling ability compared to their active counterparts. Ferrite circulators consume no power and are more suitable for lower-power applications because these are passive, unlike active quasi circulator, In this work, thin film ferrite material was deposited by employing spin-casting method [Liu 2013] and patterned with the help of Chemical-Mechanical Polishing (CMP). The spin-casting is a low-temperature process: the nano-sized barium ferrite materials can be processed into composite and spin-casted into thin film layer. This method requires only 120°C baking under external biasing filed. This is advantageous when future integration with CMOS is taken into consideration. In this paper, we present the design, simulation, fabrication and measured results of a self-bias micro-strip line Barium hexagonal Nano-ferrite (BaM) circulator on silicon wafer. This planar Y-junction circulator is 2mm by 2mm by 0.5mm in size, which is capable of future integration with the top three layers of 180nm CMOS technology. Ferrite thin film is deposited and patterned employing composite spin-casting method. Typical characterization techniques are employed together with free-space quasi-optical spectrometry to study complex permittivity and permeability of deposited film up to 120GHz. S parameters of fabricated circulators are characterized by a set of on wafer probes up to 67GHz. We observed over 15dB non-reciprocal phenomenon at 55GHz. The probes setting is shown in Fig. 1. The measured S-parameter are shown in Fig. 2.

GI-14. Structural and magnetic properties of La^{3+} substituted Co_2Z hexaferrites for tele-communicational antennas and EMI shielding applications. *A. Singh*[1] and P. Sharma[1] *1. School of Physics and Materials Science, Thapar Institute of Engineering and Technology, Punjab, Patiala, India*

Co_2Z hexaferrite ($Ba_{3-x}La_xCo_2Fe_{24}O_{41}$ with x = 0.0-0.2 and 0.6) were synthesized using solid state reaction method. X-ray diffraction confirmed the single Z-type phase formation with x = 0.0 to 0.2 and for x = 0.6, Z-type coexist with W-type. The lattice parameters were found to increase with La doping. The magnetic measurements were carried out using the Vibrating Sample Magnetometer (VSM). The saturation magnetization (M_s), magnetic coercive force (H_c) and retentivity (M_r) were increased with La content in the samples. The microstructure morphology showed that the hexagonal plate like grains appeared in pure and hexagonality and grain growth increased with La substitution. The increasing M_s indirectly played an important role between antenna operating and cutoff frequencies on the basis of its

increasing resonance frequency [1-3]. The bandwidths increased and the length of antennas decreased with the magneto-dielectric materials [4,5]. The big hexagonal grains materials are suitable for radar absorbing and EMI shielding technology because its dielectric losses increased. Therefore, La substituted Co_2Z hexaferrite can be used in miniaturized antenna fabrication and radar absorption materials.

Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany

GP-01. Domain wall motion-based spin synapsis-neuron functions manipulated by spin orbit torque in heavy metal / CoFeB/ MgO stacks.
J. Shin[1], J. Choi[2], Y. Ji[2], S. Yang[3], J. Yang[4] and J. Hong[1,2] *1. Nanoscale Semiconductor Engineering, Hanyang University, Seoul, The Republic of Korea; 2. Physics, Hanyang University, Seoul, The Republic of Korea; 3. Kriss, Daejeon, The Republic of Korea; 4. Physics, Kunsan University, Kunsan, The Republic of Korea*

Neuromorphic computing architectures basically aims to mimic brain-like behaviors through the combination of neurons strongly inter-connected by huge synapses [1, 2]. There are two key devices: artificial neuron and synapsis devices that should be carefully designed to achieve extremely low power operation and highly integrated density in a compact size. Here, we address the performance of domain wall motion (DWM), driven by spin orbit torque (SOT) -based neuron and synapsis functionality in heavy metal / CoFeB/ MgO frames under continuously repeated electrical stimulus.[3] Firstly, an in-plane direct current (DC) measurement approach was employed to identify spin orbit torque-driven effective fields without adopting the commonly used harmonic analyses, as seen in Fig. 1.[4] Proper manipulation of SOT-driven domain wall motion (DWM) under various positive/negative current pulses led to gradual variation in temporal synaptic weight: in particular, demonstration of long-term potentiation functionalities. In addition, artificial spiking neuron functions ensuring an integrate-fire (IF) behaviors in an asymmetric hall bar were detected by utilizing the input current pulses that were similar to the DC analysis current used for magnetization switching. Typical IF behaviors were shown in Fig. 2, along with the DWM along the hall bar under consecutively applied current pulses. The MOKE images clearly indicated that the neuron functions in our Heavy metal / CoFeB / Mgo frame came from SOT-driven DWM. More parameter details of the devices will be presented in the conference.

GP-02. Ion-Beam Controlled Switching Field Distributions in the Low Coercivity Regime.
S. Mendisch[1], M. Kiechle[1], V. Ahrens[1], A. Papp[1] and M. Becherer[1] *1. Department of Electrical and Computer Engineering, Technical University of Munich (TUM), München, Germany*

Perpendicular Nanomagnetic logic (pNML) is a form of domain-wall (DW) logic utilizing the anti-parallel stray fields of next-neighbor nanomagnetic islands with perpendicular magnetic anisotropy (PMA) to process information [1]. In the past, we published a comprehensive family of fully functional Boolean and non-Boolean logic devices and projected a possible power dissipation of low, single-digit Atto-Joules per equivalent NAND/NOR operation, achieved via monolithic 3D integration and global on-chip clocking [2]. However, this is only possible via tailored coercivities (H_c < 20 mT) and narrow switching-field-distributions (SFD), that are significantly smaller than the clocking window ($\sigma_c < \Delta H_{clk}$). The design goals of pNML are therefore contradictory to those of bit-patterned media, on which earlier investigations put their focus on [3]. This work opens the door to a better understanding of how partial Ga^+ and He^+ ion irradiation effects and limits coercivity and SFD in magnets with low PMA. The irradiation spots create artificial nucleation centers (ANC) by locally decreasing the PMA leading to reduced nucleation fields. This is essential for the non-reciprocal coupling in pNML. The experiments are based on the statistics of thousands of circular nanomagnets ($Pt_1\backslash Co_{0.25}[Ni_{0.7}\backslash Co_{0.15}]_{xN}$), grouped in multiple dot arrays. The arrays are irradiated with varying ion types and doses and are subsequently compared to their as-grown states. The samples are characterized via wide-field MOKE, utilizing automated image recognition and pattern matching software, which enables to track the H_c change of every magnet ($0.5 < r_{dot} <$ 1 μm). Additionally to the overall statistical analysis, this approach reveals the irradiation impact-noise ($\sigma_{\Delta Hc}$) with respect to the applied ion-type and irradiation parameter. Fig. 1 and 2 depict the SFDs and impact-noise data of a 5 ML stack before and after irradiation. While the SFDs validate the effectiveness in reducing $H_{c,mean}$ even in the low coercivity regime, the ΔH_c distribution reveals a linear dependency on the as-grown H_c.

GP-03. Current-induced or field-induced domain wall depinning of a domain wall in a circular cross-section wire with modulated diameter. A. De Riz[1], B. Trapp[2], J. Fernandez-Roldan[3], C. Thirion[2], J. Toussaint[2], O. Fruchart[1] and *D. Gusakova*[1] *1. Univ. Grenoble Alpes, CNRS, CEA, Grenoble INP, IRIG-Spintec, Grenoble, France; 2. Univ. Grenoble Alpes, CNRS, Institut NEEL, Grenoble, France; 3. Institute of Materials Science of Madrid, CSIC, Madrid, Spain*

Domain wall propagation in cylindrical nanowires with modulations of diameter is a key phenomenon to design physics-oriented devices, or a disruptive three-dimensional magnetic memory. The information stored in this type of solid-state device would be encoded by magnetic domains separated by magnetic domain walls, whose position may be controlled by introducing geometrical modulations. A smaller cross-section reduces the internal domain wall energy, and thus plays the role of the energy well. This implies that a threshold driving force must be applied to overcome the barrier. In this context, our work presents a combination of analytical modelling and micromagnetic simulations [1,2], with the aim to draw a comprehensive panorama of the physics of domain wall pinning at geometrical modulations, when moved under the stimulus of a magnetic field or a spin-polarized current. For the sake of considering simple physics, we focus on diameters of a few tens of nanometers at most, and accordingly on domain walls of transverse type. We compare the domain wall behavior subjected to the magnetic field and subjected to the spin-polarized current. Modeling with suitable approximations provides in each case simple scaling laws, which relate the critical driving force needed to unpin the domain wall to the geometry parameters. We find major difference of efficiency of the driving force between both cases: while pinning increases with the relative change of diameter between two wire segments, the pinning efficiency is much larger upon considering current rather than field, due to the drastic decrease of the current density in larger cross-section. The quantitative investigation of experimental domain-wall pinning in modulations of diameter is still in its infancy. It has been carried-out under magnetic field so far, with scattered results, however pointing at the moderate strength of pinning compared with extrinsic pinning on material defects, when considering smoothly-varying modulations. The drastically higher efficiency of pinning under current, raises hope that modulations of diameter can be designed efficiently for spin-torque fundamental or applied devices.

GP-04. Structure of domain walls in synthetic antiferromagnets with an inverted Dzyaloshinskii-Moriya interaction. *N. Pandey*[1], A. Prudnikov[1], M.P. Li[1], C.K. Mewes[2], T. Mewes[2], M. De Graef[1] and V. Sokalski[1] *1. Materials Science and Engineering, Carnegie Mellon University, Pittsburgh, PA, United States; 2. Physics and Astronomy, University of Alabama, Tuscaloosa, AL, United States*

Synthetic antiferromagnets (SAFs) are ubiquitous in magnetic storage and memory technology due to the strength of the antiferromagnetic coupling and their suppression of unwanted stray fields. More recently, SAFs have been considered for use in racetrack memory in the form of domain walls (DWs) or skyrmions where the velocities are reportedly much larger than their ferromagnetic counterparts. [1] The work presented here features a new kind of chiral DW where the top and bottom layer of the SAF have parallel internal DW magnetization directions despite AF interlayer coupling (See Fig 1). This occurs due to an inversion of the DMI sign and, consequently, the DW chirality between the layers. [2] Here we present semi-analytical calculations combined with micromagnetic modeling, using the M^3 software package, to describe the ground state of DWs in SAFs.[3] Experimental results on SAFs with tunable coupling strength and DMI are presented along with Lorentz TEM images of SAF DWs. Each layer of the SAF is based on a HM/FM/HM multi-layer where the HM is either Pt or Ir and the FM is either Co or a Co/Ni multi-layer. AF coupling strength was measured between these layers using Ru and/or Ir as the coupling layer. Peaks in AF coupling are observed consistent with an RKKY interlayer exchange mechanism. Initial Lorentz TEM (See Fig 2) using a Pt/$[Co/Ni]_6$/Co/Ir/Co/$[Co/Ni]_6$/Pt SAF show domain walls that adopt a tiger-tail pattern and a clear separation of the top and bottom domain walls with application of a perpendicular field. The possible forms of topological defects in SAF domain walls and a proposed strategy for their detection is also presented. [4]

GP-05. Systematic Characterisation of DMI in Co/Pt, Co/Ir Systems.
E. Darwin[1], C.H. Marrows[1] and B. Hickey[1] *1. Condensed Matter, University of Leeds, Leeds, United Kingdom*

Skyrmions are chiral, topologically non-trivial, spin textures which have a unique set of topological properties which lead them to be highly stable. Skyrmions which have diameters in the nanometer range, can now be stabilized at room temperature without a magnetic field and can also be manipulated using an electric current; all of which makes them suited for applications such as data storage and logic technology.[1][2][3] Skyrmions occur due to the Dzyaloshinskii-Moryia interaction (DMI), which is an additional anti-symmetric term in the exchange energy shown by Equation 1. HDMI = d12. (S1 x S2) (1) Where d12 is the DMI characteristic vector and S1 and S2 are two neighbouring spins.[4] The more recent room temperature Néel skyrmions have been observed in heavy metal/ferromagnet/heavy metal multilayers. Materials were used such as cobalt for the ferromagnet and Ir and Pt for the heavy metals. Part of the process to attain reliable and stable skyrmions is to study these materials and their properties. The DMI constant directly affects the shape, size and stability of skyrmions, so to be able to nucleate an appropriate skyrmion, it should be known how different material parameters affect the DMI. Throughout this study, measurements were made of numerous samples of materials which should invoke various DMI whilst varying only one factor in order to understand how that factor affects the DMI. The further goal was to obtain a set of material configurations with known DMI constants to aid with reliable methods for skyrmion nucleation. Figure 1a shows the set of effective DMI constants, these were attained using the bubble expansion method (Figure 1b) to find the DMI field, and SQUID measurements. Further measurements were also made to test how a different number of magnetic multilayer repeats would affect the magnetic properties of skyrmion materials to find the highest possible sample thickness. This is in order to create successful on-chip coplanar waveguides with the ability to host skyrmions with the aim of performing THz time domain spectroscopy measurements to observe possible skyrmion resonances at THz frequencies.

GP-06. Analysis of self-heating effects on current-driven ferrimagnetic domain wall motion. *G. Wang*[1], Y. Zhang[1], Z. Zhang[1,2], Z. Huang[1], J. Wang[1], K. Zhang[1], J. Nan[1], Z. Zheng[1,2], Y. Zhang[1,2] and W. Zhao[1] *1. Fert Beijing Research Institute, BDBC, School of Microelectronics, Beihang University, Beijing, China; 2. School of Electronic and Information Engineering, Beihang University, Beijing, China*

Recent progresses have demonstrated that spin-orbit torque (SOT) driven ferrimagnetic (FIM) domain wall (DW) motions near the angular momentum compensation point T_A possess extremely high velocity [1-4]. However, as FIM materials are thermally sensitive [5-6], the behavior of the current-induced FIM DW motions will be significantly influenced by self-heating. Here we analyze the impact of self-heating on the velocity of SOT driven FIM DW motions by synthetizing Joule heating effect, temperature-dependent FIM compensation effect and SOT effect [See Fig. 1]. Firstly, we investigate the dependence of DW motion velocity (v_{DW}) on temperature with different current densities in heavy metal (j_{HM}), as shown in Fig. 2(a). Fig. 2(b) shows the Joule heating effect on the temperature. The significant influence of the temperature variation on FIM DW motion is then demonstrated in Fig. 2(c). We can find that v_{DW}-t curves of small j_{HM} are steady during 1ns of self-heating. In contrast, large j_{HM} can induce high v_{DW} at the beginning of the current application. Then the v_{DW} will drop even lower than that of small j_{HM}, owing to the self-heating effect that makes the temperature away from T_A. Moreover, appropriately increasing T_A is an effective approach to increase the average speed. As shown in Fig. 2(d), when T_A=312K, the v_{DW} is kept above 1.5km/s within 1ns, resulting in the maximum propagation length. From this analysis, we summarize that suitable j_{HM} should be provided according to specific demands: large current can boost the speed for the application with short DW propagation length, such as three-terminal DW device; in the cases requiring long DW propagation length, such as racetrack memory, small current can generate stable speed and minimize the impact of self-heating. This work is conducive to the future application of FIM materials in spintronic devices.

GP-07. Current Induced Domain Wall Motion with a Ta/Gd-Fe/Si-N Magnetic Nanowire for a Magneto-optical Light Modulator. *K. Aoshima*[1], N. Funabashi[1], R. Higashida[1] and K. Machida[1] *1. NHK Japan Broadcasting Corp., Tokyo, Japan*

Magneto-optical light modulator driven by current-induced domain wall motion (CIDWM) has been developed for holography display application [1-3]. Driving speed of the device, which is proportional to domain wall (DW) velocity, has to be fast enough to refresh pixel data over large scale such as 10K × 10K or larger. Fast CIDWM has been found in a magnetic layer sandwiched by a heavy metal and an insulator, which is attributed to chiral Néel DW driven by spin orbit toque (SOT) [4-6]. However, there is not much research about how initial domains nucleated on the SOT driven nanowire and its CIDWM for a light modulator. In this article we investigate a Ta/Gd-Fe nanowire with a hard magnet(HM), and show a domain nucleation and CIDWM as fast as 180 m/s. Fig.1(a) shows a fabricated device, which comprises a Ta(3 nm)/$Gd_{22.6}$-$Fe_{77.4}$(10 nm)/Si-N(5 nm) nanowire with 500 nm width, a HM of $[Co(0.3\text{ nm})/Pd(0.6\text{ nm})]_{25}$ with 0.5 × 3 μm^2, and electrodes for current injection. As shown in Fig. 1(b) and (c), an initial domain was observed as a dark spot on the left (right) side of the HM, which was nucleated by the positive (negative) current pulse without external magnetic field after uniformly magnetized along +z-direction. This is attributed to the SOT with local in-plane component (x-direction) of fringe magnetic field induced by the HM [Fig.1(d)], which is known for the SOT switching [7, 8]. Two initial domains have been observed on both side of the HM for the nanowire without Ta [1]. As shown in Fig.2, positive (negative) DW velocity increased with an increasing positive (negative) current, indicating DW moves along the current flow which was opposite to the nanowire without Ta underlayer [1]. The velocity significantly increased as fast as 180m/s with an application of external in-plane magnetic field (H_x), which was more than an order of magnitude faster than that without Ta [1]. The fast DW motion is attributed to the chiral Néel wall promoted by the H_x and SOT induced by Ta [4-6].

In the last decade, magnetic ratchet effect of domain walls has been proposed by several groups as a working principle for spintronic devices like magnetic diodes or shift registers. Indeed, some of the proposed strategies are promising candidates to be seen in the near future in working devices. As an alternative route, we have succeeded in producing and observing magnetic ratchet effects, as well as crossed-ratchet effects, in a ferromagnetic thin film where we have nanopatterned 2D arrays of asymmetric holes in the submicrometric limit for hole sizes. The combination of Kerr microscopy, X-Ray PhotoEmission Electron Microscopy and micromagnetic simulations has allowed a full magnetic characterisation of the domain wall (DW) propagation processes over the whole array and the local DW morphology and pinning at the holes. It is found that the DW dynamics in the submicrometric size limit are governed by the interplay between DW elasticity and half vortex propagation along hole edges: as hole size becomes comparable to DW width, flat DW propagation modes are favoured over kinked DW propagation due to an enhancement of DW stiffness, and pinned DW segments adopt asymmetric configurations related with Nèel DW chirality. Both ratchet and crossed-ratchet effects have been experimentally found, and we propose a new ratchet/inverted-ratchet effect in the submicrometric range driven by magnetic fields and electrical currents [1].

GP-09. Geometrically tuned Spin-orbit torque based memristor. *R. Singh*[1] and X. Zhang[1] *1. School of Materials Science & Engineering, Tsinghua University, Beijing, China*

Spin orbit torques (SOT) based memristors have drawn much attention due to their potential application in magnetic memory and logic devices.[1] The spin-based memristors offered significant endurance and high energy efficiency as compared with other types of memristors.[2] Here, we proposed geometrically tunable Hall bar based magnetic memristors in which the gradual switching of magnetic domains in magnetic material (CoFeB) resembles memristor *R-I* curves. We modified the geometry of the conventional Hall bar in such a way that the current density (*J*) will be different in different part of the device. The current density is given by ($J=I/A$), where I is the applied current and A is the cross-sectional area of the device. Due to different current density, the magnetic domain switching in CoFeB will occur gradually. This gradual switching of magnetization gives *R-I* curve that resembles memristor behavior. The Ta(3)/CoFeB(0.7)/MgO(1.3) (the number shows film thickness in nanometers) multilayers were deposited by sputtering. To achieve good perpendicular magnetic anisotropy (PMA) property, the film stack was annealed at 220°C for 1hr. Later, lithography and etching were performed to fabricate devices. Figure 1 shows Hall resistance variation of the fabricated devices. It can be seen that the conventional Hall bar geometry (10 μm device) has only two stages (Low resistance state and High resistance state). However, other devices (30 and 50 μm devices) shows multistate resistance switching. The larger curvature device (50 μm) shows large number of switching stats (5 steps in *R-I* curve). If we varied the write current then different states of resistance can be achieved (figure 2, measured for 30 μm device). This shows multistate *R-I* curve, that resembles the memristor kind of behavior. To understand the mechanism of our device simulation and MOKE microscopy has been performed.

GP-10. Introducing multiple stable states in an antiferromagnet-free spin-orbit torque device. *P. Chen*[1], C. Yang[1] and C. Lai[1] *1. Materials Science and Engineering, National Tsing Hua University, Hsing Chu, Taiwan*

Neuromorphic computing arouses extensive interests in its associated artificial intelligence and machine learning application, which has been currently accomplished by MRAM-based analogous memory technologies [1,2]. In this work, we are going to demonstrate a Pd(6)/Co/Ta(2), numbers representing thickness in nm, trilayer device featuring the multiple stable states upon driving the spin-orbit torque (SOT) effect through, and each intermediate state was electrically determined by the amplitude of pulse voltage with a tailorable range of approximately 6 volts and was strongly dependent on the size of device. As we patterned the devices into 100-nm in linewidth, the multi-level switching behavior becomes extinct, indicating that the phenomenon might be similar with the result from others' work [3]. Absence of the multi-level nature in Pt/Co/Ta and Pd/Co/Ta(<2) trilayer suggests the uniqueness of the combined Pd/Co and Co/Ta interfaces in giving rise to the peculiar multi-level. Also the behavior was still distinct in the as-deposit Pd/Co/Ta samples, meaning the diffusion of Ta has the lowest influence. At last, we function a whole structure integrating Pd/Co/Ta with a magnetic tunnel junction for the potential MRAM-based memory application. To summarize, the new structure design sheds a new light on future analog memory application. Other reports indicate that using anti-ferromagnetic as spin current source would result in this kind of slope when switching. However, in our structure design, we achieve analog switching while at the same time did not possess any anti-ferromagnetic layers, and can be potentially well-integrated into common MTJ design.

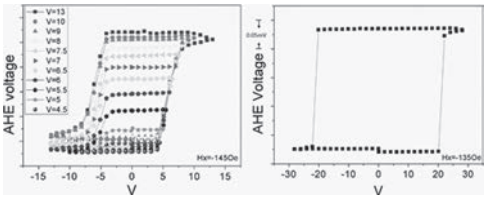

Fig. 2 Switching curves of as-deposited Pd/Co/Ta (left) and Pt/Co/Ta (right) in the 5 um width device. This set is for a comparison to show Pd/Co is necessary to give rise to the multiple stable states in Co layer upon driving SOT.

GP-11. Enhancement of spin Hall effects inducing damping-like torque in spin-orbit torque using partially A15-phase intermetallic compound W_3Ta film. *B. Chun*[1], S. Yang[1], C. Kim[1], K. Moon[1] and C. Hwang[1] *1. KRISS, Daejeon, The Republic of Korea*

In heavy metal (HM)/ferromagnet (FM) heterostructure, a spin current generated from HM with large spin-orbit coupling exerts a torque on the FM magnetization via spin Hall effects (SHE), so that for efficient magnetization switching the spin-orbit torque must be large especially for large damping-like torque is indispensable. Here, we demonstrate that the intermetallic compound W_3Ta layer with partially A15-phase can be more efficiently switch the magnetization of a FM by enhancing the damping-like torque [1]. In partially A15-phase W_3Ta/CoFeB/MgO/Ta systems, by considering the spin pumping effect, we obtained an SHE-induced damping-like torque of -0.678 (± 0.093), which was higher than that of the β-phase W/CoFeB/MgO/Ta structure of -0.477 (± 0.005). Recent theoretical report based on the Berry phase contribution to this large spin Hall effect supports our experimental verification.[1] We also studied the dependence of effective spin mixing conductance (on magnetic materials to evaluate the interface modification effect between HM/FM. Because of the larger in the W_3Ta/Co/MgO/Ta system, we obtained smaller damping-like torque of -0.541 (± 0.032) than W_3Ta/CoFeB/MgO/Ta system.

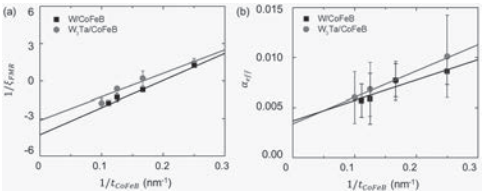

Fig. 1. (a) The damping-like torque is obtained from the intercept of the linear fit of versus $1/t_{CoFeB}$ curve and the values of W_3Ta/CoFeB/MgO/Ta and W/CoFeB/MgO/Ta system are -0.318 (± 0.048) and -0.233 (± 0.013), respectively. (b) Illustrates the CoFeB layer thickness dependence of. In this case, was found to be 0.0034 and 0.0037 for W_3Ta/CoFeB/MgO/Ta and W/CoFeB/MgO/Ta system, respectively, as obtained from the x-intercept in the linear fit of the versus $1/t_{CoFeB}$ graph.

GP-12. Magneto-optical Line Light Modulator Consisted of Single [Co/Tb] Magnetic Nanowire utilizing Current-driven Domain Wall Motion. *Y. Miyamoto*[1], Y. Hori[1], M. Endo[1] and N. Ishii[1] *1. Science & Technology Research Labs., NHK (Japan Broadcasting Corp.), Setagaya, Japan*

Spatial light modulator (SLM) [1] and magnetic nanowire (NW) memories [2, 3] that utilize current-driven domain wall motion have been proposed, in which precise control of the "bit shift" of magnetic domains is essential. SLMs are considered as future three-dimensional displays for holography. In this study, we fabricated a prototype of magneto-optical line light modulator (LLM), which was consisted of a single NW equipped with a pixel writer for forming magnetic domains in NW as shown in Fig. 1. The operation of LLM is as follows: (1) the pixel writer generates current magnetic field in one direction corresponding to the first bit datum and forms a domain in NW, *i.e.* act as the first pixel. (2) by application of driving current along NW, the written pixel is shifted to the right along NW. (3) by repeating pixel formation and shift one by one, the given serial data are stored along NW length direction as the domains with up or down magnetic moments. (4) the incident light may be modulated in polarization according to the stored pixel queue in NW, and the light modulation may be achieved by magneto-optical Kerr effect (MOKE). Fig.2(a) shows the microscopy image of fabricated LLM. The NW was consisted of Pt(3nm)/[Co(0.3)/Tb(0.6)]$_5$ film with perpendicular anisotropy on SiO_x/Si substrate, while the pixel writer was consisted of Ta(5)/Au(100)/Ta(5) with a separation layer of 18nm-thick Si_3N_4 insulator. The width and length of the NW was 3μm and 40μm, respectively. The stored pixels were observed by MOKE microscopy at wave length λ=408nm in real-time. Fig. 2(b) shows the MOKE image for post-operation of LLM. Here, the 500ns-width one pulse currents for driving and pixel writer were applied at 2.5×10^7A/cm^2 and 2.6×10^7A/cm^2 for each operation. The speed of domain shift is about 2.1m/s without existence of applied field. We have succeeded in observing bright and dark pattern referred to the stored pixels, although [Co/Tb] film showed maximum Kerr rotation angle of 0.28° at λ=650nm. A precise control of multiple domain shift can be achieved along the NW without intentional trap sites.

GP-13. Synaptic Element For Neuromorphic Computing Using Magnetic Domain Wall Device With Synthetic Pinning Sites. *T. Jin*[1], N. Sernicola[1], W. Gan[1], F. Tan[1], W. Lew[1] and S. Piramanayagam[1] *1. Nanyang Technological University, Singapore*

The ability to make devices that mimic the human brain has been a subject of great interest in scientific research. Current artificial intelligence algorithms, which are primarily based on the von Neumann architecture, are not energy

efficient[1]. Neuromorphic computing (NC), which consists of a network of synthetic neurons interconnected through synaptic devices, is expected to perform complex information processing at low power. In an NC system, synapses can be considered as the memory element of a neuromorphic device[2]. We have investigated magnetic wires made of Co/Pd multilayers with synthetic pinning sites as a potential candidate for a synaptic element. B^+ ions-implantation was utilised to locally modify the magnetic properties, which was carried out with an energy of 10 keV. A sample without implantation was also investigated as reference sample (Ref). The implantation depth was controlled by varying the thickness of an additional Ta overcoat to achieve deep-implantation (DI), medium- implantation (MI) and shallow-implantation (SI). Polar-MOKE and Kerr microscope measurements were performed to measure hysteresis switching loops and monitor DW propagation in the presence of a perpendicular magnetic field. The reference sample showed a sharp hysteresis switching curve, indicating that the magnetization reverses with a swift DW motion. Such a sample cannot be used in an NC system as synapse requires multiple states. For samples implanted with B^+, the magnetization reversal showed multiple states, indicating that the DW propagation is hindered by the pinning sites. The loops become wider for the samples with deeper implantation of B^+, indicating a stronger DW pinning, as shown in Fig. 1. The electrical measurements indicated that multiple resistive states can be achieved in samples implanted with B^+, as shown in Fig. 2. These results show that the DW device can be used as a neuromorphic synaptic element.

GP-14. Unusual phenomenon in which domain walls move in the current direction by STT in thick GdFeCo wire w/o heavy metal interface. *H. Awano[1] 1. Graduate School, Toyota Technological Institute, Nagoya, Japan*

Unusual phenomenon in which domain walls move in the current direction by STT in thick GdFeCo wire w/o heavy metal interface A. Takahashi[1], S. Sumi[1], P. V. Thack[1], K. Tanabe[1], Y. Kurokawa[2] and *H, Awano[1] 1 Toyota Technological Institute, JAPAN 2 Kyushu University, Fukuoka, JAPAN E-mail; *awano@toyota-ti.ac.jp Current-driven magnetic domain walls (DWs) in magnetic wires will be one of the attractive candidates for next generation low energy consumption memory devices. The critical current density for driving DW in RE-TM (Rare Earth Transition Metal) ferrimagnetic wire is one digit smaller than that of Co/Ni ferromagnetic wire [1]. As shown in Fig. 1 (a), when there is no Pt heavy metal layer on one side of the magnetic layer, the DW moves in the opposite direction to the current by Spin Transfer Torque (STT). On the other hand, as shown in Fig. 1 (b), when there is a hetero interface with the Pt layer, the DW moves in the current direction by the spin orbit torque (SOT). Since the SOT is just interface effect, it does not work when the thickness of the ferromagnetic layer exceeds several nm. However, we found that in the case of RE-TM wire, the SOT continues to work even if the layer thickness exceeds 10 nm [2-3]. This is considered to be the bulk SOT [4]. Therefore, the current density dependence of DW speed is investigated when the thickness of the GdFeCo wire was increased to 500 nm. The result is shown in fig. 2. In the GdFeCo wire having the hetero interface with Pt layer, the DW moves to the current direction even if the layer thickness is increased to 500 nm. However, it is hard to think that bulk SOT reaches to 500 nm. Therefore, we prepared GdFeCo wire without Pt hetero interface of the same thickness. This result is also shown in Fig. 2, but the DW moves to the current direction. In this case, SOT does not work because there is no Pt layer. Therefore, it is considered that the DW driving force is only STT. However, the DW moves opposite direction to the STT. We would like to discuss the unusual phenomenon of this current driven DW motion. This work was supported by JSPS Grant-in-Aids for Scientific Research (17H03240, 18K14128) and Research Center for smart energy technology of TTI.

GP-15. Complex Current-driven Spin-Orbit Torque Switching Behaviors In Co/Pt Multilayer-based Synthetic Antiferromagnets. *L. Zhu*[1], X. Xu[1], K. Meng[1], Y. Wu[1], J. Miao[1] and Y. Jiang[1] *1. University of Science and Technology Beijing, School of Materials Science and Engineering, Beijing, China*

Spin-orbit torques (SOTs) switching have been observed in Co/Pt multilayers with strong perpendicular magnetic anisotropy (PMA).[1] In bilayers system made of heavy-nonmagnetic metals (HMs) and ferromagnets (FMs), SOTs are derived from spin Hall effect (SHE) and interfacial Rashba spin-orbit coupling. However, in multilayers, SOTs arise from the global imbalance of the spin currents from the top and bottom interfaces for each Co layer.[1] Moreover, synthetic antiferromagnets (SyAFs) can be switched by SOTs, and the switching mechanism does not obey the usual SOTs switching rule[2] of the macrospin model[3]. Therefore, it is important to clarify the mechanism of SyAFs based SOTs switching. In this work, the film was fabricated by magnetron sputtering and patterned into a Hall bar using electron beam lithography (EBL) and an Ar ion milling technique. Then, the magnetism test and electrical measurement were taken to analyze the properties. Figure 1 presents the normalized magnetization curve (M/Ms) and the Hall resistance curve (RAHE) as a function of the out-of-plane magnetic field. It is obvious that both of the M-H and R-H loops indicate an antiferromagnetic (AFM) interlayer coupling as well as a strong PMA in the multilayer structure. As shown in Fig. 2, the magnetization can be switched with a pulse current and the orientation depends on the direction of the external field. Moreover, the anomalous switching behavior is also shown in Fig. 2. The switching orientation changes again with a larger in-plane external field. The anomalous switching behavior indicates the different switching mechanism in SyAFs. The total thickness of magnetic layer Co in our film is up to 3.2 nm, which is much thicker than previous reports, which is meaningful for real application in spintronics devices.

GP-16. Orbital Anisotropic Magnetoresistance. *H. Ko*[1], H. Park[1], G. Go[2], J. Oh[2], K. Kim[3] and K. Lee[1,2] *1. KU-KIST Graduate School of Converging Science and Technology, Korea University, Seoul, The Republic of Korea; 2. Department of Materials Science and Engineering, Korea University, Seoul, The Republic of Korea; 3. Center for Spintronics, Korea Institute of Science and Technology, Seoul, The Republic of Korea*

The spin-orbit interaction has enriched the field of spintronics through various phenomena such as the interconversion between charge and spin currents, the dependence of electrical resistance on the direction of magnetization, and so forth. Among these effects, recent studies[1,2] clarified the origin of intrinsic spin Hall effect as the orbital Hall effect which describes the electric-field-induced generation of transverse orbital current. These studies suggest that some features in the spin system are concomitant results of analogous features in the orbital system, demanding thorough research on the orbital origin of spin-related phenomena. In this work, we investigate the longitudinal orbital currents in ferromagnets (FMs) based on first-principles calculation. The longitudinal orbital currents depend on the direction of magnetization due to the effective correlation between the orbital and magnetization via concerted action of spin-orbit interaction and exchange interaction. This anisotropic behavior of orbital currents contributes to the anisotropic magnetoresistance (AMR), which we call the *orbital anisotropic magnetoresistance* (OAMR). The OAMR arises from two universal characteristics of the multi-orbital systems, the orbital hybridization and the anisotropic orbital splitting where the latter was previously unveiled as the origin of ballistic AMR[3]. We illustrate the significance of orbital

hybridization as the newly found origin of AMR and also as the common origin of OAMR and orbital Hall effect[1,2], implying the correlation between AMR and intrinsic spin Hall effect. We also predict that the OAMR appears even in non-magnetic metals through the Zeeman coupling.

GP-17. ANE and SOT effective fields in (Fe_4N, Mn_4N)/NM bilayers characterized by using harmonic Hall voltage measurements. *S. Isogami*[1] *1. Research Center for Magnetic and Spintronic Materials, National Institute for Materials Science, Tsukuba, Japan*

Spin-orbit torque (SOT) based magnetization switching is attracting great interest owing to its potential highly efficient magnetic random access memories. The SOT, originating from angular momentum transfer process from nonmagnetic (NM) to ferromagnetic (FM) layers in NM/FM bilayer systems, are strongly dependent not only on the NM but also the adjacent FM layers [1,2]. In this study, we have studied current induced SOT effective fields for the bilayer systems with nitrides such as (Fe_4N : ferromagnet, Mn_4N : ferrimagnet)/NM, where the NM = Pt and/or W. Note that the sign of spin polarization of density of state for the present Fe_4N is negative with minority-spin conduction [3], and the possible spin structure of the present Mn_4N is non-colinear order [4]. Using the harmonic-Hall voltage measurements [5], the anomalous Nernst effect (ANE) of the Fe_4N [6] and the SOT effective fields of the Fe_4N and Mn_4N were estimated as functions of measurement temperature (T) and applied fields. The inset of Fig. 1(a) shows one of the present stacking structures and the measurement configuration. Figures 1(a) and 1(b) show the 1st ($V_{1\omega}$) and 2nd ($V_{2\omega}$) harmonic Hall voltage while rotating the angle of magnetization in the film plane, respectively. When the temperature decreased from 300 K to 4 K, signs for both the $V_{1\omega}$ and $V_{2\omega}$ reversed, as shown in Figs. 1(c) and 1(d). The sign reversal can be explained by the additional ANE [6] that decreased with decreasing T, and the resultant damping-like and field-like torque efficiency at 300 K were estimated to be $\xi_{DL} \approx 0.098$ and $\xi_{FL} \approx 0.10$, respectively. The magnitude of ξ_{DL} was comparable to that of Ta/CoFeB systems [7], whereas high ξ_{FL} emerged for the Fe_4N/W system. The results of Mn_4N/Pt and Fe_4N/Pt will be shown and the specific SOT features for the bilayers with nitrides will be discussed.

GP-18. Improvement of the spin-orbit torque efficiency by thermal treatment during the Pt deposition. *W. Kwak*[1], J. Kwon[1], S. Hwang[1] and B. Cho[1] *1. School of Materials Science and Engineering (SMSE), Gwangju Institute of Science and Technology (GIST), Gwangju, The Republic of Korea*

The transfer efficiency of spin-orbit torque (SOT) to a magnetic moment in a ferromagnetic layer is determined by both the interface transparency between ferromagnetic and heavy metal layers and the bulk properties of heavy metal itself. In addition, the conversion efficiency of charge current to spin current is expected to increase as the amount of current, flowing through the interface area, increases, which is observed in the materials of Pt, Ta, and W [1]. Therefore, the SOT efficiency is supposed to be enhanced by using the highly resistive heavy metal as a spin current source. Here, we perform thermal treatment of the Pt layer to induce resistivity change (equivalently, the SOT efficiency). First, a Pt layer is deposited at 500 °C in a vacuum chamber after the buffer layer (Ta) deposition, and then cooled under the vacuum, followed by deposition of Co/Cu/Ta layers on the top surface of Pt. For comparison, the same thermal treatment is also performed after full-stack deposition. The films are patterned to the Hall bar with a width of 10 mm to estimate the transferred SOT by the harmonic measurement. Figure 1 shows the second harmonic voltage as a function of azimuthal angle with a field of 3000 Oe being applied along the Hall bar for the film of thermal annealing during Pt-deposition. From the data analysis, the resistivity of Pt is found to increase from 28.8 μΩcm to 81.81 μΩcm and the Slonczewski-like effective field to increase from 4.3 Oe/10^{11} Am^{-2} to 14.56 Oe/10^{11} Am^{-2}, indicating the enhancement of SOT efficiency. On the other hand, no significant change is observed for the film of full-stack annealing. We believe that our results provide an efficient way to improve the effective spin-Hall angle for current-driven spintronic devices.

Bordeaux / CNRS, LOMA, Bordeaux, France*

In ferromagnet/(non-magnet)/superconductor (F/(N)/S) heterostructures, suppression of superconductivity can be partially lifted when different directions of the short-range exchange field are sampled simultaneously by a Cooper pair. Partial recovery of superconducting critical temperature (DTc/Tc) is therefore expected for a multi-domain state [1]. Observation of the effect requires adjustment of a broad set of parameters: the superconducting coherence length (XsiS) vs. the layers' thicknesses (tS, tN, tF) vs. the domain and domain wall sizes (D, d). Long-range dipolar interactions further alter the recovery. For multilayers with out-of-plane anisotropy, (Pt/Co)/Nb, maximum recovery of DTc/Tc ~1% have been reported [2], preventing investigation of the influence of the magnetic configuration. In this work, we present series of experimental results for F/S (Pt/Co)/NbN and F/antiferromagnetic-metal(AF)/S (Pt/Co)/IrMn/NbN heterostructures. We created domains in the F and in the AF [3] and varied the configurations from multi- to single-domain, controlling the density of domain walls. Nitrogen-vacancy single spin magnetometry was used in search for revealing the AF configuration [4]. Electrical measurements (resistance versus temperature) across the normal-superconductor transition were performed. The AF was found fully transparent. By tuning the various parameters into play (XsiS, tS, tAF, tF, D, and d), we obtained up to a tenfold improvement of DTc/Tc (~10%), opening the pathway for novel investigations. In particular, a gradual enhancement of DTc/Tc with the density of F domain walls could be observed. Experimental data were compared to numerical calculations based on the Usadel formalism, and encompassing the main features of the phenomenon [5].

GQ-02. Exchange Bias Effects in $Mn_2Ni_{1+x}Ga_{1-x}$ Alloys. *S. Biswas*[1], T. Schaeffer[1] and M. Khan[1] *1. Physics, Miami University, Oxford, OH, United States*

A group of Mn-rich Heusler alloys exhibit the exchange bias (EB) effect, [i], [ii], [iii] a phenomenon discovered in 1956 by Meiklejohn and Bean and is signified by a shift of the magnetic hysteresis loop along the magnetic field axis. [iv], [v] The effect is of great interest both due to its fundamental aspects[vi] and its application in technologies including spin valves, magnetic recording read heads, and giant magnetoresistive sensors.[vii], [viii] The EB effect in Heusler alloys are attributed to the coexisting ferromagnetic (FM) and antiferromagnetic (AFM) interactions in the materials. Mn_2NiGa is a Heusler alloy where the Mn moments show both parallel and anti-parallel alignments. However, the material does not exhibit any EB effect. It is interesting to manipulate the magnetic interactions in this material and explore if EB can be induced in the system by stoichiometry variation. Therefore, we have systematically investigated the magnetic and EB properties of $Mn_2Ni_{1+x}Ga_{1-x}$ ($0 \leqq x \leqq 0.65$). The samples were fabricated by arc melting and annealing techniques. For $x \leqq 0.20$ no EB was observed in the $Mn_2Ni_{1+x}Ga_{1-x}$ materials (Fig. 1). As x exceeded 0.20, EB started appearing in the materials. An EB field of as large as 4000 Oe and coercive field of more than 10 kOe were observed in the materials (Fig. 2). For selected compositions, the effect of annealing temperatures on the EB properties were also investigated. The structural and magnetic properties of all the $Mn_2Ni_{1+x}Ga_{1-x}$ materials will be presented and discussed.

GQ-03. X-ray resonant magnetic reflectometry (XRMR) study of the interface between ferromagnetic transition metals and MgO. *S.E. Ilse*[1], D.B. Boltje[1,2], G. Schütz[1] and E. Goering[1] *1. Modern Magnetic Systems, Max Planck Institute for Intelligent Systems, Stuttgart, Germany; 2. Delmic BV, Delft, Netherlands*

Multilayer systems of ferromagnetic transition metals and MgO attract a lot of attention in the last years because of their application in STT-MRAMs. Especially the interface between the magnetic transition metal and MgO is of interest since the chemical and magnetic properties at this interface are important for the performance of STT-MRAM cells. Because those properties determine for example the strength of the interfacial perpendicular magnetic anisotropy and the thickness of possible magnetic dead layers [1]. With our own reflectometer dedicated to (soft-) x-ray resonant magnetic reflectometry (XRMR) we are able to study such multilayer systems and determine the chemical and magnetic properties at the interfaces [2]. With XRMR we combine the advantages of reflectometry and X-ray magnetic circular dichroism (XMCD). Thus, we are able to determine element specific chemical and magnetic depth profiles. And since, XRMR is particular sensitive to interfaces the element specific roughness of each layer can be determined as well [3,4]. To determine those depth profiles we simulate XRMR measurements using ReMagX [3-5] and fit the simulations to match actual measurements. We performed X-ray absorption spectroscopy (XAS), XMCD and XRMR measurements on Ta|CoFeB|MgO|Al2O3|Au stacks. With off-resonant reflectometry measurements at different energies, we determined the chemical depth profile, which revealed a pronounced roughness at the Ta|CoFeB interface and that especially Fe intermixes largely with other species at the interfaces. Resonant magnetic reflectometry measurements at the Cobalt and Iron L3 edge enabled us to determine the magnetic depth profile, which revealed a 10 Å and a 4 Å thick magnetic dead layer for Fe and Co, respectively, at the CoFeB|MgO interface.

GQ-04. Investigation of the interlayer thickness dependent variation of saturation magnetization in Co/RuFe/Co multilayer systems using XMCD. *F. Schulz*[1], Z. Nunn[2], E. Girt[1] and E. Goering[2] *1. Modern Magnetic Systems, Max-Planck-Institute for Intelligent Systems, Stuttgart, Germany; 2. Department of Physics, Simon Fraser University, Burnaby, BC, Canada*

The effect of interlayer exchange coupling in magnetic thin films has proven to be of great technological use, enabling the development of hard drives with very high storage densities [1-3]. And yet, there are aspects of this effect that are still not fully understood. Recent studies have found that the interlayer thickness of Co/RuFe/Co sandwiches does not only affect the type of interlayer coupling and its strength, but also causes a non-monotonous variation of the saturation magnetization of these systems [4]. In order to investigate this effect, X-ray absorption spectra have been measured in total electron yield, mainly at the L_2 and L_3 edges of Fe and Co respectively. Making use of the X-ray magnetic circular dichroism (XMCD) effect, this gives an element specific method of measuring the magnetic properties of the samples. By applying the sum rules [5-7], it was possible to determine the magnetic moment per atom coming from Co and Fe respectively. Additionally, magnetometric measurements have been performed using a superconducting quantum interference device (SQUID), which were combined with simulations using an enhanced Stoner-Wohlfarth model. With these methods, it could be shown that the change in saturation magnetization does not stem from the magnetic contribution of the Fe in the interlayer, but instead can be attributed to a non-magnetic dead layer of Co near the

interface of Co and RuFe. The thickness of this dead layer was estimated using a model that incorporates electron damping, as well as self absorption effects, to be approximately 0.1 nm. In this model, an effective electron mean free path is used to calculate the damping of electrons from buried layers.

GQ-05. Comparison on phase component and exchange bias in sputtered CoFe/MnN and MnN/CoFe polycrystalline films. *H.W. Chang*[1], Y. Chien[2], F. Yuan[3], Y. Lai[2], C.R. Wang[2], L. Horng[4] and C. Ouyang[5] *1. Department of Physics, National Chung Cheng University, Chia-Yi, Taiwan; 2. Department of Applied Physics, Tunghai University, Taichung, Taiwan; 3. iSentek Inc. Advanced Sensor Laboratory, Taipei, Taiwan; 4. Department of Physics, National Changhua University of Education, Changhua, Taiwan; 5. National Tsing Hua University, Hsinchu, Taiwan*

Exchange bias (EB), characterized by a shift of hysteresis loop originated from the interaction between the ferromagnetic (FM) and antiferromagnetic (AF) layers, could be a foundation for spin-valve (SV) and applied at various advanced spintronic devices. For practical EB system, the main requirements for AF layer include large magnetocrystalline anisotropy (K_{AF}), high Neel temperature, good corrosion resistance, environmental safety and low cost [1]. Recently, MnN is reported to be an excellent antiferromagnetic material to meet the above requirements [1-2]. In this work, CoFe/MnN and MnN/CoFe films with 5-nm-thick CoFe layer and 20-nm-thick MnN layer are prepared on 10-nm-thick Ta underlayer buffered SiO_2/Si(100) substrates at RT by magnetron sputtering at the external magnetic field of 350 Oe induced by the NdFeB sintered magnet. Magnetic properties and phase constitution of both MnN/CoFe (MnN at top of bilayer) and CoFe/MnN films (MnN at bottom of bilayer) bilayers with various annealing temperatures (T = 300-450 °C) during the external magnetic field of 1.5 kOe are compared. The experimental results show that EB field (H_E) of the studied films is highly related to phase constitution of AF layer. The increase of H_E with T possibly results from the improvement of magnetocrystalline anisotropy of AF related to the promoted crystallinity and stress release of θ-MnN phase with T. The reduction of H_E is due to the decreased volume fraction or disappearance of θ-MnN phase and the formation of impurity phases, such as Mn_4N and Mn. The induction of impurity phases is possibly related to the diffusion of part of N out of MnN phase at higher T. Higher H_E for CoFe/MnN than MnN/CoFe at T = 300-375 °C might be attributed to larger amount and higher degree of stress release for θ-MnN phase. In this study, the highest H_E=560 Oe is attained for CoFe/MnN film annealed at T = 350 °C. Finally, high interfacial exchange energy of 0.47 mJ/m² attained for CoFe/MnN films in this study is comparable to the literature (0.41 mJ/m²)[1]. Microstructure and interfacial morphology of the above films with T are also discussed. This study provides useful information to fabricate EB system with θ-MnN as an AF layer.

GQ-06. Magnetic Domain Wall Pinning at a Ferromagnet-Antiferromagnet Interface. *R.A. Khan*[1], T.R. Forrest[2], S.S. Dhesi[2], M. Ali[1], B. Hickey[1], C.H. Marrows[1] and T. Moore[1] *1. School of Physics and Astronomy, University of Leeds, Leeds, United Kingdom; 2. Diamond Light Source, Didcot, United Kingdom*

We sputter-deposited polycrystalline multilayers of Pt(2 nm)/Co(1 nm)/IrMn(t_{IrMn}) and Pt(2 nm)/Co(0.6 nm)/FeMn(t_{FeMn}) exhibiting perpendicular exchange bias (EB) [1]. These multilayers are of interest because of the coincidence of the Dzyaloshinskii-Moriya interaction [2, 3] with a vertical exchange field that could remove the need for an externally applied field to stabilise skyrmions [4]. We measured the EB as a function of the layer thickness of the antiferromagnetic (AFM) layers, IrMn and FeMn. Utilising Kerr microscopy and XMCD-PEEM imaging, the domain morphology of the ferromagnetic (FM) Co layer was studied when crossing over the paramagnetic to AFM phase transition of the neighbouring AFM layer. The domain texture is influenced by the FM-AFM exchange coupling. In the presence of EB, an initially smooth domain wall (DW) becomes rough when displaced by a field (Fig. 1). In the absence of EB, the DW remains smooth after displacement by a field (not shown). Meanwhile, a DW in a sample cooled from the paramagnetic phase (no EB) to the AFM phase (EB) maintains its smooth appearance if not displaced (Fig. 2). The different phases of the AFM layer were confirmed by identifying [5] the Néel and the blocking temperatures by performing temperature dependent magnetometry. These results indicate that the pinning experienced by a DW passing through the Co layer originates predominantly from the microstructure and magnetism at the interface with the AFM.

GQ-07. The effect of x-ray illumination on magnetic domain memory in [Co/Pd] / IrMn multilayers. *C.S. Walker*[1], M. Parkes[1], D. Keavney[2], E. Fullerton[3] and K. Chesnel[1] *1. Department of Physics & Astronomy, Brigham Young University, Provo, UT, United States; 2. Advanced Photon Source, Argonne National Laboratory, Lemont, IL, United States; 3. Center for Memory and Recording Research, UCSD, San Diego, CA, United States*

We are studying the effect that illumination by coherent x-rays may have on magnetic domain memory (MDM) in a [Co / Pd] / IrMn multilayers [1-3]. MDM is the ability of the magnetic domains to retain their exact same domain topology upon field cycling. Earlier studies have suggested that under higher dose of x-ray illumination, the material may lose its existing MDM. To investigate this potential effect we have used both x-ray resonant magnetic scattering (XRMS) along with magneto-transport measurements [4,5] to track the exchange bias while the sample is illuminated with x-rays, as illustrated in Figure 1. Magneto-transport is here used to measure the hysteresis loop of our multilayers material from which we can measure the exchange bias and its possible alteration. A loss of exchange bias would indicate that the x-rays illumination dose may alter the strength of the exchange couplings and ultimately the amount of MDM. Knowing if a loss of exchange bias has occurred requires collecting magneto-transport data as well as XRMS data and correlating the observed changes under various dose of x-ray illumination.

GQ-08. Influence of the magnetic properties of the Ni films through applications of electric field on the ZnO under layer. *C. Yu*[1] and Z. Lin[1] *1. Department of Applied Physics, National University of Kaohsiung, Kaohsiung, Taiwan*

For the bilayers system consisted of a [FM/Oxide] structure, the strain effect imposed on the FM layer induced by the inverse piezoelectric effect of the oxide film was expected. In addition, the heating effect resulted from the leakage current in the oxide film also play an important role. In this study, the magnetic properties of the Ni/ZnO bilayers under the applications of the electric fields were studied. In the virgin state, the Ni/ZnO displayed a unidirectional exchange anisotropy with a $H_c \approx$ 45 Oe and an $H_{ex} \approx$ -70 Oe. The formation of the antiferromagnetically ultrathin NiO between Ni and ZnO was expected. Moreover, in our study, the I-V curve of the ZnO film displayed a diode behaviour. Same as other reports, we observed a leakage current passed through the ZnO layer as applying a reverse bias across the bilayers. Consequently, the coercivity of the Ni films was then decreased due to the heating effect as the leakage current density > 5.1×10^4 A/m^2. In the experiments of the reverse bias modulation, the MOKE intensity can be modulated under the application of a high voltage (-8V). And the variation of the MOKE intensity directly correlated to the current flowed through the bilayers structure. On the other hand, in the case of the froward bias with a lower leakage current < 1.25×10^4 A/m^2, instead of the coercivity, the decreasing of the exchange field, H_{ex} was observed as shown in Fig. 1. The H_{ex} correlated to the spin structure of the NiO layer. We concluded that the reductions of the H_{ex} was due to the strain effect applied by the ZnO under layer. For the intermediate leakage current, 1.25×10^4 A/m^2< J< 5.1×10^4 A/m^2, the Hc and Hex were decreased as applyng the reverse and forward bias, respectively, as shown in Fig. 2. In the ZnO/Ni bilayers, the current heating and interfacial strain were two factors that influence the H_c and H_{ex} of the system.

GQ-09. Tuning of the coercivity and Kerr Signal of NiFe films by a ZnO(0001) layer. *C. Yu*[1] and H. Ko[1] *1. Department of Applied Physcis, National University of Kaohsiung, Kaohsiung, Taiwan*

The magnetic states of traditional spin electronic devices usually controlled by magnetic fields or small currents. In such devices, the thermal stability must be well controlled. To overcome the thermal disaster, voltage-control magnetic devices composed of a ferroelectric/ferromagnetic bilayer have been developed. In this study, permalloy films with 80 at% of Ni with different thickness (t) were fabricated on ZnO(0001)/highly doped N-type Si(001). The MOKE signals and hysteresis loops of NiFe were measured while the ZnO(0001) layer was subject to an electrical voltage. The piezoelectric constant d_{33} and coercivity of the ZnO(0001) film was characterized by a PFM and has values of 5.0 pm/V and 3.4V, respectively. The lattice constant of ZnO crystal, while application of 10V, changed +/-9.6% and -/+5.2% along c- and a- axes, respectively, in the case of constant volume. The threshold voltage for the reduction of coercivity (Hc) is 2.2V, 2.7 and 5.1V for t= 10, 30 and 50nm, respectively, as shown in Fig.1. And a monotonic reduction of the Hc and Kerr signal of the NiFe films was observed no matter what polarity of the electric field was. While applying 10V across the ZnO layer, the reduction ratios of the Hc (/ Kerr signal) were 64%, 12% and43% (/ 0.5mV, mV and 0.4mV) for t=10nm, 30nm and 50nm, respectively. It is clear that the strain field stored in the NiFe layer fade away as t getting larger. Fig. 2(a) showed the variation of the Kerr signal of the 30-nm-thick NiFe under a 0-10V voltage modulation. Fig. 2(b) is the variation of the peak-to-peak MOKE intensity under different voltages and periods. These phenomena can be attributed to the lattice stress of the ZnO imposed on the NiFe layer and reversed in a range of ±10V. Therefore, modulations of the values of Kerr signal and Hc of the NiFe films through application of voltage were successfully demonstrated.

GQ-10. The Role of Boron on Exchange Coupling in NiFe/$Ru_{1-x}B_x$/FeCo Trilayer Structures. *T.J. McKinnon*[1] and E. Girt[1] *1. Physics, Simon Fraser University, Burnaby, BC, Canada*

In our previous work, we found that coupling in FeCoB/Ru/FeCoB changes from antiferromagnetic to ferromagnetic after annealing above 200 ^{0}C for Ru spacer layer thicknesses below 0.5 nm. [1] This strong effect of annealing on the interlayer exchange coupling was not observed in structures having ferromagnetic layers without B coupled across a spacer layer. To understand the role of B on the interlayer exchange coupling, we studied the coupling in (111) textured NiFe(6 nm)/$Ru_{1-x}B_x$(*d*)/FeCo(4 nm) as a function of B concentration in Ru, x, and spacer layer thickness, *d*. These films were deposited at room temperature and ferromagnetic resonance and vibrating sample measurements were used to measure the coupling in as-deposited and annealed samples. It was found that in as deposited samples the sign and strength of coupling is not affected significantly for up to 15 at. % of B in Ru as shown in Fig.1. This indicates that the presence of only B in Ru is not responsible for the change in coupling in FeCoB/Ru/FeCoB after annealing [1]. Next, we annealed the samples at 250 C. For samples with boron in the spacer layer, this resulted in a strong ferromagnetic coupling for spacer layers thinner than approximately 0.5 nm, which is the same that was observed in annealed samples. These measurements are shown in Fig.2. By measuring the samples with high resolution energy-dispersive x-ray spectroscopy (EDX) and x-ray diffraction (XRD), we have determined that the presence of B within the Ru spacer layer enhances the diffusion of Fe into the Ru spacer layer. This is likely the cause of the change in coupling from antiferromagnetic to ferromagnetic that we observed.

GQ-11. New magnetic phases of thin terbium (Tb) films. *F.H. Sales*[1], A.S. Carriço[2] and A.L. Dantas[3] *1. Department of Physics, Federal Institute of Maranhão (IFMA), São Luís, Brazil; 2. Department of Physics, Federal University of Rio Grande do Norte, Natal, Brazil; 3. Departament of Physics, University of State of Rio Grande do Norte, Natal, Brazil*

In recent years a considerable research effort has been dedicated to investigate the impact of confinement and surface effects on the equilibrium phases and excitations of magnetic systems with size comparable to fundamental magnetic lengths [1-3]. Confinement effects are particularly interesting in magnetic systems in which the leading bulk magnetic phases consist of patterns made of a periodical repetition of units containing a finite number of spins. This is the case of the helical structure of rare earth metals, and the helix period might be a valuable length scale to predict the impact of finite size effects [4-6]. We report model calculations of the magnetic phases of thin terbium (Tb) films in the temperature (T) interval between 220K and 280K, and external magnetic field (H) strength up to 300Oe. We show that size and surface effects may produce relevant changes in the magnetic phases such as the presence of phases of alternate double helix (Figure 1) and deformed helix (Figure 2). Surface effects originate in the break of the exchange energy balance near the surface, and confinement effects are stronger for film thicknesses of the order of the period of the helix.

In this investigation, we are working toward creating a heterogeneous structure with zero total magnetization while possessing a net spin by developing a multilayer structure composed of Fe and NdFeB thin films on silicon substrate. Samples were prepared by DC magnetron sputtering in a high vacuum chamber. To improve the quality of multilayer thin films, nanocrystalline growth of metal compound NdFeB was achieved using a house-made vacuum compatible heater made by paralleled filaments covered with ceramic materials. Samples were heated in situ at different temperatures. It is shown that a suitable thickness of the wetting layer can reduce the roughness of the films and also prevent NdFeB from oxidization. Characterizations of samples were done with X-ray diffraction (XRD) and Vibrating Sample Magnetometer (VSM) and results indicate that the crystal structure shows dependence upon in situ heater temperature. Ferromagnetic thin films of rare earth NdFeB and transition metal Fe were separated by a non-magnetic layer (Ti). We fabricated a series of samples with different spacer layer thickness in order to study the exchange coupling between NdFeB and Fe layers. Experiments indicating that as the thickness of spacer layer changes, the magnetic coupling switches from ferromagnetic coupling to antiferromagnetic coupling.

GQ-13. Improving Exchange Bias via Oblique Incidence Deposition.
T. Gurieva[1], K. Schlage[1], L. Bocklage[1,2], S. Willing[1], M. Ramin Moayed[1] and R. Röhlsberger[1,2] *1. Photon Science, Deutsche Elektronen-Synchrotron (DESY), Hamburg, Germany; 2. The Hamburg Center for Ultrafast Imaging, Hamburg, Germany*

Exchange bias (EB) layer structures consisting of an antiferromagnetic (AFM) and a ferromagnetic (FM) material have been in the focus of intense research for decades due to their high technical relevance for the realization of thin film reference magnetizations, e.g. in magnetoresistive sensor systems of type TMR or GMR. The pressing requirement for these sensors to be increasingly robust against external magnetic stray fields, for example in automotive applications, causes the need for continuous improvement of this unidirectional AFM/FM interface pinning. Various approaches are tested to improve EB, most of them are based on a chemical or crystalline modification of the layer structure. Here we show that a small variation in the thin film deposition process without a change of chemical composition can lead to a significant improvement of the EB pinning. Deposition of the AFM layer at an oblique incidence at an optimized polar angle θ can lead to higher induced anisotropy energy into the FM layer that enlarges the sensor's possible working regime. The effect, which could be reproduced in different material systems (Fig. 1) will be investigated addressing the EB dependence on the deposition angle θ and the layer thickness of the AFM. Influences on the crystalline layer structure and thermal stability of the EB pinning will be shown. The presented approach to improve EB in polycrystalline layer systems is interesting for both, scientific investigations to identify its origin and limits as well as a convenient approach to significantly improve the stability of a reference magnetization in magnetoresistive sensor systems [1].

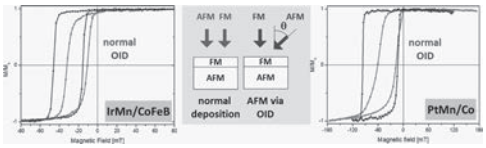

Fig. 1. Effect of oblique incidence deposition on the magnetic pinning in polycrystalline IrMn/CoFeB and PtMn/Co EB layer structures. Red curves show the magnetic behavior of the sample systems deposited at normal incidence, blue curves show the magnetic behavior when the AFM layers are deposited in oblique incidence. The strength of the EB pinning of the FM layers is significantly increased in both cases, quantitatively and qualitatively.

GQ-14. Dehydration Behavior of Hydrated MgO Thin Film Barrier-MTJs.
S. Tigunta[1], N. Valanoor[3], D. Sando[3], Q. Zhang[3] and S. Pojprapai[2] *1. School of Materials Engineering, Suranaree Univerisy of Technology, Muang, Thailand; 2. School of Ceramics Engineering, Suranaree University of Technology, Muang, Thailand; 3. School of Materials Science and Engineering, University of New South Wales, Sydney, NSW, Australia*

Magnesium oxide (MgO) thin film has been used as an insulating thin film layer of magnetic tunneling junctions (MTJs) in hard disk drives (HDDs) read head sensor [1-2]. Since the tunneling magnetoresistance (TMR) value of the MTJs can be enhanced to 600% at room temperature, the sensitivity of the read head sensor of HDDs increases [3-4]. Researchers point out that the crystallographic symmetry, electronic state and the thickness of the barrier are the crucial factors of the extremely high TMR ratio [5-6]. They attempt to control these factors. However, the hygroscopic nature of MgO is a considerate problem. Under normal atmosphere condition, the humidity from the environmental generate surface hydroxyls on their surface [7-8]. This can result in the change of structure, chemical compositions and thickness of the film. Moreover, it could lead to the degradation of MTJs and the performance of HDDs. Therefore, a better understanding of the dehydration reaction of the film is necessary for the further development of the applications of the MgO thin film. In this work, we focused on the investigation of the dehydration behavior under different atmospheres of the hydrated MgO thin film. The MgO thin films with 20 nm thickness were exposed to the humid environment for 24 h. Then, the hydrated films were annealed at various temperatures under either air atmosphere or nitrogen gas atmosphere. The roughness, the thickness and the chemical composition of the films were carried out by using the Atomic Force Microscopy (AFM), X-ray reflectivity (XRR) and X-ray photoelectron spectroscopy (XPS), respectively. The XPS results demonstrate that the MgO thin film forms the hydroxide layer over their surface after being exposed to a humid environment. The AFM results also show that the roughness of the film increases after being exposed to a humid environment. After the annealing process, the roughness of the films decreases with an increasing of annealing temperature. In addition, the XRR results also reveal that the thickness of the MgO thin film after being annealed can be recovered back to be similar to the fresh sample while the most prominent recovery is observed in the sample annealed under argon gas atmosphere.

GQ-15. Magnetization reversal mechanisms of ferromagnetic layers in NiFe/IrMn/NiFe exchange bias thin film structures. *C. Gritsenko*[1], V. Rodionova[1,2] and M. Rivas[3] *1. Institute of Physics, Mathematics and Information Technology, Immanuel Kant Baltic Federal University, Kaliningrad, Russian Federation; 2. National University of Science and Technology MISIS, Moscow, Russian Federation; 3. Departamento de Fisica, Campus de Viesques, Universidad de Oviedo, Gijon, Spain*

The exchange bias thin film structures NiFe/IrMn/NiFe based either on $Ni_{40}Fe_{60}$ or $Ni_{75}Fe_{25}$ alloy, and with different antiferromagnetic layer thickness from 2 to 10 nm were studied. Magnetization reversal mechanisms, exchange bias and coercivity fields were examined in the temperature range from room down do 80K. The ferromagnetic-antiferromagnetic interface morphology was examined by the transmission electron microscopy. Magnetic properties of the samples were studied by vibrating sample magnetometry. The magnetization reversal sequence of the two ferromagnetic layers was found to depend only on the type of NiFe alloy. In the samples with 75% relative content of Ni, the bottom ferromagnetic layers reverse prior to the top one. On the contrary, in the samples with 40% of Ni, the top ferromagnetic layers reverse prior to the bottom one. The obtained results were analyzed in terms of the switching field distribution theory. The magnetization reversal process was simulated using Matlab software. The obtained diversity in magnetization reversal sequence of the ferromagnetic layers was explained to be caused by the morphological difference of the bottom interfaces in the samples of the different types.

GQ-16. Non-collinear coupling materials and mechanism. *Z. Nunn*[1] and E. Girt[1] *1. Simon Fraser University, Burnaby, BC, Canada*

Non-collinear coupling is the relative angle control of two ferromagnetic layers separated by an interlayer. Non-collinear coupling is demonstrated experimentally by mixing a non-magnetic material which provides antiferromagnetic alignment (180°) with a ferromagnetic material which causes ferromagnetic alignment (0°). The coupling angle was found to change from 180° to 0° alignment dependent on the non-magnetic/magnetic ratio of the alloy [1]. For specific interlayer materials such as RuCo and RuFe this 180-0° transition was found to be over a wide concentration range. Fig. 1 shows the concentration, x, range for which a $Co|Ru_{100-x}\ Fe_x$ (0.75 nm)|Co structure has non-collinear alignment. The data was collected by SQUID and room temperature (298 K) as described in the methods of reference [2]. In addition to Co ferromagnetic layers, a variety of materials were found to achieve non-collinear coupling including CoFe, CoFeB, CoNi, Py and Ni. Magnetic polarization of the interlayer plays an important role in non-collinear as the interlayer of RuCo and RuFe were found to have magnetic properties. Additionally, high amounts of magnetically polarisable materials such as Pt and Pd can replace Co or Fe in RuCo or RuFe without drastically affecting the coupling properties. The interlayer mechanism which causes the non-collinear alignment of ferromagnetic layers is a complicated and frustrated system, consisting of multiple known sources leading to a non-collinear alignment of ferromagnetic layers [3][4][5]. Fig.2 shows an atomistic simulation demonstrating non-collinear coupling of ferromagnetic layers across an interlayer. This interlayer has random atom placement of magnetic and non-magnetic materials which creates sub 2 nm spatial fluctuations of ferromagnetic and antiferromagnetic coupling across the films surface. These fluctuations are the leading cause of non-collinear coupling in our structures. In addition of spatial fluctuations, the direct exchange coupling of the randomly placed atoms were also found to contribute to non-collinear coupling of the surrounding feromagnetic layers.

GR-01. Interlayer Coupling of Nano Circular $L1_0$-MnGa/ Cr/ $D0_{22}$-Mn_3Ga Tri-layered Dots Array. *Y. Kikuchi*[1], T. Shima[1] and M. Doi[1] *1. Graduate School of Engineering, Tohoku Gakuin University, Tagajo, Japan*

A lot of studies of Mn-Ga thin films have been performed, however, there are few reports about the Mn-Ga thin film in submicron scale. In this study, Mn_xGa circular dot arrays have been microfabricated and a relation between the magnetic properties and the diameter of the dots have been investigated in order to obtain the design guide line of new high-performance magnetic thin film material for multilevel ultra high-density magnetic recording[1)-3)]. The Mn_xGa thin films were prepared by alternate deposition method. The single layer thin films and multilayered thin films were grown on an MgO (100) single crystal substrate using by the ultrahigh vacuum multiple sputtering system. A Cr buffer layer was deposited, and then, Mn and MnGa layers were stacked alternately. The number n was fixed as 10 and 20, whereas the magnetic layer thickness was fixed at 20 nm. Substrate temperature during deposition of this magnetic layer was 150 and 200 °C. The MnGa circular dots were microfabricated from the continuous films through the electron beam lithography and an Ar ion milling. The diameter of the circular dots (D) was varied from 0.1 to 2.0 μm$^{\Phi}$. The crystalline structure of the films was characterized by the X-ray diffraction (XRD). The magnetic properties of the films and the dots were characterized by the super conducting quantum interference device magnetometer (SQUID), and the polar magneto optical Kerr effect (μ-MOKE). Surface roughness of the thin films and shape of the dots was confirmed by the atomic force microscope (AFM). The K_u was approximately 14 Merg/ ccfor the multilayered thin film with t_{Cr}= 5 to 20 nm, and15Merg/ ccfor t_{Cr}= 10 nm. A remarkable step was clearly observed in the third quadrant of the magnetization curve with the out-of-plane field for the film with t_{Cr}= 10 to 20 nm, which indicates the individual magnetization reversal of the top and bottom MnGa layers. It was confirmed that the values of coercivity were comparable between $L1_0$-MnGa and $D0_{22}$-Mn_3Ga at D= 0.2 μm$^{\Phi}$. Coercivity with smaller particle size less than D= 0.1μm$^{\Phi}$ will be discussed at the conference.

GR-02. (001)-textured MnGa ultrathin films grown on thermally oxidized Si substrate using CoGa buffer layer. Y. Miwa[1], *D. Oshima*[2], T. Kato[1] and S. Iwata[2] *1. Department of Electronics, Nagoya University, Nagoya, Japan; 2. Institute of Materials and Systems for Sustainability, Nagoya University, Nagoya, Japan*

Ion irradiation technique is quite useful to realize low-cost bit patterned media (BPM) with an extremely flat surface. We have previously reported that (001)-textured MnGa films were fabricated by optimizing the growth condition of the buffer layer of Cr(20 nm) / MgO(20 nm) / CrB(5 nm) / NiTa(25 nm) on thermally oxidized Si substrates, achieving low-cost fabrication of the ion-irradiation BPM [1]. Recently, it was reported that CoGa buffer layers were effective to grow (001)-textured MnGa films even with the thickness < 5 nm [2]. Since thinner MnGa films are better for realizing high-density BPM [3], we investigated the growth of (001)-textured ultrathin MnGa films by depositing the CoGa layer on the optimized buffer layer. The stack was Cr(2 nm) / MnGa(5 nm) / CoGa(30 nm) / Cr(20 nm) / MgO(20 nm) / CrB(5 nm) / NiTa(25 nm) / SiO_2(500 nm) / Si substrate. The MgO layer was deposited by e-beam evaporation and others by RF magnetron sputtering. After the deposition of Cr buffer layer, the sample was annealed at 800 °C for 1 h. Then, the CoGa layer was deposited at T_s and post-annealed at T_a for 30 min. The MnGa layer was grown on the buffer layer at 200 °C and annealed at 400 °C for 1 h. Since T_s dependence of the saturation magnetization M_s of MnGa films showed that M_s took a maximum when the CoGa layer was grown on T_s = 400 °C, T_s was fixed to be 400 °C. Fig. 1 shows out-of-plane and in-plane M-H curves of MnGa films grown on CoGa annealed at T_a = (a) 600 °C and (b) 700 °C, and the M-H curves of the films grown on an MgO substrate are also shown in Fig. 1 (c) as a reference. M_s of 290 emu/cc was obtained when T_a = 700 °C, which was almost the same value as that grown on the MgO substrate. In addition, the slope of the out-of-plane curve became steep for T_a = 700 °C, which implies the improvement of the film quality and the smooth propagation of domain walls inside the film. Thus, it is concluded that high-quality ultrathin MnGa films are obtained by using CoGa buffer layers.

GR-03. Analysis of the Relationship between Error Rate Performances and Grain Size Distributions for Recording Media in Heat Assisted Magnetic Recoding. *H. Saito*[2], S. Uesugi[3] and F. Akagi[1] *1. School of Advanced Engineering, Kogakuin University, Tokyo, Japan; 2. School of Advanced Engineering, Kogakuin University, Tokyo, Japan; 3. Graduate School of Engineering, Kogakuin University, Tokyo, Japan*

In this research, it analyzes reproducing signal waveforms which correspond to any binary recorded data patterns are obtained from the superposing calculation of isolated playback pulses in heat assisted magnetic recording [1]-[3]. Each isolated playback pulse which corresponds to a recorded symbol 1 or 0 is obtained from the average value of several playback signal amplitudes with respect to a normalized recording interval T_b. In evaluating approximate expression for an isolated playback pulse, it considers a given grain size distribution of the recording medium. The head/medium conditions to achieve an areal recording density of 2.5Tb/in^2 using micro-magnetic simulation is assumed. It assumes to present the modeling result by using FePt granular magnetic media. In the recording process, magnetization is calculated by use of the Landau-Lifshitz-Gilbert equation. In calculating this equation, the saturation magnetization, the anisotropic magnetic field and variance of the anisotropy constant are set to 820emu/cm^3, 43.6kOe and 5%,

respectively. The average grain size of the medium and the width of a grain boundary are 4.5nm and 1nm, respectively. The effective recorded magnetic field intensity under the optical spot emitting device is set to about 11kOe in a central axis of a thickness direction of the medium. The reproducing track width is 20.0nm and the standard deviation of a grain size distribution of 15% or below is assumed. Under these conditions, we get the reproducing signal waveform corresponding to the recording pattern which has the repetition period 8 of the symbol 1 or 0 alternately. Fig.1 shows an example of the reproducing signal waveforms. From the given reproducing signal waveform, we derive the approximate formula for the signal waveform corresponding to the symbol 1. Finally, using partial response maximum likelihood equalization for the reproducing signal waveforms, it evaluates the BER performances of the recorded binary data in Fig.2. From Fig.2, it is found that the improvement of the BER performance of the recording scheme is obtained if the grain size distribution of the recording medium sets about 10%.

GR-04. A Study of Detection Scheme for MR Reading of Double Granular Recording Layer. *Y. Nakamura*[1], M. Nishikawa[1], Y. Kanai[2], H. Osawa[1] and Y. Okamoto[1] *1. Ehime University, Matsuyama, Japan; 2. Niigata Institute of Technology, Kashiwazaki, Japan*

In this research, we propose a detection scheme to read double granular recording layer using the magnetoresistive (MR) read-sensor. The granular medium has the grain size fluctuation and it results in the jitter-like medium noise and so on [1]. Essentially, the writing process must be assisted by the microwave magnetic field from the spin torque oscillator (STO) [2]. However, we applied the slope model [1] for each layer for simplification of the writing process in this research. In the reading process, the MR read sensor detects the magnetic stray fields from both recording layers at a time, and the reproducing waveform includes the signals from the both layers, which we call the inter-layer interference (ILI). We define the magnetic spacing between the bottom of reader and the top of upper recording layer as Δ_1 and that of the lower layer as Δ_2. In our previous research shown in [3], we found out that it is difficult to equalize the mixed waveform from the layers to the partial response (PR) signal due to the different magnetic spacing loss. Therefore, in order to compensate the influences of the spread distribution at the equalizer output, we try to increase the number of states in the sequence decoder to estimate the levels due to the ILI in the lump decoding for the first and second layers [3], and evaluate the bit-error rate (BER) performance of the system under the specification of an areal recording density of 4 Tbits/inch^2 per layer. Figure 1 shows the bit-error rate (BER) performances for SNR_S for the system noise [4]. In this figure, the square and triangle symbols show the BER performances by the Viterbi detector [5] for single layer (4 Tbits/inch^2) in the respective cases of Δ_1 = 2.0 nm and Δ_2 = 5.0 nm with the number of decoder states N_s = 2. Furthermore, the circle symbol shows that for double layers (8 Tbits/inch^2) with $N_s = 4^7$. As can be seen from the figure, the lump decoding for the double layer shows the almost same performance as that of single layer for Δ_1 = 2.0 nm. The results show that the lump decoding was effective for the double granular recording layer.

GR-05. Extremely flat surface full granular media with cap layer consists of high-K_u CoPt grains and ferromagnetic oxide grain boundaries. *K. Tham*[1,2], R. Kushibiki[1], T. Kamada[1] and S. Saito[2] *1. Tanaka Kikinzoku Kogyo, Tsukuba, Japan; 2. Electronic Engineering, Tohoku University, Sendai, Japan*

Perpendicular recording media with a granular recording layer (GRL) and a cap layer (CL) have been adopted in the HDD industry. GRL consists of CoPt alloy grains and non-ferromagnetic oxide boundaries. To control intergranular exchange coupling[1)] and switching field[2)] in GRL, various low magnetic anisotropy (K_u) continuous layers such as, Co/Pd multilayers[3)], rare earth (RE) metal alloy layer[4,5)], and CoPtCrB layer[6)] have been proposed for the CLs. However, it is quite challenging to obtain a homogeneous structure in the thickness direction with a continuous CL deposited on the GRL[7)] which leads to inhomogeneous intergranular exchange coupling. To address the issue, we propose a granular CL consists of high K_u CoPt grains and ferromagnetic oxide boundaries. In this study, RE oxides such as Gd_2O_3, Nd_2O_3, Sm_2O_3 and CeO_2 are utilized for the ferromagnetic oxide boundaries materials. Fig. 1 shows M/M_s-H loops of media with (a) CoPt-Gd_2O_3 and (b) (CoPtCr)-10B CLs (9 nm) deposited on CoPt-B_2O_3 GRL (16 nm). M/M_s-H loop of GRL (16 nm) without CL is shown in broken line. Both media show comparable nucleation field and saturation field of 0.9 and 12.5 kOe, respectively, which are better than those of medium without CL. Evaluation of switching field ($\Delta H_c/H_c$)[8)] for media with CL thickness from 9 to 4 nm also shows comparable value from 0.08 to 0.12. This indicates that CoPt-Gd_2O_3

CL is effective to control intergranular exchange coupling and switching field in the GRL. Fig. 2 shows cross section TEM images of media with (a) CoPt-Gd_2O_3 and (b) (CoPtCr)-10B CLs. Focusing on media top surface, the medium with CoPt-Gd_2O_3 CL is extremely flat as compared to that of the medium with (CoPtCr)-10B CL. According to the EDX element analysis, homogeneous structure of magnetic grains and grain boundaries from the GRL to CL can be observed. These results suggest that CoPt- RE oxide CL is promising to realize media with flat surface and comparable magnetic properties with current CL.

GR-06. Dual-structure microwave-assisted magnetic recording using only a STO. *S. Greaves*[1] and W. Saito[1] *1. Tohoku University, Sendai, Japan*

Microwave-assisted magnetic recording is a candidate technology for use in future hard disk drives. Usually the spin torque oscillator (STO) that generates the high frequency (HF) magnetic field that assists magnetisation switching is integrated into a write head. However, it is also possible to switch the magnetisation of a grain deterministically using only the field from the STO [1,2]. In this work we examine switching of a dual structure magnetic dot using only the field from a STO. The dual structure dot consisted of two, discrete recording layers, RL1 and RL2. The 30 nm diameter STO was located above a 20 nm dual structure dot with RL2 closest to the STO. RL1 had an exchange coupled composite structure with a 3 nm hard layer and 2 nm soft layer, whilst RL2 was a 3 nm thick hard layer. A 2 ns field pulse from the STO was applied to the dot and the switching probabilities of RL1 and RL2 were calculated. Fig. 1 shows the switching probabilities of RL1 and RL2 as a function of the STO frequency. The thin lines are the switching probabilities calculated without magnetostatic interactions between RL1 and RL2 whilst the points were calculated with magnetostatic interactions between the two structures. Selective switching of RL1 and RL2 was achieved with switching probabilities greater than 0.9, although it was clear that the magnetostatic interaction was detrimental. Several approaches were examined to improve the performance, such as increasing the pulse length, reducing M_s and tuning the magnetic properties of the structures. Antiferromagnetic exchange coupling can partially compensate for the magnetostatic interaction. In practice, AFC coupling increased the switching probability for some STO frequencies, but decreased it for others. Fig. 2 shows examples of the switching of RL1 and RL2 at different STO frequencies. The magnetisation of the non-target structure was largely unaffected by magnetisation reversal of the target structure.

GR-07. Soft-Information Flipping Scheme Based on a Priori LLRs Summation for Ultra-High Density Magnetic Recording. *W. Busyatras*[2] and C. Warisarn[1] *1. College of Advanced Manufacturing Innovation, King Mongkut's Institute of Technology Ladkrabang, Bankok, Thailand; 2. Rajamangala University of Technology Thanyaburi, Pathum Thani, Thailand*

An inter-track interference (ITI) effect can degade the performance of bit-patterned media recording (BPMR) system [1-2]. Even though the two-dimensional (2D) modulation code can protect the severe ITI [3] which can efficiently improve the overall system performance, it cannot offer performance gain over the conventional system when recording system must encounter with ITI from its sidetracks. Then, the flipping technique [4] is proposed to deal with that ITI sidetrack effect using the normalized soft-information values which can improve the system performance. However, those normalized values are difficult to confirm an optimal threshold value in bit-flipping process. Therefore, this paper proposes a novel of soft-information flipping scheme to deal with mentioned shortcoming which leads to improve the bit-error rate (BER) performance. The relationship between data encoding condition and a priori log-likelihood ratios (LLRs), $\lambda_{k,l}$ obtained from SOVA detectors is utilized to be a criterion for flipping the ambiguous data bits. Here, we first calculate the normalized LLRs, $\lambda'_{k,l}$ of the k^{th} data bit and l^{th} track from $\lambda'_{k,l} = \lambda_{k,l} / \sum\lambda_{k,l}$, where $l \in \{-1,0,1\}$ represents the upper, middle and lower tracks, respectively. These normalized LLRs are compared with the threshold value for

deciding which soft-information bits should be flipped as shown in Fig. 1. Here, the optimal threshold value, α_T is obtained from our investigation which is depended on areal density (AD). For bit-flipping process, we consider only two soft-information patterns that have the sign according with [+ + +] and [- - -] in across track direction. If we found that the normalized LLRs value is less than the optimal threshold value, $\lambda'_{k,l} < \alpha_T$, then the RLL will be flipped in another directions. Simulation results indicate that, at the same user density, the proposed system provides BER performance gain over the conventional uncoded and systems as shown in Fig. 2. Moreover, the BER performance can be more improved especially when the AD is increase and high media fluctuation effect.

GR-08. Stable Oscillation of Spin-Torque Oscillator with Reduced Injected Current Density for Microwave-Assisted Magnetic Recording.

Y. Kanai[1], R. Itagaki[1] and S. Greaves[2] *1. Engineering Dept., Niigata Institute of Technology, Kashiwazaki, Japan; 2. RIEC, Tohoku University, Sendai, Japan*

The spin torque oscillator (STO) is the most important component in a microwave-assisted magnetic recording (MAMR) system [1]. Obtaining stable STO oscillation when the STO is inserted into a write head main pole (MP) – trailing shield (TS) gap is the key to realizing a MAMR system. We have reported that a tilted STO inserted into a non-parallel gap is one solution [2], however, the structure is hard to fabricate. Also, reducing the injected current density, J, in the STO is the key for long-term reliability. In this paper, a micromagnetic model analysis of a STO is performed to realize stable STO oscillation with small J. Fig. 1 shows the arrangement of the STO, write head and double-layered recording medium. The write head had a parallel MP – TS gap. We used a relatively large Gilbert damping factor $\alpha = 0.2$ in the write head, except for the MP – TS gap region ($\alpha = 0.02$), because eddy currents were not explicitly included in the model. The recording layer was assumed to be air. The MP – TS gap = 20 nm to obtain a large head field gradient. The width of the MP trailing edge = 40 nm. The STO should fit into the 20 nm MP – TS gap, therefore, we utilized transmission spin torque [3] as thin soft magnetic layers are relatively easy to fabricate. STO area = 20 nm × 20 nm at MP side. The thickness of the field generation layer (FGL) and spin injection layer (SIL) were 10 nm and 2 nm, respectively. There was a 2 nm thick non-magnetic interlayer (IL) in between the FGL and SIL. $4\pi M_s$ of FGL and SIL was 20 kG and 10 kG, respectively. α of FGL and SIL was 0.02. Anisotropy field H_k of FGL and SIL was 31.4 Oe. In the model we varied the exchange A, H_k and α of FGL and SIL. The results showed that there were optimum values for these parameters, however, they were not relatively critical to reduce J. Next, we varied θ of the write head, as shown in Fig. 1. There was a notable difference for relatively small J (3.0×10^8 A/cm^2) [2] when comparing $\theta = 0°$and 15°as shown in Fig. 2. Varying α in the vicinity of the MP gave significant changes in the FGL rotation at small J.

GS-01. Exploring magnetic resonance with a compass. *D. Nelson*[1], E. Cookson[1], M. Anderson[1], D. McKinney[2] and I. Barsukov[1] *1. Physics and Astronomy, UC Riverside, Riverside, CA, United States; 2. Santa Rosa Academy, Menifee, CA, United States*

Magnetic resonance plays an important role in today's science, engineering, and medical diagnostics. Learning and teaching magnetic resonance is challenging since it requires advanced knowledge of condensed matter physics and quantum mechanics. Driven by the need to popularize this technologically impactful phenomenon, we develop an inexpensive table-top demonstration experiment. It unveils the magnetic resonance of a hand-held compass in the magnetic fields of a permanent magnet. The setup provides an immediate visualization of the underlying physical concepts and allows for their translation to broad student audiences. This work was supported by the National Science Foundation under Grant No. ECCS-1810541.

GS-02. Magnetic Fields Web Series: Engaging Middle School Students in STEM. *P. Pena Martin*[1], J. Isberg[1], E. Ertekin[1,3], V. Lorenz[1,2] and N. Mason[1,2] *1. Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 2. Department of Physics, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 3. Department of Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, United States*

Web based media can make scientific content accessible to audiences far beyond the scientific community. We created a web series called "Magnetic Fields" that aims to introduce materials science, particularly concepts related to magnetism, and promote themes more general to STEM fields, such as persistence and the scientific process, through use of characters and a story geared towards a middle school audience. The goal is to build and maintain interest in science at an age where this tends to drop off. The four-episode arc follows a group of high school characters as they encounter a strange new material during a class field trip to a laboratory. The series is directed by John Isberg, with professional actors making up most of the cast. The series was initiated by scientists in the Illinois MRSEC, and the storyline was developed in collaboration with MRSEC students and faculty. The episodes were released in May 2019 through Youtube. We report on the process of creating this series, response to it upon release, and discussion of its use as an educational tool. The authors acknowledge primary support of the NSF through the University of Illinois at Urbana-Champaign Materials Research Science and Engineering Center DMR-1720633.

GS-03. In-class experiments with smart phones for teaching upper-level electricity and magnetism. A. Davidson[1], A. Ranjan[2] and *X. Fan*[1] *1. Physics and Astronomy, University of Denver, Denver, CO, United States; 2. Cherry Creek High School, Greenwood Village, CO, United States*

Interactive-engagement method such as studio physics [1, 2], has demonstrated higher learning gains than traditional lecturing in intro-level physics classes. However, there have been limited applications in upper-level classes, such as Electricity and Magnetism (E&M), possibly because experiments on E&M topics can be too costly and sophisticated to be carried out in the classroom. Smart phone, which is equipped with magnetic field sensors, radio signal detectors and light sensors, provides a convenient platform for carrying out E&M-related experiments. In this poster, we will present three examples of the implementation of smart-phone-based studio physics in an E&M class for Physics majors: (1) Detection of earth magnetic field inclination; (2) quantifying skin depth of aluminum foil with cellphone tower signals; and (3) Measurement of Brewster's angle. Besides sensitive sensors, smart phone also has computational power, which can be explored to further expand the breadth and depth of the smart-phone-based studio physics. Due to the wide accessibility of smart phones and the simplicity of experimental setup, we expect this teaching technique can be easily transferred to other institutes in the world.

GS-04. The Use of Virtue Modules in Physics Lab Teaching. *W. Zhang*[1], R. Bidthanapally[1], T. Sebastian[2], Y. Xiong[1,3], H. Qu[3] and J. Sklenar[4]
1. Physics Department, Oakland University, Rochester, MI, United States; 2. THATec Innovation GmbH, Mannheim, Germany; 3. Electronic and Computer Engineering, Oakland University, Rochester, MI, United States; 4. Physics Department, Wayne State University, Detroit, MI, United States

Lab sessions in physics education connect the fundamental concepts to practical examples and are effective measures of the students' understanding and reasoning through ultimate real-world tests. Many topics in condensed matter physics are known to be challenging to convey in both lectures and labs. In addition, these topics are usually resource demanding, which has been one of the challenging issues. Here, we introduce and demonstrate the use of virtue lab modules for teaching physics labs and for effectively integrating research and education. Experiments that are relevant to magnetism and spintronics include, but not limited to, spin current detecting, microwave energy harvesting, and spin-based thermoelectric effects. An important highlight of these modules is the highly-interactive laboratory learning platform. In the class, each piece of experimental hardware (e.g. electrometers, oscilloscopes, etc) will be paired with a computer-based virtual module. The individual modules mimic the hardware, which the students can use to become familiar with the hardware, acquire real-time feedback, and visualize the data acquisition dynamics, on-demand and risk-free. The virtual component is also helpful for demonstrating delicate, shared hardware in class, without risk of damaging the actual instrumentation. These individual components are connected to a central operating system and the experiment can be re-programmed by simple coding and user-interfaced commands [1]. Work at Oakland University is supported by NSF DMR-1808892.

GT-01. Structural stability and magnetic properties of the Mn-doped WS_2 thin films in *ab initio* calculations. *M. Kim*[1] and J. Hyun[1] *1. Sookmyung Womens University, Seoul, The Republic of Korea*

Two-dimensional (2D) transition-metal dichacogenides (TMDs) materials possess very interesting semiconducting, metallic, superconducting, and magnetic properties, which have been spurred lots of research in both experiment and theory to realize their advantageous features in, for example, the flexible and transparent electronics device applications. Among these TMDs, the nonmagnetic semiconductor WS_2 is one of the most exciting family of which the magnetic properties by transition metal doping exhibits exotic phenomena [1-4]. In this presentation, we report density functional theory (DFT) calculations on the Mn-doped WS_2 thin films, that is, monolayer and double layers. The spin magnetic moment of Mn-doped WS_2 monolayer is calculated to be 1.00 μ_B, respectively, at 4% impurity concentration in a 5×5 supercell. Upon the extension of the unit cell up to 7×7, we calculated the two Mn doped films to find the energy stability in accordance with the distance, which revealed that the nearest neighboring position on Mn atoms is most stable. Each total magnetic moment and Mn moments are 2.00 and 1.27 μ_B, respectively. We have examined the single as well as the double dopants of Mn in various probable interlayer doping positions using the structural stability and magnetic properties optimization and the formation energy calculations to decide the preferred doping sites as shown in Fig. 1. It was found that the single Mn dopant prefers the direct on-top positions (i) between the W atoms for the AA configuration (as shown in Fig 1(b)) and (ii) between the S and W atoms for the AB configuration (as in Fig 1(d)), to the hollow sites. The magnetic properties are also found to vary depending the configurations. *kimmy@sm.ac.kr **This work was supported by the Basic Science Research Program (No. 2017R1A2B4012972) through the National Research Foundation of Korea(NRF).

NIST Center for Neutron Research, Gaithersburg, MD, United States*

Rare-earth-based compounds have attracted attention of the scientific community as they are paradigms of multiple, often competing, interactions, such as the Ruderman-Kittel-Kasuya-Yoshida (RKKY) magnetic interactions, crystalline electrical field (CEF) effects, Kondo effect and Fermi surface effects. The interplay among these effects are complex and can lead to novel ground states. $CeAuBi_2$ is an example. It belongs to the $REMBi_2$ (RE = rare-earth, M = Cu, Au) family of antiferromagnets with competing magnetic interactions and, for RE = Ce, moderately heavy electrons [1-4]. Moreover, a breakdown of the de Gennes scaling for $CeMBi_2$ and $PrMBi_2$ implicates CEF enhancement of T_N [3, 4]. Furthermore, Au vacancies in some $CeAuBi_2$ materials indicate that disorder may also play an important role in this system [2]. Here we report the electronic and magnetic properties of stoichiometric $CeAuBi_2$ single crystals. $CeAuBi_2$ crystallizes in the tetragonal *P4/nmm* structure and orders antiferromagnetically below T_N = 19 K, the highest value reported for this compound [2, 4, 5]. At low temperatures (2 K) and ambient pressure, the application of magnetic fields parallel to the *c*-axis results in two transitions at 7.2 T and 7.7 T in the magnetoresistance, similar to $CeAuSb_2$ [6]. AC calorimetry and electrical resistivity experiments under pressure reveal that the application of external pressure favors antiferromagnetic order, which reaches a maximum T_N of 21 K at 23 kbar. Finally, neutron magnetic diffraction measurements find a commensurate antiferromagnetic structure with a propagation vector (0 0 1/2) with the magnetic moments aligned along the *c*-axis, similar to $CeCuBi_2$ [1].

GT-03. The Effect of Manganese Substituted Sodium Iron Phosphate Maricite-$NaFe_{1-x}Mn_xPO_4$. *J. Seo*[1], H. Choi[1] and C. Kim[1] *1. Department of Physics, Kookmin University, Seoul, The Republic of Korea*

Transition metal ion substitution in sodium phosphate is effective in enhancing the performance of cathode material. [1] The Mn-doped maricite-$NaFe_{1-x}Mn_xPO_4$ (x = 0.1, 0.2, 0.3, 0.4, 0.5) samples were synthesized by solid-state route. The crystallographic and magnetic properties of the effect Mn substitution were investigated by x-ray diffraction (XRD) measurement, vibrating sample magnetometer (VSM), and Mössbauer spectroscopy. The XRD patterns of $NaFe_{1-x}Mn_xPO_4$ ($0.1 < x < 0.5$) revealed that the structure had orthorhombic structure with space group of *Pmnb*. The lattice parameters and the volume of the $NaFe_{1-x}Mn_xPO_4$ increased from for a_0 = 6.866, b_0 = 8.999, c_0 = 5.047 Å and V = 311.544 Å^3 for x = 0.1, a_0 = 6.881, b_0 = 9.037, c_0 = 5.075 Å and V = 315.418 Å^3 for x = 0.5. The temperature

dependence of the magnetization curves exhibits Néel temperature (T_N) of $NaFe_{1-x}Mn_xPO_4$ decreased with the increasing Mn concentrations from 14 K for x = 0.1 and 10 K for x = 0.5, indicating in weakened antiferromagnetic interaction. The Mössbauer spectra exhibited to have asymmetrical line-shapes below T_N and were fitted with eight Lorentzian lines, due to the strong crystalline field in the distorted $Fe(Mn)O_6$ octahedral site. At room temperature, exhibits a doublet absorption line. The decrease in antiferromagnetic order can be explained by the fact that the Fe-O-Mn interaction is weaker than the interaction of the paramagnetic region.

GT-04. Atomic-layer stacking dependence of the magnetocrystalline anisotropy and Dzyaloshinskii-Moriya interaction in Fe-Co multilayers on MgO. *Y. Kato*[1], A.M. Pradipto[1], T. Akiyama[1], T. Ito[1], T. Oguchi[2], M. Weinert[3] and K. Nakamura[1] *1. Engineering, Mie University, Tsu, Japan; 2. Scientific and Industrial Research, Osaka University, Suita, Japan; 3. Physics, University of Wisconsin-Milwaukee, Milwaukee, WI, United States*

For the next generation of magnetic tunnel junctions, control of the magnetocrystalline anisotropy (MCA) and the Dzyaloshinskii-Moriya interaction (DMI) in thin ferromagnetic films has attracted much attention. A promising approach to deal with such magnetic properties is by tuning the atomic-layer stacking sequences in multilayer thin films [1]. Here, we theoretically investigated the atomic-layer stacking dependence of the MCA and DMI in prototypical Fe-Co multilayer thin films on MgO(001). The generalized gradient approximation calculations were carried out using the film full-potential linearized augmented plane-wave method [2] employing single slabs with six-atomic layers of Co-Fe on MgO(001). The MCA energy is determined as difference in total energy for magnetizations oriented along the in-plane and perpendicular directions with respect to the film plane, and the DMI parameter of the multilayers is estimated from the total energy difference with respect to the spin-spiral wavevectors. The results predict that both MCA and DMI depend significantly on the atomic-layer stacking sequences. MCA energies, ranging from 1.4 [meV/unit-area] (perpendicular magnetization) to -1.5 [eV/unit-area] (in-plane magnetization), depending on the atomic-layer stacking sequences are observed. Similarly, complicated behavior of the DMI parameters versus the atomic-layer stacking sequences is observed, where the magnitude of the DMI parameter interestingly increases by one order of magnitude compared to that of pure Fe films even though the spin-orbit coupling is quite weak. We further analyze these magnetic properties by using cluster expansion and neural network methods in order to elucidated the underlying trends. We find that the MCA is very sensitive to the short-range order in the atomic-layer stacking sequences, whereas an asymmetry in the whole film along the stacking direction may play a role in determining the DMI.

GT-05. Effects of Simultaneous Cd and Ir Doping in Ce_2RhIn_8 Antiferromagnet. *D.S. Christovam*[1], G. Silva Freitas[1], M.M. Piva[1], J.C. Souza[1], J. Leao[2], W.D. Ratcliff[2], J.W. Lynn[2], P. Pagliuso[1] and C. Adriano[1] *1. DEQ, Instituto de Física Gleb Wataghin - Unicamp, Campinas, Brazil; 2. NIST Center for Neutron Research, NIST, Gaithersburg, MD, United States*

Ce_2RhIn_8 is an antiferromagnet (T_N = 2.8 K) that belongs to the family of Ce-based heavy fermion (HF) compounds Ce_mMIn_{3m+2} (*M* = Co, Rh, Ir). This family has been heavily investigated due to its intricate phase diagrams, which display complex magnetism, disordered phases and superconducting states [1,2]. These phase diagrams result from the competition between long-range Ruderman–Kittel–Kasuya–Yosida interaction, local on-site Kondo effect and crystalline electric field (CEF) effects, which have an important role in determining the ground state (GS) and physical properties of the compound [3]. The determination of the magnetic structure of these compounds is very helpful when studying the spin anisotropy of the CEF GS, since the moment direction can relate to its symmetry properties and magnetic anisotropy. The evolution of the physical properties of the $Ce_2Rh_{1-x}Ir_xIn_8$ series and the role of Cd doping in the Ce_2MIn_8 (*M* = Rh, Ir) site have been previously investigated [2,4]. It has been shown that Ir substitution seems to suppress the antiferromagnetism (AFM) and induce a coexisting superconducting phase, as well as a disordered spin-glass phase in the Ir-rich compounds. This evolution is accompanied by an enhancement of the Kondo effect and likely changes in the CEF scheme. On the contrary, Cd doping in Ce_2MIn_8 increases T_N favoring AFM for *M* = Rh and suppresses the superconductivity for *M* = Ir, suggesting that the main role of Cd in these systems is the electronic tuning of the GS, such as for the $CeMIn_5$

compounds [5,6,7]. However, the magnetic structure of these alloys and their CEF scheme remain to be explored in greater detail. In this work, we discuss the magnetic structures of the Cd doped $Ce_2Rh_{0.5}Ir_{0.5}In_8$ antiferromagnetic alloys (T_N = 2.0 K, x = 0 and T_N = 4.2 K, x = 0.21) by neutron magnetic diffraction measurements. The evolution of these magnetic structures will be connected to preliminary studies of the CEF effects using a mean field model with tetragonal CEF and exchange interactions.

Rare earth intermetallic compounds present an intriguing interplay between the Crystalline Electrical Field (CEF), the Kondo effect and the Ruderman-Kittel-Kasuya-Yoshida (RKKY) magnetic interaction. These competing effects provide an interesting playground for the scientific community, often resulting in non-trivial ground states. In particular, the $CeCuBi_{2-x}Sb_x$ series presents antiferromagnetic ordering (3.7 K T_N 16.0 K) with an interesting evolution of the Ce^{3+} (J = 5/2) magnetic anisotropy along the series. The compound with x = 0 [1] presents a large magnetic anisotropy with the easy magnetization axis along the *c*-axis with is strongly suppressed along with T_N by Sb-substitution up to x = 0.25. At higher Sb-concentration, for x = 0.6, the magnetization easy direction rotates towards the *ab*-plane and T_N and the magnetic anisotropy starts to slightly increase as a function of Sb-concentration (x = 1 and 2). This evolution is governed by CEF effects and their changes as a function of Sb-substitution. Inelastic neutron scattering (INS) experiments were performed on single crystals of $CeCuBi_{2-x}Sb_x$ grown by the metallic self-flux technique to directly probe the CEF levels and their evolution as a function of Sb-substitution. These results will be presented and analyzed along with the macroscopic magnetic properties of these compounds to shed light on the interesting evolution of the magnetic properties of these compounds along the series.

GT-07. Interconfigurational fluctuation valence in putative topological Kondo Lattice Gd^{3+}-doped SmB_6. *J.C. Souza*[1,2], M. Carlone[3], P. Venegas[3], P. Ferrari Silveira Rosa[4], J. Sichelschmidt[2], P.E. Menegasso[1], R.R. Urbano[1], Z. Fisk[5], P. Pagliuso[1] and C. Rettori[1,6] *1. Institute of Physics Gleb Wataghin, Unicamp, Campinas, Brazil; 2. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 3. Faculdade de Ciências, UNESP, Bauru, Brazil; 4. Los Alamos National Laboratory, Los Alamos, NM, United States; 5. University of California Irvine, Irvine, CA, United States; 6. UFABC, Santo Andre, Brazil*

SmB_6 is an intermediate valence (IV) 4*f* Kondo lattice insulator with an estimated indirect semiconducting gap of $\Delta \approx 50$ K [1] which has been predicted to host nontrivial topological surface states [2]. Coherent hybridization between the Sm *4f* states and the *5d* conduction band is presumable responsible for the opening of this small gap at low temperatures [3]. Previous electron spin resonance (ESR) measurements attributed the ESR spectra in $Sm_{1-x}Gd_xB_6$ at $T \leq 10$ K to Gd^{2+} ions [4]. In this work we show that, for $T \leq$ 4 K and low enough Gd concentrations ($Sm_{1-x}Gd_xB_6$; $x \leq 0.0005$), the fine structure observed in the Gd^{3+} ESR spectra can be unambiguously simulated by a cubic crystal field and, therefore, attributed to Gd^{3+} ions located at insulating cubic sites, i.e., substituting Sm IV ions. Nevertheless, as T increases above ~ 4 K, the resonances of the Gd^{3+} ESR spectra broadens and above $T \approx 10$ K show a single resonance with an exponential line broadening, leading to an activation energy of the order of the hybridization gap, i.e., $\Delta \approx 50$ K. Based on the Interconfigurational Fluctuation model [5], the fluctuation between the $4f^n$ and $4f^{n+1}$ configurations of Sm ions provokes a fluctuating field at the Gd^{3+} site. Thus, the exchange interaction between the localized magnetic moment of Gd^{3+} and the IV Sm ions leads to a relaxation with an exponential dependence on the excitation energy of the IV ions, E_{ex} which is, notably, of the order of the hybridization gap Δ [6].

GT-08. Electron spin resonance in the non-symmorphic antiferromagnetic $Eu_5In_2Sb_6$. *J.C. Souza*[1], S.M. Thomas[2], E. Bauer[2], J. Thompson[2], F. Ronning[2], P. Pagliuso[1] and P. Ferrari Silveira Rosa[2] *1. Institute of Physics Gleb Wataghin, Unicamp, Campinas, Brazil; 2. Los Alamos National Laboratory, Los Alamos, NM, United States*

The search for topological phases protected by crystal symmetries has brought attention to non-symmorphic materials, which could host topologically nontrivial surface fermions displaying hourglass dispersion [1]. $Eu_5In_2Sb_6$ crystallizes in the non-symmorphic space group *Pbam* [2] and exhibits a colossal magnetoresistance, which might be caused by magnetic polarons. In this work, we perform electron spin resonance in the non-symmorphic antiferromagnet $Eu_5In_2Sb_6$ in the temperature range of 15 K < T < 300 K for different microwave frequencies (ν = 9.4 and 33 GHz). We observe a systematic decrease of the Eu^{2+} ESR line-width as a function of microwave frequency, which indicates a field-dependent relaxation mechanism driven by magnetic polarons, similar to previous reports in EuB_6 [3]. In addition, the Eu^{2+} g-value and ESR line-width show two distinct anisotropies when the applied magnetic field is rotated in the *ac* plane. We will discuss these anisotropies in light of a possible anisotropy in the resistivity and/or in the internal field at the Eu^{2+} site due to the magnetic structure of the compound.

GT-09. Magnetic and structural transitions in $EuAg_4As_2$ studied using ^{151}Eu Mössbauer spectroscopy. *D. Ryan*[1], S. Bud'ko[2], N. Ni[3] and C. Hu[3] *1. Physics, McGill University, Montreal, QC, Canada; 2. Department of Physics and Astronomy, Ames Laboratory and Iowa State University, Ames, IA, United States; 3. Department of Physics and Astronomy, University of California, Los Angeles, CA, United States*

Trigonal $CaCu_4P_2$–type (R-3m #166) $EuAg_4As_2$ is part of a wider family of 1-4-2 pnictides[1]. Preliminary magnetic characterization suggested antiferromagnetic (AF) ordering below T_N=15K[2] and that the Eu was divalent. The isostructural $SrAg_4As_2$ compound hosts non-magnetic, formally divalent Sr in place of Eu and serves as a well-defined reference. It is a diamagnetic semimetal with a structural transition around 110K[3] that may be electron or phonon driven. A transport and neutron diffraction study of single crystal $EuAg_4As_2$ found a similar structural event at 120K and two magnetic events at 15K and 9K[4] and suggested that short-ranged AF correlations develop at 15K followed by incommensurate long-ranged AF order at 9K with a reduced moment of 3.7μ_B[4]. Here we present the results of an extensive ^{151}Eu Mössbauer study of $EuAg_4As_2$ using crystals from the previous

work[4]. The 5K spectrum consists of a single, sharp magnetic pattern with B_{hf}=27.1(1) T and an isomer shift of –11.04(3) mm/s consistent with fully divalent Eu in a single magnetic environment with a full 7μ_B ordered moment. No trivalent Eu (<1%) was detected. The thermal evolution of the average B_{hf} (Fig.1) appears conventional, yielding T_N=14.4(1)K. However, above 8K the fitted linewidth increased significantly and a model invoking an incommensurate sine-modulated structure gave a more consistent fit. On the Mössbauer timescale (10-100ns) the ordering appears to proceed via an initial sine-modulated phase starting at 15K that squares up below 9K. We also looked for the structural transition at 120K. If the transition involved a significant change in electron density around the Eu, or a softening of a phonon associated with the Eu atoms, we might expect changes in the isomer shift or spectral area[5] respectively. No changes in linewidth, isomer shift or spectral area were detected (Fig.2). The temperature dependence of the area gave a Debye temperature (θ_D) of 184(3)K, somewhat higher than the 140K reported for $SrAg_4As_2$[3], but it should be noted that the Mössbauer value is locally weighted to the Eu site rather than representing a global average.

GT-11. Magnetic properties, Magnetic entropy and Adiabatic temperature change in antiferromagnetic NdCuGa compounds.
M.B. Tchoula Tchokonte[1], M.H. Mbulunge[1], J.J. Mboukam[2], A.K. Bashir[1,4], B. Sahu[2], A.M. Strydom[3] and D. Kaczorowski[3] *1. Physics & Astronomy, University of the Western Cape, Bellville, South Africa; 2. Physics, University ofJohannesburg, Johanneburg, South Africa; 3. Magnetic, Institute of Low Temperature and Structure Research, Polish Academy of Sciences, Wroclaw, Poland; 4. Materials Research Group, iThemba LABS, Fourie, South Africa*

Magnetic properties, magnetic entropy change ($-\Delta S_M$) and adiabatic temperature change (ΔT_{ad}) in NdCuGa has been investigated by means of magnetic susceptibility, $\chi(T)$, heat capacity, $C_p(T)$ and isothermal magnetization, $M(\mu_0 H, T)$ measurements. The compound was found to order antiferromagnetically at T_N = 7 K with a second – order phase transition as observed from $\chi(T)$, $C_p(T)$ data and the Arrott – plots. The low temperature $C_p(T)$ data just above T_N can be fitted to the Debye relationship given a Sommerfeld coefficient and Debye temperature values of Y = 0.210(1) J/mole.K and θ_D = 99(8) K. At higher temperatures, $\chi(T)$ data follows the paramagnetic Curie – Weiss behavior with an effective magnetic moment, μ_{eff} = 3.495(1) μ_B and a paramagnetic Weiss temperature θ_p = -3.8(2) K. The value obtained for μ_{eff}, is fairly close to the theoretical value of 3.62 μ_B expected for the free Nd^{3+} – ion. The magnitude of the magnetic entropy change ($-\Delta S_M$) and the adiabatic temperature change (ΔT_{ad}) was estimated from the isothermal magnetization data to be 8.59 J/kg.K and 7.1 K, respectively with the corresponding relative cooling power (*RCP*) value of 150 J/kg.K

GT-12. Magnetic Anisotropy of Rare Earth Systems.
M. Henderson[1,2], B. Ensign[1], R. Choudhary[1] and D. Paudyal[1] *1. Critical Materials Institute, US DOE, Ames Laboratory, Iowa State University, Ames, IA, United States; 2. West Chester University of Pennsylvania, West Chester, PA, United States*

Magnetic anisotropy is critical parameter in rare earth magnetism. In the presence of magnetic anisotropy, a material becomes more easily magnetized in a certain direction, and less susceptible to removal of the dipole alignment due to external magnetic fields. Many models exist for magnetic anisotropic energy density, each of which depend on the symmetry of the material. In this study, several of the symmetry dependent mathematical models, including uniaxial, cubic, hexagonal, and other configurations, have been analyzed. As for example, the simplest model used for the uniaxial anisotropic energy density uses even powers of sinusoidal functions. The models are then tested on praseodymium-based compounds with varying symmetries and structures. The compounds include Pr, $PrCo_2$, $PrCo_3$, and $PrCo_5$. The compounds also have their electronic structure examined using density functional theory based calculations. The linearized augmented plane wave method (LAPW) is used along with the local spin density approximation (LSDA), corrections for spin-orbit coupling (SOC) as well as the Hubbard model (U). Additionally, the density of states (DOS) and charge densities (Fig.1) [1] for each compound is calculated, and based on the DOS, magnetic behavior is derived through the exchange splitting of electrons near the Fermi-level. This work is supported by the Critical Materials Institute, an Energy Innovation Hub funded by the U.S. Department of Energy, Office of Energy Efficiency and Renewable Energy, Advanced Manufacturing Office. M.H. is grateful to the DOE for the assistantship and opportunity to participate in the Science Undergraduate Laboratory Internship (SULI) program.

GT-13. Peculiarity of a magnetic structure in a quasi-one-dimensional columbite $Co_{0.4}Ni_{0.6}Nb_2O_6$. *P.W. Sarvezuk*[1], M.A. Gusmao[2], J.B. Marimon da Cunha[2] and O. Isnard[3] *1. Universidade Tecnológica Federal do Paraná, Campo Mourão, Brazil; 2. Universidade Federal do do Rio Grande do Sul, Porto Alegre, Brazil; 3. Institute Néel, Grenoble, France*

Quasi-one-dimensional (Q1D) spin chain systems have a great potential applications in high-density information storage devices, quantum: information and computers, given their quantum magnetic properties. The low-dimensional magnetic behavior have been investigated in ANb_2O_6, (A = Mn, Fe, Co or Ni) compounds, they structural and magnetic properties are very interesting because the system presents weakly interacting Ising chains, which leads to his quasi-one-dimensional magnetic order. Our investigation combines specific heat and magnetic measurements; x-ray and neutron diffraction (ND). In this work, we present a Co/Ni orthorhombic structure, called columbite, which crystallize with *Pbcn* space group, whose formula is $Co_{0.4}Ni_{0.6}Nb_2O_6$. Co for Ni substitution induces a continuous lattice volume decrease, preserving the orthorhombic crystal structure. Magnetic susceptibility and specific heat measurements reveals that antiferromagnetic order occurs at 3.4 K, as consequence of a weak interchain interactions. Partial substitution of the magnetic ion tends to change the magnetic ordering observed in the $CoNb_2O_6$ and $NiNb_2O_6$. Lastly, we present this magnetic structure changes with the Ni-Co substitution.

GT-14. Multiple Antiferromagnetic structures in $HoCoGa_5$ studied by X-ray resonant magnetic scattering. *C. Adriano*[1], R.M. Grossi[1], K.R. Pakuszewski[1], P. Pagliuso[1] and C. Giles[2] *1. DEQ, University of Campinas, Campinas, Brazil; 2. DFMC, University of Campinas, Campinas, Brazil*

The relationship between magnetism and superconductivity (SC) in strongly correlated electron systems is still a subject of investigation since the existence of series of structurally related compounds is a good opportunity to explore how the evolution of the physical properties along the series can affect the ground state of each compound. In this context, the isostructural family of intermetallic compounds R_nMX_{3n+2} (R = rare earth or actinides, M = transition metal, X = In, Ga and n = 1, 2) has allowed a remarkable opportunity to further explore the relationship between magnetism, SC, crystalline electrical field effects and crystal structure. Among this isostructural family the most important members are the heavy fermions superconductors $CeCoIn_5$ [1] and $PuCoGa_5$ [2] and their related compounds. The interesting properties arise from the interaction between the 4*f* and 5*f*, respectively, with the conduction electrons. In low temperatures the *f*-electrons start to interact with the conduction electrons and the ground state is mainly determined by an intricate balance between the RKKY (Ruderman-Kittel-Kasuya-Yosida) interactions and the Kondo Effect [3]. As the SC in these materials is believed to be magnetic mediated [4] the systematic study of the non-Kondo compounds within the R_nMX_{3n+2} family is very elucidative to investigate the evolution of the magnetism of the 4*f* electrons. In this work we add new results to the Ga-based series, for which the trends observed in the magnetic properties along these series can be further explored. We report the solution of the magnetic structure of the intermetallic antiferromagnet $HoCoGa_5$ by means of the X-ray magnetic resonant technique. We found a magnetic structure consistent with a commensurate antiferromagnetic phase below 7.4 K with a magnetic propagation vector (1/2 0 1/2) and an incommensurate antiferromagnetic ordering phase between 7.4 K and 9.7 K where the spins align in the ab-plane an rotate with an angle of around 65 degrees along the c direction and with a propagation vector (1/2 0 0.359). The spin reorientation found for this compound and existing in related 5*f* compounds like $NpMGa_5$ with (M = Rh,Co) is further discussed in this work.

GT-15. Investigation of Local Magnetic Properties of CeCd as a Function of the Unit Cell Volume by means of First Principles Calculations. L.F. Pereira[1], L.M. Scalise[1], J. Mestnik-Filho[1], W.L. Ferreira[1], V.C. Gonçalves[1] and *A.W. Carbonari*[1] *1. Research Reactor Center, Nuclear and Energy Research Institute, São Paulo, Brazil*

In the work here reported magnetic hyperfine field (B_{hf}) at Cd site as well as the cerium magnetic moment (*m*-Ce) were calculated from simulation of the CeCd compound in many different unit cell volumes. Results are compared with the experimental values of B_{hf} (5.10 T) obtained with Perturbed Angular Correlation spectroscopy measurements [1] and *m*-Ce from magnetization measurements. The electronic structure calculations of the CeCd cubic cells (under normal conditions the space group is Pm-3m) were performed using density functional theory implemented on ELK and WIEN2k codes with "full-potential linearized augmented plane wave" method and the local density or generalized gradient approximations to estimate exchange-correlation energy. Three methodologies were carried out in our simulations: just spin polarized (SP); spin-orbit coupling (SO); and, SO plus *ad hoc U* parameter to treat the strong correlation in the cerium *4f* shell. The cell energy (CE), *m*-Ce and Fermi-contact contribution (B_{Fc}) of Cd-B_{hf} from electrons (labelled core and valence) inside the atomic spheres and others quantities were calculated for volume fractions varying from -14% to 5% of the experimental unit cell volume, in steps of 1%. The smallest energy and bestest Cd-B_{hf} agreement were reached when the volume is compressed by 12%. Results are discussed in terms of Ce-*4f* electron (de)localization and its strong correlation as well as hybridization effects between Cd and Ce observed through density of states plots to understand the dependence of Cd-B_{Fc} with the compression and relaxation of the cell. A brief comparison of Cd-B_{Fc} for 3 the methodologies and *m*-Ce and Cd-B_{Fc} versus volume (SP calculation) from WIEN2k are presented.

GT-16. Magnetic-Field Driven Pr-Valence Change in $(Pr_{1-y}Sm_y)_{1-x}Ca_xCoO_3$. *T. Naito[1] 1. Iwate University, Morioka, Japan*

A metal-insulator transition (MIT) and spin-state transition (SST) is known to take place simultaneously in $(Pr_{1-y}RE_y)_{1-x}Ca_xCoO_3$ (RE=rare earth elements) system. This MI-SST originates from the fact that the spin-state of Co^{3+} changes between the intermediate (or high) and low spin states. Recently, several works revealed that the valence shift of a part of Pr ions from trivalent to tetravalent played an important role in the MI-SST by the X-ray absorption spectroscopy (XAS) at the Pr L_3 edge [1]. On the other hand, we have studied a magnetic-field effect on the MI-SST to control the SST, because the magnetic-field stabilizes the higher spin states and should influence the transition temperature. As a result, we found that the MI-SST temperature decreases with increasing magnetic-field, and finally the MI-SST is fully suppressed. For instance, the magnetic-field of 9 T wiped out the MI-SST in $(Pr_{0.9375}Y_{0.0625})_{0.7}Ca_{0.3}CoO_3$ sample with the transition temperature of 41 K at zero field [2]. In this paper, we have studied the XAS at the Pr L_3 edge in magnetic-field up to 10 T for $(Pr_{1-y}Sm_y)_{1-x}Ca_xCoO_3$ system to examine the relationship between the magnetic-field effect and the valence of Pr ions. For $(Pr_{0.8}Sm_{0.2})_{0.7}Ca_{0.3}CoO_3$ with the transition temperature of about 50 K, a $4f^2$ peak due to Pr^{3+} increases with increasing magnetic-field at 50 K, and returns to the starting spectrum at 0 T by removing the magnetic-field. The valence of Pr estimated from the XAS spectra changes from approximately 3.14 at 0T to 3.09 at 10 T. The decrease in Pr-valence by applying magnetic-field is consistent with the suppression of the MI-SST. We discuss the mechanism of the change in Pr-valence induced by the magnetic-field.

GT-17. Co-site Substitution Effects on the Simultaneous Metal-Insulator and Spin-State Transition in $(Pr_{1-y}Gd_y)_{1-x}Ca_xCoO_3$. *T. Naito[1] 1. Iwate University, Morioka, Japan*

A metal-insulator transition (MIT) and spin-state transition (SST) is known to take place simultaneously in $(Pr_{1-y}RE_y)_{1-x}Ca_xCoO_3$ (RE=rare earth elements) system. This MI-SST originates from the fact that the spin-state of Co^{3+} changes between the intermediate (or high) and low spin states. Several works revealed that the valence shift of a part of Pr ions from trivalent to tetravalent played an important role in the MI-SST by the identification of the Pr^{4+}-related Schottky peak in heat capacity measurements [1] and by X-ray absorption spectroscopy (XAS) at the Pr L_3 edge [2]. The increase of the fraction of Co^{3+} by the valence change of Pr ions induced the MI-SST. In this paper, we have studied that a Co-site substitution effect by various metal elements (M=Mn, Fe, Ni, Ga, etc.) on the MI-SST in $(Pr_{1-y}Gd_y)_{1-x}Ca_x(Co_{1-z}M_z)O_3$, to clarify the relationship between the fraction of Co^{3+} and the MI-SST. For M=Mn, the transition temperature increased with increasing the amount of Mn. The introduction of Mn^{4+}, revealed by the XAS, increases the fraction of Co^{3+}, and resulted in the increase of the transition temperature. On the other hand, for M=Ni, the transition temperature decreased with the amount of Ni, and finally the MI-SST was fully suppressed at z=0.05. The results of the Ni-substitution is quite similar to the magnetic-field effect, in which the MI-SST disappeared above a strong magnetic field [3]. Although the valence of Ni was not determined by the XAS, we found that the ferromagnetic element also suppress this transition.

GU-01. Study on construction of leakage magnetic field reduction coil system for contactless power supply during EV driving. *T. Abe*[1], S. Oba[1], T. Sawa[1], S. Miyahara[1], F. Sato[1], K. Ishikawa[1], H. Mastuki[2] and S. Sasaki[3] *1. Tohoku Gakuin University, Tagajyo, Japan; 2. Tohoku University, Sendai, Japan; 3. Hikaridenshi Co.,Ltd, Osaki, Japan*

EVs are rapidly developing as a solution to the recent energy saving problems and environmental pollution, but it is difficult to say that they are still widely accepted. With the policy of becoming an all-vehicle EV by 2040 in Europe, EV shifts have spread throughout the world. However, in order to further promote EV, it is necessary to solve the issues regarding battery capacity and power supply system. As a system to solve these problems at once, a contactless power transfer system while traveling is being considered. Various proposals have been made for this system at present, but there is no system with a significant function to reduce the leakage magnetic field, and none of them has reached the practical stage. Therefore, we propose a non-contact power supply system during traveling with a function to reduce the leakage magnetic field. By this proposal, the infrastructure implementation of the contactless power supply system while driving becomes more realistic. In this study, we constructed a feed system with an extended transmission coil length using an 8-figure-coil and LC booster system. A schematic diagram of the leakage magnetic field of the 8-figure-coil is shown in Fig. 1. We compare this system with a system in which the transmitting coil proposed in the previous research[1] is rectangular and the receiving coil is in the form of spiral, and confirm that the leakage magnetic field is actually reduced. In this experiment, several sizes of feed systems were created, and the leakage magnetic field under multiple conditions was compared. A comparison of the leakage magnetic field at constant output is shown in Fig. 2. From these results, it was confirmed that the leakage magnetic field was actually reduced in the feed system using an 8-figure-coil. In this study, we constructed a system to reduce the leakage magnetic field. It was confirmed that the leakage magnetic field can be reduced by actually comparing the 8-figure-coil and the conventional spiral-shaped feeding system. In the future, we will further study the construction of coil shapes more suitable for infrastructure mounting.

GU-02. Design of Stable Feeding System Using Repeater Coils for Contactless Power Transmission System During EV Driving. *S. Oba*[1], T. Abe[1], F. Sato[1], S. Miyahara[1], T. Sawa[1], K. Ishikawa[1], S. Sasaki[2] and H. Mastuki[3] *1. Tohoku Gakuin University, Tagajo, Japan; 2. Hikaridenshi Co.,Ltd, Osaki, Japan; 3. Tohoku University, Sendai, Japan*

Many research institutes are researching the technology of contactless power transmission system during EV driving as a method to extend the cruising distance of Electric Vehicle (EV). In order to realize the system in full scale, it is necessary to extend the feeding section per power source and to form an enough power feeding section with a small number of power sources as a whole[1]. Therefore, an extension method has been proposed using a repeater coil. This method is combined with the power feeding coil that is connected to the power source to extend the feeding section. However, it is known that there is a coil configuration in which the power transmission efficiency to the load is significantly reduced. It has different characteristics depending on the number of repeater coils and the position of the load. Furthermore, the repeater method corresponding to the rectangular coil which is a coil shape that can be stably fed in the traveling direction has not been studied so far. In addition, when making a power feeding section with the same distance, using a rectangular coil requires less wire than using a spiral coil on the power feeding side. Therefore, the repeater method corresponding to the rectangular coil is required in the contactless power transmission system during EV driving. Fig. 1 shows a schematic diagram of the repeater method using the spiral coil, which has been mainly studied so far. Therefore, in this study, we examined the new repeater method that can supply EV stably on a rectangular coil. A cross coil and a rectangular coil were combined on the feeding side, and a spiral coil was used on the receiving side. Fig. 2 shows the new repeater method we propose in this study. In this new repeater method, the features of the cross coil, rectangular coil, and spiral coil are used. As a result, it was confirmed by experiments that stable power feeding to the load is possible on the rectangular coil without a place where the feeding efficiency drops significantly. Furthermore, we have also proposed a repeater method for a rectangular coil suitable for contactless power transmission to EV.

GU-03. Effect of Physical Contact on the Evolution of Cube-on-Face Texture in Fe-1%Si Steel during the Phase Transformation from γ to α. *S. Kwon*[1] *1. POSCO, Pohang, The Republic of Korea*

Recently, electrical vehicles are becoming increasingly popular and will replace the vehicles using an internal combustion engine in near future. Therefore, there is a strong demand for the development of high efficiency electrical steel for motors and generators. It is well known that the ideal texture of silicon steel for motors and generators is a cube-on-face texture, {100}<uv0>, where each grain has two <100> directions in the plane of the sheet to give excellent magnetic properties. When any sample is heat treated, it is in physical contact with the supporting material. Normally, such physical contact is not expected to affect the microstructure evolution of the sample. However, the physical contact between Fe-1%Si sheet and the Al2O3 plate was found to have a strong effect on the evolution of a cube-on-face texture during heat treatment, producing as much as 76.0% when determined by the orientation within {100} ±15'. The similar result was obtained for the tungsten and quartz plates. The results provide a promising new method to produce the high efficiency non-oriented electrical steel of a cube-on-face texture.

GU-04. Investigation of Variable Flux Characteristics in Parallel Hybrid Permanent Magnets. *Y. Jie*[1], H. Yang[1], X. Guo[1], J. Li[1] and M. Wang[1] *1. School of Electrical Engineering, Southeast University, Nanjing, China*

I. INTRODUCTION Variable flux permanent magnet (VFPM) machines [1] [2] equipped with both low coercive force (LCF) AlNiCo magnet and high coercive force (HCF) NdFeB magnet can achieve both acceptable torque capability and excellent flux adjustment range. However, the nonlinear magnetization characteristics of AlNiCo PM make precise online MS manipulation relatively complicated [2]. Thus, a C-core magnetizer device with a parallel hybrid (PH) PM arrangement is designed to provide an in-depth insightful understanding for variable flux property, as well as a utility design guideline of PH PMs [3]. In addition, an experiment-based methodology with both continuous and transient current pulse tests is proposed. II. MAGNETIZER DESIGN The finite element (FE) model of the device is illustrated in Fig. 1(a). The relationship between the proportion of NdFeB PM and the peak air-gap flux density is shown in Fig. 1(b). In order to maximize flux adjustment range when ensuring the maximum air-gap flux density reach 0.65T, an appropriate proportion of NdFeB PM is selected as 58% for the prototype manufacturing. III. EXPERIMENTAL RESULTS The prototype is shown in Fig. 2(a). The experimental results of one-way magnetization and demagnetization with continuous current are shown in Figs. 2(b) and (c), respectively. The blue line represents the major hysteresis loop, of which the left branch shows high nonlinearity that is mainly due to the nonlinear hysteresis property of the AlNiCo PM. Meanwhile, the linearity of right branch suggests that the NdFeB PM dominates the air-gap flux density. Nevertheless, the recoil line results are measured by the continuous low current tests, which reflects the linear movement trajectories of the LCF PMs during the magnetization. In full paper, the analysis of the magnetization characteristics and an equivalent hysteresis model of the PH PMs will be presented.

GU-05. On-Load Demagnetization Effect of High-Coercive-Force PMs in Switched Flux Hybrid Magnet Memory Machine. *H. Yang*[1], H. Lin[1], Z. Zhu[2] and S. Lyu[1] *1. Electrical Engineering, Southeast University, Nanjing, China; 2. Electrical and Electronics Engineering, The University of Sheffield, Sheffield, United Kingdom*

I. INTRODUCTION Hybrid magnet memory machines (HMMMs) [1] [2] equipped with both high-coercive-force (HCF) and low-coercive-force (LCF) magnets is able to achieve high-efficiency operation within a wide speed range, since the magnetization state (MS) of the LCF PMs can be conveniently magnetized/demagnetized with a current pulse. Due to the high-level current pulse, the accidental irreversible demagnetization of NdFeB PMs should be discussed. Therefore, this paper aims to establish an in-depth investigation into the on-load unintentional demagnetization (UD) behavior of NdFeB magnets in a newly developed switched flux HMMM (SF-HMMM) [3]. II. UD EFFECT IN HCF PMS Fig. 1(a) shows the structure of the proposed SF-HMMM. The NdFeB PM serves as a dominant contributor for air-gap flux, while the LCF PM acts as a flux adjustor due to its changeable MS. When the temperature is set as 120 °C, the armature and magnetizing windings are fed with 40A *q*-axis current and 50A DC current, respectively. By using the frozen permeability method (FPM) [4], Fig. 1(b) shows the field contours produced by either the resultant armature/magnetizing or individual fields. It shows that the magnetizing MMFs possibly penetrate the NdFeB PMs, and hence posing the potential demagnetization risk, as evidenced in the working point variations in Fig. 2(a).

III. EXPERIMENTAL VERIFICATION When LCF PM of the SF-HMMM prototype (see Fig. 2(b)) is with the full MS, the back-EMF is measured in advance. Afterward, the prototype machine is fed by various magnitudes of *q*-currents, and then the resultant back-EMFs are tested after withdrawing the load currents. The FE and measured peak EMFs are shown in Fig. 2(b). It shows that the back-EMF rarely varies with increasing load currents, which suggests that the HCF PMs in the proposed SF-HMMM well resist the UD effect. The detailed UD characteristics, mechanism, and dynamic test results will be given in the full paper.

GU-06. Balanced Bidirectional-Magnetization Effect of a Novel Hybrid-Magnet-Circuit Variable Flux Memory Machine. *H. Yang*[1], H. Lin[1], Z. Zhu[2] and S. Lyu[1] *1. Electrical Engineering, Southeast University, Nanjing, China; 2. Electrical and Electronics Engineering, The University of Sheffield, Sheffield, United Kingdom*

I. INTRODUCTION Variable flux memory machine (VFMM) [1]-[6] can achieve high efficiency over a wide operation range by applying a current pulse to magnetize the low coercive force (LCF) magnets. This paper combines the design concepts of parallel and series VFMMs, proposing a new hybrid-magnetic-circuit VFMM (HMC-VFMM). The HMC design can achieve wide flux adjustment range in parallel type [5] and beneficial on-load demagnetization withstand capability in series type [6]. This paper attempts to reveal and investigate a balanced bidirectional-magnetization effect of the proposed HMC-VFMM, i.e., the required demagnetizing and remagnetizing current levels are basically similar, which will benefit the inverter rating reduction and online flux control. II. CONFIGURATION AND BIDIRECTIONAL-MAGNETIZATION BALANCED EFFECT The proposed HMC-VFMM structure is illustrated in Fig. 1(a). For the parallel branch, the "U"-shaped hybrid magnets are employed. For the series branch, the HCF PMs feature a spoke-type configuration. The underlying mechanism of the balanced bidirectional-magnetization effect can be physically characterized by hysteresis curves of the LCF PM in Fig. 1(b). The load line of the HMC design is placed between those of the parallel and series cases, which allows a better balance between the magnetizing and demagnetizing currents. Meanwhile, the oversized inverter rating issue for either parallel or series VFMMs can be well avoided by appropriately reducing maximum magnetizing currents. III. EXPERIMENTAL VERIFICATION As shown in Fig. 2(a), an HMC-VFMM prototype is manufactured and tested. The FE and measured open-circuit phase back-EMF magnitudes versus various peak current pulse curves are shown in Fig 2(b). It shows that the experiments agree well with FE results. Besides, the proposed HMC-VFMM shows comparable peak demagnetization and remagnetization currents, which confirms the balanced bidirectional-magnetization effect. The detailed mechanism, characteristics analyses, and test results will be given in the full paper.

GU-07. Comparative Study of Hybrid-PM Variable-Flux Machines with Different Series PM Configurations. *F. Liu*[1], L. Cheng[1], M. Wang[1], G. Qiao[1] and P. Zheng[1] *1. School of Electrical Engineering & Automation, Harbin Institute of Technology, Harbin, China*

Variable flux PM synchronous machine (VF-PMSM) is considered as a promising candidate for adjustable-speed drive applications [1]. Since low coercivity (H_c) magnets are used, the magnetization state of low-H_c magnet in VF-PMSM can be changed through *d*-axis current pulse. It is obviously that the rotor scheme and stator winding configuration have crucial influences on the magnetization characteristic and electromagnetic performance of VF-PMSMs. In this paper, a comparison study of three proposed hybrid-PM variable-flux machines (HPM-VFMs) with both low- and high-H_c magnets is conducted, which could give an insight into the influence of the arrangement of magnets on the performance of the machines, as shown in Fig. 1. The red and the yellow blocks are the low- and high-H_c magnets, and the arrows demonstrate the magnetization directions. In order to obtain reverse salient characteristics, the optimal *q*-axis flux barrier is determined by calculating L_d and L_q under light and heavy load conditions for each rotor scheme. The contributions of high-H_c magnets to the magnetization state and no-load air-gap flux density are evaluated, and the simulation results shows that the rotor scheme II and III are much better. The influence of the width and thickness of low-H_c magnet on electromagnetic performance of HPM-VFMs is investigated. A general rule of the arrangement and usage proportion of low- and high-H_c magnets of the machine is given. 8 stator winding configurations of rotor scheme III, including integral- and fractional-slot windings, are studied and compared. It reveals that the required magnetization current is decreased as the number of slots is increased. Torque and torque ripple of rotor scheme III after being magnetized by different stator winding configurations with the same MMF are illustrated in Fig.2. Apart from 9-slot winding configuration, the torque ripple of fractional-slot configuration is much lower than that of integral-slot configuration. However, an uneven demagnetization among different pieces of low-H_c magnets is observed in fractional-slot configurations. More information and discussion will be included in the full paper.

GU-08. Study on communication element design for communication magnetic field stabilization in implanted FES. *Y. Hongo*[1], F. Sato[1], T. Abe[1] and S. Miyahara[1] *1. Tohoku Gakuin University, Tagajo, Japan*

FES (Functional Electrical Stimulation) rebuilds motor function by applying electrical stimulation to the Residual function of peripheral nerves of the limbs in Spinal cord injury. Method of FES is suggesting fully embedded element by direct power feeding [1]. A small stimulation element is embedded in the object to be stimulated, internal element receives power and communication at the same time by near electromagnetic field generated from the external feeding coil and communication coil (Fig. 1). However, the communication unit is wrapped on the feeding unit, and is magnetic couple strong. In this study, to solve for this problem, suggested low magnetic coupled model that wrapped rectangle spiral coil to feeding power solenoid coil for induced voltage cancel. Those wrapped coils are divided into three. One of those is additional coil unit that connected inverter and modulator, other units is inner coil and outer coil (Fig. 2). Additional coil generated magnetic field is reflect by those units. In drive alone this communication coil shape, a region where the magnetic field is canceled occurs inside the coil. By using two coils and giving them a phase difference, the area where the magnetic field is always canceled gradually disappears. Previous studies have shown that the region where the magnetic field disappears is minimized when the current phase difference flowing through the two coils is $\pi/2$ [2]. But, in the state of magnetic interference in a plurality of resonant circuits, it is difficult to calculate the optimum value of the phase difference by calculation. Therefore, we performed simulation by electromagnetic wave analysis using numerical analysis and parameters calculated from it. In numerical analysis, calculation is performed with the parameters of the coil actually created, and the current value and phase information obtained from it was adapt to the coil model of magnetic field analysis. The result is a significant improvement over the single low coupling communication coil model.

I. Introduction Pareto-front based multi-objective optimization algorithms have been widely employed in the optimal design of induction machines [1,2]. The number of objectives in most optimal designs is, however, limited to two, which does not satisfy the industrial requirements. In addition, the reaching steady state process in simulation is time-consuming. In this paper, a fast reaching steady-state method, in combination with a load-balanced multi-objective evolutionary algorithm, is proposed for solving the induction machine design problem with three or more objectives and improving the speed of optimization. II. The Fast Reaching Steady State Method Currently, the greatest challenge for evaluating the performance of induction machines is that it takes a long time to reach steady state in simulation. Compared with conventional methodologies, improved rotor conductivity referring method and alternating flux linkage method (AFM) [3] proposed an equivalent model in simulation, which can make the induction machine reach the steady state in a few cycles. The simulated torques using the proposed method and the conventional method are plotted alongside time, as shown in Fig.1(a). The reaching steady-state time of conventional model is more than 80ms, while it only takes roughly 8ms for the equivalent model with AFM to reach the steady-state. III. Design Example The optimal design problem of a squirrel cage induction machine, which has four objectives, is employed to verify the proposed method. A set of Pareto-front based solution is derived from the optimization algorithm, as shown in Fig. 1(b). It should be noted that the solution set shown in three-dimension is the projection of four objective vectors, which is not a smooth surface. In addition, the finite element analysis time of equivalent model could be saved by 90%, as is shown in Fig. 2. Finally, a prototype of the optimized model will be manufactured and tested to verify the method proposed in this paper.

There are a lot of paper discuss CPA in military application which was in mega joule order until now [1-6]. Although these is a CPA designed for powder spraying [7], there is no CPA designed in general purpose and only few paper present in kilo joule level CPA [8]. A 0.220 x 0.132 m^2 and 10 kJ power level compensated pulsed alternator (CPA) was designed in this paper. The rotation speed of CPA was designed in 10000 rpm, the voltage of CPA was lower than 110V and two phase system each phase including six pole was implement in this CPA. The CPA system block diagram is present in figure 1. CPA was carried by an industrial motor driven by three phase inverter to rated speed. When the fire signal bottom was turn on, thyristor based full bridge rectifier was turned to short the output circuit to the load. The electromagnetic simulation of CPA is illustrated in figure 2. The magnetic flux was compressed completely inside the CPA and conserve flux throughout the rotation. The induce current density is 3.4386 x 108 A/m2 due to the variation of the flux. Thus, each phase was induced 2.063 kA. The CPA is discharged in 4.5 ms with output circuit and load. Both A and B phase output voltage, open circuit voltage, was 90 V in rotation speed 10000 rpm. The maximum current tested with output load is 3.450 kA and average current is 15 kA in 4.5ms. The angular velocity of CPA was slow down from 10000 rpm to 9775 rpm during 4.5 ms discharge. In the simulation, the open circuit output voltage was 102V at 10260 rpm and 1050 A current was induced by CPA with load at 5500 rpm.

GU-11. Performance Evaluation of a Tubular Flux-modulated PM Linear Generator with Sandwiched Armature. *M. Ma*[1] *1. College of Electrical Engineering and Automation, Hefei University of Technology, Hefei, China*

Abstract—A novel flux-modulated permanent magnet (PM) linear generator with sandwiched armature is used for free-piston energy converter system. It shows significant advantages in terms of thrust force density, efficiency and response capability. This paper discusses issues that are pertinent to the design of the proposed linear generator. First, a two-dimensional magnetic field analytical model is developed. And then the influence of key dimensional ratios of sandwiched armature (flux-modulated layer and air-cored layer) on electromagnetic performances are discussed. Finally the effectiveness of analysis results is verified by experiment on the prototype. I. Introduction Free piston energy converter is an integrated combination of a free piston engine and a linear electrical machine. The linear generator is the key part in free-piston energy system. This paper presents a novel tubular linear PM generator with sandwiched structure, aiming to realize high power density and fast response, as shown in Fig. 1(a). The topology has the novel sandwiched armature. The sandwiched armature consists of three layers: modulated segments and windings deployed inside it, air-cored windings, and iron core. The flux-modulated layer and air-cored layer windings are series connection. The arrangement of modulated segments is based on magnetic-gear effects, which has the capability of realize high thrust density. II.analytical model A comprehensive analysis of the novel topology has been presented. The magnetic field distribution of the subdomains are solved by using boundary and interface conditions as shown in Fig. 1(b). And then some design criteria have been found. III. Performance evaluation The influence of design parameters on electromagnetic performance are analyzed. The characteristics of output voltage, efficiency, and inductance parameter are investigated. Accordingly the generator can be optimized by the match of parameters in sandwiched armature. And then the preliminary test of the proposed generator has been completed as shown in Fig. 1(c). The output performance are compared with the existing different types of tubular linear ones for the same application [1].

GV-01. Fabrication of the magnetoresistive sensor with enhanced sensitivity by the application of repetitive bending stress. *J. Kwon*[1], W. Kwak[1], S. Hwang[1] and B. Cho[1] *1. School of Materials Science and Engineering, Gwangju Institute of Science and Technology, Gwangju, The Republic of Korea*

Magnetoresistive (MR) sensors, such as spin-valves (SVs), have been widely used for magnetic field and beads sensing.[1-3] However, complicated patterning and post-annealing processes are required to fabricate SV sensors.[4] In this study, we describe the fabrication of the MR sensor by the application of bending stress, which controls the magnetization by magnetostriction effect. The structure of Ta (3)/$Ni_{79}Fe_{21}$ (4)/$Co_{70}Fe_{30}$ (1)/Cu (2.8)/$Co_{70}Fe_{30}$ (1)/Ni (3)/$Ir_{20}Mn_{80}$ (15)/Ta (1) is deposited on a flexible polyimide film where the numbers are in nm unit. The free (NiFe) and pinned (Ni) layers have positive and negative magnetostriction, respectively. The CoFe sub-layers adjacent to the Cu spacer prevent the formation of dead layers to improve the initial MR ratio value.[5] As shown in Fig. 1, after the repetitive downward bending is applied along the easy axis, the magnetic anisotropy of the free layer is weakened so that the magnetic direction is relatively easy to rotate, while the anisotropy of the pinned layer is strengthened at the flat state. Figure 2 shows minor MR loops. The MR ratio increases as the number of bending increases and the effective anisotropy field ($2H_k$) also increases as shown in the inset (pink diamond symbols). The sensitivity, defined as MR/$2H_k$, increases from 0.142 %/Oe to 0.159 %/Oe since the increase rate of the MR ratio is larger than that of $2H_k$. A notable feature is the reduction of minimum resistance (R_{min}), as shown in the inset (purple pentagon symbols). The strong correlation between R_{min} and MR ratio is inferred. A new approach in this study demonstrates the enhancement of both MR ratio and sensitivity at the same time as well as the simplicity of sensor fabrication.

Composites based on single-walled carbon nanotubes (single-walled CNTs or SWCNTs) combined with iron nanoparticles are interesting materials, which can be used for a fingerprint to identify a genuine document or a bank bill for example. We prepared some samples with CNT-based inks on four different surfaces printed by Dimatix Materials Printer DMP-2831 [1]. The composition of carbon nanomaterial was SWCNTs (76 wt. %), iron nanoparticles (11 wt. %) and other carbon phases (13 wt. %). The four different surfaces were as follows: Type 1- MF-Millipore membrane (mixed cellulose esters, 0.45 μm pore size), Type 2 - MF-Millipore membrane (mixed cellulose esters, 0.8 μm pore size), Type 3 - Office paper A4 (160 g/m^2), Type 4 – Photo paper A4 (220 g/m^2). They were cut out into L4 mm x W1 mm and three stripes were placed in a row (Fig.1 (a)). A high-Tc superconductivity SQUID (Superconducting Quantum Interference Device) was designed and fabricated using a $YBa_2Cu_3O7_{-y}$ (YBCO) thin film. The SQUID was installed in a specially designed liquid nitrogen (LN_2) cryostat, which nabled the SQUID to approach the sample as close as 1 mm [2] (Fig.1 (b)). A dc magnetic field of 2.81 mT was applied in the direction parallel to the SQUID surface to magnetize the ink sample [3]. The stripe sample was drawn above the SQUID surface with 25 mm/s. A large signal peak was detected from the ink stripes on each Millipore membrane, Type 1 and Type 2 but not on Type 3; a small peak could be seen on Type 4 (Fig.2). The signal peak was proportional to magnetization of the sample. The measurements of conductance of the samples showed that the value of conductance increased exponentially in dependence on the magnetization. The iron nanoparticles were superparamagnetic due to their small size. Therefore the increase in magnetization was due to an increase in the exchange interaction between nanoparticles when the conductance increased. We suppose that this effect

can be explained by spin-dependent tunneling between CNTs, doped by iron nanoparticles, below percolation threshold. We are planning a further not only a magnetic but a magnetoresistance measurement.

GV-03. Ultra-high Sensitivity Magnetic Impedance Sensor by Applying GHz Pulse Current. *F. Akagi*[1] and H. Ohta[1] *1. Kogakuin University, Tokyo, Japan*

Magnet-impedance (MI) sensor is highly sensitive magnetic sensor based on a magnet-impedance effect in an amorphous wire [1]. Recently, the development of a high-sensitivity MI sensor of micro size for integration into systems-on-chip has attracted attention, which is used in biological and medical fields [2, 3]. However, for detecting weak magnetic fields of several pico-tesla, as in applications such as magnetoencephalography and magnetocardiography, the MI sensor needs to be more sensitive. Honkura et al. reported that GHz-spin-rotation sensor (GSR sensor) has a largest sensitivity by using GHz pulse current [4]. In this study, the effects of frequency and damping constant on output voltage and magnetization-reversal process for the magnetic impedance sensor by applying GHz pulse current was investigated by using the Landau-Lifshitz-Gilbert equation with eddy current field. Fig. 1 shows the schematic picture of magnetic sensor. The wire, which has a diameter and a length were 10 μm and 500 μm, respectively, was discretized by rectangular prism cells of 0.2×0.2×50 μm. The resistivity was 130 μΩcm. When the high frequency pulse current rises, magnetization turns from the sensor axis direction to the circumference direction. The pickup coil detects a time change of magnetic flux in the sensor. Fig.2 shows the dependence of the output voltage on the frequency with different damping constant α. The output voltage increases with increasing frequency, however, it is steady over 3 GHz. This result coincides with the experimental result [4]. Also the smaller damping constant is, the larger the output voltage is and the stronger the dependency of the output voltage on frequency is.

GV-04. Effects of parallel and meander configuration on thin-film magnetoimpedance element. *H. Kikuchi*[1], M. Tanii[1] and T. Umezaki[1] *1. Iwate University, Morioka, Japan*

Thin-film magnetoimpedance (MI) sensor has advantages of compatibility with integrated electronic circuits and of miniaturization aiming at field detection with high spatial resolution. To enhance sensitivity, a multilayer system has been examined [1, 2]. Meanwhile, we developed MI simple monolayer elements and a contrivance of element shape such as ellipsoid, triangular, then performed sensing action with miniaturized elements less than 100-μm length [3]. Since thin-film can be patterned by a lithography, we can easily alter a configuration of sensor elements, which contributes to extensive design of sensor geometry considering active sensor area, adjusting bias field and impedance value at bias point, etc. Thus, we made parallel line type or meander type thin-film MI element, then the effects of geometry or configuration on impedance profiles were systematically investigated. Fig. 1 show concepts of the element design. In parallel line type, the total width is fixed. For example, in case of 40-μm width, each line widths of 1, 2 and 4 lines were 40, 20 and 10 μm, respectively. The total length of meander type was unified in 2 mm. Therefore the length of each vicinity for 1 and 2 turns was 1 and 0.5 mm, respectively. Fig. 2 shows the field dependence of impedance for parallel and meander type. The width of elements were 40 and 20 μm respectively. As to parallel type, the results of 1 and 2 lines show the same tendency, however, the element with 4 lines decreases impedance change. Note that the field intensity where impedance has a peak shifts to lower field compared with a case of 1 and 2 lines. The width of each line becomes narrower with increasing number of lines, which reduces a demagnetizing effect. As the amount of turn increases for meander, the impedance changes decreases. When the number of turn increases, the length per one side becomes shorter, which induces a larger demagnetizing effect.

Therefore, the magnetic field strength at which impedance peak appears shifts to higher field. The results indicate a potential of broad strategy for sensor element design.

GV-05. Localization of Rotating Magnetic Marker from the Fourier components of its Magnetic Flux Density. *A. Chiba*[1] and T. Nara[1] *1. The University of Tokyo, Tokyo, Japan*

1. Introduction Indoor localization and navigation of humans and robots have various applications. In contrast to conventional electromagnetic wave-based methods, which have accuracies of approximately 1 m owing to the multi-path effects, the use of quasi-static magnetic field has great potential for better localization accuracy because the reflection of metals does not have a considerable influence on it. Several studies have proposed using a rotating magnetic dipole for localization: rotating electrically[1] or mechanically[2]. However, to use these methods the phase of the rotating source, i.e., the direction of the dipole when the magnetic field is measured, must be known. Moreover, the maximum and minimum magnetic flux densities should be detected, which are considerably affected by noise. In this paper, we derive a reconstruction formula for the three-dimensional position of a rotating magnetic dipole in terms of the Fourier components of the magnetic flux density to improve robustness to the noise. This method does not require the knowledge of the phase of the rotating source. This is an extension of our previous study[3] in which only the azimuth angle was determined. 2. Theory and method Our reconstruction formulae are given in Equations (1), (2), and (3) in Fig. 1: the azimuth angle, $0 \leqq \varphi < \pi$, and zenith angles, $0 \leqq \psi \leqq \pi/2$, as well as the distance, r, of the rotating source from the sensor are explicitly expressed in terms of the Fourier components of the measured magnetic flux density, where ω is the angular frequency of the rotation. We rotated four serially connected neodymium magnets (length: 828 mm and diameter: 23 mm) with a motor (KM-1); the rotating speed was 240 rpm (4 Hz). Three orthogonal magnetic impedance sensors (MI-CB-1DH) were used to measure the magnetic flux density. 3. Result As shown in Fig. 2, the three-dimensional position of the source was estimated with mean absolute errors of 92.0 mm in a 4000 mm by 2000 mm domain, where z = 423 mm. This method can be used in a various situation for indoor localization, for example, of a robot with a rotating dipole. Removal of the assumptions of φ and ψ will be discussed in the paper.

GV-06. Orientation and Position of a Vector-MagnetometerOptically Referenced to an External Coordinate System. *N. Rott*[1] *1. PTB, Braunschweig, Germany*

Vector magnetometers are widely used. To calibrate them, their readings need to be orthogonalized. This is because they are composed of three sensors with individual sensitive axes, whose relative orientation to each other is not known. Furthermore, for applications such as field mapping devices, where the measurement of the magnetic flux density vector should be conducted spatially resolved, the sensor positions also need to be determined. This means, one needs to find the orientation and position of every directional sensor with respect to an external coordinate system. From the determination of sensor orientations and positions one can find the parameters to calculate the field vector in the desired coordinate system. This work presents methods to determine the sensors orientations and positions from the sensor readings under relative motion in defined magnetic fields, enabling measurements that are traceable to the angle and length scale. Our vector magnetometer is attached to mutual orthogonal faces of a mirror cube. The cube itself can be used as an optical reference and can be aligned to any external coordinate system. On the other hand, the orientation and position of every sensor can be determined relative to this cube by performing a scheme of coil and sensor rotations. By rotation about two axes the orientation of the

sensors can be referenced to the coordinate system of the mirror cube and thus transitively to the external coordinate system. The setup for angle determination reaches an uncertainty better 130 μrad. It consists of an autocollimator, two rotation stages and a well-defined homogeneous field coil with its own optical reference mirror. We will present ongoing work which addresses the determination of the translational degrees of freedom. A three-axial coil system will be introduced that can generate different gradient configurations. In combination with translation stages and optical references the position of the sensor will be determined.

GV-07. Piezoelectric strain tuned magnetic field sensor. *Z. Wang*[1] and M. Liu[1] *1. ECE, Xi'an Jiaotong University, Xi'an, China*

Anisotropic magnetoresistive sensors with high sensitivity and stability have been widely used in various industrial applications, including navigation, current sensing, position and rotation sensing, and biosensing. Traditional linear anisotropic magnetoresistive sensors used barber-pole electrodes to rotate the current direction by 45 degree in order to obtain a linear electrical output as a function of external magnetic field. However, the adoption of barber-pole electrodes greatly reduced the working area of the sensor, i.e., the part of strip beneath the barber-pole electrodes could not contribute to the magnetoresistive signal[1]. Here we report an anisotropic magnetoresistive sensor with antiferromagnetic layer to regulate the magnetization-current angle instead of barber pole electrodes. The proposed sensor design, thereby, could fully use the magnetostrictive area, and the stabilized magnetization could help suppressing magnetic noise, enhancing stability and improving linearity[2]. Moreover, we have fabricated AMR sensors on piezoelectric PMN-PT single crystals to investigate the strain effect on the magnetoresistance of the sensor. With strain tunable magnetic permeability and therefore the sensitivity of the magnetic sensor, we have demonstrated a novel magnetic sensor with tunable measurement range and tunable sensitive direction.

GV-08. Simulation of DC SQUID Output Voltage Characteristics in Time Domain. *Z. Zou*[1] *1. Space Environment Simulation Research Infrastructure, Harbin Institute of Technology, Harbin, China*

The Superconducting QUantum Interference Device (SQUID) has the highest sensitivity in the area of detecting and measuring magnetic fields so far. The flux contained in the closed superconducting loop of the SQUID is quantized in units of the flux quantum $\Phi_0 = h/(2e) = 2.07\times10^{-15}$ Wb, where h and e are Planck's constant and elementary electronic charge, respectively. When a direct current (DC) is applied to the loop, the magnitude order of the output voltage frequency may be as large as GHz due to the junction capacity of the loop is approximately in the order of pF. This paper focuses on the time-domain characteristics of the DC SQUID's output voltage. The loop is composed of two identical Josephson junctions connected in parallel. The phase differences of the junctions are governed by Josephson's equation [1]. The resistively- and capacitively-shunted junction (RCSJ) model [1-2] are utilized to calculate the output voltage numerically. The critical currents I_0, capacity (C_1, C_2), and resistance (R_1, R_2) of each junction are taken as 20 μA, 1 pF, and 3 Ω, respectively. The bias direct current applied to the loop is equal to 41 μA. Calculation results of output voltages in time domain with various values of flux (0.0~0.5 Φ_0) through the SQUID loop are demonstrated in Fig. 1. The output voltage frequency increases with the flux, which is from 7.72 GHz under 0.00 Φ_0 to 29.8 GHz under 0.48 Φ_0; the output voltage is nearly a DC voltage under 0.50 Φ_0. The average output voltage vs. flux curves are illustrated in Fig. 2. The output voltage reaches the maximum value when Φ equals $(n+1/2)\Phi_0$ (n = 0, 1, 2, ...). The impact of the flux through the loop on I_0 is also considered [3-4]. When the flux is several tens of times the quantum Φ_0, the output voltage becomes stable, and hence the device sensitivity decreases seriously. Moreover, when the ratio of the junction resistance R_2/R_1 equals 1.0, the sensitivity or the voltage-flux transfer coefficient is the largest (90.8 μV/Φ_0). Thus it is necessary to maintain the symmetry of the configuration and parameters of the junctions. The simulator device for SQUID and the noise analysis are discussed in detail in the full manuscript.

GV-09. Large-Area Granular GMR Sensors for Ultra-Sensitive Bioassays. *D. Su*[1], K. Wu[2] and J. Wang[2] *1. Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, MN, United States; 2. Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States*

Over the past few years, giant magnetoresistance (GMR) sensors have been widely employed in the detection of biomarkers. In the presence of a bias field, the stray field from the magnetic nanoparticles (MNPs) bound to the sensor surface can be detected by the GMR sensors, which is proportional to the number of captured biomarkers (Figure 1(a)). To achieve a linear response, stripe-shaped GMR biosensors with large aspect ratio have been widely used. However, the effective sensing area is significantly limited by the width of the sensor stripes. Furthermore, the GMR sensor signal was found to be highly dependent on the position of the MNPs[1], which limits both the sensitivity and repeatability of the bioassay. To increase the effective sensing area, large-area GMR biosensors based on a reverse nucleation mechanism were proposed and demonstrated[2-4]. As the MNPs bind to the sensor surface, localized magnetization reversal sites occur in the free layer of the GMR sensor (Figure 1(b) and Figure 2(a)). Our simulation results showed that by transforming a stripe into a square, the sensor signal increased by over 20 times under the same amount of MNPs. The large-area sensor signal also exhibits a linear response to the number of MNPs regardless of the position of the MNPs. Here we further propose and simulate a CoFe-Cu or NiFe-Cu granular structure as the free layer of the large-area GMR. This granular structure results in a superparamagnetic behavior, which facilitates real-time biomarker detection due to the negligible hysteresis in the MH curve. Since the ferromagnetic granules are separated by Cu, the localized reverse nucleation in the granules onsets under a lower MNP stray field compared to uniform ferromagnetic films, which further improves the sensitivity in biomarker detection (Figure 2(b)).

GV-10. Simultaneous enhancement of spin-torque diode sensitivity and detection frequency by using voltage controlled magnetic anisotropy. *N. Sisodia*[1] and P.K. Muduli[1] *1. Department of Physics, Indian Institute of Technology Delhi, New Delhi, India*

Magnetic Tunnel Junctions (MTJs) can be used for Radio Frequency (RF) detection by using the spin-torque diode effect, which was first reported by Tulapurkar *el al*.[1] in an MTJ nanopillar with in-plane magnetized magnetic electrodes (ip-MTJ). In the spin-torque diode effect, an MTJ nanopillar generates a rectified d.c. voltage (V_{mix}) when an alternating current of frequency close to the eigen frequency of the free magnetic layer of the MTJ is applied. An important parameter desirable for efficient RF detection is the high RF sensitivity, which is defined as $S=V_{pp}/P_{rf}$, where V_{pp} is the observed peak-to-peak voltage for an external RF power of P_{rf}. With recent advancements[2-6], the sensitivity of the MTJ based RF detectors has already surpassed that of the currently used semi-conductor detectors which have typical sensitivities of 4000 mV/mW. However, the detection frequency remains low <2 GHz compared to commercial RF detectors. In this work, we introduce a novel method of achieving very high sensitivity while also simultaneously enhancing the detection frequency by utilizing a combination of two different phenomena namely, (i) Voltage Controlled Magnetic Anisotropy (VCMA) [7], and (ii) parametric synchronization [8]. We show the simulated spectra with and without VCMA in Fig. 1 (a) and (b), respectively. We achieve a giant sensitivity of $>10^5$ mV/mW at a high detection frequency of around 4--6 GHz. In the insets, we also show the magnetization trajectory for both cases at the extremum points from which V_{pp} is calculated. The magnetization follows a Clamshell orbit and shows a large shift for the maximum and minimum of V_{mix} in the presence of VCMA. We will discuss the detailed d.c. bias, RF power and field dependence of the phenomenon and show that the simultaneous enhancement of sensitivity and the detection frequency is due to a large coupling of external RF signal to MTJ assisted by the VCMA effect. The results will be useful for realizing highly sensitive RF detectors with high detection frequency working at ultra-low input powers.

GV-11. Effect of Magnetic Domain Structures on Magnetic Sensing Properties of Magnetic Tunnel Junctions. *G. He*[1], Y. Zhang[1] and G. Xiao[1] *1. Physics, Brown University, Providence, RI, United States*

High performance magnetic tunneling junction (MTJ) sensors is exploited to be an ultra-sensitive solid-state magnetic sensors needed in many applications. By incorporating MTJ with magnetic flux concentrator (MFC) we can achieve picoTesla detectability, but further improvement relies on more detailed understanding of the domain structures in its magnetic layers which determines its sensing performance. Stabilized domain structures could lead to big coercivity and small sensitivity, while relaxed ones could have increased noise due to domain fluctuation. We have fabricated MTJs of multiple shapes and sizes, so we can study domain structures under various shape anisotropy and external magnetic fields, by doing transport measurement, micromagnetic simulation, magnetic force microscopy and Kerr microscopy. The domain structures and sample morphology are related to their transport properties such as sensitivity, coercivity and noise also, as we will explain in detail. Such correlation can be used as guidance for designing MTJs that integrate with MFC most effectively, to make the best magnetic sensor. This study unveils the microscopic domain states at different external fields, which also provides insights for the dynamics of different domain shapes or vortex states.

GV-12. Ferrite Impregnated Epoxy Actuators for Composite Impact Damage. J. Surakarnkha[1], *Z. Leong*[1], W. Holmes[1], P. Desai[2], J. Foreman[1] and N. Morley[1] *1. University of Sheffield, Sheffield, United Kingdom; 2. Perlemax Limited, Sheffield, United Kingdom*

Carbon fibre reinforced polymers composites (CFRCs) possess properties that outstrip their component parts, so are seeing increased adoption in sectors such as the aerospace industry. The complex structure of CFRCs, which contributes to their unique properties are also prone to an increased variety of damages such as fibre breakage, debonding, transverse-ply cracking, and delamination. This means that their failure modes are more complex, hence there are many more routes to potential failure [1]. Previous work has shown the efficacy of magnetostrictive materials as damage detection actuators; issues such as their spatial sensitivity require improvement to progress their applicability in structural health monitoring [2]. One solution is to embed magnetostrictive micron-sized particles within a suitable flexible matrix. Early simulations have shown that the strain experienced by a magnetostrictive particle embedded in a softer material will be enhanced. In this paper we demonstrate a step-by-step approach to the fabrication and optimisation of an impregnated magnetostrictive epoxy matrix that aims to satisfy these requirements. Such that the fabrication of ferrite impregnated epoxy can function as a replacement for composite surface mounted magnetostrictive ribbons as damage actuators. A ferrite impregnated epoxy actuator was fabricated from Epikote 828 and ferrite microparticles, and other polymerising additives. Their strain response was characterised with a bending rig. They were then subjected to impact damage followed by a magnetic scan using a HMC5883L sensor to visualise the damage induced (Fig. 1). Figure 1. Fabricated actuator and visualised location of damage. The results found that 1) Increased ferrite additions to the system do not change the magnetostrictive sensitivity, possibly due to interaction effects at the small scale. Thus, better magnetostrictive materials were studied to optimise the actuator behaviour and sensitivity. 2) Despite the low sensitivity of the ferrite particles, damage induced via impact testing is shown to be detectable. A contour map of the results show clearly the region of impact damage, and its effect on subsequent impacts.

GV-13. Low-Frequency Noise of Full Wheatstone Bridge Based GMR Angular Sensors. *Z. Zhou*[1], Q. An[1], S. Yan[2], W. Zhao[1,2], Q. Leng[1,3] and Z. Cao[1] *1. Beihang-Goertek Joint Microelectronics Institute, Qingdao Research Institute, Beihang University, Qingdao, China; 2. Fert Beijing Institute, BDBC, School of Electronic and Information Engineering, Beihang University, Beijing, China; 3. Goertek Inc, Weifang, China*

Giant magnetoresistance(GMR) sensor is developing towards miniaturization and better performance, especially for weak field detection. However, the low-frequency noise limits the sensitivity of the sensors for their applications. Noise analysis is an essential way to reduce sensor noise and explore the electrical and magnetic characteristics. In this paper, we test and analyze the low-frequency noise of a full Wheatstone-bridge-based GMR angular sensor, in order to improve its performance. The GMR sensor is fabricated by a concise microelectronic process[1]. As illustrated in Fig.1a the device has a full Wheatstone-bridge structure and anneals with a magnetic field along the y-axis. Its sensing direction is in x-axis. Fig.1b shows the output of the GMR sensor in two axes. It shows kinks near zero field in both axes, which will be improved with optimized process to fabricate relatively ideal bridge arms in the patterned GMR elements. The field linear range is from -50 to 50Oe while eliminating the kinks and the sensitivity is 0.16mV/V/Oe. Fig.2a shows the power spectral density (PSD) of the sensor with fitting. The 1/f noise is the main source in the frequency bands below 10kHz[2]. Fig. 2b shows the Hooge parameter α of the sensor utilized to parameterize the noise level of 1/f noise. Increase of α value indicates a higher level of the sensor noise[3]. The α value in this research is about 2*10^(-3) that indicates in

low noise level since it is generally between 10^(-2) and 10^(-3)[2] in GMR devices. It's clearly seen that the α shows a maximum without external field. This could be pure magnetic noise attributed to none single domain of the free layer in the transducer. Of course, the magnetic noise decreases when the applied field reaches the effective anisotropic field to saturate moment of the free layer because its domain is fully oriented along magnetic field direction[2]. We obtain the sensitivity of 0.16mV/V/Oe in the GMR sensor and its noise level of 10^(-8) V/√Hz. This is suitable for high accuracy angular sensing application such as geomagnetic devices and biosensors. More comparisons and analysis of low-frequency noise for our GMR sensors with improved film process will present in this paper.

HA-01. Emergent States in Artificial Spin Ice. *C. Nisoli*[2], X. Zhang[1], N.S. Bingham[1], A. Duzgun[2], J. Sklenar[3], Y. Lao[3], F. Caravelli[2] and P. Schiffer[1] *1. Physics, Yale, New Haven, CT, United States; 2. Theoretical Division, Los Alamos National Laboratory, Los Alamos, NM, United States; 3. Physics, University of Illinois, Urbana, IL, United States*

Intriguing new phenomena generally emerge from the collective behavior of numerous simple interacting degrees of freedom. Indeed, physicists typically first discover new systems and then proceed to describe them via higher level models that often deliberately neglect the detail of the building blocks. Instead, they concentrate on the relevant symmetries and interactions of an emergent description [1]. Today, advances in nano and micro fabrication, characterization, and control, can invert that approach. We can realize artificial systems whose interacting, elementary degrees of freedom can be tailor-designed for exotic behaviors in their collective, low-energy kinetics. That is the case of artificial spin ice materials [2], which can now be variously manufactured in arrays of magnetic nano-islands [3], trapped colloids [4], vortices in nano-patterned superconductors [5], or possibly with skyrmions in liquid crystals. They can produce new phenomena often non seen in natural materials, such as complex kinetics of magnetic charges and magnetic monopoles [6], new forms of frustration [7], classical forms of topological order [8], dimensionality reduction [9], or ergodicity breaking in absence of quenched disorder, while phase transitions can be engineered [10]. We will briefly summarize the fiend and then report on the more recent results in the Yale-LANL collaboration [5-10].

HA-02. Propagating spin excitations along skyrmion strings. *S. Seki*[1] *1. Department of Applied Physics and Institute of Enginnering Innovation, University of Tokyo, Tokyo, Japan*

Magnetic skyrmion, a topological soliton characterized by swirling spin texture appearing in two-dimensional system, has recently attracted attention as a stable particle-like object. In the three-dimensional system, skyrmion forms a string structure in analogy with the vortex-line in superconductors / superfluids and cosmic string in the universe, whose unique topology and symmetry may also host nontrivial response functions. In this talk, we discuss the propagation character of spin excitations on skyrmion strings. We find that this propagation is directionally non-reciprocal, and the degree of non-reciprocity, as well as the associated group velocity and decay length, are strongly dependent on the character of the excitation modes. Our theoretical calculation establishes the corresponding dispersion relationship, which well reproduces the experimentally observed features. Notably, these spin excitations can propagate over a distance exceeding 10^3 times the skyrmion diameter, demonstrating the excellent long-range nature of the excitation propagation on the skyrmion strings. The present results offer a comprehensive picture of the propagation dynamics of skyrmion string excitations, and suggest the possibility of unidirectional information transfer along such topologically-protected strings.

HA-03. Magnetization textures beyond skyrmions: bobbers, quanco balls and hopfions. *S. Bluegel*[1] *1. Peter Grünberg Institute and Institute for Advanced Simulation, Forschungszentrum Jülich and JARA, Jülich, Germany*

Magnetic textures called skyrmions are two-dimensional (2D) topological magnetization solitons localized in space with particle like properties, which are currently under intense scrutiny as a new entity for information storage and processing. The unforeseen stability comes from a chiral symmetry breaking facilated by the Dzyaloshinskii-Moriya interaction (DMI). The skyrmion and the antiskyrmion are global minimizer of the micromagntic energy functional in topological subsectors characterized by a topological invariant, the topological charge with the values Q=-1, Q=1, respectively [1]. In difference to skyrmions in ultra-thin films, in films of finite thickness and bulk crystals, skyrmions take the form of skyrmion tubes, as illustrated in Fig.1. Since skyrmion tubes are not intrinsically confined in 3D, they are considered 2D particles. This raises the fundamental and fully unexplored questions whether it is possible to localize skyrmions tubes in 3D on a nanometer scale (e.g. 50 nm or below) such that the so-formed objects are

stable, maybe even topologically protected. In this presentation we follow two approaches to localize the skyrmion tube in 3D space: (i) to cut the tube to finite length, leading to the formation of singular points at each end. Examples are the chiral bobber (ChB) and the quanco ball (QB) (see Fig.1) or (ii) connect the ends of the tupe to form a closed vortex tube, of which the hopfions present topologically protected versions (see Fig.1). Recently, we were able to extend the scope of skyrmions in cubic chiral magnets to a second class of particles: (a) ChB, first through theoretical analysis [2, 3] and then veryfied experimentally by the direct observation in thin films of B20-type FeGe by means of quantitative off-axis electron holography [4]. The interaction of electrons with such hybrid-objects [5], e.g. to understand how to move ChB by spin currents is subject to ongoing investigations. (b) Quanco ball, we show that a pair of coupled Bloch points may appear as a truely 3D localized stable state in cubic chiral magnets. Detailed analysis is presented of the stability of such objects in the interior of crystals and in geometrically confined systems [6]. We noticed that the magnetic structure of the cubic chiral magnets MnGe and FeGe in their B20 phases are quantitatively and qualitatively totally different. We introduce a novel class of magnetic exchange interactions – the topological-chiral interactions (TCI) – that can potentially dominate over the DMI in selecting the chiral ground state. The novel interactions are rooted in the so-called topological orbital moment, which manifests as a result of finite scalar spin chirality in non-coplanar magnets. The long-wave length limit of the interactions relates to the highly acclaimed Faddeev model demonstrating that the TCI are an origin of 3D magnetization textures all the way down to hopfions. -- Independent, in our search of replacing the DMI as skyrmion stabilizer we found that competing Heisenberg exchange provides a completely new mechanism model to stabilize magnetic Hopfions [8]. *Acknowledgment:* I acknowledge discussions and collaborations with G. HA-04. Magnetic Skyrmions and Hopfions in Three-dimensional Chiral Magnets. *J. Zang*[1] *1. Physics and Astronomy, University of New Hampshire, Durham, NH, United States*

In this talk, various three-dimensional (3D) topological spin textures in magnets without inversion symmetry will be introduced. The first part of the talk features the recent observation of target skyrmions in chiral magnet nanodisks through theory-experiment collaborations. Two types of zero-field target skyrmions are confirmed, and Bloch points are identified during topological transition between different types of target skyrmions. The spectrum of collective spin wave modes in target skyrmions also reveal the 3D nature of spin excitations. Second part of the talk introduces a very recent work on hopfions in chiral magnetic nanodisk. This is one of the first experimentally feasible prediction on magnetic hopfions. The hopfion in this setup is confirmed by analyzing the linking between any two equal-spin loops and calculating the Hopf invariant. Another topological configuration, the pairing between monopole and anti-monopole, is also identified in the same system. Transition from this state to hopfion, being identical to sphere-torus topological deformation, can be achieved by an external magnetic field. Dynamics of hopfions will also be discussed.

HA-05. Antiferromagnetic Textures: Eigen Modes and Spin Current Induced Dynamics. *O. Gomonay*[1], V. Kravchuk[2] and K. Everschor-Sitte[1] *1. Institute of Physics, JGU Mainz, Mainz, Germany; 2. IFW Dresden, Dresden, Germany*

Searching for new functionalities of antiferromagnetic (AF) systems, controlled by spin and/or electric current, we focus on the (spin) current-induced magnetic dynamics of AF domain walls and skyrmions [1]. First, we review different types of forces acting on the domain walls in presence of spin-orbit torques and discuss underlying switching mechanisms together with interpretation of the recent experiments [2-4]. We demonstrate that spin-orbit torques which originate from the effective staggered field at the magnetic sublattices can effectively split degeneracy of non-180 AF domains and induce fast domain wall motion toward unfavourable domain. We also predict the "Walker-breakdown effect" which sets the velocity limit for the spin-current induced motion of AF domain walls. This effect originates from simultaneous excitation of spin-waves translational domain wall motion by spin-orbit torques. Second, we discuss free and forced magnetic dynamics of an isolated AF skyrmion [5] focusing mainly on the features which have no direct ferromagnetic counterpart. In particular, AF skyrmion shows two branches of localised eigen-modes with substantially different dynamics, which can be mapped on the dynamics of the closed domain wall, see Fig.1. The low-frequency branch can be viewed as a local translations of skyrmion boundary in the direction of the domain wall normal (Fig.1a). Corresponding frequency vanishes in the limit of large skyrmion radius. The high-frequency branch is associated with the rotations of the Neel vectors respective to skyrmion boundary (Fig.1b). This type of motion is governed by competition of Dzyaloshinskii-Moria interactions and strong exchange coupling leading to a nonzero frequencies of the modes. Basing on classification of localised modes according to their spin, angular mometum and frequency we also show how the localised modes can be selectively excited by ac magnetic field or spin current. DC magnetic field which removes degeneracy of clock-and couterclockwise modes is an additional tool for manipulation of AF skyrmion dynamics. Aiming to develop an effective

formalism for description of (spin)-current induced dynamics of AF textures we extend the collective coordinate approach for the closed AF domain walls and suggest the so-called domain wall string model. This model is based on the reduced number of the dynamic variables such as domain wall position and width. In application to the localised eigen modes the model gives the correct asymptotics in a limit of large skyrmion radius. We believe that our results open a way for manipulation, control and detection of the dynamical states of AF textures.

HB-01. Nonreciprocal spin-current generation using conductance gradient in surface-oxidized copper films. *Y. Nozaki*[1,2], G. Okano[1], M. Matsuo[3], Y. Ohnuma[3] and S. Maekawa[4,3] *1. Department of Physics, Keio University, Yokohama, Japan; 2. Center for Spintronics Research Network, Keio University, Yokohama, Japan; 3. Kavli Institute for Theoretical Sciences, University of Chinese Academy of Sciences, Beijing, China; 4. Center for Emergent Matter Science (CEMS), RIKEN, Wako, Japan*

A mutual conversion between charge current and spin current (SC), *i.e.* a flow of electric charge and spin angular momentum, respectively, has been widely used to control a variety of spintronics devices. Most of traditional spin current generation based on a spin-orbit interaction (SOI) shows a reciprocity. Here, we report a strongly nonreciprocal spin current generation, where the charge-to-spin conversion has an efficiency 320 times larger than the spin-to-charge conversion in 10-nm-thick surface-oxidized Cu film (Cu*) where an oxidization level is rapidly varied within 6 nm from the surface [1]. Our experimental result suggests that the spin current is generated via novel mechanism other than the traditional SOI. The nonreciprocity has been demonstrated from the careful comparison between the unidirectional spin Hall magnetoresistance (USMR) in Cu* (charge to spin conversion) and the spin current injection into Cu* using a spin pumping technique (spin to charge conversion). The USMR is the magnetoresistance arising from the spin accumulation generated via the spin Hall effect (SHE) at the interface of a bilayer consisting of a ferromagnetic and a non-magnetic metallic thin film [2-4]. The USMR exhibits a non-linear dependence of the electrical resistance on the current amplitude, which leads to unique unidirectional properties. Owing to the USMR property that the electrical resistance exhibits a first-order variation with respect to the conversion efficiency, we can evaluate the conversion efficiency from the slope of the USMR as a function of the current. We also confirmed that similar value of the conversion efficiency could be obtained from a conventional spin torque-ferromagentic resonance (ST-FMR) experiment. As schematically shown in Fig. 1, the origin of the nonreciprocity is attributable to a nonuniform spin scattering along the thickness direction in Cu*. Unlike the ordinary SOI, the spin scattering in the Cu* is anisotropic so that the inverse conversion is no longer occurred. Moreover, we confirm that the magnitude of spin current generated in Cu* is quite similar to an estimation using our numerical model where a gradual distribution of spin scattering along the thickness is considered. Similar spin current generation using the vorticity have been observed in liquid Hg [5] and surface-acoustic-wave injected Cu film [6]. These phenomena are based on spin-vorticity coupling [7, 8] which utilizes a conversion of spin angular momentum indirectly from the macroscopic rotation of the Hg and Cu atoms, respectively. On the contrary, our experimental result is regarded as the experimental demonstration of the coupling of electron vorticity and spin current. The non-reciprocal spin current generation will greatly increases the variety of materials usable for spintronics devices because large SOI materials are not necessary.

HB-02. Spin-Orbit Torque and Dzyaloshinskii-Moriya Interaction effects in perpendicularly magnetized trilayers. *A. Gudín*[1], A. Anadón[1], R. Guerrero[1], J. Díez-Toledano[1], P. Olleros[1], F. Ajejas[1], J. Camarero[1], R. Miranda[1] and P. Perna[1] *1. Nanomagnetism, IMDEA Nanoscience, Madrid, Spain*

In magnetic multilayers, the interplay between the perpendicular magnetic anisotropy, the interfacial Dzyaloshinskii-Moriya interaction (DMI) and the dipolar coupling may result in the appearance of a variety of chiral magnetic textures, such as skyrmions, even at room temperature [1–3]. A strong DMI [4,5] usually allows the stabilization of such topological textures which can be nucleated and manipulated via spin-orbit torque (SOT) by applying external current pulses [1]. We have studied a Ta(5nm)/Co(0.8nm)/Pt(5nm)/Ta(5nm)//SiO_2(300nm)/Si patterned by optical lithography and Ar milling in 10 μm wide Hall bars. The interest of this structure lies in: i) the different spin Hall angle signs in Ta and Pt enhances the SOT, ii) large DMI has demonstrated in reference [2,5] of the order of 1.3 mJm^{-2} iii) and the possibility to neglect the interlayer coupling contribution (potentially large in systems with several repetition) that may be play a fundamental role on the effect of SOT on the magnetic behavior. We have investigated

the anomalous Hall effect (AHE) that is, generally, proportional to the out of plane component of the magnetization, as function of the magnetic field applied along the z direction. We have disclosed the effect of the SOT by detecting simultaneously the Hall resistance curve and the polar Kerr hysteresis. We observe discrepancies between both behaviors at current densities as low as $6x10^8 Am^{-2}$. We have moreover investigated these features as function as the current density and in-plane magnetic fields in order to discriminate the role of the antidamping and field like torques.

HB-03. Current-Induced Domain Wall Motion in Pd-based Multilayered Structures with Different Ferromagnetic Layer Composition. M. Kado[1], N. Umetsu[1], S. Hashimoto[1], M. Quinsat[1], S. Nakamura[1] and *T. Kondo*[1] *1. Institute of Memory Technology R&D, Toshiba Memory Corporation, Kawasaki, Japan*

We have investigated characteristics of current-induced domain wall motion (CIDWM) in the perpendicularly magnetized 3nm-Ta/3nm-Pd/[0.16nm-TM/0.22nm-Pd]*4.5/3nm-Pd/5nm-Ta multilayered structures (TM = Co, CoFe, and CoNi), as examples of the situation in which domain wall (DW) is driven, by applying current, with both spin-transfer torque (STT) and spin-orbit torques (SOT's). The systematic experiments on TM-composition dependence of CIDWM characteristics for the samples reveal that higher Fe-content gives rise to smaller threshold current density J_c, and higher Ni-content results in larger J_c to the contrary. The values J_{c_MODEL} estimated using a conventional STT-based CIDWM model [1-3] with obtained magnetic properties for the samples show almost opposite dependence in respect to the TM-composition [Fig. 1]. Although direction of the CIDWM for the Pd-based samples in this study is parallel to electron-flow, these results strongly suggest that SOT's contribute to CIDWM in the samples. Considering the contribution of SOT's is not enough to express the observed CIDWM characteristics of the samples. Fig. 2(a) shows TM-composition dependence of current-induced effective fields being associated with damping-like (H_{DL}) and field-like (H_{FL}) SOTs determined by harmonic response measurements [4]. Even though the observed H_{DL} is varied by changing TM-composition significantly, its trend doesn't match that of the J_c. To understand the characteristics, we believe that not only SOT's, but also quantitative information on Dzyaloshinskii-Moriya interaction and extrinsic DW pinning, induced with inhomogeneity of magnetic properties in the structures, should be taken into the account.

Manipulating magnetization by a charge current lays the most important foundation for modern spintronics devices. However, recent emerging spin orbit torque (SOT) in the ferromagnet (FM)/heavy metal (HM) bilayer has restricted its application in a 3 terminal device which is not favored in circuit design[1]. Moreover, the interface nature of the SOT in FM/NM bilayers hinders the thermal stability and nonvolatility[2, 3]. Here, we show these obstacles can be overcome by exploring current induced effective magnetic fields and magnetization switching in a single $L1_0$ FePt layer. Fig. 1(a) illustrates the $L1_0$ FePt crystal structure, and our films are identified to be monocrystallines of this structure by TEM and XRD. Fig. 1(b) shows anomalous Hall effect (AHE) loops associated with the strong perpendicular magnetic anisotropy of FePt. A clear current driven magnetization switching in the FePt is detected by AHE signal [Fig. 1(c)]. The current induced effective fields H_L and H_T have been quantified with a harmonic voltage method[3].As shown in Fig. 1(d), the H_L and H_T increase with t_{FePt} indicating a bulk characteristic of the SOT in $L1_0$ FePt. Moreover, the H_L and H_T are also revealed to increase with chemical ordering and therefore

their correlation with spin orbit coupling is identified. The emergence of SOT and current driven magnetization switching in FePt of centrosymmetric $L1_0$ structure is counter-intuitive from the established framework of SOT[4]. Nevertheless, several forms of symmetry breaking, such as variants, anti-phase boundaries, and gradient of lattice constant have been probed by TEM and XRD and a possible origin of the observed SOT will be discussed in the conference. By ascribing the current induced effective fields to a new form of SOT in $L1_0$ FePt, our results not only push forward the frontier of the material systems for generating spin torque, but also bring a transformative impact to the magnetic storage and spin memory applications with simple architecture, ultra-high density and readily application.

HB-05. Surfactant-aided Growth for Enhancement of Spin Orbit Torques in Platinum. *C. Garg*[1], S. Yang[1], L. Thompson[1], T. Topuria[1], A. Capua[2], B. Hughes[1], T. Phung[1], P. Filippou[1] and S.S.P. Parkin[1] *1. IBM Almaden Research Center, San Jose, CA, United States; 2. The Hebrew University of Jerusalem, Jerusalem, Israel*

Spin-orbit torques (SOT) are an effective means for controlling magnetization switching behavior in racetracks[1] and three-terminal memory devices. Typically, highly efficient SOT generators are formed from heavy elements like Pt[2], Ta and W. Increasing the magnitude of SOT by discovering new materials or modifying existing ones is an area of vigorous research. Here we show that Pt films can be successfully grown by using surfactants resulting in an altered growth. By growing perpendicularly magnetized ferrimagnetic layers on top of this altered Pt layer, we demonstrate fast domain wall motion (~300 m/s) at significantly lower current densities when compared to our earlier work[1]. SOT measurements on this sample reveal a ~52% enhancement in the damping-like component of SOT as well. We attribute this change to growth of a mixture of (111) and (100) oriented Pt grains as opposed to exclusively (111) grains in the absence of surfactant use. Our findings show a novel pathway to engineering materials for higher SOT.

HB-06. Spin orbit torque in Pt/[Co/Tb]$_2$ multilayers with non-collinear spin states. *H. Chen*[1], R. Mishra[2], H. Yang[2], S. Zhou[1] and X. Qiu[1]
1. School of Physics Science and Engineering, Tongji University, Shanghai, China; 2. Department of Electrical and Computer Engineering, National University of Singapore, Singapore

In recent years, ferrimagnetic spintronic has attracted great attention with revelations of many intriguing properties: large spin orbit torque (SOT) [1], long spin-dephasing length[2], ultra-small skyrmion, fast domain wall motion[3] *etc.* However, the studies of SOT in ferrimagnet have been still controversial, and the non-collinear spin state[4] between magnetic sub-lattices has not been considered. In this study, SOT is investigated in the Pt/[Co/Tb]$_2$ multilayers with temperature-evolving spin configurations associating with the spin flip and spin canting transitions. By modulating the net magnetization and exchange coupling of ferrimagnet through temperature, the SOT exhibits intriguing features in response to the Co magnetization. (1) It is found the non-collinear magnetic state (spin-canted state) emerges when temperature is near the magnetization compensation temperature (T_M), as shown in Fig. 1(b). (2) The longitudinal effective field (H_L) changes sign at T_M and at a lower temperature, as shown in Fig. 2(a), which is related to the transition from spin-canted state to linear spin state. The temperature dependence of transversal effective field (H_T) can be also explained by the spin state transition. (3) Both H_L and H_T shows maximum at T~T_M, which is the result of the vanishing net magnetization. (4) The effective spin Hall angle of the Pt/[Co/Tb]$_2$ multilayers is higher than that of Pt[5], indicating that ferrimagnetic nature can lead an enhancement of the SOT efficiency in this system. Our results not only demonstrate ferrimagnet as a promising candidate for spin-orbitronic application with high thermal stability, but also provide important insight into spin orbit torque in magnet with non-collinear spin structure such as ferrimagnet, synthetic antiferromagnet and spin glass *etc*.

HB-07. Effects of spin–orbit torque on domain wall motion in a Ta/MnGa/NiAl structure. *M. Yamanouchi*[1], N.V. Bao[2], M. Inoue[2] and T. Uemura[2] *1. Research Institute for Electronic Science, Hokkaido University, Sapporo, Japan; 2. Division of Electronics for Informatics, Graduate School of Information Science and Technology, Hokkaido University, Sapporo, Japan*

Spintronics devices using spin–orbit torques (SOTs) are expected to be the building blocks for next-generation electronics. Perpendicularly magnetized MnGa is a candidate for the ferromagnetic layer of such spintronics devices owing to a relatively large perpendicular magnetic anisotropy, low magnetization, and relatively high spin polarization. Although SOTs and SOT-induced magnetization switching have been reported in magnetic heterostructure based on MnGa [1,2], effects of SOT on domain walls (DWs) has not been clarified. Here, we investigated interaction between SOT and DWs created during magnetization reversal by out-of-plane magnetic field H_z under various in-plane magnetic fields H_xs along the current I direction in perpendicularly magnetized ultrathin MnGa sandwiched between Ta and NiAl. A MgO(2 nm)/Ta(5 nm)/MnGa(1 nm)/NiAl (3 nm) stack was deposited on a (001) MgO single-crystal substrate. The stack was processed into Hall devices with a 10-mm-wide channel and a pair of Hall probes. We measured transverse resistance, which reflects perpendicular component of magnetization, by sweeping H_z under various Is and H_xs. The centers of hysteresis loops under H_x are shifted along H_z axis and the shift amount is almost proportional to I, which indicates that I acts as an effective perpendicular magnetic field H_{eff} on magnetization under H_x. The slope of H_{eff} versus I varies proportionally to H_x and becomes saturated above ~0.15 T, which is consistent with the model based on the modulation of the coercive field through SOT-assisted chiral DW motion [3]. The saturated slope is well described by the interaction between the chiral DWs and the Slonczewski-like SOT originating from the spin Hall effect in the Ta layer. The saturation of H_{eff} is caused by realignment of the internal magnetization in the chiral DWs rather than that in the Bloch DWs because the saturation threshold H_x is smaller than the hard-axis anisotropy field for the Bloch DW. These results suggest that the magnetization is reversed through SOT-assisted chiral DW motion [3] This work was supported in part by Japan Society for the Promotion of Science KAKENHI Grant No. 17H03225 and the Center for Spintronics Research Network.

HB-08. Spin-orbit torques in Pt/Co based structures with inserted Tb layers. *Y. Wu*[1], K. Meng[1], J. Chen[1], Z. Li[1], J. Miao[1] and Y. Jiang[1] *1. University of Science and Technology Beijing, Beijing, China*

Spin-orbit torque (SOT) devices, which exhibit high energy efficiency, low Joule heating and small size, has attracted many attentions for its potential in industrial application [1-4]. Recent works indicated that there're two sources of SOT, spin currents from the spin Hall effect (SHE) and the spin accumulation originated from the Rashba-Edelstein effect. To enhance the SHE or Rashba-Edelstein effect is the immediate approach to realize the high efficiency of SOT. In this work, we use Tb as inserted layer to enhance the SOT in Pt/Co/Pt structures, and investigate the current-induced magnetization switching at low temperature. The schematic of the SOT device is shown in Fig. 1(a). Fig. 1(b) shows the anomalous Hall effect of the Pt/Co/Tb(0~3 nm)/Pt structures, which reveal good perpendicular magnetic anisotropy. The SOT signals are shown in Fig. 1(c). The critical switching current is significantly reduced after inserting the Tb layer, indicates that the Tb layer has enhanced the SOT efficiency. To exclude that the enhancement of the SOT may come from the insulation of the spin current from the top Pt layer, we replaced the top Pt layer by AlO_x layer. The SOT signals at 50-300K are shown in Fig. 2(a). The critical switching current density is smaller than the Pt/Co/Tb/Pt structure, as shown in Fig. 2(a) and (b), reveals that the absent of the spin current from the top Pt layer may contribute to the enhancement of SOT, but not the mainly factor. We consider that the Tb layer can increase the effectivity spin Hall angle, thus increase the spin currents, and enhance SOT efficiency. At low temperature, the Pt/Co/Tb/Pt and Pt/Co/Tb/AlO_x samples also reveal obvious SOT signal. On the other hand, the SMR measurements of the structures in Fig. 2(c) and (d) proved that the inserted Tb layer can significantly increase the effective spin Hall angle.

HC-01. Interfacial magnetoelectricity at multiferroic interfaces.
J. Santamaria[1] *1. Universidad Complutense, Madrid, Spain*

The electronic reconstruction occurring at oxide interfaces may be the source of interesting device concepts for future oxide electronics. Among oxide devices, multiferroic tunnel junctions are being actively investigated as they offer the possibility to modulate the junction current by independently controlling the switching of the magnetization of the electrodes and of the ferroelectric polarization of the barrier. In this talk I will discuss the interplay between ferroelectric polarization and the ionization of oxygen vacancies, a ubiquitous defect in perovskite oxides. Oxygen vacancies carry doping and a strain fields which can induce deep modifications of the conducting properties of tunnel barriers and may drastically change the electronic properties at their interfaces. I will discuss that coupled oxygen vacancy and ferroelectric switching is the source of novel magnetoelectric effects. In particular, I will show that the spin reconstruction at the interfaces of a La Sr MnO /BaTiO / La Sr MnO multiferroic tunnel junction is the origin of a spin filtering functionality which can be turned on and off by reversing the ferroelectric polarization. The ferroelectrically controlled interface spin filter enables a giant electrical modulation of the tunneling magnetoresistance between values of 10% and 1000%, that could inspire device concepts in oxides based low dissipation spintronics.

HC-02. Changing the Magnetic States of a Fe/$BaTiO_3$ interface through Crystal field effects controlled by Strain.
C. Amorim[1], J.N. Gonçalves[1], J.S. Amaral[1] and V. Amaral[1] *1. Physics Department and CICECO, University of Aveiro, Aveiro, Portugal*

The search for better and inexpensive magnetoelectric materials is now commonplace in solid state physics. The desired intense coupling between electric and magnetic properties, embedded in a single material, is still the main motivation of this line of research [1-3]. A magnetoelectric material that successfully manages to couple the strong, above room-temperature ferroelectricity of $BaTiO_3$ with the also strong and above room-temperature ferromagnetism of Fe would naturally be a strong candidate for applications. Using DFT, the study of a specific interface between the TiO_2 layer of $BaTiO_3$ and a monolayer of Fe atoms is presented, probing different uniaxial strain effects of the considered supercell. Several different metastable magnetic states are predicted: a perfectly balanced antiferromagnetic state, an unbalanced ferrimagnetic state, a ferromagnetic state, and a non-magnetic state where each atom has its total magnetic moment quenched. These multiple magnetic behaviors are influenced by different possible hybridizations between the Fe and Ti atoms, as well as through O's crystal field effects, which collectively change the local charge and spin density surrounding each atom (Fig. 1-2) [4]. Interestingly, these multiple magnetic states can be reversibly controlled by strain. Under optimized conditions, the interface can switch from the ferromagnetic state to the non-magnetic state, with enticing prospects for applications.

Multiferroic systems hold great promise for energy-efficient control of magnetization [1-3]. Previously, electrically-induced magnetization reorientation in negatively magnetostrictive Ni microstructues on PMN-PT has been demonstrated [4]. Positively magnetostrictive CoFeB has also drawn substantial interest for its significant tunneling magnetoresistance in magnetic tunnel junctions for strain-mediated multiferroic random access memory. In order to combine the ease of reorienting magnetization in Ni microstructures with the potential for memory applications in CoFeB, we engineered a novel strain-mediated multiferroic system, composed of bilayer Ni/CoFeB magnetostrictive microstructures on a ferroelectric $Pb(Mg_{1/3}Nb_{2/3})_{0.69}Ti_{0.31}O_3$ (PMN-PT) single crystal. This work examines the influence of the exchange coupling on the magneto-elastic behavior through electrically driven magnetization reorientation in bilayer microstructures. Arrays of 2x2 μm^2 magnetic squares of Ni/CoFeB films with various thickness combinations are imaged by X-ray magnetic circular dichroism-photoemission electron microscopy (XMCD-PEEM) to obtain element-specific magnetic contrast. The correlations between the magnetization of individual layers highlights the strong exchange coupling behavior (Fig. 1). In an electric field across the PMN-PT, a compressive strain is generated along the [100], tensile strain along [01-1] of the PMN-PT. The piezostrain tunes the magnetic anisotropy in the patterned microstructures. For pure CoFeB, the magnetic moments realign to the tensile strain direction, whereas in pure Ni the moment aligns toward the compressive strain direction. However, when both CoFeB and Ni are present in equal volume, the magnetic anisotropy tends to favor magnetization reorientation in the tensile strain direction. Quantitative analysis of PEEM images and micromagnetic simulations provides insight into the tunable magnetoelastic effect of such bilayer systems. This work highlights the potential for hybrid ferromagnetism in composite multiferroics with tunable magnetoelasticity for next-generation memory applications.

HC-04. Investigations of the magneto-strictive coupling at the interface of $SrTiO_3$ (001) /$La_{0.6}Sr_{0.4}MnO_3$/$BaTiO_3$ system. S.G. Bhat[1] and *A.P. Kumar*[1] *1. Department of Physics, Indian Institute of Science, Bangalore, India*

The quest for the search of scarcely available multiferroic/magnetoelectric materials for technological application is active since 2-3 decades. But, the artificial synthesis of the same using ferromagnet (FM)/ferroelectric (FE) heterostructure stack is an alternative [1,2]. However, growing ferromagnetic film on a single crystal of ferroelectric substrate is common for demonstrating the strain dependent magnetoelectric coupling (also known as magnetostriction coupling in the ferromagnet). The strain induced modification of FE thin films reflecting in the magnetization of adjacent FMs are not so obvious; even with the poled FE such as $BaTiO_3$ [3,4]. In this regard, we have grown high quality epitaxial 2D bi-layer of $La_{0.6}Sr_{0.4}MnO_3$(LSMO)/ $BaTiO_3$(BTO) on $SrTiO_3$(STO) with good indication of magnetization coupling to the BTO. We have grown RHEED assisted pulsed laser deposited heterostructures of LSMO/BTO on STO which exhibit a fine control on crystallographic domains of BTO. The sequence of growth clearly indicates the control of single/multi-crystallographic domains in the BTO layer along with the evident quality of the growth. We further observe a very evident modulation of magnetization across the expected structural transitions of BTO even without any electric poling, similar to single crystal study [5,6] which is rare to find in ultra-low thickness of BTO. The systematic slope change corresponding to the structural transitions of BTO can be one-to-one mapped to the lattice parameter variation of BTO and hence the magnetostriction in LSMO. Despite reports of magnetostriction studies at LSMO films on BTO single crystal, our preliminary study shows epitaxial ultrathin BTO can also exhibit an equally good magnetic coupling with LSMO. The control over the single crystallographic domains of the BTO thin films provides a unique opportunity to study the pinning of magnetic domains of LSMO in a simpler way unlike the existing studies [2,5,7] with mixed domains of BTO.

HC-05. Strain engineered multiferroic phase diagram of orthorhombic RMnO$_3$ (R = Gd - Lu) epitaxial thin films. *S. Mukherjee*[2], C. Schneider[1] and C. Niedermayer[1] *1. Paul Scherrer Institute, Villigen, Switzerland; 2. University of Oxford, Oxford, United Kingdom*

Magnetoelectric multiferroics demonstrate simultaneous coexistence of magnetic and electric order paramerters. In addition, they show unique ability of cross-coupling between order parameters. These unique properties make them exciting both for technological development and fundamental studies. Rare-earth manganites (RMnO$_3$) in orthorhombic phase is one such archetypical candidate showing magneto-electric behavior. Depending upon R-ion radii they show a wide range of multiferroic phase governed by competing magnetic interactions as shown in the multiferroic phase diagram for bulk (Fig. 1) [1, 2, 3, 4]. Interestingly, on application of epitaxial strain the multiferroic phase diagram shows a dramatic change [5, 6] (Fig. 2). The most prominent effect observed is that the ground state gets independent of the R-ion radii and is forced to demonstrate a homogenous magnetic and electric property. Under epitaxial strain the films stabilize into an E-type order with ferroelectric ordering along a-axis. This suggested that the competing interactions are tuned to favor a symmetric exchange striction mechanism for the multiferroicity. In our work, we employed neutron and x-diffraction to study the magnetic phase in detail. In addition, in-house capacitance and ferroelectric loop measurements were conducted to confirm the electric ground states. These studies also highlight the development of instrumentation which provided the unique oppurtunity to study the magnetic order of thin films (thickness~10 -40 nm) with neutron diffraction. We plan to discuss in further details and reveal the variation in the microscopic mechanism induced by epitaxial strain to tailor the multiferroic phase diagram. This presentation will help in providing the audience a better outlook on using strain to engineer physical properties of materials.

HC-06. Epitaxial Room Temperature Multiferroic Superlattices Combining Hexagonal and Cubic Ferrites. *R. Steinhardt*[1], M. Holtz[1], P. Barrozo da Silva[2], J. Mundy[3], R. Ramesh[2] and D. Schlom[1] *1. Cornell University, Ithaca, NY, United States; 2. Berkeley University of California, Berkeley, CA, United States; 3. Harvard, Boston, MA, United States*

Hexagonal rare earth ferrites offer a promising and relatively unexplored area for multiferroic materials design. An exciting new method for creating multiferroic materials by combining rare earth ferrites into epitaxial superlattices has previously been developed using $LuFeO_3$ for it's ferroelectric properties and $LuFe_2O_4$ for it's ferrimagnetism [1]. While these lutetium ferrite superlattices demonstrated magnetoelectric coupling near room temperature, for device applications we seek materials that have stronger magnetism at higher temperatures. We use molecular beam epitaxy to combine ferroelectric hexagonal $LuFeO_3$ and ferrimagnetic cubic spinel ferrite into a superlattice. Depending on growth conditions, the spinel can form as surface polycrystalline precipitates [2], ordered 3D epitaxial structures, or well-ordered superlattices. The resulting superlattices show both strong magnetism and ferroelectricity above room temperature, which is promising for device applications. Multiferroic properties such as magnetoelectric coupling are currently being investigated.

CSIR-National Physical Laboratory, New Delhi, India*

Magnetoelectric - Multiferroic (MF) materials have drawn enormous interest because of their fascinating physics and great potential for memory, spintronics, and multifunctional applications. Obtaining single-phase ME materials with strong ME coupling, understanding its origin, and manipulating the processing and composition to realize large ME coefficients at room temperature constitute the holy grail of multiferroic research and remain difficult to achieve until now. Recently Intel research group have designed magnetoelectric spin–orbit logic device utilizing a single-phase material (La doped $BiFeO_3$) which has higher switching energy (10 to 30 times), lower switching voltage (5 times) and higher logic density (by a factor of 5) than the present CMOS devices. But La doped $BiFeO_3$ still not optimal, due to its high leakage current and small ME coupling coefficient. In continuation of our search for better ME materials for device applications, we have investigated the multiferroic and ME properties of Ni-doped $Pb(Zr_{0.20}Ti_{0.80})O_3$ ($Pb(Zr_{0.20}Ti_{0.80})_{0.70}Ni_{0.30}O_{3-\delta}$). We find that the ferroelectric (T_c ~ 700K) and weak ferromagnetic (~ 602 K) phase transitions of Ni-doped PZT are well above room temperature, leading to a strong ME coupling coefficient ($a_{E,31}$) of 11.7 mV/cm. Oe (H_{ac} = 1 Oe and f = 1 kHz). We further demonstrate that Ni-doped PZT exhibits low loss tangent, low leakage current, large saturation polarization and weak ferromagnetism. Our first-principles investigations suggest the defect is likely to be responsible for the experimental ME coupling in Ni-doped PZT. The requirement of for magnetization also explains the magnetization observed experimentally as majority of Ni dopants tend to replace *B*-site cations. Ultimately, our work demonstrates Ni-doped PZT is a cost-effective room-temperature single-phase multiferroic with strong ME coupling. The strong ME coupling above room-temperature makes it a possible future alternative of other single phase multiferroics with a strong possibility for device applications.

HC-08. Room temperature multiferroicity and magnetodielectric coupling in 0-3 composite thin films. *D.K. Pradhan*[1], S. Kumari[2], P.T. Das[5], R. Vasudevan[4] and R. Katiyar[3] *1. Geophysical Laboratory, Washington, DC, United States; 2. Department of Physics, The Pennsylvania State University, University Park, PA, United States; 3. Department of Physics, University of Puerto Rico, San Juan, PR, United States; 4. Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, TN, United States; 5. Department of Physics, Bar-Ilan University, Ramat-Gan, Israel*

With the development of devices miniaturization beyond Moore's exploration, there is increasing activities in combining magnetic and electronic properties in a material for potential applications in novel multifunctional devices. Magnetoelectric (ME) composite thin films have the potential for applications in novel spintronics and multifunctional devices as they exhibit much higher ME coupling and operational temperatures compared to single phase materials. Due to the shortcomings of (2-2) layered and (1-3) vertically composite nanostructures, the ME coupling is comparatively smaller which restrict them for applications. Here we have studied the structural, dielectric, ferroelectric, magnetic and magnetodielectric properties of pulsed laser deposited 0-3 (magnetic quasiparticles (0) embedded in a ferroelectric film matrix (3)) multiferroic composite thin films. We have synthesized the (1-*x*) $Pb(Fe_{0.5}Nb_{0.5})O_3$-*x*$Ni_{0.65}Zn_{0.35}Fe_2O_4$ (*x* = 0 (PFN), 0.10 (PN1), 0.20(PN2), 0.30(PN3)) composite thin films by optimized pulsed laser deposition. The θ-2θ large angle XRD patterns (20° to 80°) showed only the diffraction peaks from the substrate and (00*l*) pseudocubic reflections from PFN and NZFO confirms that these films are highly c- axis oriented in nature, and that the secondary phases are absent. We observed the ferroelectric T_c of ~ 430, 440, 460 (+/- 5) and magnetic T_c of ~435, 526, 555 (±10) K with broad transitions for PN1, PN2 and PN3 respectively. These composite thin films exhibit ferroelectric and magnetic phase transitions above room temperature. All these nanostructures possess saturated large polarization, soft magnetization, low loss tangent and magnetodielctric coupling (observed in PN1) at room temperature which might be useful for next generation nanoscale electronic and spintronic devices. The detailed studies on structural, morphological, dielectric, ferroelectric, piezoresponse force microscopic and magnetic properties of the composite thin films will be presented in the meeting.

We report on the influence of the $BaTiO_3$ crystal microstructure on its ferroelectric response and the direct effect on the modulation of the perpendicular magnetic anisotropy (PMA) of the top Co/Ni multilayers. The presence of multiple grains in the $BaTiO_3$ significantly reduces its ferroelectric response by hindering the reorientation of the ferroelectric domains with an applied electric field, which results in a a small reduction of the PMA (Fig. 1(a)). On the other hand, the ferroelectric reorientation is complete in $BaTiO_3$ with larger crystallinity, inducing an in-plane compressive strain of 11 ppt. A large fraction of this uniaxial strain is transferred to the magnetoelastically coupled ferromagnetic layers whose magnetization switches to in-plane (Fig. 1(b)) via the inverse

magnetostriction effect. This 90° switching is featured by a giant converse magnetoelectric coefficient, close the highest values reported so far,[1,2] highlighting the outstanding magnetoelectric properties of the system composed of single-crystal $BaTiO_3$ and Co/Ni multilayers with PMA. It is also worth emphasizing the difficulty of achieving a full switching of the perpendicular magnetization to an in-plane orientation by pure voltage-driven magnetoelectric effect, which has been reported in a very scarce number of works only[3,4] and is a key feature in the applicability of such a material system in a memory device, where each magnetic orientation would represent the digital *1* and *0* states. This work reveals the critical role of the crystal microstructure within a ferroelectric substrate in the performance of multiferroic heterostructures and provides insight into the development of high energy efficient devices.

HC-10. Large magnetoelectric effects in nanoscale Ni-PZT composites measured by Anisotropic Magnetoresistance. *H. Ahmad*[1], M. Kouwenhoven[2], F. Vanderveken[1], D. Tierno[3], I. Radu[4], F. Ciubotaru[1] and C. Adelmann[5] *1. Exploratory Device, IMEC, Leuven, Belgium; 2. TU Delft, Delft, Netherlands; 3. Interconnect and Packaging Reliability, IMEC, Leuven, Belgium; 4. Compute Technologies and Enablement, IMEC, Leuven, Belgium; 5. BEOL and Spintronics, IMEC, Leuven, Belgium*

Manipulating nanomagnets by the magnetoelectric (ME) effect is highly promising for low-power spintronic applications. A ME effect can be observed in composite materials combining piezoelectric with magnetostrictive thin films. To date, the ME effect has been mainly studied in thin magnetostrictive films on bulk piezoelectric substrates. At the nanoscale, ME devices promise much larger voltage coupling coefficients due to large electric fields at low voltages. Here, we investigate nanoscale devices based on Ni-PZT thin film composites (Fig. 1) using anisotropic magnetoresistance (AMR). The devices consisted of a 1-μm-wide Ni stripe on a 500-nm-thick PZT mesa on SiO_2/Si (100) substrate. Two electrodes with 750-nm-wide gaps with respect to the Ni stripe were used to generate piezoelectric strain in the PZT. Additional contacts allowed for an AMR measurement of the Ni stripe *vs.* an applied bias voltage. Applying a DC voltage to the electrodes generates electric fringing fields in the PZT mesa, inducing strain in the PZT and the Ni stripe. The strain modifies the magnetoelastic anisotropy field in Ni by the Villari effect. The anisotropy field depends on both the strain tensor and the magnetization direction, leading to a modulation of the AMR. A COMSOL study allowed for the optimization of the magnitude of different strain components for different voltage biasing schemes. Using the most uniform and largest strain configuration, AMR was then used to extract the magnetoelastic coupling in the Ni/PZT devices. The observed variation of the AMR (Fig. 2) with the applied magnetic field and DC bias voltage led to a value of 5200 (A/m)/V, considerably larger than previously reported values for macroscopic devices [1]. This shows the great potential of scaled ME devices for low-voltage spintronic applications. Funding by the European Union's Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant No. 794354 and the FET-OPEN project CHIRON under grant No. 801055 is acknowledged.

HC-11. Strain mediated magnetoelectric coupling in Ni-Mn-In/PLZT multiferroic heterostructure for MEMS device applications. *A. Kumar*[1], S. Pawar[1] and D. Kaur[1] *1. Department of Physics, Indian Institute of Technology Roorkee, Roorkee, India*

Recently, multiferroic heterostructures are gaining popularity for magnetic field sensing applications. The fabrications of rarely studied ferromagnetic shape memory alloys (FSMAs) based multiferroic heterostructures are more fruitful because FSMAs possesses large magnetostriction compared to reported ferromagnetic oxides, terfenol-D and metglas in literature. In this report, the Ni-Mn-In/(Pb,La)(Zr,Ti)O_3 thin film based multiferroic heterostructures have been fabricated with upper (Pb,La)(Zr,Ti)O_3 layer deposited at varying temperature (550 to 650 ^oC) using magnetron sputtering. The structural, ferroelectric, ferromagnetic and magnetoelectric coupling characteristics of the fabricated heterostructures have been studied. The polarization vs electric field and magnetization vs magnetic field measurements reveal the co-existence of ferromagnetic and ferroelectric orders in all the fabricated heterostructures. The highest magnetoelectric coupling coefficient of 1.28 V/cm Oe has been observed at 420 Oe DC magnetic field, 2 Oe AC magnetic field of frequency 1 kHz for PLZT layer deposited at 600 ^oC. Such Ni-Mn-In/(Pb,La)(Zr,Ti)O_3 all thin film based multiferroic heterostructures are appropriate candidate for magnetic field sensing and microelectromechanical systems (MEMS) based devices applications.

HC-12. Room temperature magnetoelectric response in 2-2 bilayer PNNZT/CTFO thin film deposited by pulsed laser deposition.
A.H. Pandey[1], K. Miriyala[1], N. Kumar[1], N. Sowmya[1], A.R. Kulkarni[1] and N. Venkataramani[1] *1. Department of Metallurgical Engineering and Materials Science, Indian Institute of Technology Bombay, Mumbai, India*

Multiferroic (MF) materials with coexisting ferroelectricity and magnetism provided an avenue to produce large magnetoelectric (ME) response (desired ME response ~1 V/cm.Oe) with effective voltage control of magnetism and power-efficient electric-field-tunable devices [1]. The ME response is realized by a parameter called magnetoelectric voltage coefficient (MEVC), where t is the thickness of the sample and δV is the induced voltage across the piezoelectric phase [1]. With motivation to achieve high MEVC, a 2-2 bilayer composite thin film of multiferroic 0.5Pb(Ni1/3Nb2/3O3-0.35PbTiO3-15PbZrO3 (PNNZT)/Co1.2Ti0.2Fe1.6O4 (CTFO) has been deposited on Pt/Ti/SiO2/Si(100) substrate using pulsed laser deposition technique. The structural investigation by XRD and Raman spectroscopy confirms the formation of pure phase PNNZT/CTFO 2-2 bilayer laminate structure. The piezoresponse force microscopic studies confirm the ferroelectric nature of PNNZT thin films and the nano scale piezo coefficient is ~150 pm/V which is 25% higher than well known PZT thin films. The reported value of magnetization for bulk CTFO is Ms ~60 emu/g and Hc ~130 Oe and we have obtained, Ms ~30 emu/g and Hc ~1.4 kOe for CTFO in bilayer thin film. The PNNZT/CTFO 2-2 bilayer thin film gives a maximum MEVC, ~1.05 V/cm. Oe at a frequency of 1 kHz, implying that the modified composite thin film is a potential candidate for application. Our prior PNNZT/CTFO bilayer thin film yielded MEVC ~0.5 V/cm. Oe at 1 kHz [2], by substituting 0.2 Ti4+ in CoFe2O4, the magnetic properties could be enhanced to provide a higher MEVC of 1.05 V/cm.Oe. The systematic details of this bilayer development will be discussed in this paper.

HC-13. Strong Magnetoelectric Coupling in Mixed Ferrimagnetic-Multiferroic Phases of a Double Perovskite.
D. Oh[1], M. Kim[2,3], Y. Choi[1] and N. Lee[1] *1. Department of Physics, Yonsei University, Seoul, The Republic of Korea; 2. Department of Physics, Seoul National University, Seoul, The Republic of Korea; 3. Center for Correlated Electron Systems, Institute for Basic Science, Seoul, The Republic of Korea*

Exploring new magnetic materials is essential for finding advantageous functional properties such as magnetoresistance, magnetocaloric effect, spintronic functionality, and multiferroicity. Versatile classes of double perovskite compounds have been recently investigated because of intriguing physical properties arising from the proper combination of several magnetic ions. In this study, it is observed that the dominant ferrimagnetic phase is coexisted with a minor multiferroic phase in single-crystalline double-perovskite Er_2CoMnO_6. The majority portion of the ferrimagnetic order is activated by the long-range order of Er^{3+} moments below T_{Er} = 10 K in addition to the ferromagnetic order of Co^{2+} and Mn^{4+} moments arising at T_C = 67 K, characterized by compensated magnetization at T_{Comp} = 3.15 K. The inverted magnetic hysteresis loop observed below TComp can be described by an extended Stoner–Wohlfarth model. The additional multiferroic phase is identified by the ferroelectric polarization of ~0.9 μC/m^2 at 2 K. The coexisting ferrimagnetic and multiferroic phases appear to be strongly correlated in that metamagnetic and ferroelectric transitions occur simultaneously. The results based on intricate magnetic correlations and phases in Er_2CoMnO_6 enrich fundamental and applied research on magnetic materials through the scope of distinct magnetic characteristics in double perovskites.

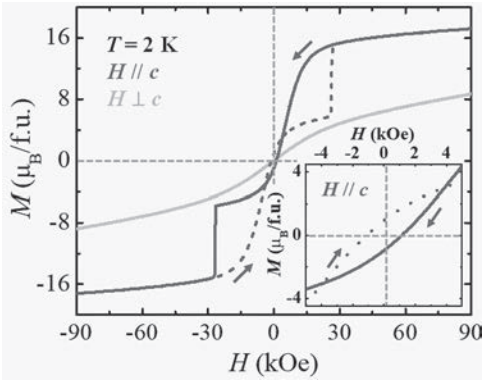

Fig 1. Isothermal magnetization (*M*) of the Er_2CoMnO_6 crystal in H//c and H⊥c, measured at T = 2 K up to 90 kOe after ZFC. The inset shows the magnified view in the range of H = ±10 kOe of the hysteresis loop in H//c.

HD-01. The Role of Inverse Faraday Effect and Magnetic Circular Dichroism in All Optical Switching. R. Guedas-Garcia[1], F. Garcia-Sanchez[1], *E. Martinez*[1] and V. Raposo[1] *1. Fisica Aplicada, Universidad de Salamanca, Salamanca, Spain*

Ultrafast control of magnetic state by circular polarized femtosecond laser pulses has been experimentally demonstrated by the nucleation of inverted regions [1], domain wall displacement [2] or the generation of an inverted domain along the path of a moving laser [3]. However, the underlying physics governing these processes still remain unclear. The most adopted hypothesis are the induction of a transient magneto-optical field due to the inverse Faraday Effect (IFE) and/or the Magnetic Circular Dichroism (MCD). Here we present micromagnetic simulations based on the Landau-Lifshitz-Bloch equation [4] that describes the magnetization dynamics in the ultrashort time scale coupled to the two temperatures model, which describes the temporal evolution of the electron and phonon subsystems of the material. The IFE is included as a magneto-optical field, whereas the MCD is taken into account by considering the different energy absorption rates depending on the magnetic state and the helicity of the laser pulses. With adequate combinations of laser fluence and the IFE-induced magneto-optic field, our modeling reproduces the magnetic states observed experimentally (see Fig. 1a). However, the MCD is not able to reproduce clearly all the domain patterns (see Fig. 1b), neither the domain wall displacement as the ones obtained in [2]. Our modeling allows to elucidate the physical mechanisms responsible for experimental observations, and it will be useful for further research of optical control of the magnetization.

Göttingen University, Göttingen, Germany*

In basic research as well as application development, magnetization manipulation remains an indispensable tool [1]. The energy transfer from the electrons to the spins is the basis for the response dynamics to optical laser excitation and thus, it determines the speed of ultrafast magnetization. The material FePt gained a special interest in magnetic storage development for heat-assisted magnetic recording [2]. However, in a seminal experiment, all-optical writing has been demonstrated for FePt nanoparticles of a magnetic hard disc media, by Lambert et al. in Science 2014 [3]. Despite a thorough investigation, the involved processes have not been disentangled entirely yet, leaving the mechanism unclear, and opening many questions about the extension of possibilities for all-optical writing as a general mechanism. In the meantime, writing experiments by single laser spots point to an asymmetric writing per each shot. As was consistently observed in different groups [4,5,6]. In the current understanding of the interaction of ultrafast excitation and heating, the influence of magnetic dichroism and the presence of the inverse Faraday effect jointly work as forces causing magnetization reversal. We calculate the switching rates of the individual FePt nanoparticles in ab-initio calculations of the optical effects (inverse Faraday effect and magnetic dichroism induced heating) included in thermal modelling. The latter then provides switching rates for the ensembles. We can trace the different processes from the beginning of the laser pulse impact [4]. In addition, this theoretical description allows us to optimize the required number of shots to write the magnetization of FePt nanoparticles and to pinpoint how to optimize the all-optical writing by tuning the laser fluence and wavelength. We review these recent developments that may lead to address an individual nanosized magnetic element in the future all-optically, for writing magnetic memory.

All-optical magnetization reversal with femtosecond laser pulses facilitates the fastest and least dissipative magnetic recording[1], but writing magnetic bits with spatial resolution better than the wavelength of light has so far been seen as a major challenge, making the application of optical techniques in recording technically challenging or even impossible. Here, inspired by electromagnetic simulations, we experimentally demonstrate that using light with the wavelength of 800 nm and without any magnetic fields, it is possible to obtain full control over two magnetic bits separated by just 80 nm. In our experiment, two bits are represented by two 10-nm thick GdFeCo layers, separated by a 80-nm thick layer of Si_3N_4, and mounted on a glass prism (Fig. 1 (a)). Upon focusing a single femtosecond laser pulse through the glass prism on to a surface of the magnetic bilayer, we toggle the magnetization exclusively within a single magnetic nanolayer without affecting the other one (Fig. 1 (b)). The choice of the toggled layer is enabled by the excitation of a plasmon-polariton[2] at a targeted interface of the nanostructure, and realized merely by rotating the polarization-axis of the linearly-polarized ultrashort optical pulse by 90°. The underlying mechanism is robust, well reproducible and relies on the polarization-dependent excitation of plasmon-polaritons in the magnetic nanostructure. Our results unveil a new tool that can be deployed to switch magnetization in targeted nanolayers of heterostructures, and paves the way to increase the density of opto-magnetic recording by a factor of at least 2.

HD-04. Optimisation of magnetisation reversal in granular HAMR media. *A. Meo*[1], S.E. Rannala[2], S. Ruta[2], R.W. Chantrell[2], P. Chureemart[1] and J. Chureemart[1] *1. Department of Physics, Mahasarakham University, Mahasarakham, Thailand; 2. Department of Physics, University of York, York, United Kingdom*

Perpendicular magnetic recording cannot provide the required increase in storage density due to the recording trilemma, and a technology that relies on the aid of heat during the writing, called heat assisted magnetic recording (HAMR), was proposed[1,2]. However, HAMRs require optimisation to become a real alternative. Therefore, we aim to investigate the writing process of HAMR granular media using a multiscale approach combining atomistic simulations and micromagnetic calculations based on Landau-Lifshitz-Bloch (LLB) formalism. Atomistic approaches can provide temperature dependent equilibrium quantities, required by the micromagnetic model, and details on the magnetisation dynamics, while micromagnetic simulations allow to simulate large systems for long times and span over a large set of parameters. We simulate HAMR magnetisation dynamics for a system of 400 identical FePt grains with a 10% distribution of Curie temperature Tc (σ_{Tc}) for different heat pulse peak temperatures by LLB calculations and we compare it with atomistic results. Fig 1(a) shows that LLB dynamics, atomistically parametrised, reproduces well the atomistic magnetisation reversal, proving its reliability. We then use it to obtain the switching probability of such grains as function of laser pulse peak temperature and length, as shown in Fig 1(b), due to the small computational cost. The switching probability is not abrupt and does not reach the maximum due to the nature of reversing

dynamics at elevated temperature (close to Tc). These findings agree with the results presented in [3], especially considering that we have simulated an isolated grain. Our initial results show the potential of such a multi-scale approach to simulate realistic systems accounting for distributions of size and magnetic properties, and emphasise the importance of optimising HAMR properties. Based on these results we plan to simulate extended systems investigating the effect of different parameters, such as the effect of the heat profile.

HD-05. A new method for fabricating granular FePt-$L1_0$ HAMR media with well-controlled nucleation and growth. *B. Zhou*[3,1], C. Xu[3,1], Y. Yan[3,1], B. Varaprasad[2,1], D.E. Laughlin[3,1] and J. Zhu[2,1] *1. The Data Storage Systems Center, CMU, Pittsburgh, PA, United States; 2. Department of Electrical and Computer Engineering, CMU, Pittsburgh, PA, United States; 3. Department of Materials Science and Engineering, CMU, Pittsburgh, PA, United States*

In HAMR, the recording happens at elevated temperatures, just below the media Curie temperature (T_c), because of the limitation of the write-head field. Thus, increasing the FePt grain height is crucial to counter the thermally induced transition jitter, especially at small grain size.[1] Therefore, it is desirable to have small, isolated and columnar shapes of FePt grains with narrow size distributions. Amorphous C is a common choice as part of the grain boundaries in order to obtain small isolated FePt grains in the nucleation stage, but it also presents many challenges, such as the formation of a double layer, the lateral growth and the bimodal distribution, all of which limit the columnar growth of FePt grains.[2-4] Thus, the C needs to be replaced in the nucleation stage. These challenges could potentially be overcome by developing pre-defined and robust matrix boundaries, which define the nucleation sites and force the FePt grains to grow columnarly with the boundaries together in the later stage of the film growth. As shown in Fig. 1 (a), such matrix template layer, which consists of a sacrificial material (Au) embedded in a matrix of another material (SiO_2), can be fabricated by co-sputtering on top of the MgO underlayer. After forming the desired microstructure, Au can be selectively etched from the SiO_2 matrix and MgO underlayer by a commercially available Au etchant (Transene Au etchant TFA). The results shown in Fig. 1 (b) to (c), which correspond to the samples in step 1 and 2, demonstrate that the SiO_2 matrix can be formed by the above-mentioned methodology. Fig. 1 (d), which corresponds to the sample in step 3, demonstrates that the FePt grains can be forced to nucleate in the trenches of the matrix where the MgO surface is exposed, with their c-axes perpendicular to the film plane. The details of the effects of the template layer on the nucleation and growth of FePt grains will be presented.

HD-06. Utilizing Boron-nitride and carbon as the hybrid grain boundary materials for controlling the grain size distribution in HAMR media. *B. Zhou*[1,2], Y. Yan[1,2], C. Xu[1,2], B. Varaprasad[3,2], D.E. Laughlin[1,2] and J. Zhu[3,2] *1. Department of Materials Science and Engineering, CMU, Pittsburgh, PA, United States; 2. The Data Storage Systems Center, CMU, Pittsburgh, PA, United States; 3. Department of Electrical and Computer Engineering, CMU, Pittsburgh, PA, United States*

Grain-to-grain Curie temperature variation (σT_c) in heat-assisted magnetic recording (HAMR) media can be reduced by controlling FePt grains size distribution. [1] However, the elevated processing temperature required for obtaining the highly ordered $L1_0$-FePt makes it challenging to obtain a microstructure with narrow grain size distribution. Although the commonly adopted FePt-C media produces well-separated FePt grains, the amorphous carbon grain boundaries appear to actually allow the continuous nucleation of new FePt grains on the MgO underlayer even at late stage of the thin film growth process. [2] As a result, this continuous nucleation of new FePt grains during film growth often lead to a broad and bimodal distribution of FePt grain size. One way to suppress the continuous nucleation of FePt grains and to gain control the grain size distributions in HAMR media is to use different grain boundary materials other than just carbon. In this study, we present a study utilizing boron-nitride (BN) and carbon(C) together as the hybrid grain boundary materials to control the microstructure of FePt grains. The thin film stack of Ta(5)|MgO(9)|FePt-$C_{35vol.\%}$ or FePt-$C_{30vol.\%}$-$BN_{5vol.\%}$(3 nm) were sputtered on a-SiO_2 substrate using an AJA Orion-8 system with base pressure better than 1 x 10^{-8} torr. All layers up to MgO were deposited at room temperature, while FePt-C or FePt-C-BN layer was deposited at 650°C. The results shown in Fig. 1 (a) and (b) are the in-plane microstructure corresponding to the samples of FePt-C and FePt-C-BN, whose grain size distributions are shown in Fig. 1(c) and (d). It can be clearly observed that the formation of the small particles is suppressed by utilizing C-BN hybrid grain boundaries. The study shows that the grain size distribution of FePt can be significantly improved.

HD-07. Temperature-Dependent Studies of Coupled $Fe_{55}Pt_{45}/Fe_{49}Rh_{51}$ Thin Films and Patterned elements. R.A. Griffiths[1], J.L. Warren[1], C. Barton[1,2], J.J. Miles[1], P.W. Nutter[1] and *T. Thomson[1] 1. School of Computer Science, University of Manchester, Manchester, United Kingdom; 2. National Physical Laboratory, Teddington, United Kingdom*

Equiatomic $Fe_{49}Rh_{51}$, with its highly unusual antiferromagnetic to ferromagnetic phase transition at approximately 370 K [1], provides the ability to create artificial multifunctional materials when combine with high-anisotropy magnetic thin films in an exchange-mediated structure [2]. We investigate the temperature dependence of switching in $L1_0$ $Fe_{55}Pt_{45}/Fe_{49}Rh_{51}$ bilayer thin films, where the $Fe_{49}Rh_{51}$ assists the switching of the $Fe_{55}Pt_{45}$ at modestly increased temperatures [3]. A simple layered macrospin model is able to capture the switching characteristics of these films and shows good agreement with experimental results, fig. 1. Patterned $L1_0$ $Fe_{55}Pt_{45}/Fe_{49}Rh_{51}$ structures measured using the anomalous Hall effect, fig.2, show a similar temperature-dependent switching behavior, paving the way for reduced switching fields in future applications including heat-assisted bit-patterned-media recording and spintronic devices.

HD-08. Using magneto-structural phase transitions to enhance the coercivity of ferromagnetic films. *R. Need*[1], J. Lauzier[2], L. Sutton[2], B.J. Kirby[1] and J. de la Venta[2] *1. NIST Center for Neutron Research, Gaithersburg, MD, United States; 2. Physics, Colorado State University, Fort Collins, CO, United States*

Storing information in magnetic recording technologies requires careful optimization of the recording media's magnetic properties. For example, heat-assisted magnetic recording (HAMR) relies on a pre-recording heating step that momentarily lowers the coercivity of the ferromagnetic recording media, and thereby decreases the energy required for each writing operation. However, reducing the coercivity of common storage media can require local temperature increases of several hundred Kelvin, which in turn can cause lateral heat spreading and limit recording rates. Here, we describe a mechanism for creating dramatic changes in the coercivity of ferromagnetic films over small temperature ranges, by coupling them to an adjacent layer that undergoes a structural phase transition with large volume change. The method is demonstrated in Ni/FeRh bilayers where the Ni layer was deposited at 300 K and 523 K, above and below the FeRh metamagnetic transition at ~370 K. When the Ni layer is grown at high temperatures and then cooled, the ~1% FeRh lattice contraction strains the overlying Ni and promotes domain wall pinning that increases the coercivity by 500% over a 50 K temperature window. This ability to thermally tune the coercivity of ferromagnetic materials, if as general as our model suggests, may open up new materials to HAMR and new avenues to magnetic information storage.

HD-09. Impact of Straightened Thermal Profiles Generated by Gapped Near Field Transducers on Recording SNR. M. Yin[1], *C. Chow*[1], Y. Qin[1], J.A. Bain[1] and J. Zhu[1] *1. Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, PA, United States*

Transition curvature is a limiting factor for areal density (AD) gain in heat assisted magnetic recording (HAMR) [1]. It arises from the curved thermal profile generated by a near field transducer (NFT). In the NFT gap device presented in [2], bringing the plasmonic underlayer closer to the NFT results in a two lobed temperature T profile. We quantitatively assess the relative impact on recording signal-to-noise ratio (SNR) using thermal profiles with reduced curvature generated by the split pole-gapped NFT recording head described in [3]. The hotspot shape is changed by reducing the interlayer (IL) thickness t_{IL} in the media stack so the plasmonic heatsink is closer to the gapped NFT. Fig. 1 shows the normalized change in T from ambient (ΔT) in the storage layer for (a) t_{IL} = 5 nm and (b) t_{IL} = 10 nm. The thinner IL results in a straighter thermal profile in the cross track direction but a larger cross track size. (Thermal management is not considered, but reduction of the IL thermal resistance and a wider hotspot will both lower ΔT_{max} for a given incident power.) The effect on SNR from the tradeoff between reduced curvatures versus adjacent track interference (ATI) from wider spot size is assessed by micromagnetic modelling. A center track is recorded on media with Curie temperature T_C = 750K ± 2%, center-to-center grain spacing of 6 nm ± 2%, and room temperature anisotropy field H_k = 80 kOe. Two side tracks are written to measure ATI on the center track. Recording is performed at T_{max} of 800K, 850K, and 900K by combining a uniform write field and the thermal profiles in Fig. 1. A reader with a Gaussian sensing function is used to read the center track. Fig. 2 shows the resulting contours of constant SNR at optimum T_{max} vs. bit and track density. The straighter, wider thermal profile in Fig. 1 does not offer significant AD gain. At 10 dB, the more curved profile has a maximum AD of 1.65 Tb/in^2 at 1100 kTPI. The straighter profile has a maximum AD of 1.5 Tb/in^2 at 840 kTPI. Detailed discussion on how track density suffers more than bit density improves in this scenario will be presented.

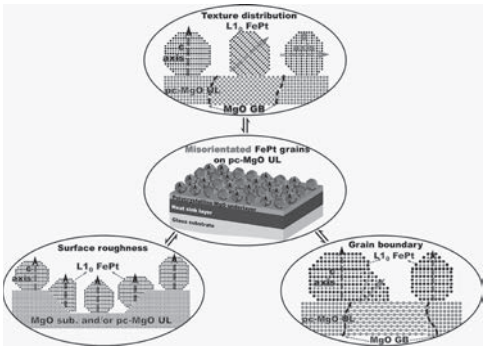
HD-10. Magnetic in-plane components of FePt nanogranular film on polycrystalline MgO underlayer for heat-assisted magnetic recording media. *Y. Takahashi*[2], J. Wang[1,2], S. Hossein[2], T. Ohkubo[2] and K. Hono[2] *1. International Center for Young Scientists (ICYS), National Institute for Materials Science (NIMS), Tsukuba, Japan; 2. Research Center for Magnetic and Spintronic Materials, National Institute for Materials Science (NIMS), Tsukuba, Japan*

A systematic study is conducted on the effect of MgO substrate/underlayer in terms of the surface roughness, grain boundary, and crystallographic texture on the magnetic in-plane components of the FePt-based heat-assisted magnetic recording (HAMR) media (Fig.1). Cross-sectional transmission electron microscope observations revealed that good (001) texture can be developed in FePt granular films even when they are grown on a rough surface of a single crystal-MgO (001) substrate or across the grain boundaries of a (001)-textured polycrystalline-MgO underlayer. The misoriented FePt grains with magnetic easy axes (c-axes) tilted away from the film normal direction mainly originate from their epitaxial growth on an initially misoriented MgO underlayer grains. Micromagnetic simulation results revealed that the FePt grains with misorientation angles larger than ~20° are attributed to the detected magnetic in-plane components (medium noise). Based on these experimental results, we discuss how to improve the (001) texture of the polycrystalline underlayer as well as to develop FePt-based HAMR media with the enhanced signal-to-noise ratio.



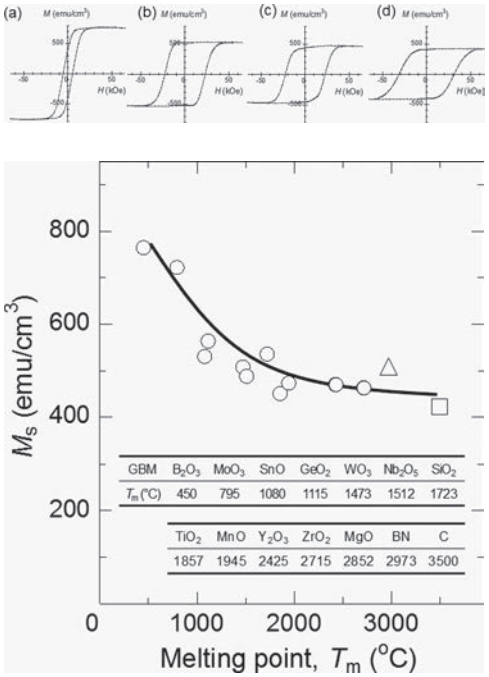


Fig.1 The effect of MgO substrate/underlayer in terms of the surface roughness, grain boundary, and crystallographic texture on the magnetic in-plane components of the FePt-based HAMR media

HD-11. Effect of melting point of grain boundary material on nanostructure and magnetic properties for $L1_0$ typed FePt granular media. *T. Saito*[1], K. Tham[2], R. Kushibiki[2] and S. Saito[1] *1. Department of Electronic Engineering, Graduate School of Engineering, Tohoku University, Sendai, Japan; 2. Tanaka Kikinzoku Kogyo KK, Tsukuba, Japan*

For granular typed perpendicular media with high areal recording density, it is necessary to realize columnar structure, high *c*-axis orientation, well magnetically isolation, and high magnetocrystalline anisotropy (K_u). In the case of conventional CoPt based granular media deposited at room temperature, the critical thickness of columnar growth (d_{cri}) and the amount of stacking faults (P_{fcc}) strongly depend on melting point (T_m) of grain boundary material (GBM). The GBM with low T_m results in well phase separation from magnetic grains in granular media, which leads to increasing d_{cri} and decreasing P_{fcc}[1,2]. On the other hand, for heat assisted magnetic recording as next generation technology, FePt based granular media on flat MgO underlayer deposited at high substrate temperature is a promising candidate. Although researches about GBM focused on electronegativity[3], surface energy[4] and cohesive energy[5] has already reported, T_m of GBM has not been focused. Therefore, we have evaluated the effect of T_m of GBM on phase separation, nanostructure, and intergranular exchange coupling for $L1_0$ typed FePt granular media with various GBMs. Figs. 1 show typical *M–H* loops of $L1_0$ typed ($Fe_{50}Pt_{50}$)–30 vol% (a) B_2O_3 (T_m (°C): 450), (b) SnO (T_m: 1080), (c) MnO (T_m: 1945), and (d) C (T_m: 3500) media with the thickness of 10 nm. Although volume ratio of non-magnetic GBM to FePt is the same amount as 30 vol%, magnetic properties such as M_s, H_c, and α are totally different among these media. Increasing H_c and decreasing α with raising T_m suggest suppression of intergranular exchange coupling. Fig. 2 shows M_s for FePt granular media plotted against T_m of the GBMs. When T_m increases from 450 °C to 3500 °C, M_s decreases from 760 to 420 emu/cm^3 monotonously. M_s for granular media reflects degree of phase separation mentioned above. These results suggest that there is trade-off relationship between promoting phase separation and suppressing intergranular exchange coupling for T_m of the GBM on the condition of a flat MgO underlayer. In the presentation, sheet texture, degree of order obtained from in-plane XRD, and K_u measured by high field torque magnetometer with 9 T will be also discussed.

HD-12. Observation of Out-of-Plane Precession in All-in-Plane Spin-Torque Oscillator for Microwave-Assisted Magnetic Recording. W. Zhou[1], S. Hossein[1], T. Taniguchi[2], S. Tamaru[2], *Y. Sakuraba*[1], S. Kasai[1], H. Kubota[2] and K. Hono[1] *1. National Insititute for Materials Science (NIMS), Tsukuba, Japan; 2. National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan*

The main challenge for realizing MAMR is to develop a spin-torque oscillator (STO) that can generate strong ac magnetic field. A new design of STO has been recently proposed, where only a soft magnetic layer is exploited as the polarizer. [1] It was predicted by both macro-spin and micromagnetic simulations that the magnetization of both polarizer and FGL oscillate together in out-of-plane precession (OPP) mode during operation under perpendicular field of about 1T from the writing pole. [2,3] However, the oscillation dynamics has not been clarified experimentally so far because

of the complex dynamics excited by the interaction between oscillating FGL and polarizer. In this study, we fabricated all-in-plane type STO and investigate its oscillating behavior. A 7-nm-thick $Fe_{67}Co_{33}$(FeCo) layer was used as the FGL while a 7-nm-thick $Ni_{80}Fe_{20}$(NiFe) layer was used as the polarizer, which were separated by 5-nm-thick Ag spacer. The thin film was microfabricated into circular shape nano-pillar device having the diameter of 28 nm. For characterization of the STO, the resistance (R), dV/dI, and the power spectral density of the device were measured with increasing bias DC voltage (U) under a constant H. Fig. 1 shows the MR curve measured under low U. Both magnetizations are aligned to the perpendicular direction over ~ 0.8 T. With Uincreased to ~ 20 mV under 0.81T, the magnetization of NiFe was reversed to the direction opposite to H by STT as indicated by the peak in dV/dI(Fig. 2(a)). As shown in the PSD mapping (Fig. 2(b)), further increase of U led to the emergence of multiple microwave signals. Here the strong microwave signal showing red shift is the result of both the FGL and the polarizer in OPP mode oscillation with different f. The microwave signals marked f_{NiFe} and f_{FeCo} in Fig. 2(b) reflect OPP mode oscillation of the NiFe and FeCo.[4] Such dynamics were well reproduced by micromagnetic simulation, as shown in Fig. 2(c). This result indicates that all-in-plane STO works to realize OPP mode oscillation in FGL and generate ac magnetic field.

HD-13. Asymmetric Far Track Erasure by Domain Walls in Recording Heads. *A. Goncharov*[1], A. Bashir[1] and P. Van Der Heijden[1] *1. Western Digital, San Jose, CA, United States*

Modern recording heads use magnetic shields around the magnetic write pole to control stray fields in the recording media. Although the primary purpose of the shield is to improve recording performance it has an undesirable side effect. This effect is known as Far Track Erasure (FTE) and is a result of erasure by the shield's stray fields on the recording media. The mechanism of erasure is governed by a sharp increase of the magnetic stray field locally underneath the domain wall during switching of the writer's polarity. The magnitude of this field in the media plane can reach several kOe within 100-150 picoseconds. It is found that these stray fields depend drastically on the orientation of the magnetization in the adjacent domains and not on the polarity of the magnetization in the domain wall or on the direction of the flux in the main pole. Micromagnetic simulations confirm this phenomenon both for the pulsed external field applied transverse to the domain wall plane in the thin film and for the recording head during main pole switching. Images of the domain wall in the shield obtained using micromagnetic simulations are shown in Fig.1. In the top image, the domain wall width is reduced at the surface of the shield, resulting in large stray fields at Air Bearing Surface (ABS). The bottom image shows the domain wall which is not affected by the main pole switching process. The difference between two cases is the relative direction of the magnetization in adjacent domains. The domain wall induced erasure has an asymmetric nature resulting in the preferred direction of the magnetization in the shield.

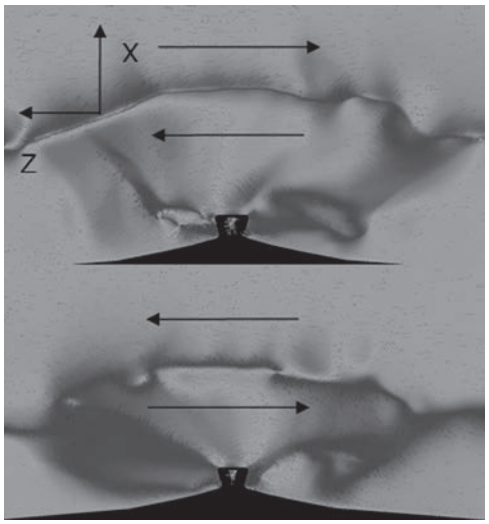

Fig. 1 Simulated domains walls in the shield during main pole magnetization switching. Top: potentially erasing domain wall, right – not erasing domain wall. Arrows show directions of the magnetization in adjacent domains. Color represents magnetization component along the X axis: red – positive, blue – negative.

HD-14. Analytical estimation of transition jitter using switching probability calculations. *N.A. Natekar*[1] and R. Victora[1] *1. Electrical Engineering, University of Minnesota, Twin Cities, Minneapolis, MN, United States*

Micromagnetic simulations are used to calculate the transition jitter, which is an indicator of the HAMR recording performance. To ensure accurate jitter values with low error bars, a high number of transitions are needed. These calculations are long (~ 300 ns) and computationally demanding. Here, we derive analytical equations that estimate the transition jitter via the switching

probability calculations for the single layer FePt media. These calculations are faster since they do not involve demag calculations. To calculate the switching probability distribution (SPD), the media is cooled from a peak temperature down to the room temperature (300K) at a constant cooling rate and the applied field is reversed at a certain temperature. Two factors mainly affect the jitter: grain size (GS) and the heat spot geometry. The GS effect on jitter is derived based on the fact that the desired transition center can lie anywhere within the grain, but the written transition must lie in a grain boundary. This effect was described in [1] and argues that the square of the jitter equals the grain size cubed divided by (12*Read Width). To model the effect of the heat spot, we use the chain rule to relate the switching probability as a function of position to the SPD. An additional factor affecting the total jitter is the size variation for Voronoi grains of the media. Essentially this is a correlation term because larger grains are expected to have smaller switching probability distributions. The resulting jitter is found to be proportional to the square of the Grain Size Distribution (GSD)*Grain Size (GS). The theoretical jitter is estimated as a sum of the jitter due to these three effects. This theoretical estimate is compared to the jitter obtained via micromagnetic simulations for different GS (Fig. 1). The close agreement of the theoretical estimate of jitter obtained using the analytical equations with the jitter values from the micromagnetic simulations shows the accuracy of the analytical equations for estimating the jitter for different grain sizes.

HD-15. Deep Neural Network: Data Detection Channel for Hard Disk Drives with High Degrees of Freedom. *Y. Qin*[1] and J. Zhu[1] *1. Data Storage Systems Center, Electrical and Computer Engineering, Carnegie Mellon University, Pittsburgh, PA, United States*

In this work, we explore the possible performance gain and underlying mechanisms of using a deep neural network (DNN, Fig.1 inset)[1,2], a machine learning (ML) method, as data recovery channel in hard disk drives to replace the conventional data detection channel. Simulated perpendicular recording with both additive white Gaussian noise (AWGN) and transition jitter noise are used for bit-error rate (BER) performance evaluation. The DNN channel is constructed with n-consecutive sampling inputs (green) and 1-bit output (red) with sequential detection. The most renowned property for DNN as data recovery channel is to adaptively optimize the detection performance by directly learning the un-equalized signals without prior knowledge of the recording channel. In this light, DNN can automatically adapt to inter-symbol interference (ISI) at any user bit density. Fig. 1 compares the detection BER as a function of signal-to-noise ratio (SNR) for DNN (solid) and conventional read channel consisting the equalizer and BCJR detector[3] (dashed) at two user bit densities. Only AWGN is included in this experiment. At same BER, it is found that the DNN channel tolerates signals of lower SNR, and the SNR gain grows at higher user bit density. This advantage is mainly because DNN can adaptively extract features/low-level signal representations that naturally embody signal characteristics. Therefore, minimal noise will be boosted by DNN during detection. Another appealing characteristic for DNN channel is the strong resilience for data-dependent noise. Fig. 2 compares the detection performance for both channels as the magnetic transition jitter noise becomes more dominant given constant total noise power. This time, the learned features uniquely show position shifts to cater for the jittering, hence enables DNN to learn the right classification boundary accurately. As a result, the DNN channel maintains similar BER with increasing jitter noise while the conventional channel detection performance severely degrades.

HE-01. Creating Chemical Qubits. J. Zadrozny[2,1], M. Graham[1], M. Fataftah[1] and *D. Freedman[1] 1. Northwestern University, Evanston, IL, United States; 2. Colorado State University, Ft Collins, CO, United States*

Harnessing synthetic chemistry we can design candidate qubits with angstrom scale precision. Within this space we can ask fundamental scientific questions and make synthetic modifications to answer those questions. For example, we can probe the impact of nuclear spin distance on electronic spin coherence. In another approach, we can link candidate qubits into arrays. These results and others will be presented.

HE-02. Control of Spin Relaxation Times via The Spin Bath and its Edge. C. Jackson[1], I. Moseley[1], C. Lin[1], S. Johnson[1] and *J. Zadrozny[1] 1. Chemistry, Colorado State University, Fort Collins, CO, United States*

Magnetic molecules are critical components in current and next generation applications in magnetic resonance imaging and quantum information processing.[1] Toward functionality in these applications, long spin-lattice relaxation (T1) and spin-spin relaxation (T2) times are desired. However, there is a fundamental challenge here – most magnetic molecules display short T1 and T2 values when in the presence of a magnetic environment (the spin bath). Bioimaging environments and information storage environments are spin-rich, and expected to induce fast relaxation (and small T1 and T2). Hence, to move toward actually using magnetic molecules for these applications, we need to understand how to design long relaxation times in highly magnetic environments. This presentation will detail previous [2] and ongoing [3,4] efforts to understand the spin-bath to molecule interaction via molecular chemistry and spin resonance spectroscopy. Specifically, we will discuss the response of the relaxation times in magnetic complexes of vanadium(IV) and cobalt(II) to specific magnetic environments, wherein we tune the magnetic species within and beyond the immediate shell of the metal ion. In both cases, we demonstrate how this tuning is an efficient means to (counterintuitively) slow down magnetic relaxation. Importantly, these results provide previously inaccessible mechanistic insight into processes governing magnetic relaxation in molecular species. In the long term, this fundamental knowledge will lead to molecules with long relaxation times in chaotically magnetic environments.

School of Chemistry, University of Leeds, Leeds, United Kingdom; 5. Institute of Petroleum Engineering, Heriot-Watt University, Edinburgh, United Kingdom*

Spin crossover occurs in compounds where the crystal field splitting of d-orbitals associated with a magnetic moment is of the order of k_BT. As a result, a change of state from low spin (LS) to high spin (HS) can occur at the so-called spin crossover temperature, T_{SCO} [1]. Crucially for caloric applications, the change of state from LS to HS can be either continuous or first order, and it can occur at temperatures up to and beyond room temperature. This makes SCO transitions of interest for caloric cooling applications. Since SCO compounds are paramagnets or diamagnets, the largest caloric effects will be barocaloric rather than magnetocaloric. The caloric potential of SCO compounds has been proposed from a thermodynamic perspective [2] and by use of a microscopic, Ising-like model [3]. In this presentation, we combine neutron scattering at pressures up to 1.2 kbar on a deuterated sample with calorimetry data and SQUID magnetometry under pressures of up to 4.5 kbar to examine the evolution of the structure and transition hysteresis of a first order SCO compound [4]. We provide the first direct experimental demonstration of a giant, low pressure barocaloric effect (BCE) and outline future research directions for the development and optimization of the BCE associated with spin crossover.

Molecular nanomagnets formed by clusters of ions with large number of unpaired electrons have attracted intense study since the discovery that molecular aggregates stabilizing high ground spin states can display Single-Molecule Magnetism (SMM). Cyclic complexes are of particular interest because of their planar high symmetry. We have studied wheel molecules of formula $\{Cr_{10}(OMe)_{20}(O_2CCMe_3)_{10}\}$, ($\{Cr_{10}\}$ from now-on, see Fig. 1a), both in bulk and evaporated by direct sublimation in UHV on metallic single-crystal surfaces [1]. When the molecules are deposited onto the Cu(111) or Au(111) surfaces, a monolayer of $\{Cr_{10}\}$ molecules, self-organized in a quasi-hexagonal 2D network is formed. The magnetic characterization of monolayer, multilayer and bulk (powder) samples of $\{Cr_{10}\}$ has revealed that this cluster exhibits an unusually high S-ground state. The magnetic characterization of grafted $\{Cr_{10}\}$ were studied byXMCD at the Cr $L_{2,3}$ edge at T=2 K and magnetic fields up to B=6T. Magnetization and susceptibility were measured by SQUID on the multilayer and the powder sample up to B=14 T. Static $M(H)$ and dc c(T) measurements resemble the curves previously reported earlier [2], where the $\{Cr_{10}\}$ wheels were described in terms of a total molecule spin S=9 ground state, with overall ferromagnetic coupling. $M(H)$ curves are shown in Fig. 1b). Although Monte Carlo simulations considering the Cr(III) as a Heisenberg S=3/2 spin entity are able to describe the $M(H)$ curves qualitatively, a static Hamiltonian based on nearest-neighbour interactions leading to a S=9 needs a particular combination of ferro- and antiferromagnetic interactions, which is hard to reconcile with the underlying five-fold symmetry of Cr_{10}. Therefore, both experimental results and theoretical considerations suggest complex ground-state properties.

HE-05. Donor Bound Magnetic Polaron in Semimagnetic Quantum Ring. *P. Kalpana*[1] and K. Jayakumar[1] *1. Nanostructure Lab, Department of Physics, The Gandhigram Rural Institute - Deemed to be University, Gandhigram, India*

The experimental realization of Quantum Rings (QR)[1] has paved the way for the theoretical physicists to give attention towards developing theoretical model for Semiconducting QR with magnetic impurity[2, 3]. In the present work, the binding energy of the donor impurity confined inside a semimagnetic QR made up of CdTe / $Cd_{1-x}Mn_xTe$ (Fig. 1) in the presence of perpendicular magnetic field (γ, a dimensionless parameter) applied externally has been focused for various Ring parameters like inner radius R_1, outer radius R_2, Ring width ΔR (= R_2 - R_1) and height of the Ring 'd' of the QR using variational principle in the effective mass approximation. The effect of Bound Magnetic Polaron (BMP)[4] on the donor states due to the presence of magnetic impurity in semimagnetic QR is considered through the calculation of Spin Polaronic Shift (SPS) using mean field theory including modified Brillouin function. The observed results of the binding energy as a function of Ring width ΔR for various 'd' by placing the impurity at the centre of the radial direction ($\rho_i = (R_1+R_2)$ / 2) and the axial direction ($Z_i = 0$) of QR shows that the binding energy increases as 'R_2' decreases from the bulk limit towards the narrower size of the Ring. The donor states are strongly affected by the applied magnetic field which can be ascertained from the rapid fall of binding energy when the strength of γ increases from γ = 0.05 (1.5Tesla) to γ = 0.1 (3Tesla). In the absence of magnetic field, the enhancement in the exchange interaction between the spin of the carrier and the spin of the Mn^{2+} ion is promising only for the Ring parameter d ~ 40Å and R ~ 80Å. But the same is not true when the system is subjected to strong γ as the height of the Ring gets lowered because of the reduction in potential barrier height, $Cd_{1-x}Mn_xTe$. Moreover, the applied field aids the strong exchange interaction which leads to the larger polaronic shift for γ = 0.1 (Fig. 2). The results are presented and discussed.

Molecular overlayers on substrates have a broad field of application in catalysis, sensing, molecular electronics, light-to-energy conversion, etc. In particular, iron-phtalocyanines (FePc) are being investigated as viable substitutes for precious metals in catalysis of the Oxygen Reduction. Recent studies of FePc on Ag(110) have shown that sub-monolayer phases are catalitically active [1]; remarkably, in oxygen-dosed phases O2 intercalates between the molecules and the surface, thereby substantially changing the Fe magnetic moment. Reversible switching of the Fe magnetic moment in some low-density (LD-R1/R2) FePc phases upon an oxygenation-annealing cycle has been demonstrated [2]. In this contribution, we report on the oxygenation capabilities and associated magneto-structural changes of higher-density FePc/Ag(110) phases, the oblique (OB) and square (SQ)/quasi-squared (R3) high-density phases, investigated by combining high-resolution Scanning Tunneling Microscopy (STM), Scanning Tunneling Spectroscopy (STS), Density Functional Theory (DFT) simulations and x-ray magnetic circular dichroism (XMCD) at the Fe L2,3, edge. The STM images reveal the steric impediments of high-density phases to allocate O2 between the FePc and the substrate, which result in less efficient oxygenation / deoxydation processes compared to previously reported LD phases. In the SQ/R3 squared phases, only a fraction of the molecules are able to oxygenate, rotating and suffering a displacement. For the OB oblique phase, the oxygenation efficiency is smaller; and among the oxygenated molecules, only a minor fraction do rotate, while the majority allocate O2 without rotation. The XMCD spectra of the oxygenated phases reflect the different distribution of non- oxygenated, oxygenated-rotated and non-rotated species in the samples (Fig. 1).

HE-07. Strain Effects in Atomic Spin Model. *Y. Hsiao*[1], O.G. Udalov[2], I.S. Beloborodov[2], C.S. Lynch[3] and G. Carman[1] *1. Mechanical and Aerospace Engineering, UCLA, Los Angeles, CA, United States; 2. Physics, California State University, Northridge, Northridge, CA, United States; 3. University of California, Riverside, Riverside, CA, United States*

Recent demands for high-density magnetic storage have resulted in the need for atomistic scale magnetic devices. Strain control of magnetic devices have been demonstrated to be the most energetically viable solution for high-density magnetic storage [1]. For successful implementation of these devices, magnetic modeling techniques are used to better understand magnetization behavior. Atomistic discrete simulation methods have been developed to bridge the gap between micromagnetics and electronic structure [2][3]. However, currently developed atomic spin codes do not incorporate elastodynamics effects. These effects are necessary for determining magnetic states of strain-mediated devices and other strain-related magnetic properties. Here, we introduce coupling between mechanical (phonons) and magnetic (magnons) degrees of freedom into the atomic spin approach. A simple system of two atoms incorporating magnetoelastic effects was tested. Coupled Landau-Lifshitz-Gilbert (LLG) equation, governing the magnetization dynamics, and Newton's equation of motion to govern the mechanical behavior are studied to demonstrate mutual influence of magnetic and mechanical degrees of freedom. Strain effects are introduced as a correction term to both the exchange and anisotropy constants. Magnetoelastic coupling in two-atom system leads to essential modification of magnetic ground state from canted antiferromagnetic to ferromagnetic configuration.

HE-08. Fractional Skyrmions in Ensembles of Exchange-Coupled Nanoparticles. *R. Skomski*[1], A. Ullah[1], B. Balasubramanian[1], W. Zhang[1] and D.J. Sellmyer[1] *1. Physics and Astronomy & NCMN, University of Nebraska, Lincoln, NE, United States*

Conduction electrons exchange-interacting with noncollinear spin structures accumulate a Berry phase that translates into an emergent magnetic field and yields a topological Hall effect (THE) [1]. We investigate the THE in magnetic nanoparticles containing partially developed (fractional) skyrmions, which is a new research direction. The particles are conducting through compaction or embedding in a conductive matrix, and the THE depends on crystal structure, particle size, grain orientation, and grain-boundary morphology. Point-group analysis yields a canonical division into centrosymmetric crystals, noncentrosymmetric crystals (NCSC) without Dzyaloshinski-Moriya (DM) interactions, NCSC with DM interactions but no spin spirals, and NCSC supporting both DM interactions and helical spin structures [2]. However, inversion symmetry, polarity, and chirality, which lead to this four-fold distinction, are not the only consideration. For example, our experiments show that compacted Co nanoparticles do not exhibit a measurable THE, in contrast to the crystallographically very similar NiMnGa (point group D_{6h}). The emergent field includes both radial and angular contributions, both depending on the real-structure morphology. The angular integration shows that the THE decreases with particle size, which agrees with our recent magnetization measurements on MnSi [3] and Co nanoparticles. Second, the THE may be zero for nanoparticles that directly touch each other, due to the involvement of Erdmann-Weierstrass boundary conditions. This mechanism, Fig. 1, strongly reduces the THE but is not fully operative in the case of weakly magnetic grain boundaries and in the presence of a nonmagnetic matrix. Furthermore, strong magnetization gradients near the particle's surface violate Berry's adiabacity condition [4], a consideration much more important in nanoparticulate systems than in ordinary skyrmionic thin films. — This research is supported by DOE BES (DE-FG02-04ER46152).

HE-09. Slow magnetic relaxation in well crystallized, monodispersed, octahedral and spherical magnetite nanoparticles. E. Navarro[1], Y. Luengo[2], S. Veintemillas[2], M. Morales[2], F. Palomares[1], U. Urdiroz[1], F. Cebollada[3] and *J.M. González*[1] *1. Nanostructures and Surfaces, Instituto de Ciencia de Materiales de Madrid, Madrid, Spain; 2. Energy, Environment and Health, Instituto de Ciencia de Materiales de Madrid, Madrid, Spain; 3. POEMMA-CEMDATIC, Universidad Politécnica de Madrid, Madrid, Spain*

Thermally activated relaxation over energy barriers concurrently related to local properties and interparticle interactions constitutes a major contribution to both the coercivity and the applied field frequency dependence of that quantity [1]. We have measured the slow magnetic relaxation of magnetite nanoparticles (NPs), synthetized by using the oxidative precipitation technique, having spherical (S) and octahedral (O) shapes and monodispersed size distributions with average diameters (S NPs) and major diagonals (O NPs) of 21 nm as determined by transmission electron microscopy (TEM). The characterization of the slow relaxation behavior of our NPs was completed at temperatures in the range from 5 K up to 290 K by measuring the time dependence of the magnetization at constant temperature and applied field (the measurements were taken at different fields having magnitudes of the order of the dc coercivity, measured by cycling the field at a rate of 3.2 x $10^2 Am^{-1}s^{-1}$). From our data we evaluated the temperature dependencies of a) the irreversible demagnetization susceptibility, b) the fluctuation field (associated to the thermally induced demagnetization occurring during the measuring time range) and c) the activation volume (corresponding to the demagnetization produced by the fluctuation field). From our results we conclude that i) the irreversible susceptibility peaks in both samples at ca. 135 K (Verwey transition temperature [2]) and ii) the temperature variation of the activation volume shows (Fig. 1) similar values in both samples for temperatures below ca. 135 K and, in the whole considered temperature range, corresponds to an increase of the activation volume by a factor of 10 (S NPs) and 30 (O NPs) with respect to the average NPs volume measured by TEM. Those large increases of the activation volume are compatible with a transition of the thermal activation processes from local to collective.

HE-10. Probing Superparamagnetism in Fe_3O_4 Nanoparticles with Muon Spin Relaxation. *B.A. Frandsen*[1], C. Read[1], J. Stevens[1], M. Christianson[1], C.S. Walker[1] and K. Chesnel[1] *1. Physics and Astronomy, Brigham Young University, Provo, UT, United States*

The transition from the superparamagnetic state to the blocked state in assemblies of single-domain magnetic nanoparticles remains a topic of sustained experimental and theoretical study in the field of nanomagnetism. Historically, most experimental work on superparamagnetism has relied on magnetometry techniques that are sensitive to the macroscopic magnetization of the nanoparticle assemblies. However, local probes of magnetism such as muon spin relaxation (μSR) can provide valuable complementary information to aid our understanding of superparmagnetic dynamics and the blocking transition mechanism. Here, we present a μSR characterization of the transition from the superparamagnetic state to the blocked state in monodisperse Fe_3O_4 nanoparticle samples ranging in size from 5 nm to 20 nm. Analysis of the thermal evolution of the μSR asymmetry spectra (see Fig. 1) allows us to extract relevant physical quantities from the data, including the blocking temperature, characteristic spin fluctuation rates, and the relative phase fractions of the superparamagnetic and blocked states. We discuss systematic trends as a function of temperature and particle size. In addition to providing valuable information about the superparamagnetic behavior of Fe_3O_4 nanoparticles, this work demonstrates the utility of the μSR technique for investigations of magnetic nanoparticles, motivating future studies of related systems.

HE-12. Tuning the Properties of Colloidal Magnetic Particles for Thermometry on the Nanoscale. *A.J. Biacchi*[1], E. De Lima Correa[1], F. Zhang[1], T. Moffat[1], W. Tew[1], M.J. Donahue[1], S. Woods[1], C. Dennis[1] and A.R. Hight Walker[1] *1. National Institute of Standards and Technology (NIST), Gaithersburg, MD, United States*

Accurate, local, remote, and real-time temperature measurements are essential for many technological applications. While conventional thermometry can accurately measure the temperature of a microscale spot on a surface, magnetic nanothermometry is being explored as a method to measure temperature at comparable spatial resolution throughout a volume. Although progress has been made in the development of magnetic nanothermometry,[1] current methods still lack the sensitivity necessary for widespread application. Specifically, the nanomaterials display only modest changes in magnetization with temperature; this response must be strengthened to improve the signal-to-noise ratio as a prerequisite to practical volumetric nanothermometry. Recent theory has predicted sharp temperature features in magnetization can be induced in bilayer nanoparticles, where each layer is composed of a different magnetically coupled material.[2] Here, we engineer solution-synthesized nanoparticles and measure their magnetization dependence on the temperature of their local environment. Prudent selection of the material composition, morphology, and layer thickness provides a means to control the magnetic interaction arising from the coupled layers. This modulation of interfacial properties allows for different magnetic transition temperature regimes and sensitivities, thus providing an opportunity to engineer these nanothermometers' performance as a function of their constituent magnetic coupling. Over the range 100 K to 350 K, under an applied magnetic field of 0.01 T, these structurally complex samples show considerable temperature-dependent change in magnetization. To better understand the underlying causes of the magnetic response, extensive structural characterization was performed. Results collected from X-ray scattering and diffraction, Raman spectroscopy, and high-resolution electron microscopies provide correlations between the nanoscale structure of these particles with their magnetic thermosensistivity. These improved systems of heterostructured, magnetic nanoparticle thermometers will subsequently form the basis of a metrological program for spatially resolved, 3D, high-sensitivity measurements of temperature.

HE-13. Structural and Magnetic Properties of Co_3V Nanoparticles. *O. Tosun*[1], B. Balasubramanian[2,3], R. Skomski[2,3], D.J. Sellmyer[2,3] and G.C. Hadjipanayis[1] *1. Physics & Astronomy, University of Delaware, Newark, DE, United States; 2. Physics & Astronomy, University of Nebraska, Lincoln, NE, United States; 3. Nebraska Center for Materials and Nanoscience, University of Nebraska, Lincoln, NE, United States*

We have investigated the structural and magnetic properties of Co_3V nanoparticles prepared by the cluster-beam deposition (CBD) technique. The composition, structure and magnetic properties of the nanoparticles have been characterized by energy-dispersive X-ray spectroscopy (EDS), X-ray diffraction (XRD), high-resolution transmission electron microscopy (HR-TEM), and magnetometry, respectively. Bulk Co_3V exists in two phases: An ordered hexagonal (Al_3Pu-type) low-temperature phase (LTP) and a cubic $L1_2$ (Cu_3Au)-type high-temperature phase (HTP) [1, 2]. Both the LTP and HTP are paramagnetic at room temperature. As-made Co_3V nanoparticles with an average size of 6 nm exhibit a mixture of the LTP and HTP. Thermomagnetic measurements performed showed that the as-made nanoparticles are ferromagnetic with Curie temperature (T_C) of 380 K. Hysteresis-loop measurements revealed that the as-made nanoparticles have saturation magnetization (M_s) values of 65 and 75 emu/cm^3 and coercivity (H_c) values of 0 and 0.30 kOe at 300 and 50 K, respectively. When the particles are annealed at 573 K for 4 hours, their size is increased to 20 nm and the particles show predominantly the HTP structure. Their magnetic properties drastically change; their M_s values increased to 300 and 325 emu/cm^3 and H_c values to 0.10 and 0.50 kOe at 300 and 50 K, respectively. The dramatic increase in the magnetic properties of the Co_3V nanoparticles could be attributed to segregation of excess Co on the particles surface which can lead to polarization of the neighboring Co atoms on the surface.

HF-01. Electronic, magnetic and structural properties of epitaxial Co_2MnZ (Z=Al, Si, Ga, Ge, Sn, Sb) Heusler alloys. *C. Guillemard*[1,2], S. Petit-Watelot[1], J. Rojas-Sanchez[1], P. Le Fevre[2], F. Bertran[2] and S. Andrieu[1] *1. Nanomagnetism and Spintronics Team, Institut Jean Lamour, Nancy, France; 2. Cassiopée Beamline, Synchrotron SOLEIL, Saint-Aubin, France*

Although giant magneto-resistance was discovered more than 25 years ago, the development of spintronics is still very active due to a continuous flow of discoveries. In most spintronics studies, standard transition metals like Fe, Ni, Co (and alloys thereof) are conveniently used. However, alternative materials with superior electronic properties are desirable. In particular, a class of materials called Half Metal Magnets (HMM) in theory satisfies such properties [1]. HMM compounds are metallic for majority spins and insulator for minority spins which leads to exciting properties for spintronic and magnonic devices. For instance, 100 % of spin polarization was obtained in Co_2MnSi(001) epitaxial layers grown by Molecular Beam Epitaxy (MBE) [2], confirming its HMM behavior and explaining the huge TMR observed in Co_2MnSi-based magnetic tunnel junctions [3]. Moreover, extremely low Gilbert damping values (down to 7 $x10^{-4}$) were measured, confirming the reduction of the magnetic damping [2]. We propose here a study of MBE grown Co_2MnZ (Z=Al, Si, Ga, Ge, Sn, Sb) epitaxial layers. In a first step, a structural investigation of the chemical ordering in the series is presented through high resolution scanning electron microscopy (Fig.1), confirming the $L2_1$ chemical ordering in our Heusler layers (except for Z=Al). Additionally, the spin polarization of each layer is measured using spin-resolved photoemission spectroscopy and is compared with *ab initio* calculations. Then, ultra-low effective damping values are confirmed for the whole series (down to 4.6 $x10^{-4}$) using broadband ferromagnetic resonance and finally, the interplay between spin polarization and magnetic damping is analyzed [4].

HF-02. Structural characterization and magneto-transport properties of magnetron co-sputtered ferromagnetic Weyl semimetal Co2TiGe. *D. Dyck*[1], A. Becker[1], T. Matalla-Wagner[1], J. Koo[1], I. Ennen[1], K. Rott[1] and G. Reiss[1] *1. Physics Department, Center for Spinelectronic Materials & Devices, Bielefeld, Germany*

Weyl semimetals theoretically promise exotic transport properties and are also interesting for spintronic devices. Thus, the research is pursued with high effort in the recent years [1, 2]. Implementation in real life applications requires a scalable and energy efficient approach. As a highly tunable material class, Heusler compounds are particularly interesting in this respect [3, 4]. Here, we investigate the ferromagnetic Weyl semimetal candidate and transition metal based Full Heusler compound Co2TiGe [5, 6, 7]. X-ray diffraction (XRD) analysis and φ-scans of the magnetron co-sputtered thin films show a highly textured $L2_1$ structure of the 225 (Fm-3m) space group with a lattice constant of 5.81 Å at room temperature which is close to the literature value [5]. Transmission electron microscopy (TEM) confirms the high crystallographic quality and smooth growth. The magnetic properties have been examined by magneto-optical Kerr effect (MOKE) and vibrating sample magnetometry (VSM). The results (Fig. 1) show a magnetic moment of 1.4 Bohr magneton per formula unit at room temperature and 1.9 μ_B / f.u. at 5 K. The extrapolated saturation magnetization and Curie temperature are 1.92 μ_B / f.u. and 379.3 K, respectively, which is in accordance to the theoretical predictions and recent results for bulk samples [5]. In addition, magneto-transport measurements have been carried out. The resistivity shows the expected metallic behavior and the residual resistance ratio of approximately 1.5 is in good agreement with the literature values [8]. The residual resistivity is around 50 μΩcm. The temperature dependent anomalous Hall effect

(AHE) shows a decreasing Hall resistivity and increasing perpendicular saturation magnetization for decreasing temperatures. Figure 2 shows, that the anomalous Hall conductivity is only weakly dependent on the longitudinal conductivity, which is considered as an indication for Weyl halfmetallicity as their chiral anomaly contributes to a dominant intrinsic mechanism. Additionally, FMR and TMR measurements have been performed on the samples.

HF-03. Large anomalous Hall angle in topological semimetal Co2MnGa thin films. *Y. Zhang*[1,2], G. Dubuis[1,2] and S. Granville[1,2]
1. Robinson Research Institute, Victoria University of Wellington, Wellington, New Zealand; 2. MacDiarmid Institute for Advanced Materials and Nanotechnology, Wellington, New Zealand

Full Heusler ferromagnet Co2MnGa is predicted to be a magnetic Weyl semimetal. having a large net Berry curvature near the Fermi energy associated with nodal lines and Weyl points[1, 2]. Moreover, Tung *et al*.[3] and Manna *et al*.[4] found the anomalous Hall current would be nearly fully spin-polarized, even though Co2MnGa is not a half-metallic ferromagnet for charge current. These exotic transport properties, along with the large Curie temperature $T_c \approx 694$ K, make Co2MnGa an ideal candidate for studying the interplay of topology and magnetism and realizing room temperature spintronics applications. Recently, bulk Co2MnGa crystals have shown large anomalous Hall and giant anomalous Nernst effects, which support the predicted Weyl behaviour, however so far there is little evidence from thin films. We have systematically investigated the transport properties of epitaxial Co2MnGa thin films with thicknesses from 5 nm to 50 nm. For the 50 nm film, both anomalous Hall conductivity (σ_{xy}) and longitudinal conductivity (σ_{xx}) increase monotonically on cooling and approach a constant 812 Ω^{-1} cm^{-1} and 7250 Ω^{-1} cm^{-1}, respectively, at low temperature, as shown in Figure 1. Figure 2 shows the thickness dependence of the anomalous Hall angle, measured from 300 K to 3 K. The thick films show a new room temperature record for anomalous Hall angle 9.7%. For films with thicknesses below 20 nm, the anomalous Hall angle becomes much smaller and is temperature independent due to a significantly lower anomalous Hall conductivity. The magnetotransport properties of the thick films (above 20 nm) resemble those of bulk Co2MnGa, but for films thinner than 15 nm the sudden decrease in indicates size-dependent changes to the electronic properties near the Fermi level.

HF-04. Spin-gapless Semiconducting Nature of Co-rich $Co_{1+x}Fe_{1-x}CrGa$. *D. Rani*[1], E. Enamullah[1], L. Bainsla[2], K. Suresh[1] and A. Alam[1] *1. Physics, IIT BOMBAY, Mumbai, India; 2. WPI Advanced Institute for Materials Research, Tohuku university, Sendai, Japan*

Spin gapless semiconductors (SGSs) are an interesting class of materials which bridge the gap between semiconductors and half-metallic ferromagnets. This class of materials shows band gap in one of the spin channels and a zero band gap in the other [1]. The structural, electronic, magnetic, and transport properties of Co-rich SGS $Co_{1+x}Fe_{1-x}CrGa$ are investigated using both theoretical and experimental techniques. The key advantage of Co-rich samples $Co_{1+x}Fe_{1-x}CrGa$ is the high Curie temperature (T_C) and magnetization, without compromising the SGS nature (up to $x = 0.4$), and hence our choice. The quaternary Heusler alloys $Co_{1+x}Fe_{1-x}CrGa$ ($x = 0.1$ to 0.5) are found to crystallize in LiMgPdSn-type structures. The measured Curie temperature increases from 690 K ($x = 0$) to 870 K ($x = 0.5$). The obtained T_C for $x = 0.3$ (790 K) is found to be the highest among all previously reported SGS materials. Observed magnetization values follow the Slater-Pauling

rule[2, 3]. Measured electrical resistivity, in the temperature range of 5–350 K, suggests that the alloys retain the SGS behavior up to x = 0.4, beyond which it reflects metallic character. Unlike conventional semiconductors, the conductivity value (σ_{xx}) at 300 K lies in the range of 2289 S cm−1 to 3294 S cm−1, which is close to that of other reported SGS materials [4, 5]. The anomalous Hall effect is comparatively low. The intrinsic contribution to the anomalous Hall conductivity increases with x, which can be correlated with the enhancement in chemical order [6]. The anomalous Hall coefficient is found to increase from 38 S/cm for x = 0.1 to 43 S/cm for 0.3. Seebeck coefficients turn out to be vanishingly small below 300 K, another signature for being SGS [5]. Ab-initio calculations indicates that the spin-gapless behavior is retained in the system for x < 0.375 and the alloy becomes HM for x ≥0.375. As such, Co-rich CoFeCrGa is a promising candidate for room temperature spintronic applications, with enhanced T_C, magnetic properties, and SGS nature [7].

HF-05. Observation of positive linear magnetoresistance in epitaxial Mn_2CoAl films. *K. Kudo*[1], S. Yamada[2,1], A.N. Hattori[3], H. Tanaka[3,2] and K. Hamaya[2,1] *1. Department of Systems Innovation, Graduate School of Engineering Science, Osaka University, Toyonaka, Japan; 2. Center for Spintronics Research Network, Graduate School of Engineering Science, Osaka University, Toyonaka, Japan; 3. Institute of Scientific and Industrial Research, Osaka University, Ibaraki, Japan*

Spin-gapless semiconductors (SGSs) have been widely explored in the field of spintronics [1,2]. Recently, one of the ferromagnetic Heusler alloys, Mn_2CoAl (MCA), was theoretically and experimentally regarded as an SGS because positive and linear magnetoresistance (MR) due to the quantum linear MR effect [3] was observed despite a ferromagnetic material. However, the previous work was demonstrated in bulk samples [2], which could not be applied to electronics device structures. Although there are lots of studies of MCA films [4-7] for device applications, the positive linear MR effect has not been observed yet in the films. Here we demonstrate high-quality epitaxial MCA films showing the positive linear MR effect for the first time. Epitaxial MCA films were grown on $MgAl_2O_4$(100) substrates at 100 °C by using molecular beam epitaxy. From HAADF-STEM image and EDX line profiles (Fig. 1), we can confirm stoichiometric and uniform MCA layers on $MgAl_2O_4$(100). We also observed XA- or $L2_1$-ordered structures from XRD measurements. Figure 2 shows field-dependent MR curves for a representative MCA film at low temperatures. In addition to the small anisotropic MR (AMR) effect in low magnetic-field region, clear positive and linear MR curves, similar to bulk-MCA [2], are observed even for the film. For the MCA films, we also observed nearly temperature-independent electrical resistivity [2] and gate-tunable resistivity by using electric-double-layer field effect transistors [5] (not shown here). Although the estimated carrier concentration was ~10^{22} cm^{-3}, relatively large compared to bulk-MCA (~10^{20} cm^{-3}) [2], we consider that the observed positive linear MR effect due to the quantum linear MR effect originates from the gapless-like electronic band structure near the Fermi level in MCA [2]. This work was partly supported by JSPS KAKENHI (No. 16H02333, 18KK0111) and JST-CREST (No. JPMJCR18J1).

HF-06. The atomic ordering dependence of valence electronic structure in half-metallic $Co_2Fe(Ga_{0.5}Ge_{0.5})$ Heusler alloy observed by hard X-ray photoemission spectroscopy. *K. Goto*[1,2], Y. Sakuraba[2], Y. Miura[2], I. Kurniawan[2,1], A. Yasui[3], K.R. Loku Singgappulige[3], Z. Chen[2,1], H. Tajiri[3], A. Kimura[4] and K. Hono[2,1] *1. University of Tsukuba, Tsukuba, Japan; 2. Research Center for Magnetic and Spintronic Materials, National Institute for Materials Science, Tsukuba, Japan; 3. Japan Synchrotron Radiation Research Institute, Sayo, Japan; 4. Hiroshima University, Higashi-hiroshima, Japan*

Recently, large MR ratio over 50% at room temperature have been demonstrated in CPP-GMR devices using half-metallic Heusler alloy, $Co_2FeGa_{0.5}Ge_{0.5}$ (CFGG),[1] which is promising for future applications such as a next generation read head for HDD. However, it is still an open question how much intrinsic spin-polarization in the bulk region (β) and how β changes with temperature. To find an answer to this question, it is crucial to see the bulk electronic structure of the Heusler alloy and investigate its correlation with bulk sensitive spin-dependent transport. In this study, first, anomalous XRD was performed for CFGG thin films annealed at different temperature at BL13XU SPring-8 to quantitatively evaluate the degree of atomic ordering including the order between Co and Fe. Then, hard X-ray photoemission spectroscopy (HAXPES) was performed at BL09XU SPring-8 to observe how half-metallic valence band (VB) structure forms with atomic ordering. Fig 1 shows the X-ray energy dependence of $I_{(002)}/I_{(004)}$ intensity ratio of different ordered CFGG measured by AXRD. The enlargement of the peak at Co *K* absorption edge indicates the improvement of Co-Fe ordering with increasing annealing temperature. Fig. 2(a) shows VB HAXPES spectra. The observed variation of VB structure agrees well with the spin integrated DOS calculated by the *ab initio* calculation results for different atomic ordering evaluated by AXRD (Fig 2(b)). Structures A-E corresponded to structures a-e in Fig. 2(b) are enhanced with the atomic ordering. In contrast, the structure Z around $E_B = 0.3$ eV is suppressed with the atomic ordering. This result suggests HAXPES directly observed the existence of in-gap state by Co-Fe disordering and the formation of half-metallic gap by improving Co-Fe ordering. The spin-dependent transport property of CFGG will be discussed from viewpoint of the electronic structure in bulk region based on our HAXPES study.

HF-07. Nanoscale Magnetic Phase Competition Across the $Ni_{50-x}Co_xMn_{40}Sn_{10}$ Phase Diagram: Insights from Small-Angle Neutron Scattering. *S. El-Khatib*[1,2], K. Bhatti[2], V. Srivastava[3], R. James[3] and C. Leighton[2] *1. Physics, American University of Sharjah, Sharjah, United Arab Emirates; 2. Chemical Engineering and Materials Science, University of Minnesotta, Minneapolis, MN, United States; 3. Department of Aerospace Engineering and Mechanics, University of Minnesota, Minneapolis, MN, United States*

Ni_2MnSn-derived $Ni_{50-x}Co_xMn_{25+y}Sn_{25-y}$ alloys are prime examples of off-stoichiometric Heusler alloys recently discovered to exhibit attractive magnetic properties and extraordinarily reversible martensitic phase transformations. Multiferroicity, magnetic phase competition/separation, magnetic shape memory, and magneto-, elasto-, and baro-caloric effects result, generating great interest and application potential [1]. Here, we use small-angle neutron scattering (SANS) (previously applied only at a single *x* [2]) to explore all three regions of the $Ni_{50-x}Co_xMn_{40}Sn_{10}$ phase diagram (Fig. 1) [1]. Wide temperature and scattering vector range (20 – 500 K, 0.004 – 0.2 $Å^{-1}$) SANS on $x = 2$, 6, and 14 polycrystals (e.g., Fig. 2) provides a detailed picture of the evolution in magnetic order and inhomogeneity. Phase separation into short-range coexisting ferromagnetic and antiferromagnetic regions is deduced below the martensitic transformation at $x = 2$ and 6, with ~13 nm ferromagnetic cluster spacing. Remarkably, at $x = 14$, where the martenstic transformation is suppressed and ferromagnetic austenite is stabilized to low temperatures, nanoscopic magnetic inhomogeneity nevertheless persists. Distinct ferromagnetic clusters (~36 nm spacing) in a ferromagnetic matrix are observed at intermediate temperatures, homogenizing into uniform ferromagnetism only at low temperatures. This unusual ferromagnet cluster/ferromagnet matrix inhomogeneity, as well as subtleties of magnetic cluster freezing, are discussed in light of nuclear magnetic resonance data [3,4], and the recent observation of annealing-induced core/shell nanoprecipitates. Implications for origins of magnetic inhomogeneity in such alloys will be discussed.

HF-08. Giant current-orientation effect of the anisotropic magnetoresistance in Co_xFe_{1-x} single crystal films. *F. Zeng*[1], Z. Ren[2,4], Y. Li[3], J. Zeng[1], J. Miao[2], W. Zhang[3], Z. Yuan[4] and Y. Wu[1] *1. Department of Physics, Fudan University, Shanghai, China; 2. School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China; 3. Department of Physics, Oakland University, Rochester, MI, United States; 4. Department of Physics, Beijing Normal University, Beijing, China*

Anisotropic magnetoresistance (AMR) is one of the most fundamental magneto-transport properties. Although in polycrystalline system AMR is independent of the current orientation, in single crystalline system the current orientation with respect to the crystal axis could influence AMR owing to the crystal symmetry breaking. So far, the reported current orientation effects on AMR have been restricted to 100 % ~ 200 % in semiconducting ferromagnetic alloys [1]. Understanding the current-orientation effect on AMR in metallic crystalline alloys could be crucial for further revealing the intrinsic mechanism of the spin-dependent transport properties in magnetic materials. In this work, we systematically studied the current-orientation effect of AMR in single-crystal Co_xFe_{1-x} alloys, which have recently aroused tremendous interests due to the ultralow Gilbert damping exhibited [2]. For Co concentrations x between 0.2 and 0.65, we found a significantly large current-orientation effect of the AMR. At x=0.65, for example, the difference in the relative magnitudes of the AMR ratio reaches over 4000 % for current along <100> an <110> directions. But the planar Hall effect shows a clear reciprocal relationship for this two current directions. In addition, the current-orientation effect of the AMR also strongly influences the spin rectification effect at gigahertz frequencies. The experimental AMR observations are consistently described by a symmetry-based phenomenological model and first-principles calculations. The band structure calculation explains the giant anisotropic AMR effect in Co_xFe_{1-x} alloys, which reveals that AMR is related to the nodal ring points in the electronic band structure. This large current-orientation AMR effect is expected to have significant potential to be implemented in future dc and high-frequency spintronics devices, e.g., as a signal readout technique.

Magnetic ordering, interfacial effects, and spin-orbit coupling can effectively break symmetries in crystal structures, and thus have been observed to generate magnetoresistances with anisotropic properties. Spin Hall magnetoresistance was detected in YIG/Pt systems in 2013 [1-2], while more recently, uniaxial magnetoresistance [3-5] and anomalous Hall magnetoresistance [6-7] have been discovered. In addition to direct applications for resistance control or magnetic direction detection, these effects can probe the strength and nature of the underlying mechanism by which the symmetry is broken. Spin Hall magnetoresistance and anomalous Hall magnetoresistance have been used to understand spin accumulations generated by spin-orbit coupling, and it is possible that other spintronics effects, including potential spin-induced planar Hall magnetoresistances, may be probed through magnetoresistance effects. While longitudinal magnetoresistance effects have been studied in some depth for simple ferromagnets, transverse magnetoresistance (Hall voltage) effects have received less attention. We have conducted an investigation of transverse and longitudinal magnetoresistance in sputtered permalloy ($Ni_{80}Fe_{20}$) and permalloy/heavy metal bilayers as the permalloy's magnetization is manipulated with external magnetic fields up to 14 T. We have particularly focused on the transverse magnetoresistance generated as the magnetization of the permalloy is rotated into the out-of-plane direction.

We report magnetoresistance signals indicative of novel symmetry-breaking mechanisms in ferromagnetic systems and discuss the implications of these findings. This work was supported as part of Quantum Materials for Energy Efficient Neuromorphic Computing, an Energy Frontier Research Center funded by the U.S. DOE, Office of Science.

(Ba,K)(Zn,Mn)$_2$As$_2$ is a new *p*-type diluted ferromagnetic semiconductor, which crystallizes in the tetragonal $ThCr_2Si_2$ structure (*I*4/*mmm*) [1]. The host compound $BaZn_2As_2$ is a narrow-gap semiconductor with a band gap of 0.2 eV [2]. Since Mn^{2+} substitution for Zn^{2+} does not introduce carriers to the system, it is possible to control the number of holes independently by substituting K^+ for Ba^{2+}. The Curie temperature (T_C) reaches 230 K exceeding the highest T_C = 200 K of (Ga,Mn)As. Owing to the layered crystal structure, this material has a perpendicular magnetic anisotropy [3]. In this study, to reveal the origin of the uniaxial magnetic anisotropy, we have measured K 9.6%- and Mn 19.5%-doped single crystals using the angle-dependent x-ray magnetic circular dichroism (AD-XMCD) method. AD-XMCD is a unique method by which one can directly measure the anisotropy of spin and orbital magnetic moments. In addition, by aligning the spin magnetic moment perpendicular to the incident x ray (transverse geometry), one can probe the anisotropic distribution of the 3*d* spin density [4]. The obtained x-ray absorption spectra (XAS) and XMCD spectra were similar to those of (Ga,Mn)As [5] as shown in Fig. 1. This indicates that the ferromagnetism is carrier-induced as in the case of (Ga,Mn)As. Figure 2 shows the XMCD spectra taken with the transverse geometry (TXMCD). The observed finite dichroic signals originate from the aspherical distribution of 3*d* electrons, and indeed the TXMCD spectra were well reproduced by the configuration-interaction cluster-model calculation incorporating the D_{4h} crystal-field splitting. Since hole carriers were found to reside in the d_{xz} and d_{yz} orbitals in the calculation, we propose that lifting the degeneracy of p-$d_{xz,yz}$ hybridized orbitals at the Fermi level caused by spin-orbit interaction is responsible for the perpendicular magnetic anisotropy of this compound.

We report on the experimental observation and theoretical studies of a self-assembled Fe-rich (In,Fe)As nano-lamellar structure that is driven by anisotropic spinodal decomposition at the growth front during laser heating-induced recrystallization of Fe-implanted InAs [1]. Pseudomorphically embedded in the InAs lattice, those Fe-rich nano-lamellae are perpendicular to the (001) surface and parallel to the in-plane [1-10] crystallographic direction. The Fe atoms are substitutionally incorporated at the indium sites. Magnetic measurements indicate a typical blocked superparamagnetic behavior suggesting strong ferromagnetic orderings inside the Fe-rich nanostructures, but weak coupling between the nano-lamellae. Our findings explain the surprisingly high apparent Curie temperatures and unexpected two- and eight-fold symmetry of crystalline anisotropic magnetoresistance found previously in Be-doped n-type (In,Fe)As grown by molecular beam epitaxy [2]. Prompted by these results we discuss how a different d-level electronic configuration of Fe in InAs and Mn in GaAs [3] affects the magnetic ion incorporation and spatial distribution and, thus, magnetism

and anisotropy. Our results also indicate that the directional distribution of impurities or alloy components setting in during the growth may account for the observed nematicity in other classes of correlated systems.

Historically, comprehensive studies of dilute ferromagnetic semiconductors, e.g., *p*-type (Cd,Mn)Te and (Ga,Mn)As, paved the way for a quantitative theoretical description of effects associated with spin-orbit interactions in solids, such as crystalline magnetic anisotropy. In particular, the theory was successful in explaining *uniaxial* magnetic anisotropies associated with biaxial strain and non-random formation of magnetic dimers in epitaxial (Ga,Mn)As layers. However, the situation appears much less settled in the case of the *cubic* term: the theory [1] predicts switchings of the easy axis between in-plane <100> and <110> directions as a function of the hole concentration, whereas only the <100> orientation has been found experimentally. Here, we report on the experimental observation of such switchings by magnetization and ferromagnetic resonance studies on a series of high-crystalline quality (Ga,Mn)As films [2]. Our findings are described by the mean-field *p-d* Zener model [1] augmented with three new ingredients [2]. The first one is a scattering broadening of the hole density of states, which reduces significantly the amplitude of the alternating carrier-induced contribution. This opens the way for the two other ingredients, namely the so-far disregarded single-ion magnetic anisotropy and disorder-driven non-uniformities of the carrier density, both favoring the <100> direction of the apparent easy axis. Accordingly, when the disorder gets reduced a switching to the <110> orientation is possible in a certain temperature (as presented in Fig. 1) and hole concentration range. The work has been supported by the National Science Centre, Poland through UMO - 2011/02/A/ST3/00125 grant.

Two-dimensional (2D) transition metal dichalcogenides (TMDs) have attracted enormous attention due to their unique spin-locked valley properties. Breaking valley degeneracy is an approach to manipulate the valley degree of freedom for classical and quantum information applications. Based on the idea of realizing diluted magnetic semiconductor, introducing magnetic transition metal ions into TMDs may provide a convenient route to introduce magnetic order, and break the time reversal symmetry. In situ doped manganese (Mn) in monolayer molybdenum disulfide (MoS_2) via vapor phase deposition techniques was reported earlier. However, the doping concentration was low and there was no direct demonstration by magnetic measurements. In this work, we developed an effective approach to dope MoS_2 monolayer with controllable concentration of Mn ions. In this approach, a single phase Mn-doped MoO_3 compound precursor was used to synthesize Mn-doped MoS_2. The magnetic properties of monolayer Mn doped MoS_2 and undoped MoS_2 were measured with Quantum Design Magnetic Property Measurement System (MPMS), which indicated that the ferromagnetism of monolayer MoS_2 was enhanced dramatically (as shown in Figure 1). Furthermore, we use magneto-optical measurements to investigate the valley properties.

Ferrimagnet (FIM) is an excellent platform to explore the antiferromagnetic spintronics because it shows antiferromagnetic spin dynamics at the magnetization or angular momentum compensation points. For example, the ultrafast domain wall motion was indeed realized in angular-momentum-compensated GdFeCo-FIM [1]. However, at the compensation points, the effect of spin dynamics on the electrical transport have received less attention, despite the exotic electrical transport in magnetic materials (e.g. various magnetoresistance effects) lies at the heart of spintronic applications. Moreover, the recently discovered unidirectional magnetoresistance (UMR) in ferromagnet/heavy-metal bilayers is a good probe to study on the interaction between spin dynamics and the electrical transport because the UMR is possibly induced by the spin-current-driven magnon excitation [2-4]. In this study, we investigated the magnon-induced UMR in CoGd 10/Pt 5 (nm) bilayers with composition variation and compared it with Brillouin light scattering (BLS) spectra in order to clarify the effect of the spin dynamics on the spin transport across the compensation point. Figure 1(a) shows that the UMR is obtained from bilayers with different compositions. We found that two peaks near zero field, representing magnon-induced UMR, are clearly enhanced in the magnetization-compensated $Co_{65}Gd_{35}$/Pt bilayer. Figure 1(b) presents the center frequencies of BLS spectra under different in-plane fields as a function of Gd concentration, demonstrating that the lowest value appears at 35% of Gd. This indicates that CoGd has the smallest magnon gap at the magnetization compensation point. Thus, we can conclude that the magnon-induced UMR is effectively generated by the strong magnon excitation due to a small magnon gap. These results suggest that the dynamics of FIM is strongly correlated to the magnetoelectrical transport.

Large magneto-conductance effect has received considerable attention for reconfigurable logic applications[1,2]. However, practical efforts to develop this new device suffer from low signal-to-noise ratio and scale down issues. Here we investigate magneto-conductance in InAs nanowires which have high mobility and narrow band-gap in comparison with silicon-based nano-channelones, leading to highly sensitive to the magnetic field. Due to impact ionization mechanism, this material exhibits a considerable change of conductance in response to a bias voltage[3] (see Fig.1). We demonstrate that this impact ionization is controlled effectively by the magnetic field as well. This feature comes from the magnetic field dependent carrier generation and recombination. The correlation between impact ionization and magnetic field results in the four-order-change of magneto-conductance. Thus, our devices can be used as an electrical switch whose ON/OFF state is determined by the magnetic field. Moreover, this ON/OFF state is dependent on the polarity of magnetic field: for a given field strength, the device shows ON state for a certainsome field direction, while it becomes OFF state for the opposite direction (see Fig.2). Through photoconductivity measurement, we experimentally verify this diode characteristics is caused by the recombination at the nanowire surfaces. We believe that this work shows the possibility of application for reconfigurable logic devices[1,2].

HG-01. Chiral Exchange Drag. *S. Yang*[1] *1. IBM Research - Almaden, San Jose, CA, United States*

Long-range interactions between quasiparticles give rise to a 'drag' that affects the fundamental properties in condensed matter physics like Coulomb drag [1]. Drag typically involves the exchange of linear momentum between quasiparticles affecting transport properties. We recently discovered a new form of drag, "Chiral Exchange Drag", that involves the exchange of angular momentum between two current-driven magnetic domain walls (DWs) [2]. We found that the DWs motions are correlated and determined by the strength of the drag. For example, when the drag is below a threshold value, the DWs move together at a constant intermediate velocity with a steady leakage of angular momentum from the faster to the slower wall. On the other hand, we showed that when the drag exceeds a threshold value, an entirely different dynamic can take place in which the faster DW's magnetization oscillates synchronously with a precessional motion of the slower DW's magnetization, and angular momentum is continuously transferred between them: "Chiral Exchange Drag Anomaly". Our findings demonstrate a method for delivering spin angular momentum remotely to magnetic entities showing analogues with Dirac fermions.

HG-02. Ultrafast Current-Driven Domain Wall Motion in Magnetic Insulting Garnets. *L.M. Caretta*[1], S. Oh[2], T. Fakhrul[1], D. Lee[2], S. Kim[3], C. Ross[1], K. Lee[2,4] and G. Beach[1] *1. MIT, Cambridge, MA, United States; 2. Korea University, Seoul, The Republic of Korea; 3. University of Missouri, Columbia, MO, United States; 4. KU-KIST, Seoul, The Republic of Korea*

The study of the dynamics of magnetic quasiparticles, such as chiral skyrmions and domain walls (DW), has attracted much attention, not only for its underlying physics, but also for its potential technological applications in next-generation memory and logic operations. As such, the urge to push the boundaries of quasiparticle velocities to their fundamental limits has been of strong interest. Research of quasi particle dynamics has focused on chiral spin textures in metallic ferromagnet systems, where a heavy metal underlayer, such as Pt, provides both a large spin-orbit torque and an interfacial DMI[1–3]. However, damping in metals is generally high, which limits the spin texture mobility. Furthermore, ferromagnets have fundamental limits for spin texture speed[4]. A broader, ubiquitous class of materials, magnetic insulating garnets, have been extensively studied for their technologically desired spintronic properties[5]. Their low damping and ferrimagnetic dynamics make them ripe candidates for ultrafast spin textures. Moreover, the Dzyaloshinskii-Moriya interaction (DMI) has recently been observed in these materials, and spin-orbit effects from adjacent heavy metal layers have been used to manipulate the magnetisation in these materials[6,7]. Here, we use a pure spin current from an adjacent Pt overlayer to characterise chiral DW motion in epitaxial iron garnet films with perpendicular magnetic anisotropy. By studying both the rare-earth dependence and thickness dependence of the DMI, we find that the DMI is a general feature of rare-earht iron garnet films, and that DMI manifests from the substrate oxide – magnetic oxide interface. We use the significant interfacial DMI and a large spin-orbit torque to drive chiral DWs in GGG/TmIG/Pt to over 2000 m/s. Moreover, we characterize the dynamics in this system as a function of both TmIG thickness and temperature. Finally, we demonstrate current-driven DW motion in low-damping GSGG/BiYIG/Pt to record velocities of over 4000 m/s, approaching the magnon group velocity in the system.

Spintronics, which is the basis of a low-power, beyond-CMOS technology for computational and memory devices, remains up to now entirely based on critical materials such as Co, heavy metals and rare-earths. Here, we show that Mn_4N, a rare-earth free ferrimagnet made of abundant elements [1], is an exciting candidate for the development of sustainable spintronics devices. Mn_4N thin films grown epitaxially on $SrTiO_3$ substrates possess remarkable properties, such as a perpendicular magnetisation, a very high extraordinary Hall angle (2%) and smooth domain walls, at the millimeter scale [2]. Moreover, domain walls can be moved at record speeds by spin polarised currents, in absence of spin-orbit torques. This can be explained by the large efficiency of the adiabatic spin transfer torque, due to the conjunction of a reduced magnetisation and a large spin polarisation [3]. The domain wall velocity can reach over 900m/s at $1.4e^{12}$ A/m^2. This result is close to that obtained for chiral Néel walls driven by spin orbit torques in ferrimagnetic films with Dzyaloshinskii-Moriya interaction. Finally, we show that the coercivity of Mn_4N films can be tuned by a gate voltage, this ability constituting a tool for DW manipulation. Through the application of gate voltages through the $SrTiO_3$ substrates, the Mn_4N (4 nm) coercive field can be modulated with a large efficiency, reaching -15pJ/m^2, a value larger than those obtained for sub-nm thick layers.

HG-04. Domain wall dynamics in ferrimagnetic strips explained by means of a two interacting sublattices model. *E. Martinez*[1], V. Raposo[1] and O. Alejos[2] *1. Universidad de Salamanca, Salamanca, Spain; 2. Universidad de Valladolid, Valladolid, Spain*

The development of racetrack memories is attracting much interest in the recent times. [1] Many efforts have been addressed in that way, particularly, the finding of optimal systems allowing fast displacement of domain walls (DWs). Recent experimental evidence shows that DW velocities in the order of 1km/s can be achieved along ferrimagnetic (FiM) strips. [2-3]. Additionally, it has been found a linear relationship between DW velocity and the magnitude of the applied current. [2-4]. Based on these promising experimental results, here we provide a full micromagnetic (mM) study dealing with FiM strips. Our mM simulations treat them as constituted by two ferromagnetic sublattices, coupled by means of an additional inter-lattice exchange interaction. Such micromagnetic simulations are also backed up with an extended one-dimensional model, [5] that, differently from other approaches based on effective parameters, also considers the FiM as formed by two coupled sublattices with experimentally definite parameters. Such approach permits to infer results not achievable from the mentioned effective models. The model has been applied to two different structures. In the first case, a FiM strip on top of a heavy metal is considered. The interface in this case promotes the existence of an interfacial asymmetric exchange, that allows current driven domain wall motion (CDDWM) due to spin orbit torques. The CDDWM involves rigid DWs with stationary magnetic moment orientation, that at the angular momentum compensation temperature (TA) keeps aligned with the current, leading to linear increases of DW velocities with current magnitudes. DW velocities are then maximized at TA. Secondly, the FiM strip is not considered to lie on a heavy metal, and then interfacial asymmetric exchange is absent. CDDWM is dominated by the spin transfer torque, and DW precessional regimes result due to reduced magnetostatic interactions. As long as this situation holds, DW velocities are also proportional to current magnitude, and they are again maximized at TA, when precession freezes, leading to a CDDWM characterized by rigid DWs. Briefly, our methods allow to explain experimental observations of relevance for the future development of DW based devices.

In the last decade, two revolutionary concepts in nano magnetism emerged from research for storage technologies and advanced information processing. The first suggests the use of magnetic domain walls in ferromagnetic nanowires to permanently store information in domain-wall racetrack memories. The second proposes a hardware realization of neuromorphic computing in nanomagnets using nonlinear magnetic oscillations in the GHz range. Both ideas originate from the transfer of angular momentum from conduction electrons to localized spins in ferromagnets, either to push data encoded in domain walls along nanowires or to sustain magnetic oscillations in artificial neurones. Even though both concepts share a common ground, they live on very different time scales which rendered them incompatible so far. Here, we bridge both ideas by demonstrating the excitation of magnetic auto-oscillations inside nanoscale domain walls using pure spin currents. This presentation will shed light on the current characteristic and spatial distribution of the excited auto-oscillations.

HG-06. Tuning magnetic chirality by dipolar interactions. *J. Lucassen*[1], M.J. Meijer[1], F. Kloodt-Twesten[2], R. Frömter[2], O. Kurnosikov[1], R. Duine[1,3], H. Swagten[1], B. Koopmans[1] and R. Lavrijsen[1] *1. Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands; 2. Center of Hybrid Nanostructures, Universität Hamburg, Hamburg, Germany; 3. Institute for Theoretical Physics, Utrecht University, Utrecht, Netherlands*

Chiral magnetism has gained enormous interest in recent years because of the anticipated wealth of applications in nanoelectronics. The demonstrated stabilization of chiral magnetic domain walls and skyrmions has been attributed to the actively investigated interfacial Dzyaloshinskii-Moriya interaction (iDMI). Recently, however, predictions were made that suggest dipolar interactions can also stabilize chiral domain walls and skyrmions, but direct experimental evidence has been lacking. Because the net chirality determines, for example, the interaction of magnetic textures with spin-orbit torques, it is vital that we understand the interplay between the iDMI and dipolar fields. [1] Here, we show that dipolar interactions can indeed stabilize chiral domain walls by directly imaging magnetic domain walls in archetype Pt/CoB/Ir multilayer stacks using scanning electron microscopy with polarization analysis (SEMPA) as shown in fig. 1. [2] The strength of the iDMI and dipolar interactions are systematically tuned by varying the thickness of magnetic Co layer. We find that the competition between the iDMI and dipolar interactions can reverse the domain-wall chirality and verify our interpretation with an analytical model and micromagnetic simulations. Finally, we suggest that this competition can be tailored by an interlayer Ruderman-Kittel-Kasuya-Yosida interaction and provide the first experimental data in this direction. This experimental and modeling work unambiguously confirms that dipolar interactions play a key role in the stabilization of chiral spin textures. This insight will open up new routes towards balancing interactions for the stabilization of chiral magnets.

HG-07. Magnetic domain wall devices for artificial neural network. *S. Siddiqui*[2], S. Dutta[1], A. Tang[1], L. Liu[1], C. Ross[1] and M. Baldo[1] *1. Massachusetts Institute of Technology, Cambridge, MA, United States; 2. Argonne National Laboratory, Lemont, IL, United States*

Spintronics promises intriguing device paradigms where electron spin is used as the information token instead of its charge counterpart. In the future cognitive era, nonvolatile magnetic memories hold the key to solve the bottleneck in the computational performance due to data shuttling between the processing and the memory units. The application of spintronic devices for these purposes requires versatile, scalable device design that is adaptable to emerging material physics. We design, model and experimentally demonstrate spin orbit torque induced magnetic domain wall devices as the building blocks (i.e. linear synaptic weight generator and the nonlinear activation function generator) for in-memory computing, in particular for artificial neural networks. Spin orbit torque driven magnetic tunnel junctions show great promise as energy efficient emerging nonvolatile logic and memory devices. In addition to its energy efficiency, we take advantage of the spin orbit torque induced domain wall motion in magnetic nanowires to demonstrate the linear change in resistance of the synaptic devices. Modifying the spin-orbit torque from a heavy metal or utilizing the size dependent magnetoresistance of tunnel junctions, we also demonstrate a nonlinear activation function for thresholding signals (analog or digitized) between layers for deep learning. The analog modulation of resistances in these devices requires characterizing the resolution of the resistance. Since domain wall in magnetic wires is the nonvolatile data token for these devices, we study the spatial resolution of discrete magnetic domain wall positions in nanowires. A complete neuromorphic hardware accelerator using embedded nonvolatile magnetic domain wall devices can also revolutionize computer architectures by embedding memory into logic circuits in a fine grained fashion.

The challenge of developing an efficient artificial neuron for machine learning is impeded by the use of external CMOS circuits to perform both leaking and lateral inhibition. To resolve this issue, we previously proposed a spintronic leaky integrate-and-fire (LIF) neuron with no external circuitry. This was achieved with a three-terminal magnetic tunnel junction (3T-MTJ) device with an externally applied magnetic field that provides a constant leaking force. We also demonstrated that the neurons recognize handwritten digits with an accuracy of 94% when used as the output layer of a neural network [1],[2]. Here, we propose the two alternate LIF neurons shown in Fig. 1, where the leaking capability is implemented by shifting the neurons' DWs in the direction opposite of integration using a non-uniform energy landscape resulting from either shape or magnetic anisotropy variation. First, for anisotropy-gradient-induced leaking, the DW shifts in a standard rectangular DW track, from regions of higher anisotropy to regions of lower anisotropy [3]. Second, for shape-based leaking, we developed a trapezoidal DW track that induces an energy landscape more favorable to the DW existing in the narrower region of the track than the wider region, causing the DW to shift from the wide region to the narrow region in the absence of external stimuli [4]. Fig. 2 demonstrates the combined integrating and leaking functionalities of an LIF neuron using shape-based DW drift. By combining our proposed neurons with 3T-MTJ synapses [5], we aim to develop a monolithic neural network system using only 3T-MTJ devices.

Current-induced magnetic domain wall (DW) motion has attracted immense interest, not only in the context of shift registers for futuristic non-volatile 3D data storage concepts, but also from a fundamental point of view. Experimental efforts focused on flat nanostrips which, however, suffer from intrinsic DW instabilities, greatly limiting DW speed and their reliable use in potential applications. In contrast, simulations and theory state that cylindrical nanowires (NWs) should not experience the same fundamental issue and simultaneously give rise to fascinating new physics [1,2]. Key to these predictions is the novel Bloch-point wall (BPW), which is unique to NWs [3]. It has a distinct topology and exhibits azimuthal curling of magnetic moments around a Bloch-point [4], a local vanishing of magnetisation, at the DW core. This feature and its rotational symmetry are at the origin of the steady state dynamics of this DW type, allowing theoretical speeds of over 1000 m/s and the controlled emission of spin waves (spin-Cherenkov effect) [5]. So far, experiments for DW dynamics in NWs are missing. Here we report unprecedented experimental results on current-induced DW motion in NWs [6]. We use magnetic force microscopy and shadow X-Ray Magnetic Circular Dichroism coupled to PhotoEmission Electron Microscopy (XMCD PEEM) to image DWs in 90 nm diameter $Co_{30}Ni_{70}$ NWs before and after the

application of nanosecond current pulses. We evidence that although previously disregarded, the Œrsted field induced by the current plays a crucial and valuable role: above a well-defined threshold current, it stabilises exclusively BPWs with a unique circulation (Fig. 1). This allows BPWs to reach velocities > 600 m/s (Fig. 2), quantitatively consistent with predictions, thereby also approaching the conditions where the spin-Cherenkov effect are expected.

HG-10. Dynamics of domain wall transport in a magnetic nanotrack shared by multiple magnetic tunnel junctions. *E. Raymenants*[1,3], V. Nguyen[1], D. Wan[1], S. Couet[1], O. Bultynck[1,3], I. Radu[1], M. Heyns[1,3] and T. Devolder[2] *1. imec, Leuven, Belgium; 2. CNRS, C2N, Palaiseau - Paris, France; 3. KU Leuven, Leuven, Belgium*

Domain-wall (DW) based device concepts are explored for racetrack memory [1] and spin-logic applications [2]. So far, research was mainly focused on the study of DW transport in a single magnetic nanotrack, lacking the read/write elements for a practical DW-based device implementation. Here, we present dynamics of DW transport along a nanotrack in a fully integrated DW device with CoFeB/MgO-based perpendicular magnetic tunnel junctions (pMTJs) as read/write elements. Our device is scalable and compatible with MRAM technology. DW nucleation by spin transfer torque (STT), transport and detection by tunneling magnetoresistance (TMR) were demonstrated by time-resolved measurements in a track shared by three MTJs [3]. DW velocity between neighboring pillars was extracted as function of applied field (Fig. 1). Similar DW velocities were found in CoFeB blanket films [4]. This confirms that nor the challenging fabrication process [5], nor the fact that the track is highly scaled (i.e. 150 nm wide), are detrimental for DW transport in our devices. Time-resolved measurements at three neighboring MTJs, show that the DW dynamics in the parallel to anti-parallel (P2AP) transition are not simply symmetric to the AP2P transition, Fig. 2. This asymmetry can be attributed to fringing fields induced by the pinning layer in the pMTJs [6]. Additionally, it was found by VNA-FMR that the anisotropy is non-uniform along the track, leading to DW pinning [7]. The impact of the fringing fields and the non-uniform anisotropy on the dynamics of DW transport along the nanotrack are validated by micromagnetic simulations using OOMMF (inset of Fig. 2) These devices provide insightful information on domain wall dynamics in fully integrated device structures.

HG-11. Modelling of the Spin Transfer Torque Induced Domain Wall Motion in a Perpendicularly Magnetized Thin Disk. *P. Bouquin*[1,2], T. Devolder[1], S. Rao[2], G.S. Kar[2] and J. Kim[1] *1. Centre de Nanosciences et Nanotechnologies, Palaiseau, France; 2. IMEC, Leuven, Belgium*

In spin transfer torque magnetic random access memories the magnetization of a perpendicularly-magnetized thin disk is reversed by a polarized spin current. Knowing the intermediate states that the magnetization undergoes during the reversal is of paramount importance since it determines device performances. It has been shown previously that domain walls (DW) are expected to be involved in the reversal of disks measured [1] or simulated [2]. It is therefore necessary to develop a model for DW dynamics within a perpendicularly-magnetized disk under spin transfer torque. We present such a model, using as a starting point the *(q,φ)* model (DW position and tilt angle) that was already developed for DW dynamics within an infinite stripe [3]. We include the exact geometry of the system, which introduces new effective fields acting on the DW such as demagnetizing fields or a DW position dependent stretch field. The geometry has an important impact on the DW dynamics as seen in the figure. The DW moves at a constant drift velocity with in addition correlated oscillations of its position and tilt angle. The frequency and amplitude of the oscillations vary along the DW displacement. The manner in which the DW crosses the disk center depends on initial conditions: in some cases it is done in a linear fashion, while in other cases the wall can get stuck and position oscillations of strong amplitudes are expected near the center (Fig. 1). Therefore, if we assume that the initial conditions in which the DW is nucleated are not fully deterministic, the reversal through DW motion presents an intrinsic stochasticity. Our result is compared with micromagnetic simulations yielding a good qualitative match, which corroborates our model assumptions. Then we discuss the impact of the external field or external voltage applied to the system. In certain conditions DW annihilation through the stretch field are predicted near the disk edges, which is consistent with the impossibility to nucleate a DW from the edges of a disk that was previously reported in micromagnetic simulations [4].

HH-01. Dysprosium Iron Garnet Films on Si with Large Grains and Perpendicular Magnetic Anisotropy. *J. Bauer*[1], E.R. Rosenberg[1] and C. Ross[1] *1. Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, MA, United States*

Rare earth iron garnets (REIGs) are magnetic insulators that can be grown in nanometer scale films with perpendicular magnetic anisotropy (PMA), making them attractive for studies of spin orbit torques (SOT) and chiral spin textures. PMA has been achieved in epitaxial films of several REIG systems on garnet substrates due to magnetoelastic anisotropy from epitaxial lattice mismatch strain[1-2] and in polycrystalline REIG films due to the thermal expansion mismatch between the film and substrate following a high temperature anneal[3]. However, it is of interest to develop PMA garnet films on silicon for practical spintronic devices using SOT from an adjacent heavy metal layer. Here we report the growth and properties of polycrystalline dysprosium iron garnet (DyIG) films on Si (100) substrates. Films were grown by pulsed laser deposition and were crystallized by a rapid thermal anneal (850 °C/5 min.). After the anneal, films were in tensile strain, which combined with the negative magnetostriction coefficients overcomes the shape anisotropy and results in PMA. X-ray diffraction shows phase-pure garnet, and atomic force microscopy (AFM) of the films indicates sub-nanometer surface roughness with large grain sizes on the order of 10 μm in a 41 nm thick film. Vibrating sample magnetometry (VSM) measurements of a 41 nm DyIG/Si film showed PMA with a saturation magnetization of 20 emu cm^{-3}, slightly lower than bulk, and a coercivity of ~4.5 kOe. The film coercivity can be tuned from 2.5-6 kOe by varying the annealing temperature, and the anisotropy field is in excess of 10 kOe. The magnetic compensation temperature of the films is ~190 K, about 30 K below the bulk compensation temperature. Spin Hall magnetoresistance (SMR) measurements on a Pt (4 nm)/DyIG (22nm)/Si Hall cross demonstrated out of plane Hall resistivity of $11*10^{-4}$ μΩ*cm and imaginary spin mixing conductance G_i of $1.0*10^{13}$ $\Omega^{-1}m^{-2}$, comparable to other REIG materials, indicating high interfacial spin transparency.

HH-02. Sol-Gel Synthesized YIG Nanoparticles with Low Magnon Damping. *J. Silva*[1], R. Vilarinho[1], S.A. Bunyaev[1], J.A. Moreira[1], G.N. Kakazei[1] and A.M. Pereira[1] *1. IFIMUP, Porto, Portugal*

Epitaxial Yttrium Iron Garnet (YIG) films are actively used in magnonics and spin caloritronics since YIG is an excellent electrical insulator with the lowest known Gilbert damping parameter α_G below 10^{-4}. However, polycrystalline YIG nanoparticles, prepared by different methods, so far demonstrated rather high values of α_G. To improve this issue, we varied different sol-gel fabrication parameters, namely the drying temperature, drying time, and calcining time. The morphological analysis at room conditions evidenced that YIG has a cubic structure, such that the particles aggregate in the form of prisms. The phase formation and the crystallographic structure were ascertained by XRD and Raman scattering at room temperature. The cubic symmetry of all the as-prepared samples was confirmed, and the lattice parameter was found to be 1.24 nm. We estimate the crystallite sizes to range from 63 nm to 111 nm. The Raman spectra confirm the garnet structure of the synthesized YIG [1,2]. No bands assigned to magnon excitations were observed, suggesting these are not Raman-active in YIG due to symmetry constraints. The isothermal magnetic hysteresis cycles were measured at room temperature and the saturation magnetization M_{sat} and coercive field H_c were determined. M_{sat} varied from 20.0 emu/g to 25.4 emu/g when H_c had similar values (around 80 Oe) for all the samples. Finally, the broadband ferromagnetic resonance (FMR) in the frequency range 0-20 GHz was measured on a sample with the highest value of M_{sat}. Using Kittel formulas, we were able to fit the experimental resonance frequency vs magnetic field dependence using typical parameters for epitaxial YIG films. α_G was obtained using the procedure described in Ref. [3], based on the fact that

the apparent damping α_{app} converges at high fields, as seen in Fig. 1 and the obtained value $\alpha_G = 0.075$ is about two times lower than $\alpha_G = 0.12$, reported previously for sol-gel synthesized polycrystalline YIG nanoparticles [4]. This result is particularly relevant because it paves the way for the use of polycrystalline YIG in microwave, magneto-optical and spincaloritronics applications.

M. gryphiswaldense synthesizes cubo-octahedral shaped magnetite nanoparticles, called magnetosomes, with a mean diameter of 40 nm [1]. The high quality of the biosynthesized nanoparticles makes them suitable for numerous applications [2,3]. Aiming to further increase their potential applications, different authors have focused on modifying the main properties of magnetosomes by doping them with transition elements [4,5]. In this work, we present a complete and novel characterization of magnetosomes synthesized in Mn or Zn-rich medium. X-ray absorption spectroscopies at Fe and Mn/Zn *K* and $L_{2,3}$-edge evidence the incorporation of Mn and Zn into the magnetite structure concomitant with drastic changes in their magnetic properties (Fig.1). The low incorporation of these elements, below 1%, is however not sufficient on its own to explain the decrease on the coercive field and remanence. Our experimental and theoretical findings suggest an additional change of the morphology of the magnetosomes synthesized in the supplemented mediums. Thus, we have accurately reproduced the magnetization dynamics by using a magnetic model that considers the competition between the magnetocrystalline and shape anisotropies.

HH-04. Separation of sublattice magnetism in $Tb_3Fe_5O_{12}$ using magneto-optical spectroscopy. *L. Beran*[1], E.R. Rosenberg[2], J. Setina[1], A.U. Quindeau[2], J. Zázvorka[1], C. Ross[2] and M. Veis[1] *1. Charles University, Prague, Czechia; 2. Massachusetts Institute of Technology, Cambridge, MA, United States*

Ferrimagnetic garnets with perpendicular magnetic anisotropy have drawn a considerable attention in recent years due to the possibility to control their magnetism via spin orbit torque [1]. These materials exhibit three magnetic sublattices where magnetic ions are surrounded tetrahedrally, octahedrally and dodecahedrally by oxygen atoms. The net magnetic properties are tunable with temperatureand changing of growth parameters. Compensation temperature near the room temperature is important for utilization of these materials in novel spintronic concepts. However, physical mechanisms responsible for the changes in this temperature remain still not well understood. Separation of the sublattice magnetism can give in important information and insight into compensation mechanism of these materials. Here we present temperature and field dependent magneto-optical spectroscopy of $Tb_3Fe_5O_{12}$ (TbIG) in the vicinity of the compensation temperature. The spectral dependence of magneto-optical Faraday and Kerr effect allowed us to disentangle the contributions from all three sublattices in TbIG thin films. Investigated samples were grown by pulsed laser deposition onto GGG (111) substrates. The Kerr and Faraday magneto-optical spectroscopies were measured in the spectral range from 1.2 to 5 eV using rotating analyzer method [2]. The spectra were fitted using the framework of paramagnetic and diamagnetic lines derived from microscopic theory of magneto-optical effects. These lines origin in electronic transitions of magnetic ions in various sublattices. Figure 1 shows the room temperature Faraday rotation spectrum of 38 nm thick TbIG layer decomposed into the contributions of different sublattices. Field dependent measurements showed the inverse magnetic behavior of tetrahedral and octahedral sublattices, while the dodecahedral sublattice followed the octahedral one. Presented separation approach can be used on wide variety of ferrimagnetic garnets.

HH-05. Improved Magnetorheological Response in $Zn_{0.2}Fe_{2.8}O_4$ nano-hollow spheres. *P. Saha*[1] and K. Mandal[1] *1. Department of Condensed Matter Physics and Material Science, S. N. Bose National Centre for Basic Sciences, Kolkata, India*

Potential applications of Fe_3O_4 nanostructures can be enhanced by preparing nano-hollow spheres (NHSs) instead of nanoparticles. We prepared $Zn_xFe_{3-x}O_4$ (x=0.0, 0.1, 0.2, 0.3, 0.4, 1.0) NHSs with different Zn doping concentration. Temperature dependent magnetic studies indicate their increase in saturation magnetization (M_S) with Zn doping, attaining a maximum for x=0.2 and then fall off with increasing Zn content [Fig. 2], due to replacement of antiferromagnetically coupled Fe_A^{3+} ions on the A site by non-magnetic Zn^{2+} ions and transformation of Fe_B^{2+} to Fe_B^{3+} at B site for maintaining charge neutrality. The dynamic magnetic properties studied by analysing ac susceptibility revealed spin cluster interaction in our systems. Magnetorheological (MR) effect is a reversible phenomenon which arises due to the chain formation [Fig 2] of suspended magnetic particles in a carrier fluid under external magnetic field and in turn increasing the effective viscosity. Micron or nano-sized particles with low-density and high saturation magnetization are desirable for magnetorheological applications. As saturation magnetism is an important parameter for magnetorheology, $Zn_{0.2}Fe_{2.8}O_4$ NHSs can be an interesting candidate. We have prepared silicon oil based MR fluids by dispersing $Zn_{0.2}Fe_{2.8}O_4$ and Fe_3O_4 NHSs of diameter 700 nm, each with 50 wt. % and studied their magnetorheological response in flow mode. $Zn_{0.2}Fe_{2.8}O_4$ shows much better MR response than Fe_3O_4. The hollow interior makes the sub-micron sized spheres stable in carrier fluid due to reduced density. The curve of shear stress vs shear rate under externally applied magnetic field is fitted with various established model such as Herschel-Bulkley (HB) fluid model and Bingham Plastic (BP) model to understand the MR mechanism. The viscoelastic modulus is studied under oscillatory shear rate at different applied magnetic field to comprehend the viscous and elastic properties under the deformation. We have simulated theoretical model using dipolar interaction and it matches well with the experimental behaviour.

HH-06. Structural, magnetic and electrochemical activity of $Ti_{0.5}Ni_{0.5}Fe_2O_4$ nanoparticles synthesized by high energy ball milling. *N.S. Osman*[1,2], N. Thapliyal[3], T. Moyo[2] and R. Karpoormath[3] *1. Medical and Biological Applications, Institute of Laser, Sudan University of Science and Technology, Khartoum, Sudan; 2. School of Chemistry and Physics, University of KwaZulu-Natal, Durban, South Africa; 3. Department of Pharmaceutical Chemistry, Discipline of Pharmaceutical Sciences, College of Health Sciences, University of KwaZulu-Natal, Durban, South Africa*

High energy ball milling technique was used to synthesize $Ti_{0.5}Ni_{0.5}Fe_2O_4$ nanoparticles. The spinel phase structure was formed after short milling time of 1.5 hours. The phase formation was confirmed by X-ray diffraction measurements. William-son plot shows homogenous strain in the sample. The elemental composition was confirmed by energy dispersive X-ray and further by inductively coupled plasma optical emission spectrometry. The morphology was studied by high-resolution transmission electron microscope and high-resolution scanning electron microscope. The results show mono-dispersive character of the synthesized sample. The magnetic properties were investigated by vibrating sample magnetometer and Mössbauer spectroscopy. The values of the saturation magnetization and coercive field are 71.5±0.1 emu/g and 216±16 Oe respectively. The electrochemical sensing characteristic of the synthesized nanoparticles was investigated using cyclic voltammetry. The $Ti_{0.5}Ni_{0.5}Fe_2O_4$ nanoparticles modified glassy carbon electrode ($Ti_{0.5}Ni_{0.5}Fe_2O_4$/GCE) displayed excellent electrocatalytic behaviour towards potassium ferricyanide, a typical redox species as evidenced by a

decrease in peak potential and a substantial increase in peak current. The $Ti_{0.5}Ni_{0.5}Fe_2O_4$ nanoparticles are thus envisaged to be novel and promising candidates for constructing electrochemical sensors with high performances.

HH-07. Mössbauer and Magnetometry Studies of Ferrite Particles for Magnetic Resonance Imaging Thermometry. *M. Przybylski*[1], J. Zukrowski[1], N. Alghamdi[2], J. Stroud[2], J.H. Hankiewicz[2,3] and Z. Celinski[2,3] *1. Academic Centre for Materials and Nanotechnology, AGH University of Science and Technology, Kraków, Poland; 2. BioFrontiers, University of Colorado BioFrontiers (BioFrontiers - UCCS), Colorado Springs, CO, United States; 3. MRX Analytics, PBC, Colorado Springs, CO, United States*

Designing ferrites' composition to achieve the best possible particles for magnetic resonance-imaging thermometry (tMRI) requires that one understand the distribution of the magnetic ions in a crystal structure. To do this we carried out Mossbauer and magnetometry studies of MgZn and CuZn ferrites. However, not all Mössbauer measurements allowed us to determine Fe ion distributions due to relaxation nature of the collected spectra. Figure 1 shows such a case of the Mössbauer spectra (MS) acquired in MgZn ferrite. Even at 80 K, the spectrum has a relaxation character possibly due to an oscillation of domain walls in ferrites [1] or due to oscillations of the magnetic moments in nanometer-size domains. Figure 2 shows that MS of some CuZn ferrites at 80 K exhibit relaxation character even though for all studied compositions the Curie temperature is well above 80 K [2]. Our spectra were fitted using method described by Rancourt [3], within the Blume-Tjon model [4]. The only way to "switch off" magnetization relaxations was by reducing the temperature down to ~ 4K. The results of fitting MS at 6K for the same samples confirm the tendency observed by XRD [5]: with increasing Zn concentration, Fe cations are displaced by the Zn cations from the tetrahedral to octahedral sites. Analysis of MS allowed us also determine values of hyperfine fields and isomer shifts. To select the best ferrites' composition for tMRI, MS studies were augmented by SQUID measurements of magnetization vs. temperature.

HH-08. Crystallographic inversion-mediated superparamagnetic relaxation in Zn ferrite and Mn-Zn ferrite nanocrystals. *R. Sai*[1], R. Kahmei[1], S. Arackal[1], N. Bhat[1], M. Yamaguchi[2] and S.A. Shivashankar[1] *1. Centre for Nano Science and Engineering, Indian Institute of Science, Bengaluru, India; 2. Dept. of Electrical Engineering, Tohoku University, Sendai, Japan*

Magnetic nanoparticles are excellent microwave absorbers owing to their large ferromagnetic resonance (FMR) loss [1]. The natural FMR frequency, which originates from magnetocrystalline anisotropy of the material and is observed near or below 1 GHz in spinel ferrites, can be exceeded in nanoparticles via superparamagnetic relaxation (SR) [1, 2]. The characteristics of SR are generally tuned by employing magnetic core-shell nanostructure and thus, by altering dipolar interactions between particles [2, 3]. However, adding a non-magnetic shell causes loss in effective permeability. In this paper, we explore dipolar interactions in superparamagnetic zinc ferrite ($ZnFe_2O_4$) nanocrystalline (ZF-NC) and manganese-zinc ferrite ($Mn_{0.5}Zn_{0.5}Fe_2O_4$) (MZF-NC) with various degree of crystallographic

inversion. Various ZF-NC and MZF-NC samples were synthesized by a solution-based, low-temperature (<200 °C), microwave-assisted solvothermal (MAS) process [4]. Owing to the far-from-equilibrium process, the resultant as-synthesized nanocrystals possess a very high degree of crystallographic inversion. The samples were then subjected to rapid thermal annealing (2 min at 300 °C and 500 °C, with a heating rate of 200 °C/min) to alter the degree of inversion without a noticeable change in crystallite size. The crystal structures, particle shapes, and compositions of the nanocrystalline sample were characterized by XRD, SEM, and electron probe micro-analysis. The samples are phase-pure, with particle size in the range 4.5 to 8.4 nm and their compositions are stoichiometrically correct. Partial inversion in the crystal structure of both ZF-NC and MZF-NC was evidenced by Raman spectroscopy and confirmed by XPS. The dipolar interaction study was performed in a SQUID magnetometer by measuring the FC-ZFC magnetization at two different dc bias fields – 50 Oe and 500 Oe, on the temperature range 5 K to 350 K (Fig. 1). The dipolar interaction is present in both as-prepared ZF-NC and MZF-NC, but the interaction is stronger in MZF-NC. The role of crystallographic inversion-mediated superparamagnetic relaxation on the FMR characteristics is being discussed for the first time.

HH-09. Soft Magnetic and Structural Properties of $(Fe_{75}Co_{25})_{75}(Al_{50}Si_{50})_{25}$ Alloy Thin Films. *T. Nakano*[1,2], B. Nepal[2], Y. Tanaka[1], S. Wu[2], K. Abe[1,2], G.J. Mankey[2], T. Mewes[2], C.K. Mewes[2] and T. Suzuki[2] *1. Materials Development Center, TDK Corporation, Narita, Japan; 2. Center for Materials for Information Technology, The University of Alabama, Tuscaloosa, AL, United States*

Improvements in soft magnetic properties such as low coercivity (H_C) and low effective damping parameter (α_{eff}) are indispensable and previous works on FeCoAl [1] and FeCoSi [2, 3] thin films reported the soft magnetic properties attractive for future high frequency device applications. However, few studies about FeCoAlSi alloy thin films have been found in literature [4]. This work presents a systematic study of the soft magnetic properties of $(Fe_{75}Co_{25})_{75}(Al_{50}Si_{50})_{25}$ alloy thin films. Multilayers of [$Fe_{75}Co_{25}$ (0.7 nm)/ $Al_{50}Si_{50}$ (0.4 nm)]×N, where N is the number of repetitions, were sputter-deposited onto MgO (100) single crystal substrates using DC magnetron sputtering in Ar atmosphere of 4mTorr. The substrate deposition temperature (T_S) was varied from ambient to approximately 400 deg.C. The thickness was varied from 10 to 300 nm. Structural analyses were performed by XRD and TEM. Measurements of magnetic properties were carried out by VSM and longitudinal MOKE. The magnetization dynamics were evaluated by ferromagnetic resonance at room temperature over a frequency range from 12 to 66 GHz. As shown in the XRD pattern in Fig.1, the DO_3 phase is found in the sample fabricated at T_S = 410 deg.C, while an amorphous phase is produced with T_S = 40 deg.C and a bcc phase is present for T_S = 100 to 300 deg.C. The dependences of (a) saturation magnetization (M_S), (b) Hc and (c) α_{eff} on T_S are shown in Fig.2. The values of M_S and Hc are approximately 700 emu/cm^3 and 4 Oe, respectively, and remain nearly constant throughout the entire range of Ts. The α_{eff} decreases and then slightly increases with T_S. The minimum value of α_{eff} is 2.2×10^{-3}. Further optimization of fabrication condition is in progress aimed at further improving soft magnetic and dynamic properties. The thickness dependence of the soft magnetic properties will also be reported. This work is in part supported by the MINT-TDK collaboration program.

HH-10. Microstructure of novel Fe-Mn soft magnetic powders produced by hydrogen reduction of nanoferrites. *N. Imaoka*[1], Y. Kawakami[1] and K. Ozaki[1] *1. Magnetic Powder Metallurgy Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Nagoya, Japan*

The global market for electric vehicles is expected to reach 15 million units by 2020. Currently, soft magnetic stators for electric motors in automotive applications are typically assembled by stacking several hundreds of rolled electrical steel sheets with surface insulating layers. Herein, we have attempted to develop novel high-performance soft magnetic powders using a simple and low-cost fabrication process for solidification of powders. In our previous paper [1], we reported on high-magnetization Fe-Mn powders that can be easily solidified by conventional powder metallurgy processes. Fe-Mn powders doped with 0.1 at% manganese (hereafter denoted as Mn0.1) were prepared by the reduction of $(Fe,Mn)_3O_4$ nanopowders using hydrogen gas. The starting nanopowders with a particle size of 5–50 nm were prepared by our aqueous process [2, 3]. The saturation magnetization of the Mn0.1 sample was about 219 emu/g, and the sample exhibited a coercivity of 0.1–1 Oe, as measured using a vibrating sample magnetometer. An example of this domain structure observed using Lorentz transmission electron microscopy (TEM) is shown for the Mn0.1 TEM specimen in Fig. 1 [1]. The different domains divided the sample into rectangular strips across its thickness. The magnetization direction of these domains alternated, leading to a closure domain, formed by large magnetic walls. However, such domain structures are not normally observed. We further investigated the microstructure of the Mn0.1 powders by TEM and electron diffraction (ED). The satellite spots of the {110} main diffraction in the ED patterns were observed near the forbidden reflections due to extinction rules, such as 100 and 111 reflections, as shown in Fig. 2. Furthermore, layers of thickness of a few tens of nanometers were observed by dark-field TEM images obtained from satellite reflections. These layers are suggested to have a long period structure in Fe-Mn powders. On the basis of these results, we discuss the mechanism of magnetization reversal in Mn0.1 powders.

HH-11. Magnetic properties of FeCoMnCrSi multi-principal element alloy. *R. Jangid*[1], K. Ainslie[1] and R. Kukreja[1] *1. Materials Science and Engineering, University of California, Davis, CA, United States*

High entropy alloys (HEA) or multi-principal element alloys (MPEAs) have recently gained interest due to their unique properties such as high-temperature strength, exceptional ductility, and potential applications in permanent magnets.[1, 2] However, the magnetic behavior of MPEA thin films as a function of temperature is still not well understood as most of the studies have focused on bulk magnetic properties and thus have not been able to identify the behavior of individual elements in this complex multi-dimensional compositional space.[3-6] In this study, we focus on one such system, FeCoMnCrSi, which contains 95 at% of magnetic elements including both ferromagnetic (Fe, Co) and antiferromagnetic ions (Mn, Cr). Thin films with different thicknesses were deposited on a silicon (001) substrate using magnetron sputtering. The X-Ray diffraction measurements show coexisting FCC and HCP phases while energy dispersive x-ray analysis shows that both phases have the same composition. Hysteresis loops show two orders of magnitude enhancement in magnetization for thin film samples when compared to bulk sample. Magnetization as a function of temperature shows a spin glass phase transition near room temperature and ferromagnetic transition near 150 K, which increases to 250 K for films with lower thickness. Consequently, the film thickness can be used to tailor the ferromagnetic transition and the magnetization of MPEAs. These studies provide detailed characterization of magnetic and structural properties of FeCoMnCrSi HEA which is critically needed to guide the design and development of MPEA based soft magnetic systems.

HH-12. Impact of Post-Annealing Temperatures and Durations on the Composition of Iron Nitride. *L. Jiang*[1] and Y. Jiang[2] *1. Chemical Engineering, UC Berkeley, Berkeley, CA, United States; 2. Jiangnan University, Wuxi, China*

In this paper, we investigated the effect of different post-annealing temperature and duration on the extent of transformation from α-Fe(bcc) into γ'-Fe_4N (fcc). After iron and nitrogen were mixed during ball-miling, post-annealing activated the diffusion of nitrogen atoms inside the amorphous phase. As a result, γ'-Fe_4N was formed. In our experiment, all the samples were obtained from the same batch of ball-milled iron nitrite, and they were post-annealed at three different temperatures of 150, 200 and 300 Celsius for 24, 48, 72 and 96 hours. X-ray diffraction was used to characterize the compositions of the post-annealed samples. With the help of the XRD spectra, the relative proportions of the two phases, γ'-Fe_4N (fcc) and a-Fe(bcc), could be determined qualitatively. Diffraction peaks at 2θ=42.5° and 44.5° had the best resolution and the highest intensities. 44.5° corresponds to (110) plane of bcc α-Fe, and 42.5° reflects (111) plane of fcc γ'-Fe_4N. By comparing the relative intensities between the two peaks, a general, qualitative evaluation of the extent of phase transformation could be obtained. In general, a growing intensity of the 42.5° peak relative to the 44.5° peak indicated a greater degree of transformation from α-Fe(bcc) into γ'-Fe_4N (fcc). Under lower post-annealing temperatures of 200 °C and 150 °C, γ'-Fe_4N showed significant presence, but the proportion of the two phases α and γ' tend to fluctuate dramatically as the duration of post-annealing increased. Steady growth of γ'-Fe_4N was not observed. At certain instances, the proportion of γ'-Fe_4N was even shown to derease, possibly converting back to a-Fe. Thus, it became uncertain whether post-annealing at low temperatures of 200 °C and 150 °C helped to propel the transformation at all. At 300 Celsius, the desired γ'-Fe_4N phase was formed very gradually. The γ'-Fe_4N phase grew at a very steady rate. No fluctuation of phase proportion took place as observed at 150 and 200 Celsius. In conclusion, 300 °C was found to be a very suitable post-annealing temperature for the purpose of furthering the phase transformation from α-Fe to γ'-Fe_4N after balling milling, due to the observed steady growth rate and high extent of phase transformation.

HH-13. $M_xFe_{3-x}O_4$ (M = Li, Zn, Al, Zr, Ce or Hf) nanoparticles: possible *in-vivo* switch during magnetic hyperthermia. *N.K. Prasad*[1], M. Srivastava[1], S.K. Alla[1,2], A. Gangwar[1], S.K. Shaw[1], S. Singh Meena[3] and R.K. Mandal[1] *1. Metallurgical Engineering, Indian Institute of Technology (Banaras Hindu University), Varanasi, India; 2. Basic Science and Humanities, Vignan's Institute of Information Technology, VishakhaPatnam, India; 3. Solid State Division, Bhabha Atomic Research Center, Mumbai, India*

The iron oxide based nanoparticles (MNPs) (e.g. $M_xFe_{3-x}O_4$ or γ-$M_xFe_{2-x}O_3$) have suitable magnetic properties as well as biocompatibility and hence are used for cellular therapy, tissue repair, targeted drug delivery, magnetic resonance imaging, magnetic hyperthermia treatment (MHT) of cancer, etc. [1]. However, to avoid damage to the surrounding tissues the essential requirement is that temperature during MHT should not go beyond 48 °C. Such controlled heating is possible for MNPs with Curie temperature (T_C) which is less likely for such biocompatible oxides. In our recent studies, we observed that the substituted $M_xFe_{3-x}O_4$ (M = Li, Zn, Al, Zr, Ce or Hf and $0 \le x \le 1$) nanoparticles display stabilization of temperature (T_S) near 42 °C during MHT experiments which are shown in table 1 [2-7]. Nevertheless, the values of T_S were varying for the same material with applied external fields. In contrast, the unsubstituted Fe_3O_4 or γ-Fe_2O_3 did not show such T_S values at any fields. The structural, microstructural and magnetic characterizations for all the materials were carried to analyze the variation in the properties after doping.

HH-15. Bi and Ce-substituted Terbium Iron Garnet thin films for integrated photonics. *T. Fakhrul*[2], S. Tazlaru[1], L. Beran[1], E. Tsotsos[2], E.R. Rosenberg[2], M. Veis[1] and C. Ross[2] *1. Charles University, Prague, Czechia; 2. Materials Science and Engineering, MIT, Cambridge, MA, United States*

Cerium and Bismuth doped yttrium iron garnet (YIG) films have excellent magneto-optical (MO) figure of merit (ratio of Faraday rotation to optical absorption) in the near-IR and have been incorporated into on-chip optical isolators. Recently, rare earth garnets have also been developed for MO applications that have the advantage of not requiring garnet seed-layers to crystallize on Si. Here we examine the structure and the optical and magnetic properties of polycrystalline thin films of terbium iron garnet ($Tb_3Fe_5O_{12}$, TbIG) and Ce and Bi substituted TbIG grown on Si substrates using pulsed laser deposition (PLD). TbIG and $Ce_xTb_{3-x}Fe_5O_{12}$ crystallize on Si without a seed layer. However, increasing Ce content, for example in $Ce_{1.5}Tb_{1.5}Fe_5O_{12}$, made crystallization without a seed layer difficult. The growth conditions that produced polycrystalline single-phase TbIG films were at temperatures of 750^{o}C and at oxygen pressures of 2-10 mTorr, with a rapid thermal anneal at 900^{o}C/3 min. The magnetic moment of TbIG, Ce_1Tb_2IG and Bi_1Tb_2IG were 40, 60 and 10 kA/m respectively. This is lower than that of YIG due to the proximity to the compensation temperature of TbIG films, 330 K. TbIG and $Ce_{0.25}$TbIG films on Si were polycrystalline without any secondary phases. Faraday rotation of TbIG/Si, Ce_1TbIG/Si and Bi_1TbIG/Si films measured at a wavelength of 1550 nm was +600^{o}cm^{-1}, -800 ^{o}cm^{-1} and -400^{o}cm^{-1} respectively. The figure of merit of the TbIG was found to be 900 ^{o}dB^{-1} and the effect of Ce and Bi substitutions in TbIG on the figure-of-merit is studied in detail. Temperature and spectral dependence of the Faraday rotation, optical absorption and refractive index is also characterized in this work.

HI-01. Tape in the Cloud -- Technology Developments and Roadmaps Supporting 80 TB Cartridge Capacities. *R. Fontana*[1], R. Biskeborn[1], M. Lantz[2] and G. Decad[1] *1. Systems, IBM, San Jose, CA, United States; 2. Research, IBM, Zurich, Switzerland*

Tape provides critical storage needs for the Cloud as evidenced by continued growth in exabyte (EB) shipments of tape media. This paper outlines the present storage landscape environment for tape, HDD, and NAND flash, describes the tape roadmap for capacity improvements, and presents recording data on narrow track, 32 channel, TMR tape heads spanning read sensor widths from 1.0 um to 0.20 um to show the potential for 80 TB cartridge operation. This paper details the following points. First, the storage landscape for tape and HDD shows annual increases in manufactured EB of 15% to 20%. For the last 6 years the ratio of HDD EB to tape EB has remained constant, ~ 6%. Specifically, tape technology has demonstrated sustained importance in data storage. In 2017 manufactured EB data for tape and HDD were 44 EB and 745 EB respectively. Figure 1 shows these data. Second, the 2015 INSIC tape roadmap projects an annual areal density growth rate of 31% and annual cartridge capacity growth rate of 41%. Enterprise drive characteristics (TS1160) achieved these projections in 2017 (~ 12 Gbit/in^2) with 20 TB cartridge capacities, implying that cartridge capacities of ~ 80 TB in the next 4 years will likely be achieved via evolutionary developments in head/media technology and not from revolutionary developments required for HAMR and MAMR. Third, to demonstrate the extendibility of tape technology, recording data (particularly channel SNR) are presented for sensor widths from 1.0 um widths (20 TB cartridge capacity) down to 0.20 um sensor widths (potentially 80 TB cartridge capacity). The data, shown in Figure 2, were obtained using multi track (32 channel) read/write modules, which are compatible with Linear Tape Open (LTO) operation, on media that presently supports 20 TB cartridge capacities. Channel SNR improvements for the lower trackwidth data will improve with optimized media (smaller particle size) and reduced sensor recession. In summary, near term tape strategies to achieve 80 TB tape cartridge capacities exist and demonstrate that tape technology will remain a critical storage component for the cloud.

HI-02. Pico-Tesla Sensitive Magnetoelectric Magnetometer Based on Delta-E Effect. *C. Dong*[1], Y. He[1] and N. Sun[1] *1. Northeastern University, Boston, MA, United States*

Ultra-sensitive, compact size, and low cost magnetometers for DC and low frequency magnetic field measurement are significant in bio-magnetic sensing and magnetic anomaly detection. We present a resonant magnetoelectric (ME) magnetometer, which utilizes the magnetic field induced elastic modulus change, i.e. the ΔE effect in the magnetostrictive layers. The sensor is based on a magnetostrictive/piezoelectric heterostructure, and the magnetic field induced elastic modulus change will result in electromechanical resonant frequency shift in the ME heterostructure, which can be read out through the impedance of the piezoelectric layers. By integrating four of such ME sensors into a Wheatstone Bridge circuit structure, the impedance change in each sensor unit will induce a voltage output between the two branches of the circuit, which can accurately reflect the change of magnetic field. The maximum frequency shift of the ME sensor unit due to magnetization has been characterized as 12.7%, and with 0.3 mT bias magnetic field, the sensor has the highest frequency sensitivity of 8.2 kHz/mT. By driving all the sensor units at frequency between the resonance and anti-resonance, where the slope of the impedance curve over frequency gives the highest impedance sensitivity of 318 Ohm/Hz, the magnetometer has an overall sensitivity of 6.65×10^4 V/T, and an extremely low limit of detection of 90 pT for DC magnetic field.

HI-03. Four-level Dual-track Readback Scheme for Synchronized Interlaced Magnetic Recording. S. Yoon[1] and *E. Hwang*[1] *1. Gwangju Institute of Science and Technology, Gwangju, The Republic of Korea*

In this study, multi-level joint-track readback scheme is proposed for interlaced magnetic recording (IMR) with synchronized tracks. IMR provides an areal density capability (ADC) gain by pre-fixing the recording orders as interlaced and customizing the write configurations for neighboring tracks [1]. Heat-assisted IMR is introduced to achieve extra ADC gain by jointly modulating the optical spot over the high coercivity media [2]. In addition, inter-track interference (ITI) cancellation [3] and array-reader schemes [4] are introduced for IMR to reliably retrieve recorded data. Dual-track readback IMR with an array reader jointly covering neighboring tracks is also investigated for doubling the read data rate but with complicated skew effects by multiple readers [5]. This study focuses on the feasibility of the dual-track readback by a single wide reader, by taking advantage of interlaced feature of the IMR. By synchronized writing of neighboring tracks in an interlaced manner, a single wide reader covering two-tracks jointly is capable of capturing four-level (4L) signals. The single-reader based dual-track read (DTR) IMR relaxes the skew issues and processing overheads in the array reader based IMR. The 4L-DTR IMR channel is illustrated in Fig. 1. The wide reader captures two neighboring tracks jointly but with different weights by differentiated relative track widths of the written tracks. For example, when bottom tracks are initially written widely and later trimmed by the top tracks as in Fig. 1, the raw waveform, $\underline{r}$, is processed by analog front-end (AFE) and loops to get ADC sample sequence, $\underline{x}_{4L}$, which has four levels. Fig. 2 illustrates the raw waveforms and histograms of ADC samples of the 4L-DTR IMR conditioned on the input data. Due to the inevitable read offsets, the relative weights of the target signal are varying and the joint 4L equalizer $\underline{h}(\delta)$ need to be adaptively adjusted by accounting the read-offset δ for equalized output $\underline{y}_{4L}$. Then, the equalized samples are later processed by multi-level detector as two-bit sequence, $\underline{z}_{2b}$.

HI-04. Statistical Analysis of Read-back Signals in Magnetic Recording on Granular Media. *F. Slanovc*[1], C. Vogler[1], O. Muthsam[1] and D. Suess[1] *1. Faculty of Physics, University of Vienna, Vienna, Austria*

The simulation of magnetic writing and read-back processes on granular media becomes computationally expensive for individually computed switching probability of each single grain within the writing process (see [1,2]). The a priori calculation of switching probability phase diagrams (as in [3]) allows an arbitrary amount of writing processes afterwards. For a conventional writing method, the magnetization of each grain (up or down) is chosen according to the extracted switching probabilities from the diagram (see Fig. 1). It requires $m>1$ repetitions to investigate the mean signal as well as the noise (see [4,5]). In addition, the different grain alignment in various media must also be taken into account for further $n>1$ repetitions in order to obtain correct statistics for the final read-back signal. In this work we present two different methods that improve the statistical evaluation of the read-back. In the first approach we avoid setting the magnetization to up respectively down. Instead, we just assign each grain its magnetization probability. In the read-back process, we combine the probabilities to calculate a mean signal and its variance. Afterwards n repetitions on different media lead to the final read-back signal. The second approach does not even require a certain granular medium and directly correlates the switching probabilities in certain areas of the magnetic medium according to the mean grain diameter of the medium. In this case no statistical repetitions are necessary, both signal and noise can be determined directly from the magnetization

probabilities. Finally, we conclude that the different methods show good agreement and that the statistical behaviour of the evaluated signal-to-noise ratio is improved. (see Fig. 2). Nevertheless, we also find that fewer repetitions do not automatically mean faster computation time, since determining the right correlation between the switching probabilities is also computationally complex.

HI-05. Development of High Resolution Programable Oversampling MI Sensor System with 32-bit ADC for Multi-Channel Bio-Magnetic Measurements. *J. Ma*[1] and T. Uchiyama[1] *1. Department of Electrical Engineering, Graduate School of Engineering, Nagoya University, Nagoya, Japan*

1. Introduction Recently, we have reported a high performance Pk-pk VD-type MI magnetometer [1]. In order to further improving noise performance and achieving higher spatial resolution for bio-magnetic sensing, there is a tendency to develop a multi-channel integrated system for micro magnetic sensors. In this study, we have developed a high resolution programable oversampling MI sensor system, as a unit module for multi-channel integrated bio-sensor system, based on Pk-pk VD-type MI sensor system. 2. Programable Oversampling MI sensor system The new developed MI sensor system is combined with Pk-pk VD-type MI sensor system and programable oversampling ADC & digital filter system. As illustrated in Fig. 1(a), we program the ADC configuration, sampling frequency, down sampling factor, and Filter configuration by Python; and communicate to FPGA with these programed ADC & Filter systems. After receiving the configuration programs from PC, the FPGA will setup ADC & Filter systems and control the ADC by supplying controlling and configuration signals. As illustrated in Fig. 1(b), we measure output noises in time domain of new MI sensor system with 30 Hz lowpass filter. The output RMS noise is about 10 pT with a 30 Hz lowpass filter. Fig. 2(a) illustrates magnetic noise spectral density of programable oversampling MI sensor system. The noise floor is lower than 1 pT/Hz$^{1/2}$ in the frequency range from 1 Hz to 100 Hz. It is 1/10 of noise level of previous MI gradiometer [2]. Furthermore, we have investigated high frequency noise components via new MI sensor system. Fig. 2(b) illustrates magnetic noise spectral density of new MI sensor system with 0.5 MHz sampling frequency. The noise peak at 800 Hz and the reduction of noise floor after 800 Hz are because of 800 Hz lowpass filter in analog circuit. Meanwhile, the noise peaks at high frequency component marked with red circle in Fig. 2(b) are oscillation noises.

HI-06. Radio-frequency magnetic noise of magnetic vortex states in magnetic tunnel junctions. *R. Okuno*[1], M. Goto[1,2], S. Tsunegi[3], K. Yakushiji[3], H. Kubota[3], A. Fukushima[3], S. Yuasa[3], H. Nomura[1,2] and Y. Suzuki[1,2] *1. Graduate School of Engineering Science, Osaka University, Toyonaka, Japan; 2. Center for Spintronics Research Network, Osaka University, Toyonaka, Japan; 3. National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan*

Understanding the magnetic noise is important for realizing highly sensitive magnetic field sensors. Currently, the magnetic noise such as magnoise [1], nonlinear magnoise [2], and 1/f noise [3] has been investigated in magnetic tunnel junctions (MTJs) with single domain states. Moreover, the low frequency noise has been studied in a MTJ with the magnetic vortex state. It is the candidate for a highly sensitive sensor with wide dynamic range because of its negligible hysteresis and high saturation field [4]. However, the magnetic noise of the magnetic vortex state is not studied in wide frequency range. In this study, we investigate the magnetic noise in the MTJ with a magnetic vortex state in the free layer (FL) in radio-frequency (RF) range. Figure 1 shows the noise measurement circuit. The film stack structure is Buffer/ IrMn(6)/ CoFe(2.5)/ Ru(0.85)/ CoFeB(2.1) and CoFe(0.4) pinned layer/ MgO(1.1)/ FeB(5) magnetic vortex FL/ MgO(1.1)/ Ta(5)/ Ru(5) (nm in thickness). The external magnetic field is applied in an antiparallel direction to the pinned layer. Figure 2 shows the magnetic field dependence of the magnoise spectrum. From the magnetoresistance curve (MR curve), the FL is the magnetic vortex state in 0 mT, and the single domain state in 40 and 80 mT. The magnoise peak is caused by a rotation of a vortex-core in the magnetic vortex or a precession of the magnetization in the single domain by the heat at room temperature. From Fig. 2, the magnoise peak of the magnetic vortex appears in lower frequency than the single domain state. Furthermore, we observed 1/f magnetic noise of the magnetic vortex in the MHz frequency range. Our results provide the fundamental knowledge for the magnetic field sensor using magnetic vortex. This research was supported by Bilateral Programs (MEXT) and JSPS KAKENHI (Grant No. JP16H03850).

HI-07. Optimization of thin film magnetoimpedance structures for low field sensing applications. *E. Fernandez-Martin*[2], N. Lete-Segura[1], J. Beato[3], C. Gomez-Polo[3] and A. Garcia-Arribas[1,2] *1. Electricidad y Electronica, Universidad del Pais Vasco (UPV/EHU), Leioa, Spain; 2. BCMaterials, Basque Center on Materials, Applications and Nanostructures, Leioa, Spain; 3. Departamento de Ciencias, Universidad Publica de Navarra, Pamplona, Spain*

The magneto-impedance (MI) is the great change of the electrical impedance that soft ferromagnetic materials exhibit when an external magnetic field is applied. The impedance change with magnetic field is related to the reduction of the effective cross section available for the ac current to flow due to the skin effect. In previous studies, we have systematically optimized the preparation conditions, structure and combination of shape and induced anisotropies to enhance the MI ratios and sensitivities on $Ni_{80}Fe_{20}$ multilayers [1-3]. In this work, $[FeNi(50nm)/Ti(6nm)]_8$ /Cu(400nm)/ $[Ti(6nm)FeNi(50nm)/Ti(6nm)]_8$ 12x0.5 mm samples were sputtered onto silicon. During the deposition, a 250 Oe magnetic field is applied parallel to the film plane in order to induce a uniaxial magnetic anisotropy perpendicular to the long side of the sample. Cooper electrical contacts are deposited at both ends of the samples and to connect the elements of the meanders. We aim to determine the best strategy to increase the field sensitivity of the MI samples by impedance matching to 50 Ω. There are mainly two options: one is to adapt the impedance of the prepared sample by a combination of passive elements. The matching is then done for a certain field and frequency (Fig. 1). The matched sample maintains the original relative MI ratio (240 %) and sensitivity (170 %/Oe - derivative of the MI ratio), but the impedance sensitivity is increased by an order of magnitude, from 4 Ω/Oe to 40 Ω/Oe. The second option is to increase the length of the MI element, by forming a meander structure. This option needs a more detailed study due to the role played by the increased self-inductance of the structure. For this reason, we have

simulated different meander configurations. The simulations show an increase of MI ratio as the distance between the meander elements is reduced and a substantial increase of the MI ratio with the number of meander elements (Fig. 2), that seems to saturate with 9 elements.

HI-08. Detection of Strain Direction Using a Flexible Exchange-Biased Spin Valve. *H. Matsumoto*[1,2], S. Ota[1,2], A. Ando[3] and D. Chiba[2,4]
1. Department of Applied Physics, The University of Tokyo, Bunkyo, Tokyo, Japan; 2. Institute of Scientific and Industrial Research, Osaka University, Ibaraki, Osaka, Japan; 3. Murata Manufacturing Co., Ltd., Nagaokakyo, Kyoto, Japan; 4. Center for Spintronics Research Network, Osaka University, Toyonaka, Osaka, Japan

Magnetization direction of ferromagnetic metal thin films can be controlled by applying a tensile strain [1, 2]. Based on this, we have recently developed a strain direction sensor formed on a flexible substrate [3], which is a giant magnetoresistive pseudo spin valve (SV) with a strain-sensitive Co free layer and a strain-insensitive NiFe pinned layer [3]. Only the magnetization of the Co layer rotates to the strain direction, while the magnetization of the NiFe layer always points toward an assisting magnetic field H_a direction. Thus, a resistance R of the SV changes depending on the strain direction. Here we show H_a-free strain direction sensing [4]. To realize this, a flexible exchange-biased SV (EBSV) is formed. In this case, the magnetization of the free layer can more freely rotate by strain application without being disturbed by H_a because the exchange bias (EB) only pins the NiFe layer. As a result, the sensitivity is improved. We also demonstrate a human body motion detection using this sensor [4]. We prepared a Co/Cu/NiFe/FeMn EBSV on a flexible substrate. Fig. 1 shows the dependence of the R change on tensile strain ε measured for the EBSV without H_a (top panel) and for the pseudo SV measured under $\mu_0 H_a$ =20 mT (bottom panel) [3]. θ is the angle between the EB or H_a direction and ε axis. As seen in the curve for θ = 90°, R of the EBSV increases more sharply by ε application and saturates at smaller ε compared with the pseudo SV case, meaning that the strain direction can be identified more sensitively. We fabricated a finger motion sensor using the flexible EBSV. As shown in Fig. 2, the sensor can identify which finger is bent. The authors thank T. Sekitani and T. Koyama for their useful discussion and technical help. This work was partly supported by Murata Manufacturing Co., Ltd., JSPS KAKENHI (Grant Nos. 25220604 and 17J03125) from JSPS, and Spintronics Research Network of Japan.

HI-09. Flexible magnetoelectronics for interactive wearables. G. Canon Bermudez[1] and *D. Makarov[1] 1. Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany*

The recent rapid advance and eagerness of portable consumer electronics stimulate the development of functional elements towards being lightweight, flexible, and wearable. Next generation flexible appliances aim to become fully autonomous and will require ultra-thin and flexible navigation modules, body tracking and relative position monitoring systems. Key building blocks of navigation and position tracking devices are magnetic field sensors. Although there is a remarkable progress in the field of shapeable magnetoelectronics [1], there is no technology available that can enable sensitivities to geomagnetic fields of 50 μT and, ultimately, magnetic fields of smaller than 1 μT in a mechanically compliant form factor. If available, these devices would contribute greatly to the realization of high-performance on-skin interactive electronics [2-5] and point of care applications [6,7]. Here, we will present technological platforms allowing to realize not only mechanically imperceptible electronic skins, which enable perception of the geomagnetic field (e-skin compasses) [8], but also enable sensitivities down to ultra-small fields of sub-50 nT [9]. We demonstrate that e-skin compasses allow humans to orient with respect to earth's magnetic field ubiquitously. Furthermore, biomagnetic orientation enables novel interactive devices for virtual and augmented reality applications. We showcase this by realizing touchless control of virtual units in a game engine using omnidirectional magnetosensitive skins.

HI-10. Variable Temperature Study of Noise and Field Detectability in Magnetic Tunnel Junctions with Superparamagnetic Free Layers. *Y. Zhang*[1], G. He[1], X. Zhang[2] and G. Xiao[1] *1. Department of Physics, Brown University, Providence, RI, United States; 2. Division of Physical Science and Engineering, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia*

Magnetic tunnel junctions (MTJs) with a superparamagnetic free layer have attracted attention due to its linear and hysteresis-free behavior, as well as possible reduction of low-frequency *1/f* noise. A comprehensive study on superparamagnetic MTJs under various conditions is currently lacking. In this work, we have performed a systematic study on transport and noise properties of superparamagnetic MTJs over a broad range of frequency, magnetic field, and temperature. From the magneto-transport properties, we have found a size variation of nanoclusters composing the free layer. Such size distribution is important in understanding the smooth change of noise and sensitivity near the blocking temperature of superparamagnetic transition. Particularly, relationship between *1/f* noise and sensitivity is closely examined. Different scaling relations between *1/f* noise and sensitivity have been found in ferromagnetic and superparamagnetic states. The change of scaling law implies that magnetic nanoclusters in ferromagnetic and superparamagnetic states are under different thermodynamic conditions. An explanation based on fluctuation-dissipation theorem is given. This result shows that noise measurement is an efficient tool in understanding thermodynamics of nanostructures. Finally, significance of scaling law to MTJ performance and approaches to further optimize superparamagnetic MTJs will be discussed.

HI-11. MTJ Based Magnetic Sensor for Current Measurement in Grid. *K. Gao*[1], X. Yin[3], Y. Yang[2], D. Ewing[4], P.J. De Rego[5] and S. Liou[2] *1. Research and Development, International Business and Technology Service Corporation, North Oaks, MN, United States; 2. University of Nebraska, Lincoln, Lincoln, NE, United States; 3. Western Digital Corporation, Fremont, CA, United States; 4. Department of Energy's Kansas City National Security Campus, Kansas City, KS, United States; 5. New Mexico Operations, Department of Energy's Kansas City National Security Campus, Albuquerque, NM, United States*

Here we review the status and the challenges utilizing MTJ based magnetic sensor for Grid sensing [1-4]. We show that with both modeling and experiment measurement optimized MTJ based magnetic (RemG) sensor can be utilized to monitor Grid current, particular for each individual transmission line measurement. Unlike the traditional approach where the sensing element needs to be either integrated, in contact with or near the transmission line, this measurement can be based on a contactless or a "remote" sensing setup, where the sensor is placed away from the Grid line. We have demonstrated that, utilizing special designed and optimized MTJ based magnetic sensor, we are able to conduct remote real time measurement of the magnetic field generated from the Grid current [5]. From sensor perspective, the sensitivity, the signal to noise ratio and the linearity can all meet the target device requirement. Combined with finite difference time domain microcurrent model, one can back calculate current waveform in each line when complex Grid topology is present [6]. This approach enables a system to detect the situation of the Grid. MTJ based sensing technology with high sensitivity, small size, light weight and low power consumption and potential low cost have been shown [5]. We do see that as the complexity of the Grid topology increases, the system complexity increases significantly. From sensing perspective, MTJ based sensor is ideal to conduct a "remote" sensing, in a way it can be placed meters away from the Grid line. One of the challenges is that the complex topology and multiple Grid lines may exists with different current levels. The other challenge is that with an improved sensing capability provided by MTJ sensors, significant more data can be collected, the system bottle neck has been shifted to transfer of data instead of sensing.

HI-12. Noise Optimization in Magnetic Tunnel Junctions. *J.E. Davies*[1], J. Watts[1], J. Novotny[1], D. Huang[1] and P.G. Eames[1] *1. Advanced Technology, NVE Corporation, Eden Prairie, MN, United States*

MgO-based tunneling magnetoresistive (TMR) sensors are blossoming into a large and dynamic application space [1]. One of the key goals in sensor development is minimization of the noise; which is dominated by a magnetic *1/f* component at low frequencies and Johnson noise at high frequencies [2]. While noise minimization by itself is a noble goal, and has become somewhat of a technology marketing point, there are significant trade-offs when looking at the TMR sensor's best application space. We have evaluated the noise parameters of a number of sensor configurations and found that the sensors with the lowest measured noise floor in (μV/V/ÖHz) did not have the lowest detectivity (nT/ÖHz). This is on account of the sensitivity playing the dominant role in determining the detectivity and comes at the expense of the sensor's size and linear range. These other parameters set the ultimate bounds for sensor performance. One clear path forward is to maximize the TMR. Egelhoff, *et al.* showed that there are diminishing returns on improving the overall noise when the TMR is much higher than 100%. However, TMR maximization is bountiful when it comes to increasing sensor range, minimizing size and hysteresis. Additionally, improvements to the traditional Wheatstone bridge design with shielded MTJ resistors by moving to a push-pull bridge configuration yields a nearly 100% increase in the sensitivity; adding to the design space. This is challenging to achieve monolithically due to having to pin MTJ reference layers in opposing directions. TMR and sensor configuration thus become the two biggest areas for sensor performance gains. We demonstrate these improvements in recently fabricated sensors and are able to achieve <10 pT/√Hz@ 1 kHz and <1 nT/√Hz @ 1 Hz while maintaining a linear range greater than 0.1 mT.

HI-13. A Full Sample-Type MI Magnetometer with Programable Circuit for High Compatibility. *K. Shi*[1] and T. Uchiyama[1] *1. Graduate School of Engineering, Nagoya University, Nagoya, Japan*

The MI sensor which is based on magneto-impedance effect in an amorphous wire used for numerous applications[1], such as electronic compass, foreign matter detection, healthcare[2]. However, the conventional circuit are still working with sample-hold(S/H) circuit that are not suitable for all type of MI sensor.in this work, we propose a novel circuit design for MI sensor system that consists of analogue integration circuit and a field-programmable gate array (FPGA)to sample the whole waveform of sensor's output. The external magnetic field was generated by a Helmholtz coil. And the whole system is put in Permalloy shield box (50dB@2Hz). The controllable integration of the two parts of the MI sensor output can be achieved by the FPGA controlled circuit. Figure.1 (a)shows The output waveform of the MI sensor is divided into two areas by the rising and falling edges of the excitation pulse. which have opposite conversion rates of the external magnetic field. In order to maximize the sensitivity of the system, we integrate the two parts separately.Figure.1 (b)shows the two parts of the MI sensor output have the same sensitivity to the external magnetic field, which has different sensitivity ratio than S/H mode circuit [3]. Figure.2 shows the external magnetic field is set to a 10 Hz sine wave with an amplitude of 300 pT. The decibel value near 10 Hz in the previous system is -25 dB, in the proposed system, the decibel value near 10 Hz is -35 dB. By adjusting the integral distribution ratio of the two parts, we can reduce the noise and improve the SNR. We have demonstrated a new MI sensor system based on FPGA-based programmable circuits. Compared with the conventional S/H circuit system, the proposed system has better compatibility to the MI sensor, and it is not necessary to adjust the switch opening time for better performance. The results show that the proposed system has high resolution and high signal to noise ratio.
