TU-01. Neuromorphic Computing with Spintronic Devices.
D. Querlioz[1] *1. Centre de Nanosciences et de Nanotechnologies, Univ Paris-Sud, Palaiseau, France*

In recent years, Artificial Intelligence (AI) has progressed to an astonishing level through the development of algorithms known as deep neural networks. Nevertheless, AI has to face a challenge: its considerable energy consumption, order of magnitudes higher than brains on similar tasks. Neuromorphic computing aims at designing systems whose operating principles are to some extent inspired by brains, to reduce the energy consumption of AI. In this tutorial, we will try to understand why brains are more energy efficient than current AI, and how spintronic devices and materials can help close this energy gap. Looking at the organization of the brain will teach us fundamental lessons on the design of neuromorphic systems, which should closely associate computational units (artificial neurons) and memory units (artificial synapses). We will see that one of the biggest challenges, however, is the inadequacy of current memory technologies. We will then study how spin torque and other spintronic memories, which naturally resemble synapses, can by contrast provide a solution. Second, we will study recent developments that use the physics of spintronic devices, such as spin torque nanooscillators, directly for implementing artificial neurons. We will see the benefits and the challenges of this approach to computing, which mimics very closely the way that brains use their own basic devices. The specificities of spintronics, which can be tuned and engineered finely, are particularly exciting for this vision and open different perspectives in terms of scaling. We will also see that neuromorphic systems are sometimes less demanding in terms of device properties than conventional systems, which can allow using devices in a more optimal fashion. We will study the two main applications of neuromorphic hardware (inference and learning hardware), and show that they have very different device requirements. We will finally compare two visions for neuromorphic computing: the AI approach, which can bring immediate applications, and the longer term neuroscience-inspired approach. All these approaches do not call for the same device work.

3:20

TU-02. Quantum Computing. *K. Itoh*[1] *1. Applied Physics and CSRN, Keio University, Yokohama, Japan*

This tutorial talk consists of the following three parts. 1) General introduction of quantum computing; from its basic concept to descriptions of a variety of quantum computing device schemes. 2) Introduction of the state-of-the-art in the silicon-based, spin qubit quantum computer development. 3) Introduction of quantum software developments for application in chemical engineering, financial engineering, and artificial intelligence fields. A priority is placed on the intuitive understanding for non-experts. Please come and enjoy.

4:10

TU-03. Benchmarking Quantum Computers and Future Directions for Superconducting Quantum Hardware. *H. Paik*[1] *1. IBM Q, IBM T J Watson Research Center, Yorktown Heights, NY, United States*

While the fully fault-tolerant universal quantum computing system is still many years ahead, building an early quantum computer with quantum advantage becomes a feasible near-term milestone that we can realistically plan. Increasing number of near-term applications has been accelerating the development of quantum hardware in the industries, and as quantum system size grows, we need a whole system metric to evaluate the level of hardware performance. I would like to introduce the quantum volume (arXiv:1811.12926) as a system-level metric that quantifies quantum computational power of early quantum computing processors, and will present an example of performance comparison among IBM Q public quantum processors in the cloud. The quantum volume depends on various individual component metrics such as gate fidelity and crosstalk. I will discuss some of the challenges in building superconducting quantum hardware and suggest few directions to improve the quantum volume.

AA-01. Fundamental Spin Interactions Underlying the Magnetic Anisotropy in the Kitaev Ferromagnet CrI_3. *I. Lee*[1], F.G. Utermohlen[1], K. Hwang[1,2], D. Weber[1], C. Zhang[1], J.v. Tol[3], J.E. Goldberger[1], N. Trivedi[1] and P.C. Hammel[1] *1. The Ohio State University, Columbus, OH, United States; 2. Korea Institute for Advanced Study, Seoul, The Republic of Korea; 3. National High Magnetic Field Laboratory, Tallahassee, FL, United States*

In the two dimensional (2D) limit, magnetic anisotropy is known to be a key element in stabilizing the ferromagnetism.[1-3] However, the comprehensive Hamilitonian of the fundamental spin models explaining the experimental data such as magnetic anisotropy field, Curie temperature T_c and Dirac gap[4], has yet to be established. In this talk, we present the detailed magnetic anisotropy of a CrI_3 single crystal obtained through the measurement of angle dependence of ferromagnetic resonance (FMR). Also, we present a Hamiltonian describing the anisotropic spin interactions in 2D in terms of the experimentally measured Heisenberg, Kitaev, off-diagonal symmetric exchange and quadrupole interactions that incorporate the material's crystal symmetries. Calculation of T_c using spin wave theory and comparison with the experimentally known values reveal that CrI_3 is a Kitaev-dominant ferromagnet rather than Heisenberg. We also find that the off-diagonal symmetric exchange interaction stabilizes the long range of 2D ferromagnetic order by opening the magnon gap ~ 0.4 meV at the center of the Brillouin zone and we predict a Kitaev-interaction-induced ~ 5 meV magnon gap opening at the Dirac point. This work clarifies the complex anisotropic behaviour of spins in CrI_3, opening a route towards 2D ferromagnets with higher T_c and magnetically frustrated quantum spin liquids based on Kitaev physics.

AA-02. Optical and electrical control of 2D magnets. *C. Jin*[1], Z. Tao[2], K.F. Mak[1,2] and J. Shan[1,2] *1. Kavli Institute at Cornell for Nanoscale Science, Cornell University, Ithaca, NY, United States; 2. School of Applied and Engineering Physics, Cornell University, Ithaca, NY, United States*

Two-dimensional (2D) van der Waals magnets have attracted much recent interest [1-8]. The 2D nature of these materials is expected to give rise to distinct physics from their bulk counterparts [1-2]. In addition, as atomically-thin layers, they can be easily incorporated into device architectures and van der Waals heterostructures to enable novel functionalities such as

gate-controllable magnetism and spin-filter tunneling [3-8]. In this talk, I will describe our recent magneto-optical spectroscopy studies to investigate the unique physical properties, such as modified magnetic coupling and enhanced spin fluctuations, in 2D magnetic insulators. I will also discuss our efforts on controlling these properties with optical and electrical methods, and the potential implications on the emerging spin phenomena as well as novel magnetic devices.

AA-03. Magnon Transport in Quasi-Two-Dimensional Van Der Waals Antiferromagnets. *W. Xing*[1] *1. Peking University, Beijing, China*

Recently, the emergence of 2D van der Waals magnets down to atomic layer thickness provides exciting platforms for exploring quantum magnetism and spintronics applications. To explore 2D magnets towards the future magnonics applications, we have investigated the magnon transport properties in quasi-2D van der Waals $MnPS_3$. In this talk, I will present the experimental observation of long distance magnon transport over several micrometers in quasi-2D van der Waals antiferromagnetic insulating $MnPS_3$. The transport of magnons could be described using magnon-dependent chemical potential and magnon relaxation length. As the quasi-2D $MnPS_3$ thickness decreases, a shorter magnon relaxation length is observed, which could be attributed to the surface-impurity-induced magnon scattering. Furthermore, I will introduce the electric field effect on the metal-insulator transition in multilayer ferromagnetic semiconducting $Cr_2Ge_2Te_6$, and the anomalous Hall effect mechanisms in ferromagnetic metallic $Fe_{0.29}TaS_2$.

AA-04. Epitaxial Growth and Magnetic Properties of Room Temperature 2D van der Waals Ferromagnets. *R. Kawakami*[1] *1. Dept. of Physics, The Ohio State University, Columbus, OH, United States*

Monolayer van der Waals (vdW) magnets provide an exciting opportunity for exploring two-dimensional (2D) magnetism for scientific and technological advances. One of the important direction is the epitaxial growth of 2D magnets with high ordering temperatures and large areas, which complement the work on smaller exfoliated materials. In this talk, I will discuss the development of room temperature ferromagnetism in the monolayer limit for epitaxial $MnSe_2$ vdW layers [1]. Since bulk Mn-Se compounds are not ferromagnetic and bulk van der Waals crystals of $MnSe_2$ do not exist, we rely on molecular beam epitaxy to grow far from equilibrium and epitaxially stabilize $MnSe_2$ layers on GaSe(0001) and $SnSe_2$(0001) epilayers. Magnetization measurements of monolayer $MnSe_2$ films on GaSe and $SnSe_2$ epilayers show ferromagnetic ordering with a large saturation magnetization of ~ 4 Bohr magnetons per Mn, which is consistent with density functional theory calculations predicting ferromagnetism in monolayer 1T-$MnSe_2$. Growing manganese selenide films on GaSe up to high thickness (~ 40 nm) produces α-MnSe(111), and an enhanced magnetic moment (~ 2x) compared to the monolayer $MnSe_2$ samples. Detailed structural characterization by scanning transmission electron microscopy (STEM), scanning tunneling microscopy (STM), and reflection high energy electron diffraction (RHEED) reveal an abrupt and clean interface between GaSe(0001) and α-MnSe(111). In particular, the structure measured by STEM is consistent with the presence of a $MnSe_2$ monolayer at the interface. These results hold promise for potential applications in energy efficient information storage and processing. Beyond these initial studies, we have investigated the growth of room temperature ferromagnets $MnSe_2$ and VSe_2 [2] on a variety of substrates including topological insulator Bi_2Se_3, III-V semiconductor GaAs(111), and highly-oriented pyrolytic graphite (HOPG). Among these studies, the heterostructures of magnetic layers with topological insulators are particularly interesting for current induced magnetic switching via spin-orbit torque. Further, these investigations have led to the synthesis of $MnBi_2Se_4$ a layered antiferromagnetic topological insulator, which integrates a $MnSe_2$ layer within a Bi_2Se_3 quintuple layer (i.e. septuple layer with a sequence of Se-Bi-Se-Mn-Se-Bi-Se). We report the growth, structural characterization, and magnetic and electronic properties of such materials.

AA-05. Magnetic Order Near Room Temperature in Fe_5GeTe_2. *A. May*[1] *1. Oak Ridge National Lab, Oak Ridge, TN, United States*

$Fe_{5-x}GeTe_2$ is a van der Waals layered compound with Curie temperatures of 260-310K.[1,2] It is metallic and easily cleaved into thin flakes.[2] This material has similarities with the heavily-studied compound $Fe_{3-x}GeTe_2$,[3-6] but the compounds possess different crystal structures and physical properties. This talk will focus on the magnetic properties of $Fe_{5-x}GeTe_2$ single crystals, which possess a Curie temperature that depends on processing conditions. One of the magnetic sublattices remains dynamic down to approximately 120K, and these fluctuating moments greatly impact the transport properties. Exfoliation of bulk single crystals has produced 10nm thick flakes, which appear to have the high Curie temperature of the bulk based on Hall effect measurements.

AB-01. Resonant Raman Spectroscopy of the Chiral Antiferromagnet $CoNb_3S_6$. *N. Hassan*[3,1], A. McCreary[1], N. Ghimire[2] and A.R. Hight Walker[1]
1. The National Institute of Standards and Technology, Gaithersburg, MD, United States; 2. Department of Physics & Astronomy, George Mason University, Fairfax, VA, United States; 3. Department of Physics and Astronomy, Johns Hopkins University, Baltimore, MD, United States

A new class of topological materials are made by inserting transition metal atoms into the atomic lattice of a well-known two-dimensional material. We report here the first full Raman characterization of the chiral antiferromagnet $CoNb_3S_6$; i.e. cobalt-doped NbS_2. $CoNb_3S_6$ exhibits a large c-axis anomalous Hall effect (AHE) not entirely attributable to the small intrinsic ferromagnetic component (Co) along the c-axis [1]. This interesting behavior suggests that the enhancement in AHE may be a combination of magnetic field in the presence of the near-Fermi energy Weyl nodes. Theory claims that interacting Weyl fermions could give rise to spin density waves [2]. Neutron scattering experiments of $CoNb_3S_6$ [3] showed incommensurate peaks; however, it was not clear whether the peaks are due to a spin spiral or a spin density wave. Magneto-Raman spectroscopy represents an optimal method to differentiate these structures. Wavelength- and polarized-dependent Raman spectra collected at room temperature from $CoNb_3S_6$ flakes are analyzed specifically in relation to the vibrational modes seen in NbS_2. Experiments of temperature- and magnetic field-dependent Raman spectroscopy to seek magnon (spin wave) signatures will be detailed.

AB-02. Large Interfacial Spin-Orbit Torques in Permalloy/$NiPS_3$ Bilayers. *C. Schippers*[1], H. Swagten[1], B. Koopmans[1] and M. Guimarães[2]
1. Department of Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands; 2. Zernike Institute for Advanced Materials, University of Groningen, Groningen, Netherlands

With the emergence of spin-orbit torque based magnetic random-access memories, novel and more efficient ways of generating spin-orbit torques (SOTs) for switching the magnetization of a ferromagnetic layer have gained a lot of interest. Most methods use a heavy-metal layer to generate these torques, e.g. the spin-Hall effect in platinum. However, it has been theoretically demonstrated that interfacing the ferromagnet with an insulator with spin-orbit coupling can generate a variety of SOTs [1]. However, as heavy metals also generate SOTs in the bulk, it can be difficult to distinguish between the bulk and interfacial contribution. To investigate the generation of interfacial SOTs, we use nickel-thiophosphate ($NiPS_3$), a two-dimensional Van der Waals antiferromagnet, for generating interfacial SOTs on its interface with a ferromagnetic permalloy (Py, $Fe_{0.2}Ni_{0.8}$) layer. As $NiPS_3$ is an insulating material, any measured torque at the ferromagnet must be interfacial of nature. Moreover, $NiPS_3$ has a reduced symmetry in its antiferromagnetic phase. This can allow for the presence of an out-of-plane damping-like SOT, a type of torque that is often limited by symmetries in a material. Although this torque has been observed in the low-symmetry Van der Waals material WTe_2 [2], using $NiPS_3$ would provide a way of controlling this torque with the antiferromagnetic phase-transition. In this contribution we have used Hall-bar devices (Fig. 1) to perform harmonic Hall measurements (Fig. 2) to quantify the SOTs in our structures. We observe large interfacial out-of-plane field-like and in-plane damping-like torques the $NiPS_3$/Py bilayers, comparable to values of bulk heavy-metal-based SOT devices, such as Pt/Py bilayers. However, while it is allowed by symmetry, the out-of-plane damping-like SOT has not been observed. Our current efforts are focused at understanding our findings. We envision that this research adds to the understanding of the nature of interfacial spin-orbit torques and contributes to designing and optimizing future spintronics applications.

AB-03. Vortex-antivortex dynamics in easy plane antiferromagnetic materials. *G. Finocchio*[1], R. Tomasello[2], F. Garesci[1], M. Carpentieri[3], P. Khalili Amiri[4] and V. Lopez[4] *1. University of Messina, Messina, Italy; 2. FORTH, Heraklion, Greece; 3. Politecnico di Bari, Bari, Italy; 4. Northwestern University, Evanston, IL, United States*

It has been shown that AFM order, i.e. the Néel vector, can be manipulated optically, with strain, and electrical current. The latter is of particular relevance for the design of antiferromagnetic memories [1,2] and oscillators[3,4]. In addition, images of antiferromagnetic order in micrometer size devices show the presence of multiple domains [5], and in some materials also vortex and antivortex states can be stabilized[6]. Up to now, studies of domain wall statics and dynamics driven by spin-hall have been performed in perpendicular materials[7], while a systematic numerical study on vortex and antivortex pair dynamics is still missing. Here, we performed micromagnetic simulations to study static and dynamical properties of vortex antivortex pair stabilized in antiferromagnetic materials with easy plane anisotropy with circular shape on top an extended heavy metal with large spin-orbit coupling. The antiferromagnetic state is modeled by means of two vectors m1 and m2. These represent the normalized (with respect to the saturation magnetization) magnetizations of the two sub-lattices, whose dynamical manipulation is described by two coupled Landau-Lifshitz-Gilbert (LLG) equations[4]. We created a stability phase diagram dot diameter vs. anisotropy constant comparing the energy of vortex-antivortex, vortex and uniform state. Our results shows that in dot with diameter above 400nm the ground state of the Néel order can be strongly nonuniform. Figure 1(a) and (b) show an example of ground state having multi vortex and antivortex and antivortex pair ((a) z-component and (b) y-component of the Néel vector) calculated in a device with a diameter of 4000nm, as can be observed a very complex pattern is observed. We then consider the dynamics driven by spin-hall effect in vortex-antivortex pair with same and opposite polarity.

AB-04. Anomalous transport properties of hexagonal Mn_3Sn thin films. *P. Zilske*[1], S. Kurdi[2], G. Reiss[1] and J. Koo[1] *1. Center for Spinelectronic Materials and Devices, Bielefeld University, Bielefeld, Germany; 2. Department of Materials Science and Metallurgy, University of Cambridge, Cambridge, United Kingdom*

In the last decade, antiferromagnetic spintronics has been recognized as a very important field for future magnetic memory or logic applications [1]. Recently, the $D0_{19}$ ε-Mn_3X (X = Ga, Ge, Sn) system has emerged as a new candidate for active elements in spintronic devices. Theoretical calculations and first experimental results have shown large anomalous Hall and anomalous Nernst effects for those non-collinear antiferromagnets. However, these properties are only studied in detail in single crystal bulk samples, and achieving high quality thin films is required for their realization in devices [2-4]. Here, we report on structural, magnetic and transport properties of Mn_3Sn thin films. Epitaxial Ru/Mn_3Sn thin films were grown on c-Al_2O_3 single crystal substrates via magnetron co-sputtering. For detailed structural analysis, we performed high-resolution X-ray diffraction (XRD) measurements and transmission electron microscopy (TEM). The X-ray study reveals highly epitaxial films and single phase growth of the Mn_3Sn. Furthermore, TEM images show smooth interfaces and no inter-diffusion of any elements. In addition to the structural characterization, magnetic as well as transport properties has been measured. The in-plane M-H curve reveals clear hysteresis loop with remanence close to the bulk value. The hysteresis shows both small coercivity (15 mT) and saturation field (100 mT), cf. Fig.1. In addition, clear magnetic field dependent anomalous transport properties (anomalous Hall effect (AHE) and anomalous Nernst effect (ANE)) were obtained. The corresponding room temperature AHE, ρ_{zx}, and ANE, α_{xz}, data are also shown in Fig.1. Along those crystallographic directions, AHE and ANE have not yet been reported in thin film systems. In addition, temperature dependent AHE measurements will be discussed.

AB-05. Direct Probe of Uncompensated Magnetization at the Surface of an Antiferromagnetic FeF Layer. *P.N. Lapa*[1], I.V. Roshchin[2] and I.K. Schuller[1] *1. Department of Physics, University of California San Diego, La Jolla, CA, United States; 2. Department of Materials Science and Engineering, Texas A&M University, College Station, CA, United States*

Using a novel transport technique, we discovered a peculiar behavior of the uncompensated magnetization (UM) formed at the surface of an antiferromagnetic FeF layer. The key to this is the fabrication of an epitaxial antiferromagnet-conductor-ferromagnet spin valve [1], specifically, FeF (30nm)/Cu(10nm)/Co(5nm)/Ti(5nm). When the valve is cooled down to 10 K in in-plane magnetic field, the angular dependence of resistance can be represented as a superposition of two harmonics with 180° and 360° periodicity (Fig. 1). The 180° harmonic is present in the entire studied temperature range and it is caused by the anisotropic magnetoresistance of the Co layer. The 360° harmonic appears only at temperatures below Neel temperature of FeF (78 K). This is interpreted as due to a giant magnetoresistance caused by the scattering of charge carriers polarized by the Co layer on the UM at the FeF /Cu interface. The minimum of this harmonic occurs at the pinning direction of the UM. When the valve is cooled down in a magnetic field

applied along the easy axis of the FeF layer, the UM is pinned in the direction opposite to the cooling field. This discovery unambiguously confirms the earlier hypothesis for the mechanism of the positive exchange-bias effect observed in the FeF/ferromagnet bilayers [2] and the direction of the pinned UM in FeF [3-4]. Furthermore, the observation that the uni-directional anisotropy (180° asymmetry of the magnetoresistance) is preserved even in the field as high as 9 T, indicates that even such a field cannot break the UM pinning. For all cooling field orientations, even when it is perpendicular to the easy axis, the UM is pinned along the easy axis. This fact, combined with the pinning persisting in a high magnetic field clearly indicates that UM is rigidly coupled to the antiferromagnetic staggered order in FeF2. This discovery may be essential for applications in the area of antiferromagnetic spintronics. This research was supported by the Office of Basic Energy Science, U.S. Department of Energy, BES-DMS funded by the Department of Energy's Office of Basic Energy Science, DMR under grant DE FG02 87ER-45332.

AB-06. Coherent Magnetic Small Angle Soft X-Ray Scattering for Structural and Dynamic Characterization of a Free-Standing B2-Ordered FeRh Thin Film. *J. Massey*[1], R.C. Temple[1], T. Almeida[2], R. Lamb[2], N. Peters[1], R. Campion[3], R. Fan[4], D. McGrouther[2], P. Steadman[4] and C.H. Marrows[1] *1. University of Leeds, Leeds, United Kingdom; 2. University of Glasgow, Glasgow, United Kingdom; 3. University of Nottingham, Nottingham, United Kingdom; 4. Diamond Light Source, Didcot, United Kingdom*

B2-ordered FeRh undergoes a first order phase transition from an antiferromagnet (AF) to a ferromagnet (FM) upon heating through the transition temperature ~ 380 K [1]. The FM phase through has been studied extensively through the phase transition using magnetic imaging techniques [2, 3, 4]. However, only one study exists that attempts to characterize the development of the AF phase through the transition and little is known about the properties of this phase [4]. Here, by combining both X-Ray Magnetic Circular Dichroism (XMCD) and X-Ray Magnetic Linear Dichroism (XMLD) with Small Angle X-Ray Scattering, it is possible to track the structural behaviour of both magnetic phases through the transition of a free-standing B2-ordered FeRh thin film. These studies reveal a change in the measured scatterer through the transition within the available Q range from FM domain walls to FM domains using XMCD and between FM domain walls and AF domains using XMLD. It is also seen to be possible to measure the dynamic behaviour of both magnetic phases by performing X-Ray Photon Correlation Spectroscopy (XPCS) studies throughout the transition. Fitting to stretched exponential relaxation model, characterised by the stretching exponent, β, the investigations performed using XMCD demonstrate a change in the dynamics behaviour across the transition consistent with the change in scatterer seen in the structural analysis. The investigations using XMLD, however, show a contrasting behaviour and reveals that various relaxation processes are introduced into the system alongside the AF material. By combining the two investigations it is possible to build up a comprehensive picture of how the dynamic behaviour changes through the transition. These investigations show that direct measurements of the structural and dynamic behaviour of the fully AF state are possible using this technique.

The exchange interaction is key for ferroic magnetic coupling and responsible for major phenomena in magnetic materials. This fundamental interaction combined with spin-orbit coupling leads to two components: symmetric and antisymmetric. While the symmetric term, generally referred to as a Heisenberg exchange coupling, gives rise to ferro- and antiferro-magnetism, the antisymmetric exchange coupling – Dzyaloshinskii-Moriya interaction [1,2] has recently attracted particular interest owing to its significant role in stabilizing topologically non-trivial spin textures [3-8] in a ferromagnetic layer. Beyond the *intra-layer* exchange coupling limited to a single ferromagnetic layer, the *interlayer* exchange coupling can also lead to ferro- or antiferromagnetic alignments of magnetic multilayers. This has served as a crucial element for modern devices and recently attracted renewed interests in the community in line with an emerging field of antiferromagnetic spintronics [9-11]. Most of the relevant studies, however, have so far focused only on its symmetric component, although its antisymmetric counterpart can arise, particularly, in systems with an inversion symmetry breaking

and spin-orbit coupling [12-14]. Here, we present experimental demonstrations of the antisymmetric interlayer exchange coupling in perpendicularly magnetized synthetic antiferromagnets [14]. Asymmetric hysteresis loops under an in-plane field unambiguously reveal a unidirectional and chiral nature of this novel interaction, which cannot be explained by any existing coupling mechanisms but by chiral interlayer exchange coupling, resulting in canted magnetizations. Theoretical studies by *ab initio* methods also suggest that such chiral interlayer exchange coupling is ultimately related to the spin-orbit coupling in multilayers and a reduced symmetry in the plane of multilayers. Our observation of chiral interlayer exchange coupling paves the way for engineering magnetic structures in particular in three-dimensions, which would enable novel unconventional logic devices.

AB-08. Signal-to-Noise Ratio and Maximum Detected Frequency of Terahertz-Frequency Spectrum Analyzer Based on an Antiferromagnetic Tunnel Junction. P. Artemchuk[1], S. Louis[2], O. Prokopenko[1], *V. Tiberkevich*[3] and A.N. Slavin[3] *1. Faculty of Radio Physics, Electronics and Computer Systems, Taras Shevchenko National University of Kyiv, Kyiv, Ukraine; 2. Department of Electrical and Computer Engineering, Oakland University, Rochester, MI, United States; 3. Department of Physics, Oakland University, Rochester, MI, United States*

An antiferromagnetic (AFM) tunnel junction (ATJ) is an ultra-fast spintronic device which seems to be promising for THz-frequency signal generation, detection and processing [1-3]. Here we calculate the signal-to-noise ratio (SNR) and maximum detected frequency of the previously proposed [3] spectrum analyzer based on a current driven Pt/IrMn/MgO/Pt ATJ as a function of two geometrical parameters: thickness d of the MgO tunneling barrier and the device lateral size a. The output voltage U_{dc} of the ATJ-based spectrum analyzer is reduced when the input signal frequency f increases, mainly due to the spurious influence of the ATJ capacitance [3]. When the input frequency reaches a certain value f_{max}, the detected voltage U_{dc} drops below the Johnson-Nyquist (JN) noise voltage U_{JN} making the signal detection impossible. We analyzed the dependences of the SNR = U_{dc}/U_{JN} and maximum frequency f_{max} of an ATJ spectrum analyzer on the MgO barrier thickness d and ATJ lateral size a. These results are calculated for the input signal power of 1 μW and temperature T = 293 K and are presented in Figs. 1, 2. As seen from Fig. 1, the SNR strongly decreases with the increase of the signal frequency f, while its dependence on the junction's lateral size a is relatively weak. The optimum size a of the ATJ junction is around 300 nm, where the maximum detected frequency f_{max} reaches 0.38 THz (see dashed line in Fig.2). The maximum frequency f_{max} strongly decreases with the increase of the barrier thickness d (see solid line in Fig.2), which is caused, mainly, by the exponential increase of the ATJ resistance and impedance mismatch between the ATJ and the 50 Ω input transmission line. Thus, an ATJ-based spectrum analyzer with optimum parameters (d ~ 1 nm, a ~ 300 nm) can be used for room-temperature detection of low-power (~ 1 μW) input signals with frequencies of up to ~ 0.38 THz.

AB-09. Anisotropic Magnetoresistance and Unidirectional Magnetoresistance in Pt/FeRh Bilayers. *J. Sklenar*[1], H. Saglam[2], J. Oh[1], G. Hamilton[1], Y. Li[2], W. Zhang[3], S. Zhang[2], M. Gilbert[1], A. Hoffmann[2] and N. Mason[1] *1. University of Illinois at Urbana-Champaign, Urbana, IL, United States; 2. Argonne National Laboratory, Lemont, IL, United States; 3. Oakland University, Rochester, MI, United States*

In this work, we demonstrate a unidirectional magnetoresistance (UMR) effect in the antiferromagnetic phase of a Pt/FeRh bilayer. To date, UMR effects have now been established within a plethora of thin film heterostructures containing a ferromagnet and a non-magnetic layer capable of generating spin-currents. Two examples are found in ferromagnets adjacent to spin Hall metals or topological insulators [1, 2]. The origin of UMR is sometimes attributed to magnetization dynamics in the magnetic layer from the adjacent material producing the spin current. Importantly, these high frequency dynamics are generated and detected (via UMR) without the need for more specialized high-frequency electronics [2, 3, 4]. The UMR we observe appears after a large enough "threshold" current density is reached in the Pt. This suggests that the UMR is arising at the onset of antiferromagnetic magnetization dynamics being induced in the FeRh. Along with the UMR, we will present a detailed study on the related anisotropic magnetoresistance

(AMR) effect in both the ferromagnetic and antiferromagnetic phase of Pt/FeRh, upon which the UMR signal is superimposed. Work at The University of Illinois at Urbana-Champaign was supported by the National Science Foundation MRSEC program under NSF award number DMR-1720633. Work at Argonne was supported by the U.S. Department of Energy, Office of Science, Materials Sciences and Engineering Division.

(a) An illustration of our devices which are Pt/FeRh films patterned into a constricted geometry. The width of the Pt/FeRh wire is 500 nm and the Pt layer is 5 nm thick. We have studied FeRh layers having thicknesses between 7.5 -30 nm. A current bias can be applied across the device while a longitudinal resistance measurement is made. The resistance is measured as a field is rotated in the *xy*, *zx*, and *yz* plane. (b) The angular dependence of the Pt/FeRh bilayer is shown as a 4 T field is rotated in the *xy* plane with a 6 mA current bias present. The angular lineshape is a combination of a two- and four-fold AMR which we can identify as non-crystalline and crystalline magnetoresistance effects in the FeRh. Additionally, a UMR signal is identified which is not present at lower current densities.

AB-10. Topological Hall effect in weakly canted antiferromagnets.
J.J. Nakane[1], K. Nakazawa[2] and H. Kohno[1,3] *1. Physics, Nagoya University, Nagoya, Japan; 2. Earth and Space Science, Osaka University, Osaka, Japan; 3. Center for Spintronics Research Network (CSRN), Osaka University, Osaka, Japan*

The topological Hall effect (THE) is a Hall effect caused by a noncoplanar spin texture, or its spin chirality, in ferromagnetic conductors. This effect is absent in antiferromagnets due to the cancellation of the two sublattice chiralities [1,2]. If the moments are canted, however, the overall spin chirality, hence the THE, can be finite. Motivated by a recent experiment [3], we studied the THE in a weakly canted antiferromagnet with textured Néel (n) and uniform (l) components of magnetization. Treating the textured Néel component by a spin gauge field and the uniform component perturbatively, we derived an analytical expression for the topological Hall conductivity (THC). The result is first order in uniform moment, and is proportional to an emergent magnetic field, $\nabla\times A_{AF}$, where $A_{AF} = l.\partial_i n\times n$ is an emergent vector potential in antiferromagnets, which consists of the spin-chirality density (triple scalar product), $l.\partial_x l\times\partial_y l$, and a term $\sim(A_{AF}\times\nabla|l|)_z$ that arises from the spatial variation of the magnitude of the uniform moment. In the limit of small s-d exchange coupling $J_{sd}<<|\mu|$, where μ is the chemical potential measured from the antiferromagnetic gap center, the THC is linearly proportional to J_{sd} (a result analogous to the behavior of the THE in the weak-coupling region in ferromagnets [4,5]).

AB-11. Extraordinary magnetic anisotropy and relaxation dynamics in the non-collinear antiferromagnet $IrMn_3$.
S. Jenkins[1], R.W. Chantrell[1] and R.F. Evans[1] *1. Physics, University of York, York, United Kingdom*

Antiferromagnets have gained significant interest in recent years due to their potential application in antiferromagnetic spintronic devices and neuromorphic computing where the antiferromagnet is the active element. In non-collinear antiferromagnets such as IrMn the symmetry and temperature dependence of the effective anisotropy are poorly understood due to the difficulty in experimental measurements and the complexity of the materials. Iridium Manganese (IrMn) is the material of choice for most spintronic devices due to its high thermal stability and large exchange bias. Theoretical and experimental calculations of the effective anisotropy constant for IrMn differ by two orders of magnitude. Both theoretical[1] and experimental measurements[2] agree that the anisotropy has a uniaxial form but this contradicts the usually assumed relationship between crystallographic symmetry and the temperature dependence of the anisotropy from the Callen-Callen law. Here we calculate the effective anisotropy energy surface of $IrMn_3$ using an atomistic spin model with the VAMPIRE code[3] as shown in Fig. 1. We find a unique cubic-like symmetry of the anisotropy not seen in ferromagnets and that meta-stable spin structures lower the overall energy barrier to a tenth of that estimated from simple geometrical considerations, removing the discrepancy between experiment and theory. Fig. 2 shows the temperature scaling of the anisotropy energy barrier this has an exponent of 3.92, close to a uniaxial exponent of 3[4]. Our results demonstrate the importance of non-collinear spin states on the thermal stability of antiferromagnets with consequences for the practical application of antiferromagnets in devices operating at elevated temperatures.

AB-12. Magnetic and Electrical Transport Properties in Epitaxial Thin Films of the Non-Collinear Antiferromagnet Mn_3Sn. *J.M. Taylor*[1], A. Markou[2], E. Lesne[1], C. Felser[2] and S.S.P. Parkin[1] *1. NISE, Max Planck Institute of Microstructure Physics, Halle (Saale), Germany; 2. Solid State Chemistry, Max Planck Institute for Chemical Physics of Solids, Dresden, Germany*

A promising candidate for topological antiferromagnetic (AF) spintronic applications is the non-collinear AF Mn_3Sn [1]. Here, symmetry breaking inverse triangular AF order generates Berry curvature around Weyl points [2], in turn inducing novel electrical transport properties [3-5], as well as an anomalous magneto-optical Kerr effect (MOKE) [6]. This is enabled by a DMI mediated canting of Mn moments, which produces a small magnetization in the basal planes of the material and thus allows external manipulation of domain structure via external magnetic field [7]. In this work, the deposition of thin films of hexagonal Mn_3Sn down to thicknesses as low as 10 nm is reported [8]. X-ray diffractometry and transmission electron microscopy are used to demonstrate high-quality crystal structure, as well as to determine epitaxial growth relationships. Using lattice engineering on either $SrTiO_3$ or MgO substrates, films with both c-axis (0001) orientation and a novel (40-43) orientation are prepared. In the latter case, where a component of the uncompensated magnetic moment lies out of plane, a large anomalous Hall effect (AHE) is measured at room temperature with $\mu_0 H_c$ = 1.3 T. The angular dependence of ρ_{xy} is consistent with the crystallographic orientation of the hexagonal basal planes, indicating the intrinsic relationship between epitaxial thin film structure and the unique magnetotransport properties observed. These are accompanied by a large MOKE signal measured in polar geometry, which we observe in thin films of Mn_3Sn for the first time. However, SQUID magnetometry and X-ray magnetic circular dichroism measurements indicate a tiny uncompensated Mn magnetization, suggesting these phenomena have their origin in Berry curvature driven by the chiral spin texture. Finally, temperature dependent magnetotransport measurements demonstrate the onset of a large topological Hall effect, corresponding to an expected magnetic phase transition close to 50 K. Not previously reported for films of Mn_3Sn, this suggests further interesting applications of this material in its helical magnetic state. These results indicate the potential of Mn_3Sn thin films for use in AF *chiralitronic* devices.

AB-13. Magneto-optical Spectra of a Strained Non-collinear Antiferromagnet: Ab Initio Theory. *J. Zemen*[1,2], H.K. Singh[3], H. Zhang[3], F. Johnson[2], D. Boldrin[2], A. Mihai[4], B. Zou[4], L. Beran[5], J. Zázvorka[5], M. Veis[5], O. Heczko[1,6] and L. Cohen[2] *1. Faculty of Electrical Engineering, Czech Technical University in Prague, Prague, Czechia; 2. Department of Physics, Imperial College London, London, United Kingdom; 3. TU Darmstadt, Darmstadt, Germany; 4. Department of Materials, Imperial College London, London, United Kingdom; 5. Faculty of Mathematics and Physics, Charles University, Prague, Czechia; 6. Institute of Physics, Prague, Czechia*

We present magneto-optical spectra in an antiferromagnetic (AF) structure of metallic Mn_3AN (A = Ga, Sn, Ni, Ir). Magneto-optical Kerr Effect (MOKE) was measured in a closely related triangular AF structure of Mn_3Sn last year [1], which was the first observation of MOKE in an AF metal. The related Anomalous Hall Effect (AHE) has been measured in the same non-collinear AF system recently [2]. The family of Mn-based antiperovskite nitrides with general formula Mn_3AN shows promise for a wide range of applications in spintronics [3,4] and solid-state cooling [5,6]. The functionality is mainly derived from the frustrated exchange interactions in the triangular AF structure and its response to strain [4]. The intrinsic contribution to MOKE has been simulated for the cubic ground state of compounds with A = Ga, Zn, Ag, Ni recently [7]. Here we focus on the MOKE spectra of strained systems where the lower symmetry allows for novel magnetic phases that we predicted earlier [8]. We employ the Projector-Augmented Wave method (PAW) and linear response theory as implemented in the VASP code to derive the Kerr angle and ellipticity. Figure 1 shows simulated spectra for Mn_3GaN: the solid line corresponds to unstrained lattice with triangular AF order (the so-called G^{5g} representation) where MOKE vanishes due to the high symmetry; the dashed line is obtained for the same structure subjected to 1% compressive biaxial strain which results in canting of the local moments and finite MOKE; the dash-dotted line describes a collinear ferrimagnetic phase (local Mn moments aligned with the [110] axis, $FIM_{[110]}$) which we expect to form at 1% biaxial strain and elevated temperatures [8]. We compare our results for canted triangular and FIM phases to the corresponding MOKE spectra measured above and below the Néel temperature in Mn_3NiN and Mn_3GaN thin films deposited on different perovskite oxide substrates. We observe a qualitative agreement of the data below Néel temperature which can be interpreted as a confirmation of the desirable triangular AF structure of the thin film.

AB-14. Antiferromagnetic Skyrmion Crystals in Frustrated Triangular Lattices. *A.S. Raeliarijaona*[1], W. Fang[1], P. Chang[1,2], K. Belashchenko[1] and A. Kovalev[1] *1. Physics and Astronomy, University of Nebraska-Lincoln, Lincoln, NE, United States; 2. Computational and Data Sciences, George Mason University, Fairfax, VA, United States*

We investigate the existence of skyrmion crystal in antiferromagnetic triangular lattice in the presence of Dzyaloshinskii-Moriya interaction and magnetic anisotropy. As a possible realization, we studied transition metal dichalcogenides (TMDs) MoS2, decorated with magnetic atoms, such as Co, Cr, Mn, Fe, using first-principles density functional calculations. We further performed Monte Carlo simulations to calculate the zero-temperature phase diagram, as well as the finite temperature phases. We demonstrate that in these triangular systems we can realize antiferromagnetic skyrmion crystals, which reside on three sublattices, whose onset is facilitated by the magnetic anisotropy. The characteristics of the phases and the phase transition are obtained by computing the spin structure factor and the specific heat.

AB-15. Magneto-transport properties in the chiral antiferromagnet Mn_3X(*X*=Sn, Ge) thin films. *A. Kobayashi*[1], D. Qu[1,2], T. Higo[1,3], S. Nakatsuji[1,3] and Y. Otani[1,3] *1. ISSP, University of Tokyo, Kashiwa, Japan; 2. Institute of Physics, Academia Sinica, Taipei, Taiwan; 3. JST-CREST, Kawaguchi, Japan*

Antiferromagnets have recently attracted considerable attention as a key material for next generation devices owing to their advantages such as negligible stray field and high-frequency spin dynamics [1]. However, because of the absence of magnetization, neither electrical detection nor externally manipulation of the Néel state is possible although these functions are essential for the spintronic devices. Surprisingly large spontaneous transverse responses have recently been found in the noncollinear kagome-lattice antiferromagnets hexagonal Mn_3X (*X*=Sn, Ge). It exhibits large anomalous Hall [2-5], anomalous Nernst [6], and magneto optical Kerr effects [7] at room temperature. All these phenomena are characterized by the cluster magnetic octupole moment[8]. It also has been found that the spin Hall effect has an anomalous sign change when its triangularly ordered spins switch orientation in Mn_3Sn, because of the momentum-dependent spin splitting [9]. In noncollinear antiferromagnets, novel types of spin currents have been demonstrated to occur by symmetry arguments and calculations [10]. These spin currents have a longitudinal component of spin polarization and are analogous to spin-polarized currents in ferromagnets. This suggests the novel transport properties related to the spin-polarized currents such as magnetoresistance effect can be expected in Mn_3X. In this work we tried the synthesis of hexagonal Mn_3X (*X* = Sn, Ge) thin films by DC-magnetron sputtering. We obtained high quality hexagonal Mn_3Sn single phase [11], in addition to hexagonal, tetragonal and cubic phases of Mn_3Ge. The ferrimagnetic tetragonal Mn_3Ge has been known to have the large perpendicular magnetic anisotropy, the high spin polarization and the low Gilbert damping effect [12]. These features indicate the tetragonal Mn_3Ge is a good candidate material for spin-transfer-torque random access memory. For Mn_3Ge cubic system, only ferromagnetic $L1_2$ [13], and ferrimagnetic α-Mn structure [14] have been reported so far, however, our cubic structured Mn_3Ge showed pure antiferromagnetic behavior suggesting to take γ-Mn like disordered structure. The various magneto-transport properties for Mn_3X (*X*=Sn, Ge) will be reported.

Since the first demonstration by Kiselev et al. [1], the technology of spin torque nano-oscillators (STNO) has made important progress improving device characteristics, such as the output power and generation linewidth, and demonstrating a large range of novel functionalities, such as DC-to-RF conversion for microwave signal generation, RF-to-DC conversion for microwave signal detection, and, also, different operational regimes, such as injection locking and frequency or amplitude modulation. Proof-of-concept systems based on STNOs have emerged imitating a neural network for vowel recognition [2], demonstrating wireless data transmission using OOK protocols [3], frequency synthesis based on a phase-locked loop [4], and microwave power harvesting to provide DC drive for nanoelectronics components [5]. The defining feature of STNOs is their nonlinear amplitude-frequency dependence that allows one to control the generated frequency via applied current on a nanosecond time scale. This fast tuning of an STNO is exploited here to demonstrate two RF systems making use of vortex-state STNO devices generating about 1 μW of output power. The first one is a communication system which is using a robust wireless protocol that overcomes problems of STNO phase stability by combining modulation with injection locking. The potential of this system is demonstrated through wireless voice transmission over 10 m distance, using conventional radio receivers [6]. The second system is an ultrafast spectrum analysis predicted in [7] that outperforms existing analogs based on VCO and YIG oscillators. A fully-functional nano-sized spectrum analyzer implementing FPGA was developed to demonstrate spectrum analysis on μs timescales for complex time-varying signals. The developed RF systems based on the state-of-the-art STNO devices demonstrate the characteristics that are sufficient to propose an alternative, nano-scale solutions for IoT and microwave signal processing applications. Financial support is acknowledged from ERC MAGICAL N° 669204, the French space agency CNES, the enhanced EUROTALENT program, as well as from the NSF of the USA Grants Nos. EFMA-1641989 and ECCS-1708982.

AC-02. Computational Random Access Memory and Applications for Artificial Intelligence (AI). *J. Wang*[1] *1. Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States*

To enable local or edge AI like family-based robots and self-driving cars without using cloud computing, the power consumption for any available computing system is still four to six orders of magnitude higher than needed. This is largely because in modern computing architecture, also named as von Newman architecture, data is fetched from memory, travels through interconnects, is processed in a logic circuit, and is stored back into memory. We proposed a complete new architecture to realize the computation without data transfer between the memory and logic circuit [1,2]. Our idea is to directly use the memory cells to carry out the computation [1-3], e.g. compute at the data just mimicking the way our brain operation. We name this new computing architecture as computational random access memory (CRAM) [2]. We proposed and demonstrated a basic concept, voltage controlled logic (VCL). Fig. 1 shows the design illustration of voltage controlled logic performing a NAND operation with '1' and '0' inputs. We use MTJs as the basic units. Two parallel connected MTJs with high and low resistance states represent logic '1' and '0' respectively and serve as the two inputs of the NAND operation. The third MTJ at the bottom will act as a detector to detect if the parallel resistance of the two input MTJs is below a certain value and serve as the output of the NAND operation. In the case shown in this figure, the output MTJ is pushed beyond its own critical current and switched to logic '1' as expected for a NAND operation with '1' and '0' input. In this case, the state variable (resistance) is converted to current, which is quasi-linearly combined, and analyzed using the output MTJ as the threshold detector. In [1] we showed that there can be sufficient write margin between the input states. This new architecture can be implemented using a variety of available and proposed devices [2]. To implement a STT-RAM based CRAM, we introduce a 2T1M cell architecture shown in Fig. 2a. When the wordline for memory (WLM) is logic high, the cell behaves identically to the 1T1M MRAM cell, and the MTJ is accessible for read/write operations across bitline (BL) and bitline bar (BLB). However, when bitline for logic (BLL) is high, the access transistor to the shared logic line (LL) is enabled and the cell can be accessed for VCL operations using BL. Figure 2b shows a 2-input CRAM gate that is functionally equivalent to the 2-input VCL gates [1,2]. For a logic operation, the first two cells are loaded with the input data, either from a previous CRAM operation or by writing the data to RAM using the memory mode. BLL is enabled for these cells, which connects all of them to the LL. This allows for the function of CRAM to be entirely reprogrammable. Modeling and benchmarking for STT-RAM based CRAM vs other near and in memory computing has been carried out for different applications including bioinformatics computing [4], pattern recognition [5], binary-neural-net-based image classification [6]. Using digit recognition as an example, the energy efficiency could be improved by 40 times and the execution time was improved by 1400 times compared to the latest near memory computing scheme [5].

AC-03. Perpendicular Magnetic Anisotropy Tunnel Rectification Magnetoresistance Effect for In-Memory Computation. *K. Zhang*[1,2], K. Cao[1,2], Y. Zhang[1,2], J. Nan[1,2], Z. Zheng[1,2], L. Chen[1,2] and W. Zhao[1,2]
1. Fert Beijing Institute, Beihang University, Beijing, China; 2. School of Microelectronics, Beihang University, Beijing, China

In-memory computation (IMC) based on Spintronic devices shows promise to meet high-speed and low-power demands for information processing [1-4]. Recently, the discovery of tunnel rectification magnetoresistance (TRMR) [5] effect blazes a new path towards realizing efficient and multi-dimensional regulation capabilities. Here, an IMC scheme based on TRMR effect in perpendicular-magnetic-anisotropy (PMA) magnetic tunnel junction (MTJ) and diode hybrid structure (Fig. 1(a)) is demonstrated. The current-voltage (I-V) curves for parallel (P) and antiparallel (AP) states indicate the coexistence of rectification behavior and tunnel magnetoresistance (TMR) effect (Fig. 1(b)). We further perform TRMR measurement, in which alternating current (AC) is applied to generate direct-current (DC) voltage. High up to 275% TRMR ratio is observed at AC=150 μA (Fig. 1(c)). The TRMR is defined as TRMR = $(V_{AP}-V_P)/(V_P)\times100\%$, V_{AP} (V_P) representing the rectification voltage under AP (P) state. The MR value of the hybrid structure could be widely tuned with the varied DC offsets at AC=400 μA (Fig. 1(d)). Leveraging the AC/DC-regulated capability of the TRMR effect, we propose a scheme to implement IMC. Two MTJs in series are combined with a diode in parallel to construct a logic unit (Fig. 2(a)). The AP (P) state of MTJs is regarded as logic input '1' ('0'). The measured rectification voltage is the logic output and positive (negative) voltage represents logic output '1' ('0'). Using our established model, the I-V curves with AC = 500 μA for different states of the two MTJs could be figured out (Fig. 2(b)). By tuning the DC offset and setting different configurations, reconfigurable logic operations, including AND, OR, NOR and NAND could be realized (Fig. 2(c)). NOR logic operation is experimentally carried out to further validate the proposed scheme.

Magnetic memories have received boosted interest due to their nonvolatility, infinite endurance and fast read/write rates. However, existing magnetic memories confront challenges of relatively large write energy and limited on-off-ratio. To address the challenges, we propose a new memory device, the *spin-orbit-torque field effect transistor* (SOTFET), which has

potential for a large reduction in energy dissipation and significant increase in on-off-ratio, while retaining the virtues of magnetic memories. The basic structure of a SOTFET is shown in Fig. 1. The SOTFET gate stack is on top of a semiconductor channel and comprises three layers: a topological insulator (TI), a ferromagnet (FM), and a multiferroic insulator (MF) from the top to bottom. The working principle of a SOTFET is described as follows. When a charge current flows through the TI layer, transverse spin currents with different spin polarization separate and spins accumulate at the surfaces of the TI layer due to spin-momentum coupling[1]. Through spin-orbit-torque (SOT), the spin accumulated at the TI/FM interface switches the magnetization (M) of the FM that has a perpendicular magnetic anisotropy. Due to the exchange coupling between the FM and the MF[2], the magnetic dipole of the MF is also switched together with the M in the FM. Since the M and electric polarization (P) are strongly coupled in the MF material due to the Dzyaloshinskii-Moriya interaction (DMI)[2], the electric dipole in the MF switches in tandem. The resulting switching of P in the MF gates the semiconductor channel, which resembles FeFETs and NCFETs[3]. Therefore, the semiconductor channel acts as the read-out component, offering a high on-off-ratio. Here, we present a preliminary model of the SOTFET. The switching dynamics of M is modeled by the Landau-Lifshitz-Gilbert (LLG) equation[4]. The interaction between M and P is captured by DMI. And the P dynamics is modeled by Landau-Khalatnikov (LK) equation[5]. Our modeling results (Fig. 2) show that with FM and MF strongly coupled, the P in MF can be switched by applying current in the TI layer.

Spintronic memory devices not only complement or displace conventional CMOS memory device due to their lower power consumption and faster operating speed, they are also promising candidates for logic devices [1]. Here, we present a stateful in-memory current-driven reconfigurable logic device based on the spin Hall effect. Using a double Hall cross structure sharing a common Hall bar, we show that the anomalous Hall voltage due to magnetization states across device channels can be interpreted as logical outputs. With appropriate thresholds and rectification, the logic device is demonstrated to operate as AND, NOR, XNOR, XOR, NIMP and Converse NIMP logic gates. By integrating a field line on each device, it is also possible to generate sufficient local Oersted field to break the switching symmetry typically required for deterministic spin-orbit torque switching in type-z devices. This allows on-the-fly reconfigurability of the individual double Hall cross devices. The device design also eliminates the need for reset pulses. Furthermore, the device can be operated in two modes: In Mode (I), the device logic gate is determined by the read currents, and the logic states are represented by the device magnetization. Mode (II) operates conversely, where the device logic gate is determined by the magnetization, and the logic states are represented by the read current. Finally, we simulate through compact modelling a half-adder based on the double Hall cross logic device.

AC-06. Proposal of Nonvolatile Logic-gates using Voltage-Control Spintronics Memory cell for AI application. *H. Yoda*[1], Y. Ohsawa[1] and Y. Kato[1] *1. Spin-Orbitronics Technologies, Inc., Kawasaki, Japan*

Recently, Artificial-Intelligence (AI), Machin-Learning (ML), and IOT have become hot topics and edge-computing should play a crucial role. Since the number of the edge-devices is estimated to exceed that of cellar phones by a factor of 10 and the edge-devices employ AI technologies, the edge-devices require both inexpensive micro-processors and ultra-low energy-consumption memories. However conventional technologies such as SRAM-based technologies and conventional nonvolatile memory technologies are thought to be unable to satisfy such requirements. Voltage-control spintronics memory (VoCSM) were proposed for a high-speed nonvolatile memory, a high-density nonvolatile memory, and a nonvolatile logic-gate applications [1], [2], [3]. This paper focuses on VoCSM-cell based logic-gates for the edge-devices. First half of this talk reviews the VoCSM developments

and the features of VoCSM-cells and the latter half focuses on VoCSM-cell based logic-gates for AI applications, including Voltage-Control Spintronics Logic (VoCSL). First, the VoCSM concept and the cell performances such as its small critical switching current, its low writing energy-consumption per bit, good write-error rate (WER), and unlimited endurance are reviewed. Second, the ultimate ultra-low energy-consumption of VoCSM-cell is estimated [4]. Third, VoCSM-cell-based logic-gates are reviewed [5], [6]. Fig.1 shows a straight-forward VoCSM-cell based logic-gate. The VoCSM-cell has 3 terminals and can be used as logic-gates. The terminal-1 & -2 are connected to the spin-hall electrode and the terminal-3 is connected to the MTJ. The terminal-1 is to supply write-current (I_w) as an input-1 and the terminal-2 is to apply voltage as an input-2. The terminal-3 is to sense the resistance of the MTJ to output the signal. Since the available magnetoresistance ratio (MR) is not large enough to read the data directly, the sense amplifier must be added as shown in the figure. Fig.2 shows another type of VoCSM-cell based logic-gate. In this case, the input-1 is a stored data in the MTJ and the input-2 is the voltage applied by the terminal-2. AND and OR logic-gates can be easily realized just by changing the write-current directions. Forth, binary-neural-network is reviewed. Since logic-gates should work frequently, unlimited endurance is one of must requirements. Because of this, most of nonvolatile memories cannot be used as a working memory for the logic-gates. Therefore, SRAM-based circuitries were proposed for AI [7]. The demerit of SRAM-based circuitries is large cell-size in addition to large leakage-current. It typically requires 6 transistors for the memory cell and additional circuitries for convolution of data. Fifth, after the importance of an XNOR-gate in AI applications especially for binary neural network is reviewed, several types of exclusive nor (XNOR) gates using VoCSM-cells including a new one are introduced in detail and explained their operations by which they work. These VoCSM-cell based XNOR gates have very simple structures because they do not requires additional circuitries [8]. The demerits of conventional MTJ based logic-gates are energy consumptions in writing data and reading data. However, in the case of VoCSM-cell based logic-gates writing voltage is very low and if the amplifiers are located in the peripheral circuits as shown in Figs.1 & 2, there is not a severe issue [6], [8]. The latter is an in-memory logic concept [6]. Finally, the benchmarking against existing volatile logic-gates and conventional MTJ based logic-gates. The issues and the possible solutions are addressed at the conference.

AC-07. Development of Domain Wall Type Spin Memristor with Magnetic Fixed Layer. *T. Ashida*[1], T. Shibata[1], M. Ohta[1], S. Yamada[1], T. Shinohara[1], Y. Terasaki[1] and T. Sasaki[1] *1. Technology & Intellectual Property HQ, TDK Corporation, Ichikawa, Japan*

In recent years, various memristors have been studied for use as analogue neuromorphic computing devices [1,2]. Magnetic domain wall (DW) type spin memristor is one of those memristors and has been expected to show typical conductance change behavior. Recently, we experimentally demonstrated linear and symmetric conductance change of the spin memristor [3]. In the past report, we utilized a current induced DW injecting method to verify the concept. This method is suitable for operating a single element, but not preferable for evaluating a multiple element array. Thus, we paid attention to a magnetic fixed layer method, which can initialize multiple elements at once just by applying an external magnetic field. In this study, we developed a three-terminal MTJ element with the magnetic fixed layer and evaluated its conductance change behavior. Top-pinned type three-terminal MTJs were fabricated on a Si substrate. The film design was Si wafer /buffer /DW layer /CoFeB Free layer /tunnel barrier /CoFeB Reference layer /SAF-pinned layer. A DW fixed layer was fabricated on one side of DW layer. The typical junction size was 225 nm in width and 1000 nm in length, respectively. Fig. 1 shows magnetization configurations of the element. First, the element was totally reset by a strong magnetic field (+5kOe). Subsequently, a weak opposite field (-1.5kOe) was applied to reverse only the DW layer. Then, a single DW was introduced by the fixed layer, and conductance change was enabled by utilizing DW propagation driven by spin transfer torque (STT). On the other hand, the change was not observed when the element was applied after positive filed of +1.5kOe. The result indicated successful DW creation by the simple magnetic field operation which is important to realize the memristor array system. More details will be discussed in the conference.

Authentication based on magnetoresistive RAM would represent a real breakthrough, since it offers several advantages with respect to the True Random Number generator (TRNG) state-of-art [1]. We report on the proof-of-concept of spintronic TRNGs. They are realized by a bilayer W/CoFeB having a perpendicular easy axis, a current flow in the W gives rise to a spin-orbit torque (SOT) that drive the CoFeB state in a non-uniform configuration that evolves randomly to one of the two equilibrium states once the current is switched-off. Our findings show that TRNG can be activated by SOT opening exciting directions for novel applications of spintronics in security and, in particular, as a building block for reconfigurable Physical Unclonable Functions (PUFs) [2]. MTJs have been proposed for PUF development where the secret is derived thanks to magnetic textures such as domain wall or in spin-transfer torque MRAM (STT-MRAM) by applying current pulses near the value of 50% of switching probability. The idea developed in this work is to use the SOT-MRAMs as a building block for the PUF (see Fig.1). The main difference with STT-MRAM is the use of three terminals to separate the read and write operations. The information is written with the SOT originated by a current flowing in a heavy metal while the information is read via the resistance of the MTJ built on top of the heavy metal. Micromagnetic simulations of the magnetization dynamics in devices with perpendicular ferromagnets show that the switching occurs via nucleation process and that a stochastic switching is possible [3]. We experimentally considered a single circular dot (diameter 1 μm) with stable perpendicular magnetization as initial state, we applied a current pulse of 4 mA (voltage 8 V) for a duration of 15 ns. The current is able to drive the magnetization out of the equilibrium. When removing the current pulse, the magnetization goes back to the perpendicular direction, upward or downward, with a probability of about 50%. More numerical and experimental details and the proposed general architecture will be presented in the full paper.

AD-01. Spin-Orbit Torque in Graphene/Co Hetero-system. *K. Song*[1], A. Manchon[1] and u. Schwingenschlögl[1] *1. King Abdullah University of Science and Technology, Thuwal, Saudi Arabia*

Due to the growing demand of low-power, fast data processing, non-volatile magnetic random access memories are being considered as powerful alternative to current semiconducting technology [1]. In this context, the spin-orbit torque (SOT) technique has opened new development of innovative magnetic devices beyond memories and data storage [2]. The emblematic mechanism underlying the SOT technique is the interfacial Rashba effect that emerges at interfaces in the presence of strong spin-orbit coupling. This effect is particularly efficient at the interface between transition metal ferromagnets and topological insulators [3,4]. In conventional SOT devices, a heavy metal (Pt or W) adjacent to the magnetic layer is used to provide large spin-orbit coupling. Alternatively, it is also possible to exploit the spin-orbit coupling of the magnetic material itself by interfacing it with, e.g., a non-magnetic insulator [5]. We investigate interfacial spin texture and SOT at the interface between Co (001) and a graphene monolayer, a system that has recenlty been predicted to display large Rashba effect [6, 7], see Fig. a. When graphene is attached to the surface of Co (001), the inversion symmetry is broken, which results in the onset of a built-in perpendicular electric field. As a result, in the presence of the large SOC of Co, Rashba effect emerges at the interface. Therefore, *a spin density* driven by a net current can be achieved at the interface, bringing SOT into such a heterostructure [8]. Using first-principles calculations, we compute the band structure and project it onto Wannier orbitals to obtain the tight-binding Hamiltonian. Non-equilibrium properties then are derived by the Kubo formula. We show that Co atoms at the interface exhibit spin-momentum locking, which is line with the phenomenological picture presented above. Close to the Fermi level, the graphene Dirac cones couple with the Co 3*d* states around the K and K′ points (Fig. c), resulting in a spin texture odd in momentum k (Fig. *d*). This special spin texture promotes current-driven SOT. Our results show that the SOT can be used to electrically control the magnetization of the Co layer, and to realize fast non-volatile data reading and writing.

AD-02. First-principles calculation of spin-orbit torque in TMD/ ferromagnet bilayers. *F. Xue*[1,2], J. Li[3] and P. Haney[2] *1. Institute for Research in Electronics and Applied Physics & Maryland Nanocenter, University of Maryland College Park, College Park, MD, United States; 2. Physical Measurement Laboratory, National Institute of Standards and Technology, Gaithersburg, MD, United States; 3. Joint Institute for Computational Sciences, University of Tennessee, Knoxville, TN, United States*

Motivated by recent discoveries of unconventional out-of-plane antidamping torque in WTe2/Permalloy system, we calculate the spin-orbit torque generated in two-dimensional transition metal dichalcogenide(TMD)/ferromagnet heterostructures using first-principles methods and linear response theory. Because of the strong spin-orbit coupling and the reduced crystal symmetry in these TMD materials, an unconventional form of the out-of-plane antidamping spin-orbit torque exists even when magnetization is in-plane, which is not allowed in the more common Pt/ferromagnet systems. Our numerical calculation of spin-orbit torques in heterostructures such as WTe_2/Co and MoTe_2/Co shows both out-of-plane and conventional anti-damping torques with comparable magnitude, around a few thousands \hbar/2e (\Omega m)^{-1}, when electric-field is applied perpendicular to the mirror plane of TMDs, which is consistent with the experimental observations. We find that the computed value of the unconventional out-of-plane antidamping torque is more sensitive to the details of the atomic structure of the Co layer and spin-orbit coupling strength of transition metal atoms than the conventional antidamping-like torque. Our numerical work confirms the existence of novel forms of spin-orbit torque in low crystal symmetry system, where the new out-of-plane spin-orbit torque could be useful in switching nanomagnets with perpendicular magnetic anisotropy for high-density applications.

AD-03. Spin-torque control of the anomalous Hall conductivity in non-collinear antiferromagnets. G. Gurung[1], *D. Shao*[1] and E.Y. Tsymbal[1]
1. Department of Physics and Astronomy, University of Nebraska Lincoln, Lincoln, NE, United States

Non-collinear antiferromagnetic materials have recently aroused significant interest due to the non-vanishing Berry curvature and the associated anomalous Hall effect sensitive to magnetic ordering. Especially interesting are antiperovskite compounds $ANMn_3$ (A = Ga, Cu, Ni) and their alloys, where the Néel vector can be reversed by the spin transfer torque. In this work, we explore series of antiperovskite compounds $Ga_{1-x}Ni_xNMn_3$ with competing Γ_{4g} and Γ_{5g} phases, where the magnetic moments of Mn atoms are aligned non-collinearly in the (111) plane. A spin-polarized electric current flowing the [111] direction produces a spin-transfer torque rotating the magnetic moments in the (111) plane. Based on the Landau-Lifshitz-Gilbert-Slonczewski equation, we model spin dynamics in these non-collinear antiferromagnets and obtain conditions at which a pulse of the spin-polarized current reverses the Néel vector and thus changes sign of the anomalous Hall conductivity. We find that the required current density largely depends on the magnetocrystalline anisotropy energy controlling the stability of the Γ_{4g} and Γ_{5g} phases. Using density functional theory methods, we calculate the magnetocrystalline anisotropy energy and the anomalous Hall conductivity in these antiperovskite compounds and find the optimum conditions for the current-induced reversal of the Néel vector. Our results demonstrate that the non-collinear antiperovskite antiferromagnets can be efficiently employed in spintronic devices.

AD-04. Sub-terahertz magnetization dynamics in ferrimagnets driven by spin-transfer torques. *I. Lisenkov*[1], R. Khymyn[2], J. Åkerman[2], N. Sun[3] and B.A. Ivanov[4] *1. Winchester Technologies LLC, Burlington, MA, United States; 2. Department of Physics, University of Gothenburg, Gothenburg, Sweden; 3. ECE, Northeastern University, Boston, MA, United States; 4. Institute of Magnetism, Kiev, Ukraine*

The magnetic oscillations under spin transfer torque (STT) in antiferromagnetic (AFM) materials may reach up to THz frequencies due to a strong exchange interaction [1,2]. However, AFMs, such as NiO, possess a fundamental symmetry: their magnetic sublattices are identical and compensate each other. Therefore, experimental detection of Neel's order oscillations [3] is much harder than then detection of ferromagnetic resonance. Like AFMs, ferrimagnets (FiMs) have two counter-parallel magnetic sublattices bounded by the exchange interaction, but different magnetic atoms form these sublattices. Therefore the angular moment of each sublattice is different. The difference in the spin-angular moment enclosed on the sublattices is termed as a "spin-uncompensation." Here we develop a theory of spin-transfer torque induced dynamics in slightly uncompensated FiM materials [4]. We demonstrate that the difference in the angular momentum in each sublattice principally affects FiM magnetization behavior. As an example, we consider a bi-layer Pt/GdFeCo spin-Hall oscillator, see Fig. 1. DC electrical current runs in the Pt layer inducing STT acting on FiM. The trajectory of Neel's vector precession, driven by pure spin current, is conical, in contrast to a flat circle in the case of AFMs. At the same time, due to the exchange interaction, the frequency of these oscillations can reach sub-THz frequencies. The conical type of precession is essential, as it allows for a non-zero AC spin-pumping from FiM back into the Pt layer. The AC spin-current induces a non-zero THz electrical voltage via the inverse spin-Hall effect. In Fig. 2, we plot a dependence of the DC to AC spin-Hall resistance in a case of different spin-uncompensation of the magnetic sublattices. The dependence of the Hall resistance on the spin-uncompensation is non-trivial: a small spin-uncompensation creates a detectable spin-Hall voltage in a broad range of frequencies. At the same time, a relatively large uncompensation leads to smaller bandwidth of sub-THz generation.

The spin Hall effect couples charge and spin transport, enabling electrical control of magnetization. A quintessential example of spin-Hall-related transport is the anomalous Hall effect (AHE), first observed in 1880, in which an electric current perpendicular to the magnetization in a magnetic film generates charge accumulation on the surfaces. Illustrated in Fig.1, we report the observation of a counterpart of the AHE that we term the anomalous spin-orbit torque (ASOT) [1], wherein an electric current parallel to the magnetization generates opposite spin-orbit torques on the surfaces of the magnetic film. We interpret the ASOT as due to a spin-Hall-like current generated with an efficiency of in $Ni_{80}Fe_{20}$, comparable to the spin Hall angle of Pt [2]. Similar effects are also observed in other common ferromagnetic metals, including Co, Ni, and Fe. First principles calculations corroborate the order of magnitude of the measured values. This work suggests that a strong spin current with spin polarization transverse to the magnetization can be generated within a ferromagnet, despite spin dephasing. The large magnitude of the ASOT should be taken into consideration when investigating spin-orbit torques in ferromagnetic/nonmagnetic bilayers.

AD-06. Cr-induced Perpendicular Magnetic Anisotropy and Field-Free Spin-Orbit-Torque Switching. *T. Chuang*[1], C. Pai[2] and S. Huang[1] *1. Department of Physics, National Taiwan University, Taipei, Taiwan; 2. Department of Materials Science and Engineering, National Taiwan University, Taipei, Taiwan*

Current-induced spin-orbit torque (SOT) switching in a heterostructure with perpendicular magnetic anisotropy (PMA) has attracted great attention as a new writing method for spintronic devices. However, this highly attractive switching scheme is often accompanied by an unfavorable external magnetic field. In this work, we demonstrate polarity-controlled *field-free* SOT switching in 3d Cr, as shown in Fig. 1. Moreover, we find that Cr metal can induce strong interfacial PMA, without either heavy metal or MgO layer. Most importantly, field-free SOT switching could be achieved without introducing asymmetrical geometrical pattern, heavy metal, additional ferromagnetic or antiferromagnetic layers. We show that the underlying cause for the deterministic field-free switching lies in the slanted columnar microstructure, whose tilting angle is only around 5°, for the otherwise uniform thin films. The direction of oblique columnar structure dictates the up and down orientations of the PMA layer [1]. Our results uncover the significant role of 3d materials and shed light on field-free SOT magnetization switching.

AD-07. Enhanced Spin-Orbit Torque in Co/Pt System with Interfacial Oxidation Layer. *K. Hasegawa*[1], T. Koyama[2,3] and D. Chiba[2,3] *1. Applied Physics, The University of Tokyo, Bunkyo, Japan; 2. Osaka University, Ibaraki, Japan; 3. Center for Spintronics Research Network, Ibaraki, Japan*

In-plane current-induced spin-orbit torque (SOT) in ferromagnet (FM)/heavy metal (HM) heterostructures has attracted much interest as a new method for writing information in magnetic memories. Recent experiments have shown that the oxidation of entire FM or HM layer can significantly affect the SOT efficiency [1,2]. Since the FM/HM interface condition is assumed to be more essential for the SOT, control of the interface oxidation is crucial to examine the oxidation effect. Here we show the SOT efficiency is enhanced by inserting a thin CoO layer into Co/Pt interface [3]. Ta/Pd/Co layers were first deposited on thermally oxidized Si substrate. Then, the surface of the top Co layer was exposed to air to form surface oxidation layer (CoO). Finally, the CoO surface was covered by a Pt layer (an interface-oxidized (IO) sample). We also prepared an unoxidized (UO) sample with similar areal magnetic moment as a reference. Even though the insulating CoO is expected to reduce the spin-Hall-effect-induced vertical spin current injection from the Pt to Co, the damping-like (DL) and field-like (FL) SOT effective fields for the IO sample are several-fold and nearly an order of magnitude larger than those for the UO sample, respectively, at any current densities flowing in the Pt (see Fig.). The increase in the SOT is most likely attributed to the enhancement of the Rashba-Edelstein effect which originates from the oxygen-induced modulation of the electron distribution near the Co/Pt interface. The significant enhancement of FL torque is consistent with the above speculation because the Rashba-Edelstein effect mainly contributes to the FL torque. Since the enhancement of SOT is crucial for the efficient SOT-driven magnetization switching, the interface oxidation becomes one of important keys for developing the future magnetic memory devices. This work was supported by JSPS KAKENHI and Spintronics Research Network of Japan.

AD-08. Anatomy of Intrinsic Spin-Orbit Torque in Pt/Co Bilayer: Effect of Interfacial Co Oxidation. *F. Mahfouzi*[1] and N. Kioussis[1]
1. Physics and Astronomy, California State University, Northridge, CA, United States

Spin-Orbit torque (SOT) has recently attracted a lot of attention as a method to switch nano-scale magnetic bits, due to its promising features in terms of high efficiency and scalability. SOT is a relativistic phenomena that has its origin in the atomic spin-orbit couplings (SOC) in systems with broken inversion symmetry and is often separated into damping (Slonczewski)-like (DL) and field-like (FL) components. Despite the experimental successes in achieving magnetic switching using SOT, its microscopic origin in terms of the chemical environmental properties of the interface, thus far remains elusive [1]. In this work, we present a novel theoretical approach within the framework of the Green's function approach and first principles electronic structure calculations which allows to elucidate the microscopic origin of the spin-orbit torque (SOT) in heavy metal (HM/ferromagnet (FM) bilayers. We show that the SOT can be decomposed into spin-pumping and spin-orbital components and demonstrate that, (*i*), the FL-SOT is dominated by the spin-orbital component which can be expressed in terms of the difference of current-induced spin-resolved orbital moment accumulation at the interfacial HM atoms adjacent to the FM and (*ii*), the spin-orbital component cancels out the spin-memory loss contribution to the spin-Hall conductivity resulting in an enhancement of the total DL-SOT. We apply this approach to the Pt/Co bilayer to study the Pt-thickness dependence of both components of the SOT and the effect of interfacial Co oxidation on the SOTs. The theoretical results for the SOT versus Pt thickness are in excellent agreement with experiment [2]. The calculations reveal that in the presence of oxygen atoms adjacent to the interfacial Pt layer, the hybridization of the spin majority p-derived orbitals of oxygen atoms with the d-orbitals of interface Pt layer results in a significant reduction of the current-induced spin-majority orbital moment accumulation on the Pt layer, while the spin-minority contribution remains intact. This, in turn results in a sign reversal of the FL-SOT as observed in recent experiments [3]. Supported by NSF Grant No. ERC TANMS-1160504.

AD-09. Deterministic Spin-Orbit Torque Switching by a Light Metal Insertion. *A. Razavi*[1], H. Wu[1], Q. Shao[1], C. Fang[2], K. Wong[1], X. Han[2], G. Yu[2] and K. Wang[1] *1. Electrical and Computer Engineering, University of California, Los Angeles, Los Angeles, CA, United States; 2. Institute of Physics, Chinese Academy of Sciences, Beijing, China*

Spin-orbit torque (SOT) switching of magnetization is a promising emerging technology for non-volatile spintronic memory and logic applications [1, 2]. However, deterministic switching of perpendicular magnetization with SOTs requires an additional symmetry breaking [3], which is typically provided by an external magnetic field, making it impractical for applications. In this work, we present that by inserting a slightly asymmetric light-metal at the heavy-metal/ferromagnet interface of SOT heterostructures, current-induced out-of-plane effective magnetic fields are introduced that enable deterministic switching without the external magnetic fields. The creation of out-of-plane fields in such a structure (W/Ti/CoFeB) is explained by the Rashba-Edelstein effect and is a consequence of the in-plane structural symmetry breaking. The obtained out-of-plane effective fields enable deterministic SOT switching (Fig. 1). In contrast to previous reports [3], the innovation of this work is the use of a light metal insertion (Ti) with a long spin diffusion length and a negligible spin-orbit coupling, which results in uniform perpendicular magnetic anisotropy, coercive field, spin-orbit torque, and switching current density throughout the sample, despite the asymmetry of the Ti layer (Fig. 2). Furthermore, we show the scalability of our approach for field-free deterministic switching down to nanometer devices by fabricating a series of Hall bars with different sizes. Our work provides a physical understanding of field-free switching mechanism in asymmetric structures and provides a practical route for the implementation of spintronic memory and logic devices based on SOTs.

AD-10. Enhanced Spin Orbit Torques in Rare Earth Pt/[Co/Ni]$_2$/Co/Tb Systems. *Q. Wong*[2], C. Murapaka[2,1], W. Law[2], W. Gan[2], G.J. Lim[2] and W. Lew[2] *1. Indian Institute of Technology(Hyderabad), Hyderabad, India; 2. Nanyang Technological University, Singapore*

Substantial spin Hall contributions from rare earth (R) metals have been theoretically predicted due to the their partially filled *f*-orbitals, however, determination of spin Hall efficiency with R metal being a heavy metal replacement remains lacking. We report the enhanced effect of the R metal, Tb on the spin-orbit torque (SOT)-induced switching in Pt/[CoNi]$_2$/Co/Tb with perpendicular magnetic anisotropy (PMA). In this study, SOT efficiency was characterised using a H_z-biased harmonic measurement based on analytical solutions, as well as current induced magnetisation switching. Through the systematic variation of Tb thickness from 5nm to 9nm, the harmonic analyses reveal substantial enhancement of the SOT damping-like and field like terms. A relatively large spin Hall angle of Tb, was determined to be–0.18 to –0.480 for the thickness range. The increase of magnetisation switching efficiency with increasing Tb thickness affirms the sizeable anti-damping torque that was responsible for the deterministic switching. The negative sign of the spin Hall angle could also be observed by the sign change in the resistance-current hysteresis loop. These results affirm that Tb plays a significant role in contributing to the SOTs in these structures as the increased Tb concentration leads to an enhancement of the effective spin Hall angle and switching efficiency. Furthermore, angular dependence of the field-like term suggests the enhanced presence of the interfacial spin-orbit coupling. As such, rare earth Tb proves to be a potential alternative for spin Hall based switching.

Materials exhibiting high spin-orbit coupling such as heavy metals (HM) and topological insulators have been recently intensively studied due to their potential application in spintronics devices [1]. Driving charge current through such elements results in spin current generation that may be used for both magnetization switching and magnetization dynamics induction in a neighbouring ferromagnetic (FM) layer using spin orbit torque (SOT). We present studies on various combination of multilayers including HM: W, Ta, Ir, Pt and FM: Co, CoFeB. In FM/HM bilayers, based on the thickness dependent resistance and SOT-induced ferromagnetic resonance, the amplitude of the damping-like and field-like SOT components, as well as the interface contribution is extracted using an analytical model [2]. In addition, in FM/HM/FM systems, the HM can be used both as a source of the spin current and as a tunable coupler between two FM layers. Figure 1 presents the mixing voltage dependence from the SOT-induced dynamics in Co(5)/Pt(0-10) (thickness in nm) bilayers enabling determination of the spin Hall angle based on the model. In the optimized structure Co(5)/Pt(3-4)/Co(1) a field-free SOT-switching of perpendicuarly magnetized Co(1) coupled to the in-plane magnetized Co(5) was measured by applying different current to the Hall bar, while measuring anomalous Hall voltage - Fig. 2. [3]. In the discussed paper different material systems will be presented. Acknowledgements The project is supported by National Science Center, Poland, Grant No. 2015/17/D/ST3/00500. AD-12. Influences of interfacial oxidization on surface magnetic energy, magnetic damping and spin-orbit-torques in Pt /ferromagnet /capping structures. *D. Lee*[1,2], W. Jeong[1,2], D. Yun[1,2], S. Park[3], B. Ju[1], H. Koo[2], B. Min[2], K. Lee[1] and O. Lee[2] *1. Korea University, Seoul, The Republic of Korea; 2. Korea Insutitute of Science and Technology, Seoul, The Republic of Korea; 3. Korea Basic Science Institute, Daejeon, The Republic of Korea*

Recently, spin-orbit torques (SOTs) have attracted much attention because the mechanism can efficiently reverse the magnetization in multilayers of heavy metal(HM)/ferromagnet(FM)/insulator with strong spin-orbit coupling (SOC). Although most of the research to date has focused on the HM/FM interface at which the generation of spin-current (J_S) and the enhancement in magnetic damping (α), several recent works have suggested that the physical and chemical properties of the capping (CAP) can also change the characteristics of SOTs. In addition, our previous work [1] demonstrated that the insertion of an ultrathin magnetic dusting layer between FM and MgO layers can play an important role in the determination of magnetic damping. Nevertheless, there is still a dearth of experimental work studying how the FM/CAP interface contributes to surface magnetic energy (K_S), α, SOT efficiencies (θ_{DL} and θ_{FL}) in HM/FM/CAP heterostructures. In this presentation, we present our experimental results [2] that investigate how a naturally formed magnetic oxide at the interface influences the magnetic properties. We examined six different series of layer stacks consisting of Pt / FM(Co or Py) / CAP (MgO, HfO and TaN). We illuminate, by utilizing X-ray photoelectron spectroscopy (XPS) and spin-torque ferromagnetic resonance (ST-FMR) measurements, an additional relaxation pathway of spin current in Pt/FM/CAP systems, namely the FM-oxide at the FM/CAP interface. The XPS showed the presence of interfacial FM-oxide, and ST-FMR demonstrated the deterioration of PMA associated with a formation of interfacial FM-oxides for both Co and Py samples. The interfacial oxide significantly influences α indicating an extra magnetic damping. This implies that the interfacial FM-oxide is a decent spin-current conductor, for instance, by incoherent magnon generation at the interfacial CoO, even above its magnetic ordering temperature (T_N). Our results facilitate a better understanding of the interfacial oxide contributions on the PMA, magnetic damping, and SOTs in Pt/FM/CAP systems.

AD-13. Disentanglement of Spin Orbit Torques in Platinum/Colbalt Bilayers with the Presence of Spin Hall Effect and Rashba-Edelstein Effect. *Y. Du*[1], H. Gamou[1], S. Takahashi[2], S. Karube[1,3], M. Kohda[1,3] and J. Nitta[1,3] *1. Department of Materials Science, Tohoku University, Sendai, Japan; 2. Advanced Institute for Materials Research, Tohoku University, Sendai, Japan; 3. Center for Spintronics Research Network, Tohoku University, Sendai, Japan*

We present a quantitative disentanglement of the current-induced spin orbit torques (SOTs) from the spin Hall effect (SHE) [1] and Rashba-Edelstein effect (REE) by performing a detailed harmonic Hall measurement in epitaxial Pt/Co bilayers. In-plane magnetized thin films of Pt(t_{Pt})/Co(1.95)/AlO_x(2) (thickness in nm) are fabricated into Hall bars for SOT measurement. Considering that both SHE and REE contribute to the DL-SOT, the data in Fig. 1(b) with t_{Pt} = 1.3-4.0 nm is fitted with $H_{DL} \approx H_{DL0}[1\text{-sech}(t_{Pt}/\lambda_{Pt})] + H_{DL2}$, where H_{DL0} and λ_{Pt} are the saturated DL-SOT from bulk Pt and the effective spin diffusion length (SDL) in Pt in this region, H_{DL2} is the saturated REE-induced DL-SOT at Pt/Co interface. The analysis above at different T yields an intrinsic contribution to the SHE and the Elliot-Yafet (EY) spin relaxation in *bulk* Pt, which agrees with previous studies [2,3]. A comparison of T-dependent DL-SOT and FL-SOT in thicker Pt region (*e.g.* t_{Pt} = 6.0 nm) shows that the SHE-induced FL-SOT is negligible in our samples. The t_{Pt} dependence of FL-SOT is thus fitted with $H_{FL} \approx H_{FL1}[1\text{-sech}(t_{Pt}/d_{REE1})]\text{sech}(t_{Pt}/\lambda_{Pt'}) + H_{FL2}[1\text{-sech}(t_{Pt}/d_{REE2})]$, where H_{FL1} and H_{FL2}, d_{REE1} and d_{REE2} are the saturated FL-SOT, effective REE thickness at sub./Pt and Pt/Co interfaces, respectively. Note that $\lambda_{Pt'}$, the SDL with t_{Pt} = 0.2-1.1 nm, is estimated from the λ_{Pt}-conductivity plot. The corresponding ξ_{FL1} and ξ_{FL2} [Fig. 2(a)] show comparable magnitude but opposite sign, consistent with the REE. Finally, the REE-induced DL-SOT from sub./Pt (ξ_{DL1}) interface is obtained with $H_{DL} \approx H_{DL1}[1\text{-sech}(t_{Pt}/d_{REE1})]$ $\text{sech}(t_{Pt}/\lambda_{Pt'}) + H_{DL2}[1\text{-sech}(t_{Pt}/d_{REE2})] + H_{DL0'}[1\text{-sech}(t_{Pt}/\lambda_{Pt'})]$, where H_{DL1} is the REE-induced DL-SOT from sub./Pt interface, $H_{DL0'}$ is the saturated SHE-induced DL-SOT with t_{Pt} = 0.2-1.1 nm, estimated based on the H_{DL0}-resistivity plot. The obtained ξ_{DL1} and ξ_{DL2} [Fig. 2(c)] show opposite sign and agree with the sign of ξ_{FL1} and ξ_{FL2}. This work provides a unified picture of the SOT in SH systems with both SHE and REE.

AD-14. First-principles calculation of the thickness dependence of spin-orbit torque in Co/Pt and Co/Au bilayers. *K. Belashchenko*[1], A. Kovalev[1] and M. van Schilfgaarde[2] *1. Department of Physics and Astronomy, University of Nebraska-Lincoln, Lincoln, NE, United States; 2. Department of Physics, King's College London, London, United Kingdom*

The dependence of spin-orbit torque on the thickness of the heavy-metal layer in Co/Pt and Co/Au bilayers is studied using the first-principles non-equilibrium Green's function formalism [1] combined with the Anderson disorder model. For Co/Pt, the torque is well described by a combination of damping-like, field-like, and planar-Hall-like terms, while in Co/Au only damping-like and field-like terms are important. The damping-like torque has the same sign in Co/Pt and Co/Au and behaves as a sum of the spin-Hall contribution, which increases with thickness in agreement the spin-diffusion model, and an interfacial contribution that is particularly large in Co/Pt. Variation of the disorder strength reveals a relatively small contribution of skew scattering compared to the dominant intrinsic contribution. The field-like torque has opposite signs in Co/Pt and Co/Au, and its variation with thickness is nonmonotonic. The planar-Hall-like term in Co/Pt increases with thickness, suggesting it is related to spin-Hall effect.

AD-15. Magneto-optical detection of spin-orbit torques with oblique incidence angle. *C.A. Gonzalez-Fuentes*[1] and C. Garcia[1] *1. Physics, UTFSM, Valparaiso, Chile*

Experimental techniques for the accurate quantification of spin-orbit orbit torques (SOTs) are crucial for the progress of applied spintronics. Up to date the detection of SOTs have been largely dominated by electrical detection methods, like Second Harmonic Generation [1] and Spin-Torque Ferromagnetic Resonance [2]. However, the interpretation of the data in these cases is difficult since requires the consideration of a variety of potential artifacts originated from magneto-transport, thermo-electric and spin-to-charge conversion effects [1]. Magneto-Optical Kerr Effect (MOKE) detection of SOTs [3], on the other side, has arisen as an alternative strategy to solve the above mentioned problems, since it can probe the magnetization reorientation directly, decoupled from the above mentioned artifacts. In this work we demonstrate the magneto-optical detection of the spin-current generated by the Spin Hall Effect in a Pt layer, injected into adjacent layer of NiFe. The damping-like component (DL) of SOT acts as an effective field on NiFe magnetization, inducing a tilting whose magnitude let us to deduce the spin hall angle of Pt (θ_{SH}). With this method we obtained a value of θ_{SH}=0.088 ± 0.006, falling inside the range of previously reported values measured with non magneto-optical methods. Respect to previously published similar works [3,4], our method employs oblique incidence angle, which allow us also to quantify the in-plane component of the Oersted by hysteresis loop shift measurements in longitudinal MOKE, without modifying the optical set-up. This, in turn, was employed for accurate calibration of the current density in Pt, without the need of assuming an equivalent electrical circuit for the NiFe/Pt bilayer [3].

AE-01. Spin-to-charge conversion in magnetic Weyl semimetals.
S. Zhang[1], A. Burkov[2], I. Martin[1] and O. Heinonen[1] *1. Materials Science Division, Argonne National Laboratory, Lemont, IL, United States; 2. Department of Physics and Astronomy, University of Waterloo, Waterloo, ON, Canada*

Weyl semimetals (WSM) are a newly discovered class of quantum materials which can host a number of exotic bulk transport properties, such as the chiral magnetic effect, negative magnetoresistance, and a novel anomalous Hall effect [1,2]. In this work [3], we theoretically investigated spin-to-charge conversion in magnetic WSMs with a single pair of Weyl nodes and broken time-reversal symmetry. We found that a charge current can be induced by injecting a pure spin current into a magnetic WSM layer from an adjacent nonmagnetic metal layer. Formally, the induced charge current was calculated by solving for the scattering wave functions and the nonequilibrium distribution functions in each layer in the ballistic regime. Interestingly, we found the spin-to-charge conversion in magnetic WSMs exhibits remarkable features that are distinctly differently from that arising from either the Rashba or Dirac surface state in various magnetic heterostructures studied previously [4]. For one thing, the induced charge current depends on spin and flowing directions of the injected spin current with respect to the crystallographic axes of the magnetic WSM; in particular, it vanishes along the direction parallel to the line connecting the two Weyl nodes, regardless of the direction of the injected spin. In addition, we showed that there exists a strong dependence of the induced charge current on the position of the Fermi level as well as on the separation between the two Weyl nodes. Therefore, spin-to-charge conversion may not only serve as experimental probes of magnetic WSMs but may also provide extra knobs for controlling the spin-charge conversion in these topological materials. Work by S.S.-L.Z., A.A.B. and O.G.H. was supported as part of the Center for the Advancement of Topological Materials, an Energy Frontier Research Center funded by the U.S. Department of Energy (DOE), Office of Science. AE-02. Light–spin conversion through interfacial spin–momentum locked states in semimetal heterostructures.
H. Hirose[1], M. Kawaguchi[1] and M. Hayashi[1] *1. Physics, The University of Tokyo, Tokyo, Japan*

Irradiation of circularly polarized light with angular momentum of +1 or -1 causes spin selective excitation. This allows the generation of anisotropic spin polarized photocurrent under illumination of circular polarized light if the sample has spin–momentum locked states. This phenomenon, known as circular photogalvanic effect (CPGE), has been studied in semiconductor heterostructures[1] and topological insulators[2]. We have studied the helicity dependent photocurrent in semimetal heterostructures. We measure the photocurrent under illuminating a continuous wave laser in the visible range. We find the photocurrent in Cu/Bi heterostructure strongly depends on the helicity of the light as shown in Fig.1. The helicity dependent photocurrent is significantly reduced for a Bi single layer film, and the effect is nearly absent for a Cu single layer film. Conventional interpretation of the CPGE suggests that this photocurrent may be generated due to the existence of spin–momentum locked states of Rashba type at the Cu/Bi interface. However, the light energy of the visible light to excite carriers is about a hundred times larger than the bandgap of semi-metallic Bi. We therefore consider that the CPGE of the Cu/Bi heterostructure may have a different origin compared to conventional systems[3]. We discuss the origin of the helicity dependent photocurrent in the semimetal/metal bilayer systems.

AE-03. Enhanced Gilbert Damping in Sputter Deposited Topological Insulator/Ferromagnet Heterostructures.
N. Bhattacharjee[1], I. Lisenkov[2], J. Wang[1] and N. Sun[1,2] *1. Electrical and Computer Engineering, Northeastern University, Boston, MA, United States; 2. Winchester Technologies LLC., Burlington, MA, United States*

Topological insulators (TI) have been known to possess topologically protected surface conducting states [1]. A TI placed in contact with a ferromagnetic (FM) generates spin-orbit torques (SOT) on the magnetization in FM [2,3]. A signature of SOT in FM/TI bilayers is an enchantment of Gilbert damping in FM. SOT in TI/FM heterostructures have been reported previously with TI films epitaxially grown with molecular beam epitaxy [2, 3]. Here we report enhanced Gilbert damping in sputter deposited

TI/FM $Bi_xTe_{(1-x)}$/CoFeB (BT/CFB) films. Samples of 20nm BT film were grown on a Si/SiO_2 substrate at 250°C and at 30°C followed by 20nm CFB deposition at 30°C (room temperature) using RF and DC magnetron sputtering respectively. X-ray diffraction (XRD) measurements reveal a crystalline 250°C BT film compared to an amorphous 30°C BT film (Fig. 1). Room temperature broadband ferromagnetic resonance (FMR) measurements were conducted for 250°C and 30°C heterostructures and a control sample where the TI was substituted with 3nm Al. A FWHM resonance linewidth was extracted and is shown in Fig. 2 as a function of frequency. The control and 30°C samples show almost identical linewidth, but the 250°C sample linewidth is much broader. The Gilbert damping coefficient, α, for the 250°C sample is 0.3, compared to 0.03 for 30°C and 0.02 for control. The calculated spin-mixing conductance, $g_{\uparrow\downarrow}$ for the 250°C sample is ~ $4x10^{21}m^{-2}$ which is in an order of magnitude higher than reported value for CFB/Pt films [4]. Moreover, the presence the crystalline TI on FM induces static effects on the magnetization. M-H loop measurements reveal a dramatic increase in the coercive field for the 250°C sample in contrast to the control and 30°C samples. This suggests a change in the surface magnetic anisotropy in the heterostructure due to spin-orbit coupling [5] at the interface, which occurs only for the crystalline phase of BT. Further, spin-torque FMR studies on our samples is being carried out to characterize the effects on magnetization dynamics due to TI/FM interfaces.

AE-04. Topology and the consequences for spintronics and beyond.
C. Felser[1,2] and K. Manna[1] *1. Max Planck Institute, Dresden, Germany; 2. SEAS, Harvard University, Cambridge, MA, United States*

Topological insulators, Weyl and Dirac semimetals and new Fermions are new quantum states of matter, which have attracted considerable interest from the condensed matter community. Heusler compounds are a remarkable class of materials which exhibit a wide range of extraordinary multi-functionalities including tunable topological insulators, half metallic ferromagnets and non collinear topological spin structures [1]. The required band inversion has already been unambiguously identified by angle-resolved photoemission (ARPES) and transport [2, 3]. Weyl and Dirac semimetals open up new research directions and applications that result from the large Berry phases that they exhibit: these lead to giant anomalous Hall effect (AHE), giant anomalous Nernst and spin Hall effects (SHE) and topological spin structures [4]. Examples discussed in the talk are Mn_3Sn, $Co_3Sn_2S_2$ and Co_2MnGa. In the 2D limited we propose a Quantum anomalous Hall effect for $Co_3Sn_2S_2$ [5, 6].

Heusler compounds exhibiting typical s–p band inversion (Topological insulator). By breaking time-reversal symmetry, Weyl semimetals can exist in various magnetic Heusler materials, such as Co2MnAl (magnetic Weyl semimetal), Heusler compounds also host real-space topological states because of the existence of non-collinear magnetic structures and an anomalous Hall effect in zero moment compounds (Anomalous Hall effect), owing to spin-rotation symmetry breaking, a spin Hall effect (Spin Hall effect). A strong Dzyaloshinskii–moriya interaction leads to the observation of antiskyrmion structures in the tetragonal Heusler alloy (Antiskyrmion).

AE-05. Spin-mixing conductance of ferromagnet/topological-insulator and ferromagnet/heavy-metal heterostructure: A first-principles Floquet-nonequilibrium Green function approach. *K. Dolui*[1], U. Bajpai[1] and B.K. Nikolić[1] *1. Department of Physics and Astronomy, University of Delaware, Newark, DE, United States*

The magnitude of experimentally observed spin pumping in ferromagnet/topological-insulator and ferromagnet/heavy-metal heterostructures is routinely interpreted in terms of standard spin-mixing conductance (SMC). However, this quantity is not well-defined when strong spin-orbit coupling (SOC) is present directly at the interface. Nevertheless, an effective SMC can be extracted as the pre-factor in pumped spin current I^S_z vs. precession cone angle θ dependence, as long as such dependence remains $I^S_z \propto \sin^2\theta$. Here we compute directly the pumped spin current, using noncollinear density functional theory Hamiltonian combined with charge conserving Floquet-nonequilibrium Green function formalism, flowing into semi-ininite Cu electrodes of two-terminal multilayers Cu/X/Co/Cu, where X = Bi_2Se_3, Pt and W and Cu. We show that pumped spin current gets reduced in the presence of interfacial SOC. However, stacking sequence and materials selection for constituting the heterostructure can eventually modulate the effective SMC [1].

Superconducting spin currents - the flow/transfer of spin angular momentum through proximity-induced equal-spin triplet states into singlet superconductors (SCs) – are a key to practical superconducting spintronics1. Recent theoretical[2-4] and experimental efforts[5-7] have been devoted to showing that spin-orbit coupling (SOC) in conjunction with a magnetic exchange field hex generates the spinpolarized triplet supercurrents. Here we demonstrate that when perpendicularly magnetized Pt/Co/Pt spin sinks are proximity-coupled to Nb (singlet SC), spin-pumping efficiency in the superconducting state can be tuned by controlling the tilt angle θCo of the Co layer because it alters the degree of orthogonality between SOC and hex at the Nb/Pt/(Co/Pt) interface[2,3]. We also disentangle the contribution of interfacial SOC to the θCo-dependent superconducting spin-pumping efficiency from the other contributions by inserting a thin Cu spacer with weak SOC at the Nb/Pt/(Co/Pt) interface and find a sinusoidal maximum at θCo = 450, reflecting characteristic features of Rashba SOCinduced triplet pairing[2,3].

Lately, the unidirectional spin Hall magnetoresistance (USMR) has been observed in ferromagnetic (FM)/heavy metal (HM) bilayer systems [1, 2]. The USMR effect, being different from the spin Hall magnetoresistance (SMR), leads to the resistance change when either current direction or magnetization are reversed. This effect is explained by a drift-diffusion theory [3], where a spin Hall effect (SHE) induced spin accumulation can control electron mobility dependence on spin-polarization. The USMR can be used for reading memory devices, which can distinguish between in-plane states [4]. In addition, it was shown that in FM/HM systems with large spin-orbit coupling, a charge current flowing through the system generates spin-orbit torques (SOTs) that can switch the magnetization of the FM layer [5]. This effect is of large interest as a tool to control the magnetic state of a spintronic device, e.g. in SOT based magnetic random access memories. We report in this work USMR investigations of Pt/Co, Ta/Co and their trilayer systems. With variation of the HM position relatively to the FM, we are able to control interfacial spin accumulation and thus tune USMR strength. We found that additionally to the USMR there are other effects in both longitudinal and transverse geometries with sin 2φ symmetry. We identify these effects as anisotropic magnetothermopower (AMTP) and planar Nernst effect (PNE). For the bilayer systems, we found that R_{AMTP}/R_{USMR} is 4% and 30% for Pt and Ta cases respectively. For the samples containing Pt, a magnetic proximity effect occurs, which is responsible for the creation of a thin spin-polarized Pt layer in the vicinity of the FM [6, 7]. In this case, one has to take into account the additional Pt magnetic layer for the evaluation of a sample magnetic moment as well as of the magnetotransport properties. X-ray resonant magnetic reflectometry (XRMR) is a powerful method to characterize spin-depth profile as well as to extract Pt magnetic moment via ab-initio calculations. In this work, we use a combination of vibrating sample magnetometry (VSM) and XRMR as an effective tool to separate the Co magnetic moment from the additional induced moment in Pt.

Tuning spin-orbit coupling (SOC) in semiconductors is of high interest as it could open a door towards spin manipulation with electric fields in an all-semiconductor technology platform. The existence of Rashba states at the subsurface of Ge(111) has been demonstrated by photoemission measurements and ab initio calculations [1]. Here we investigated the variation of the electrical resistance of Ge(111) grown epitaxially on semi-insulating Si(111) under the application of an external magnetic field. We report the observation of a unidirectional magnetoresistance (UMR) that scales linearly with

both the applied current density j and the magnetic field B. At low temperature, the UMR dominates all other MR contributions and can reach several percent for a magnetic field of 1 T and a low current density of 0.3A.m^{-1}. A similar MR behavior was reported in the literature in the topological insulator Bi_2Se_3 and two-dimensional electron gases, though orders of magnitude smaller than in Ge(111). Within a simple model based on spin –dependent scattering, we provide a new interpretation of UMR. We ascribe the origin of this magnetoresistance to the interplay between the externally applied magnetic field and the current-induced pseudo-magnetic field applied in the spin-splitted subsurface states of Ge(111). It progressively vanishes, either using a negative gate voltage due to carrier activation into the bulk (without spin-splitted bands), or by increasing the temperature due to the Rashba energy splitting of the subsurface states lower than ~58 kB. The highly developed technologies on semiconductor platforms point toward a ready optimization of the phenomenon.

AE-09. Spin transport measurements in metallic Bi/Ni nanowires.
M. Tokuda[1], N. Kabeya[1], K. Iwashita[1], H. Taniguchi[1], T. Arakawa[1,2], D. Yue[3], X. Gong[3], X. Jin[3], K. Kobayashi[1,4] and Y. Niimi[1,2] *1. Graduate School of Science, Osaka University, Toyonaka, Japan; 2. Center for Spintronics Research Network, Osaka University, Toyonaka, Japan; 3. Department of Physics, Fudan University, Shanghai, China; 4. Graduate School of Science, University of Tokyo, Bunkyo-ku, Japan*

Bismuth (Bi) is known as a material with strong spin-orbit interaction because of its large atomic number. Thus, Bi-related materials have been extensively studied in the field of spintronics. In terms of electrical conductivity, Bi thin film exhibits semiconducting behaviour in the temperature dependence of resistivity. However, when a few nanomator thick ferromagnetic nickel (Ni) film is put under Bi, the Bi/Ni bilayer thin films have a metallic transport property and even become superconductors below $T_C \approx 4$ K [1]. According to magnetization measurements with Bi/Ni thin films, the Ni layer keeps ferromagnetism even below T_C [2]. These results indicate that the Bi/Ni bilayer is a fascinating platform to study spin transport in nomal and superconducting state. The purpose of the present study is to investigate the spin transport properties in metallic Bi/Ni nanowires using the spin absorption method. Our spin transport device consists of ferromagnetic Py ($Ni_{81}Fe_{19}$) and metallic Bi (35 nm)/Ni (2 nm) nanowires bridged by a Cu stripe which enables us to transport spin accumulation generated at the Py/Cu junction to the metallic Bi/Ni nanowire (see the inset of Fig. 1). As shown in Fig. 1, the Bi/Ni nanowire shows a typical metallic temperature dependence in the resistivity and the superconducting transition at 4 K, which is similar to those in Bi/Ni thin films. Next we measured the inverse spin Hall effect (ISHE) in the Bi/Ni nanowire above T_C (see Fig. 2). The detected ISHE signal is small and positive (at 10 K), in contrast to that of Bi-doped Cu [3]. We also performed nonlocal spin valve measurements above T_C. The estimated spin diffusion length (≈3 nm) is much smaller than that of Bi alone (≈20 nm) [4]. In the presentation, we will mention some of our preliminary results below T_C.

AE-10. Electrical detection of diffusive spin current absorbed at Ag/Bi Rashba interface. *D. Ito*[1] and T. Kimura[1] *1. Physics, Kyushu university, Hukuoka, Japan*

Ag/Bi bilayer is well known as a representative interface for producing a strong Rashba spin-orbit interaction.[1] Owing to the strong spin-orbit coupling, an efficient spin-charge conversion, so-called inverse Rashba-Edelstein effect (IREE), is expected at the interface. Indeed, several groups have reported the observation of the IREE by mean of the spin pumping technique in the stacking multi-layered structures. However, such a spectroscopy measurement based on the ferromagnetic resonance gives rise to other undesired effects such as anisotropic magnetoresistance and anomalous Nernst effect, which make it difficult to analyze the IREE accurately. On the other hand, a nonlocal spin injection in a lateral spin valve structure enables us to provide an ideal platform for characterizing the diffusive spin current. Here, we develop a novel lateral structure for quantitative evaluation of IREE. Figure 1 shows the scanning electron microscope image of the fabricated device used for the present study. The nonlocally injected spin current from the CoFeAl strip is significantly absorbed in the Bi/Ag interface, resulting in the spin-charge conversion through IREE. The converted charge current can be detected as the electric voltage along the Bi/Ag wire. Although the spin diffusion in the Bi/Ag bilayer is strongly suppressed by the strong spin absorption, the highly spin-polarized CoFeAl electrode enables to induce the detectable spin current over several tens of nanometers. Figure 2 shows a representative electric signal measured at room temperature. A magnetic hysteresis loop consistent with IREE was clearly observed with the magnitude of 40 micro-Ohm. In the presentation, we will report the temperature dependence and the distance dependence of the IREE signal.

AE-11. Tunable Spin-charge Conversion Across The Metal-insulator Transition in Vanadium Dioxide. *T.S. Safi*[1] and L. Liu[1] *1. EECS, Massachusetts Institute of Technology, Cambridge, MA, United States*

The charge-to-spin conversion efficiency is a crucial parameter in determining the performance of many useful spintronic materials. Usually, this conversion efficiency is an intrinsic material property, which cannot be easily modified without invoking chemical or structural changes in the underlying system. Here we demonstrate successful tuning of charge-spin conversion efficiency via the metal-insulator transition in a prototypical metal-insulator transition material. Vanadium dioxide (VO2), a quintessential strongly correlated electron compound, undergoes a temperature-driven structural phase transition near room temperature. This abrupt change in its electrical, optical, and thermal properties at transition has generated great interest from both technological and fundamental research perspectives; however, the spin related phenomenon remains largely unexplored. By employing ferromagnetic-resonance-driven spin pumping and the inverse spin Hall effect measurement, we find a swift, dramatic change in the spin pumping signal (decrease by >80%) and charge-spin conversion efficiency (increase by five times) upon transition. The large enhancement in the spin pumping signal across the metal-insulator transition provides the first evidence of variable spin-charge conversions of this material. The dramatic change in spin-charge conversion efficiency concomitant with the phase transition provides additional knobs to modulate the spin-charge conversion efficiency, leading to extra flexibilities in spintronic device design as well as providing new functionalities for spintronic devices, such as tunable spin-based memory and energy-harvesting devices.

AE-12. Spin transport in thermally-evaporated polyacene films and the derivative films induced by the spin-pumping. Y. Tanaka[1], T. Kono[1], M. Yamamoto[1], H. Tsujimoto[1], Y. Teki[2] and *E. Shikoh*[1] *1. Engineering, Osaka City University, Osaka, Japan; 2. Science, Osaka City University, Osaka, Japan*

Molecular materials are promising on the viewpoint of the spin transport because of their weak spin-orbit interaction. The spin transport in thermally-evaporated pentacene films at room temperature (RT) was achieved with the spin-pumping driven by the ferromagnetic resonance (FMR) [1, 2] although the spin transport mechanism was unclear. In this study, to clarify the mechanism, the spin transport in evaporated tetracene films and TIPS-pentacene films were tried by the spin-pumping. Since a tetracene molecule has less π-electrons per molecule than pentacene, the spin transport mechanism can be considered on a viewpoint of the π-electron number difference. A TIPS-pentacene, which is a pentacene-derivative molecule, was focused to investigate the spin transport mechanism from another viewpoint of the film crystallinity difference. Pd(10)/molecules (0 to 100)/$Ni_{80}Fe_{20}$(25 nm in thick) tri-layer samples were formed on SiO_2 substrates by using EB deposition or thermal evaporation. To avoid breaking the samples during $Ni_{80}Fe_{20}$ depositions, the substrate temperature was kept under 270 K. When the FMR of the $Ni_{80}Fe_{20}$ is excited with an ESR system, a pure spin current is injected from the $Ni_{80}Fe_{20}$ layer into the Pd layer via the molecular film. Then, the spin current is converted to a charge current due to the inverse spin-Hall effect (ISHE) in the Pd layer and detected as an electromotive force. For a control experiment, samples with a Cu layer instead of the Pd layer were formed since Cu has weaker spin-orbit interaction than Pd. The spin transport in a tetracene film has not been achieved yet because it was hard to form continuous tetracene films by thermal evaporation due to the high saturated vapor pressure. On TIPS-pentacene samples with a Pd layer, output voltages were observed under the FMR of the $Ni_{80}Fe_{20}$ and the voltage sign was inverted at the magnetization reversal of the $Ni_{80}Fe_{20}$. Meanwhile, no output voltages from the TIPS-samples with a Cu layer were observed under the FMR of the $Ni_{80}Fe_{20}$. These indicate that the output voltage observed from the TIPS-samples with a Pd is due to the ISHE. That is, the spin transport in evaporated TIPS-pentacene films by the spin-pumping was achieved at RT [3].

The adaptability of crystal antiferromagnets (AF) and synthetic antiferromagnets (SAF) in spintronic devices based on spin Hall effects has emerged during the last years. Recent works, both theoretical and experimental, highlight the role of AF not only as spin current injectors but also as angular momentum propagators in ferromagnetic/heavy metal layer (FM/ML) structures. The use of AF as spin current injectors into adjacent normal metals with strong spin orbit coupling (SOC) could lead to an enhancement of the spin Hall signal near the spin-flop transition in uniaxial antiferromagnets. In this work we report the use of a SAF (antiferromagnetically exchange coupled Co/Ru/Co) as a spin current injector and the observation of spin pumping and inverse spin Hall effect in [SAF]/Pt heterostructures [1,2]. By exploiting the interlayer exchange coupling strength (oscillatory RKKY-like coupling) and the spin-flop transition in the magnetization process of the SAF it is possible to rotate the magnetization of the Co layers at given angles away from the external magnetic field direction in resonance condition. The misalignment due to the spin-flop magnetization process combined with the spin pumping and the inverse spin Hall effect, allow to control and detect the polarization direction of the spin current pumped into the Pt. The control of the polarization direction of the spin current was also achieved by controlling the interlayer exchange coupling (IEC) via variations in the Ru spacer in the SAF-Pt system. By controlling the IEC strength and the spin flop transition in the magnetization process, it is also possible to produce spin currents polarized in different directions. Our results can lead to important advances in hybrid spintronic devices with improved functionalities, particularly the ability to control the polarization direction of spin currents and also the change of the sign of the ISHE signal induced in a metallic layer with the strong spin-orbit interaction.

Grain-oriented elctrical steel is generally used in electrical machines like transformers. Laser surface treatment of such materials mainly used for iron losses reduction may also reduce noise and vibration due to magnetostrictive loads reduction. Surface laser treatment supplies additional stresses that changes the domain structure's configuration and modifies the magnetic and mechanical behavior. Laser treatment effect on magnetoelastic properties that characterize the magnetostrictive behavior is proposed. Experimentations are established in a single sheet tester (SST) where mechanical and magnetic macroscopic transient signals, as such the acceleration, the average induction and the applied magnetic field are synchronously measured. Mesoscopic magnetostrictive strain is identified with the measurements using a simple finite element mechanical approach. Next, magnetomechanical coupling between the magnetization process sensitive to laser treatment and the induced magnetostriction is considered for characterizing magnetoelastic properties. The latter are correlated with the static and dynamic mesocopic properties derived from the identification of the measured magnetic signals and the 1-D Maxwell diffusion model. We finally propose a parametric study that helps to understand the effect of different laser treatments on the magnetostrictive strain and the identified magnetoelastic properties. This strategy is the key for the reduction and eventually the optimization of noise and vibration in electrical machines next to iron losses reduction.

AF-02. Measurement of Demagnetization Factors and their Distribution in Assemblies of Magnetic Nanoparticles.
S.M. McCann[1] and *T. Mercer*[1,2] *1. Jeremiah Horrocks Institute for Mathematics, Physics & Astronomy, University of Central Lancashire, Preston, United Kingdom; 2. Department of Physics, University of liverpool, Liverpool, United Kingdom*

Continuiing interest in assemblies of magnetic nanoparticles is an important area of study, including superparamagnetic nanoparticles (SPNs) that offer potential biomedical applications such as drug delivery [1] and hyperthermia treatment [2]. Measuring the intrinsic magnetic properties of a sample requires determination of its dimensionless demagnetization factors, N_d, and thereby the *effective* applied field. Existing techniques are *unsutiable* for SPNs as they either require closure points of hysteresis loops or distinct anisotropy field, H_k, peaks found in transverse susceptibility, χ_t, curves of textured samples [3]; where a small AC field is applied transverse to a DC field, H_{DC}. Herein a new method is described for χ_t curves of randomly packed (untextured) SPN powders typically used; as shown in Fig. 1 for a magnetite sample of particle size ~ 10 nm packed in glass microslides of internal thickness, t, of 0.40 mm. Two χ_t curves as a function of H_{DC} are given for orientation (i) in-plane with the sample width, w, and (ii) out-of-plane (across t) for a w:t aspect ratio of 10:1. Widening of the peak across t in comparison to w is due to the increase by ΔN_d in this direction. From our development of established theory [4], we show that $\chi_t \propto 1/H_{DC}$ at saturation and hence the onset of approximately linear behaviour is expected at high field values beyond this point. This is indicated in Fig. 1 at around 500 and 550 kAm^{-1} across w and t respectively, resulting in a ΔN_d value of (0.21 ± 0.03). Confidence in the result was given by a computational model we developed based on interaction of poles at particle surfaces, yielding ΔN_d of (0.16 ± 0.02), (0.17 ± 0.02) and (0.19 ± 0.02) for the mean, median and mode respectively. A typical *number distribution* obtained from the model is shown in Fig. 2, where most particles have N_d values either below (across w) or above (across t) the factor of ⅓ expected for a uniform sphere. The resultant *spatial distribution* of N_d will also be given and discussed.

AF-03. A geometry-independent moment correction method for the MPMS3 SQUID-VSM magnetometer. *C. Amorim*[1], F. Mohseni[1], V. Amaral[1] and J.S. Amaral[1] *1. Physics and CICECO, Universidade de Aveiro, Aveiro, Portugal*

The sensitivity and automation capabilities of modern superconducting quantum interference device magnetometers are currently unmatched [1]. The measured moment values are, however, prone to deviations from their actual value due to geometric effects, namely sample size, shape, and radial offset [2,3]. A knowledgeable operator will correct measured moment values taking these effects into account. The current procedure for the MPMS3 magnetometer is based on an available simulation tool, valid for both VSM and DC methods [4]. Still, determining the correction factor requires samples with well-defined geometric shapes together with accurate sample dimensions and the usually difficult to determine radial offset [5]. There is no current solution to correct geometry effects of irregular shaped samples. Via an extensive use of the available Sample Geometry Simulator tool [4], in all available geometries, with sample dimensions and radial offset values limited only by the sample chamber volume, we find a systematic relation between the difference of VSM and DC measurements and the corresponding geometric correction factors of the MPMS3 SQUID-VSM device. This relation follows a clear trend, independent of sample size, shape or radial offset, for a given pair of DC scan length and VSM amplitude values. Exploiting this trend, a geometry-independent correction method is here presented and validated in worst-case scenario measurements of metallic Fe powder. In this data set, we observed a maximum deviation to the expected result of 32.5%, which was reduced to just 1.1%, by following the proposed correction method. While the presented methodology requires both DC and VSM data, its ease of use on irregular shaped samples and unknown radial offset values, can be of wide application by the magnetism/magnetometry community.

AF-04. Broadband (kHz-GHz) visible light imaging of magnetic field with a combination of magnetic losses films and thermofluorescent coatings. H. Ragazzo[1], S. Faure[2], F. Issac[1], D. Prost[1], J. Carrey[2] and *J. Bobo*[3] *1. DEMR, ONERA, Toulouse, France; 2. INSA, LPCNO, Toulouse, France; 3. CEMES, CNRS, Toulouse, France*

Characterization of the electromagnetic field emitted by various sources (antenna, radar, coils...) is an important issue, either for civil or defense applications. The measurement of the electromagnetic field may be performed by a local probe, but infrared thermography imaging is a competitive alternative way. The latter method, called EMIR [1] (ElectroMagnetic InfraRed) has been used for years in particular at ONERA where it had been developed. We have subsequently improved EMIR method in order to probe microwave magnetic fields by using high permeability films composed of ferromagnetic microparticles in an insulating matrix or patterned ferromagnetic films [3]. More recently, we have successfully implemented this technique in the domain of visible light, named as EMVI [3] (Electro Magnetic Visible Light Imaging). As in the EMIR method, a thin film (sensitive to either electric field or magnetic field) is heated by the emitted field. This sensing film is coated with a polymer doped with fluorescent molecules (rhodamine B in our case). As the fluorescent emission of rhodamine depends on the temperature of the film, we get a thermofluorescent sensor. We will review several applications of EMVI method applied to various systems including induction flatcoils (operating in the 100-300 kHz range), metamaterial patch antenna [4,5] and HIS (High Impedance Surface) used in space applications (devices operating in the 1-5 GHz range). With the latest optimized version of our EMVI setup, using an array of green LEDs (40 W total light power, wavelength 535 nm) and a SCMOS camera, we could detect temperature changes down to 20 mK, magnetic field sensitivity lower than 1 A/m and a spatial resolution related to our camera and optics (typically 10 to 100 micrometers). We will also review the perspectives of development of EMVI for microscopy applications.

AF-05. Dynamic magneto-optical imaging of magnetic materials – bridging the gap from microseconds to nanoseconds. M.J. Klug[1] and *J. McCord*[1] *1. Institute for Materials Science, Kiel University, Kiel, Germany*

Magnetic domain imaging provides direct access to the effective magnetic properties of materials from the macroscale down to the nanoscale. The analysis of the magnetic domain behavior by quasi-static magnetic domain imaging [1] has become an essential part for the characterization of magnetic materials. Using pulsed LED illumination sources, magnetic imaging with millisecond time resolution is possible. The stroboscopic wide-field imaging of magnetization dynamics with picosecond and faster time resolutions is achievable [2,3]. Yet, single shot magnetic imaging in the range from microseconds to nanoseconds, or in the MHz regime is nearly unexplored. Here, we introduce an imaging setup allowing for the imaging of magnetization responses with a highly flexible adjustable time resolution. Using a high-power solid-state laser with variable exposure, stroboscopic and especially single shot imaging with laser pulses down to 10 nanoseconds is demonstrated. Examples, displaying the feasibility of the various magnetic imaging modes, are the imaging of current induced domain wall propagation in magnetic nanowires (Fig. 1a) and domain repeatability in the magnetic reversal in electrical steel samples (Fig. 1b). Results of single shot and stroboscopic imaging with down to one microsecond time-resolution are directly compared. Imaging of electrically induced magnetization reversal in magnetoelectric composite samples at 0.5 MHz with 20 nanoseconds exposure reveals modulated magnetization reversal modes due to magneto-elastic self-energy effects (Fig. 1c and 1d). Single shot imaging of nucleation modes of magnetic bubbles with 10 nanoseconds time resolution display different stages of bubble generation (Fig. 1e). Other examples of the relevance of dynamic magnetic domain imaging in the MHz regime will be shown. Magnetic domain observations of magnetization dynamics dominated by domain wall nucleation and movement dominated processes, also on a single shot level, are now accessible directly from DC to the nanosecond regime with continuously variable illumination exposure. This work was supported through the Collaborative Research Centre CRC 1261 Magnetoelectric Sensors: From Composite Materials to Biomagnetic Diagnostic.

AF-06. Microsphere-assisted super-resolution magneto-optic imaging.
M. Vogel[1], A. Hendriks[2,1], J. Pearson[1], A. Hoffmann[1] and S.G. te Velthuis[1]
1. Materials Science Division, Argonne National Laboratory, Lemont, IL, United States; 2. Department of Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands

The diffraction limit [1] is a fundamental barrier in optical imaging, restricting the resolution for optical microscopy. The diffraction limit can be surpassed by the photonic nanojet phenomenon, generated by a lens-like dielectric micro-object [2]. Microspheres have been demonstrated as a powerful platform to challenge the diffraction limit by creating a virtual image with enhanced resolution and magnification [3,4]. Here we report on wide-field MOKE (Magneto-Optical Kerr effect) measurements harnessing the resolution enhancement of microspheres in an oil-immersion environment with white light illumination. In-plane and perpendicular magnetized domain configurations are imaged with and without the additional optical element. An increase of the spatial resolution is demonstrated for longitudinal and polar Kerr configuration. Our findings may serve as a way to optically study magnetization dynamics at smaller length scales. *Work at Argonne was supported by the US-DOE, Office of Science, MSED. AF-07. Field dependence chirality in ferromagnetic multilayers probed by dichroism in x-ray resonant magnetic scattering.
E.O. Burgos Parra[1,2], J. Chauleau[1,2], W. Legrand[1], N. Reyren[1], F. Ajejas[1], D. Maccariello[1], S. Collin[1], H. Popescu[2], K. Bouzehouane[1], V. Cros[1], A. Fert[1] and N. Jaouen[2] *1. Unité mixte de physique CNRS/Thales, CNRS, Paris, France; 2. Synchrotron SOLEIL, Saint-Aubin, France*

Chiral magnetic structures induced by Dzyaloshinskii-Moriya interaction (DMI) [1] have been proposed as the cornerstone of new technology applications such as high-density data storage devices or neuromorphic computing [2], due their room temperature stability and efficient current induced motion. Recent studies of the amplitude of magnetic satellites of a crystal Bragg peak by Zhang *et al*. [3] showed that x-ray resonant magnetic scattering (XRMS) is a powerful tool to access to the relevant topological parameters of these magnetic structures. In this work, we use small angle reflectivity XRMS to reveal directly the chiral properties of FM multilayers with tailored magnetic chiralities driven by spin-orbit-related effects at interfaces [4,5]. We show that it can straightforwardly and unambiguously determine the main characteristics of chiral magnetic distributions in perpendicularly magnetized multilayers [4]: its chiral nature, the quantitative winding sense (clockwise or counterclockwise), and its type, *i.e.* Néel or Bloch. Moreover we prove that this approach combined with micromagnetic simulations reveals hybrid chiral spin texture in multilayers [5]. Finally, we studied the in plane field dependence intensity of the dichroism and the appearance of second order diffraction peaks, usually forbidden on these systems. An asymmetric change of the intensity of the magnetic asymmetry lobes and a hysteretic behavior of these ones with the external field suggest a complex interplay between the hybrid domain wall state existing in these systems and DMI fields. Projects ANR-15-GRFL-0005, ANR-17-CE24-0025, MIPR#HR0011831554 and H2020 F FET Proactive 824123 are acknowledged for their financial support.

For transition metal oxides (TMOs), a change in oxygen stoichiometry can drastically modify their physical characteristics, such as electronic and ionic conductivity, ferroelectricity and magnetism. Varying the oxygen content in TMOs results in a transformation between structures such as perovskites (P) ABO_3, brownmillerites (BM) $ABO_{2.5}$, and square planar ABO_2 structures [1]. In this work, we study the evolution of physical properties by modifying the oxygen stoichiometry of $La_{0.7}Sr_{0.3}CoO_3$ (LSCO) thin films by exposing them to highly reducing environments. Under optimized annealing conditions (temperature > 400 ºC and oxygen partial pressure < 10^{-12} atm), the equilibrium P-LSCO phase undergoes a drastic topotactic transformation into the highly metastable oxygen-deficient BM-LSCO phase. The x-ray diffraction spectra indicate that a complete transformation of the entire film volume to the BM-LSCO phase has occurred with a 5.27% change in the out-of-plane lattice parameter compared to the parent P-LSCO phase. Despite this enormous lattice distortion, the BM-LSCO phase remains fully coherent with the underlying $(LaAlO_3)_{0.3}(Sr_2TaAlO_6)_{0.7}$ substrate. Resistivity and soft x-ray magnetic spectroscopy measurements demonstrate that the BM-LSCO phase is an antiferromagnetic insulator with Néel temperature above 300 K, in contrast to the P-LSCO phase which is a ferromagnetic metal below its Curie temperature ~ 220 K. These distinct changes in functional properties suggest that topotactic transformations are a promising route towards next generation memory and neuromorphic devices based on electric-field-driven movement of oxygen anions. The work was supported as part of the Quantum Materials for Energy Efficient Neuromorphic Computing, an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science. This research used resources of the Advanced Light Source, which is a DOE Office of Science User Facility under Contract No. DE-AC02-05CH1123.

Magnetic singularities such as vortices, antivortices, Bloch points and merons drive magnetization reversal in magnetic nanostructures and in perpendicular magnetic anisotropy thin films and multilayers [1,2]. For film thickness above a few nm, magnetostatic and surface effects create 3D magnetic patterns that are not easy to resolve with standard microscopy techniques. We have recently developed 3D magnetic reconstruction tomography [3] with a combination of soft X-ray transmission microscopy and magnetic dichroism. This method allows us to reconstruct the magnetization vector at ~ 25 nm lateral resolution and to localize magnetic singularities in thin films (thickness up to ~300 nm). In this work, we present the

tomographic reconstruction of the 3D magnetization configuration in a 240 nm thick NiFe/NdCo/NiFe multilayer as shown in the figure. We observe a periodic Mx-Mz domain pattern that coexist with a My-Mz closure structure across the multilayer thickness. We also identify different magnetic singularities (merons and Bloch points) at stripe bifurcations and characterize their topological configuration from the reconstructed vector magnetization maps. Work supported by Spanish MINECO (FIS2016-76058 (AEI/FEDER,EU))) and European Union's Horizon 2020 research and innovation program under Marie Sklodowska-Curie grant ref. H2020-MSCA-IF-2016-746958.

AF-10. Determination of fine magnetic structure of magnetic multilayer with quasi antiferromagnetic layer by using polarized neutron reflectivity analysis. *Y. Zhong*[1], Y. Kurokawa[1], G. Nagashima[1], S. Horiike[1], T. Hanashima[2], D. Schönke[3], P. Krautscheid[3], R.M. Reeve[3], M. Kläui[3] and H. Yuasa[1] *1. Kyushu University, Fukuoka, Japan; 2. Neutron Science and Technology Center, CROSS, Naka, Japan; 3. Institute of Physics, Johannes Gutenberg-University Mainz, Mainz, Germany*

Recently antiferromagnetic (AFM) spintronics are drawing attention owing to the high resonance frequencies and zero stray fields [1,2]. In particular spin torque oscillation (STO) in AFM is attractive from the viewpoint high frequency generation. However, it is hard to directly observe STO. Therefore, we fabricated the novel quasi-AFM layer which has multiple domains with alternatively anti-parallel magnetization by using biquadratic magnetic coupling between two FM layers through an Fe-O layer [3-7]. The magnetic property of the quasi-AFM layer is expected to have properties that are intermediate between AFM and FM, which is useful to understand AFM dynamics. Since the fine magnetic structure of quasi-AFM is important to control STO frequency, we carried out polarized neutron reflectivity (PNR) analysis by BL17 SHARAKU in MLF, J-PARC. The Ta/Ru/IrMn/CoFe(A)/Fe-O/CoFe(B)/Cu/CoFe(C)/Cu/Ta films were sputtered on thermal oxidized Si wafers and annealed in a field to fix the magnetization of CoFe(A) in x direction by IrMn. If magnetizations of CoFe(A) and CoFe(B) are coupled with angles of about ±90 deg through Fe-O, the CoFe(B) would become the quasi-AFM, and it was roughly confirmed by M-H curves in Fig.1(a). Next, CoFe(B) magnetization was directly observed by SEM with polarization analyzer (SEMPA) in Fig.1(b). In low field, we expected the CoFe(B) to be quasi-AFM and in that case the x component of magnetization should be zero. However, scanning electron microscopy with polarization analysis images indicated that the CoFe(B) does not have perfect 90 deg magnetization with respect to CoFe (A) but various magnetic directions were observed in CoFe (B). The more accurate magnetizations were estimated by PNR analysis shown in Fig.1(c), indicating the CoFe(B) has magnetization of $1.35m_B$ in x direction. The average angle between the magnetization of CoFe(A) and CoFe(B) was estimated as ±42 degrees from $\cos^{-1}(1.35m_B / 1.82m_B)$. Such a microscopic magnetic configuration cannot be obtained unless we use SEMPA and PNR analysis, and provide an important insight to control magnetic structure of quasi-AFM.

AF-11. Soft X-ray Induced Changes at the Exchange Biased NiO/Fe_3O_4 Interface. *P. Steadman*[1], J. Wollschlager[2], R. Fan[1], T. Pohlmann[2], K. Kuepper[2], P. Bencok[1] and M. Sussmuth[1] *1. Diamond Light Source, Didcot, United Kingdom; 2. University of Osnabrueck, Osnabrueck, Germany*

Magnetite (Fe_3O_4) is predicted to be half-metallic making it an ideal candidate for many spintronics applications. As one of the magnetic layers in a tunnel junction a half metallic will give a huge magnetoresistance and therefore a very sensitive device. Soft X-ray reflectivity has been used to study the magnetic depth profile in the exchange biased system Ni0/Fe_3O_4.[1,2] By tuning the X-ray energy to the L_3 absorption edge the scattered X-ray intensity is sensitive to the Fe magnetic moment.[3] The current study found that the incident beam causes irreversible changes to the Fe_3O_4 film

(see Fig. 1). By performing spectroscopy across the L_3 edge growth of the Fe^{2+} peak occurred with a decay of the Fe^{3+} peak indicative of reduction of the film (see Fig. 2). Rather surprisingly, these changes occur only in the Fe_3O_4 film near the interface whilst the majority of the film, including the surface, remains intact. This could be the result of strain or other structural differences near the interface that cause the Fe_3O_4 to be insulating even though the rest of the film is conducting. Strong production of secondary electrons could cause damage confined to the interface. The damage was strongest at the Fe *L* and O *K* resonances. No changes were detected in the NiO film. It is important to note that this damage could be minimised to an acceptable level by reducing the beam intensity.

AF-12. Exploring magnetic materials at beamline P09 at PETRA III.
J. Mardegan[1], S. Francoual[1], J. Sears[1] and P. Bereciartua-Perez[1] *1. Petra III, DESY, Hamburg, Germany*

P09 at PETRA III facility is a dedicated beamline to perform mainly resonant X-ray scattering and diffraction with several sample environment, such as cryostats, electromagnets and magnets enabling to investigate strongly correlated and magnetic materials. Using an in vacuum double phase retarder system, P09 is a unique beamline able to perform full polarization analysis between 2.7 and 15 keV [1,2]. This covered energy-range allows the scientific community to explore a wide range of materials, such as the 3-5d transition metals, besides the lanthanide and actinide series. In order to expand the investigated scientific cases, further developments have taken place allowing the users to perform: (a) magnetic scattering in the tender X-ray range; (b) magnetic scattering at high pressure and low temperatures (pressure of tens of GPa and temperature below 50 K); (c) magnetic circular dichroism [3]; magnetic reflectivity [4] and (d) full magnetic structure determination [5]. Hereby I will present the new experimental set-ups available at beamline P09 along with some of the recent scientific results obtained mainly with magnetic circular dichroism and magnetic reflectivity techniques, in which powder, single crystals and thin films have been investigated.

School of Applied and Engineering Physics, Cornell University, Ithaca, NY, United States

In an ideal Néel antiferromagnet (AF), each lattice-site spin is adjacent to an oppositely-pointing spin such that all spins are compensated [1]. In real AFs some spins are uncompensated [2], resulting in local magnetic moments within the AF. These uncompensated moments (UMs) are responsible for exchange bias [3], the most important current application of antiferromagnets. UMs are difficult to detect directly because any signal they produce is typically overwhelmed by the ferromagnetic (FM) layer in exchange-biased AF/FM bilayers. In this work [4] we use magneto-thermal microscopy [5,6] to image the uncompensated moments in FeRh, a room-temperature AF which undergoes a 1st-order phase transition from AF to FM at T_C near 100 °C [7]. In the AF phase below in Fig. 1, we image MgO(001)/20 nm FeRh/10 nm Pt as a function of magnetic field H_{app}. By taking the average and half-difference between positive and negative fields, we resolve both *pinned* UMs [8], which are strongly coupled to the AF bulk and are unaffected by applied magnetic field, and *unpinned* UMs, which are weakly coupled and can be reoriented by a 1 kOe applied field. In Fig. 2 we image as a function of temperature and magnetic field near T_C, where FM domains first nucleate and then percolate through the sample. Within the transition region, we observe some FM domains nucleating with an orientation that is not parallel to H_{app}, even when H_{app} is much greater than the coercivity field of the FM moments. This indicates that the emergent FM domains are exchange-coupled to the AF bulk. Our results provide new insight into the role of UMs in the magnetic phase transition in FeRh and suggest a general method for spatially resolving UMs in AF metals with magneto-thermal microscopy.

AF-14. Options for Exchange Stiffness Measurement in Thin Films.
R.D. McMichael[1] *1. Physical Measurement Laboratory, National Institute of Standards and Technology, Gaithersburg, MD, United States*

Exchange stiffness is difficult to measure accurately, and it is also an essential parameter for predicting device behavior. The need for exchange stiffness data, especially for ultrathin films, has grown with materials development for a variety of novel magnetic device applications. Here, we compare ideas for exchange stiffness measurement with emphasis on methods that avoid patterning. Without a lithographic length scale, the film thickness is used to gauge the exchange length, essentially by comparing thickness-dependent magnetostatic fields with wavevector-dependent exchange fields. The competition between these terms leads to features in the spin wave dispersion relation and in low frequency behavior. Results include models of parallel-pumped spin wave excitation and of low-frequency instabilities, both in films with perpendicular magnetic anisotropy and thickness less than 5 nm. Parallel pumping provides a probe of the spin wave dispersion relation, which includes a minimum spin wave frequency at $k \neq 0$, a saddle point, and a local maximum at $k = 0$. The calculated pumping instability threshold reveals the exchange-dependent minimum frequency, but is otherwise relatively featureless, so additional data would be needed to determine the exchange stiffness. The static magnetization configuration also has an exchange-dependent instability. With applied field in plane, there is an instability to finite k fluctuations at $H_{crit} \approx H_u + M_s\, t^2 / (4\, l_{ex})^2$ where H_u is the in-plane saturation field, M_s is the magnetization, t is the thickness and l_{ex} is the exchange length. Due to the sensitivity near the critical field, this instability exists only for applied fields that are very precisely aligned with the anisotropy hard axis, within 0.01° in our example ($\mu_0 M_s$ = 0.5 T, H_u = 0.05 T, t = 2 nm, l_{ex} = 5.8 nm).

(a) Critical pumping fields for parallel-pumped excitation of spin waves. Below the frequency minimum, the critical field diverges. Inset: spin wave dispersion for *k* parallel to and perpendicular to the in-plane magnetization.

(b) Stability analysis of a film with perpendicular magnetic anisotropy. The color scale indicates the equilibrium magnetization angle. Within the outlined region, k ≠ 0 ripple becomes unstable.

AG-01. Controlling the Dzyaloshinskii-Moriya Interaction through interface modifications. *H. Nembach[1,2] 1. Quantum Electromagnetics, National Institute of Standards and Technology, Boulder, CO, United States; 2. JILA, University of Colorado, Boulder, CO, United States*

The Dzyaloshinskii-Moriya Interaction (DMI) gives rise to chiral magnetic structures, which include chiral spin-chains and skyrmions. The latter have recently received much attention, especially for their potential application for magnetic data storage. Each skyrmion would represent a bit and would be moved along a racetrack. DMI requires broken inversion symmetry and can exist in the bulk as well as at interfaces, for example at interfaces between a ferromagnet and a material with large spin-orbit coupling like heavy metals. More recently it has been shown that interfacial DMI can also exist at interfaces with graphene and oxides. We use Brillouin Light Scattering spectroscopy (BLS) to determine the DMI from the non-reciprocal frequency-shift Damon-Eshbach spin-waves [1]. In order to gain deeper insight into the underlying physics of DMI and explore ways, on how to tune the DMI through interface modifications, we prepared several sample series to study different aspects of the DMI. First, we prepared a Cu/$Co_{90}Fe_{10}$ and a Pt/$Co_{90}Fe_{10}$ sample series, which were in-situ oxidized for different times and subsequently capped to prevent any further oxidation. Density functional theory calculations have demonstrated that the hybridization and the associated charge transfer is important for the DMI and that interfaces with an oxide can have DMI. Our BLS measurements showed that oxide interfaces have DMI. Moreover, the spectroscopic splitting factor *g*, which we determined with ferromagnetic resonance spectroscopy, is correlated to the DMI. This is an indirect confirmation of the theory predictions regarding the role of hybridization and charge transfer [2], [3]. Next, we prepared a sample series, where we introduce a Cu dusting layer at the interface between a CoFeB and Pt to disrupt the Heisenberg exchange directly at the interface. SQUID magnetomety shows that the Cu dusting layer reduces the proximity magnetization in the Pt. The proximity magnetization is a direct result of the exchange coupling and can be seen as a measure for its strength. The DMI has the same Cu thickness dependence, see Fig.2, and we can conclude that the Heisenberg exchange and the DMI are correlated. We measured a similar correlation before for a $Ni_{80}Fe_{20}$ thickness series on Pt [1]. In another study, we investigated the impact of interface disorder on DMI. We irradiated Ta/CoFeB/Pt samples with 40 keV He+ ions. We find that the DMI first increase for lower ion fluences, before it is reduced for the highest fluence. This shows that an increase of disorder at the interface is beneficial to achieve high DMI. In contrast, ferromagnetic resonance measurements showed, that the perpendicular anisotropy monotonically decreases with ion irradiation. This shows that both phenomena have different underlying physics even though both involve spin-orbit coupling. Finally, we studied the role of interface symmetry on DMI. So far, most work on DMI has been carried out for highly symmetric interfaces. Low symmetry systems can have anisotropic DMI and can potentially support anti-skyrmions. We prepared a Pt/Fe(110) sample and found that the DMI is anisotropic with the strongest DMI along the [001] direction, which coincides with the magnetic easy axis, Fig.2.

The Dzyaloshinskii–Moriya interaction (DMI) is an asymmetric exchange interaction that stabilizes chiral spin textures. It is induced by inversion symmetry breaking in chiral lattices or at interfaces [1,2]. Recently the interfacial DMI has been found in magnetic layers adjacent to the transition metals due to strong spin-orbit coupling [3], and at interfaces with graphene due to the Rashba effect [4]. In this work, we report the observation of significant DMI induced by chemisorption of oxygen on a ferromagnetic layer. The sign of this DMI and its large magnitude – despite the low atomic number of oxygen – are derived by examining the oxygen coverage dependent evolution of domain wall chirality. We find that the oxygen-induced DMI is comparable to the DMI induced at interfaces with most transition metals. This result extends the understanding of the DMI and supports oxygen-related design of spin-orbitronics devices. Support by the NSF (DMR-1610060 and DMR- 1905468), UCOP (MRP-17-454963), and DOE (DE-AC02-05CH11231) is gratefully acknowledged.

Magnetic skyrmions [1,2], topologically protected magnetic quasi-particles, are at the core of many of the recently proposed spintronic devices. Many different materials systems have been shown hosting magnetic skyrmions at room temperature [3-6]. However, usually an external magnetic field is required to stabilize skyrmions in un-patterned magnetic thin-films, and this is not desirable for real applications due to scalability issues. Accordingly, it is highly desirable to have a robust and tunable protocol to build materials systems hosting magnetic skyrmions in zero external magnetic fields. Here we report the observation of isolated magnetic skyrmions at room temperature and zero magnetic field, stabilized through interlayer exchange coupling [7,8] between a *reference* magnet and a *free* magnet (Fig. 1). By carefully choosing the material and the thickness of the non-magnetic interlayer in between the two magnets, we are able to tune the chirality and the size of the observed skyrmions, whose 3D spin-texture is directly imaged by spin-polarized low energy electron microscopy. Our findings open up possibilities to the development of skyrmion-based spintronic devices suitable for general-use applications which go beyond modern nanoelectronics.

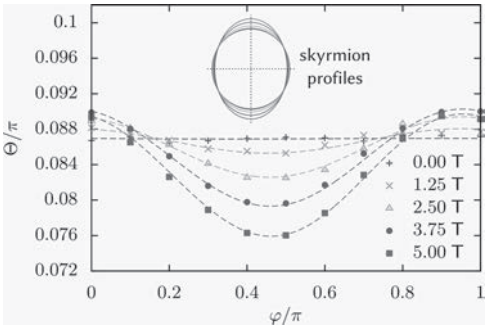
AG-04. Orientation dependent Current-induced Motion of Skyrmions with various Topologies. *M. Weissenhofer*[1] and U. Nowak[1] *1. University of Konstanz, Konstanz, Germany*



As they are small in size and easily movable by electric current, Skyrmions are promising candidates for next generation magnetic logic and memory devices. However, due to their non-trivial topological properties Skyrmions propagate along trajectories which deviate from the current direction, according to the so-called Skyrmion Hall effect (SHE) [1]. We study the current-driven motion of metastable localized spin structures with various topological charges in a $(Pt_{0.95}Ir_{0.05})$/Fe bilayer on a Pd(111) surface. We perform atomistic spin model simulations based on the Landau-Lifshitz-Gilbert equation with additional spin torque terms using a model hamiltonian parametrized by ab initio calculations [2,3] which are well supported by an approach based on the generalized Thiele equation. While the Dzyaloshinsky-Moriya interaction (DMI) in this system renders Skyrmions with $Q = 1$ energetically favorable, those with other topological charges are stabilized by the frustration of the exchange interaction, although being deformed by the DMI [4]. We demonstrate that besides a distinct dependence on the topological charge itself the dynamic response of Skyrmionic structures with topological charges $Q = -1$ and $Q = 3$ to a spin-polarized current exhibits

an orientation dependence due to the aforementioned deformation leading to a different SHE along different axis of the respective Skyrmion profiles (Fig. 1) [5]. This orientation dependence was found to increase with decreasing external field strength and consequently with increasing size of the skyrmions. We further show that such an orientation dependence can be induced by applying an in-plane external field which leads to an elongation of the Skyrmion profile along the field direction (Fig. 2). This possibly opens up a new promising pathway to the manipulation of skyrmion dynamics as it allows for the decrease of the Skyrmion Hall angle.

AG-05. Insulator Spin-orbitronics: spin-orbit torque switching and skyrmions stabilized by chiral exchange interactions in thin film garnet heterostructures. *S. Ding*[1,2], A. Ross[1], R. Lebrun[1], S. Becker[1], K. Lee[1], I. Boventer[1], S. Das[1], J. Yang[2], G. Jakob[1] and M. Kläui[1] *1. Physics, Johannes Gutenberg University Mainz, Mainz, Germany; 2. Physics, Peking University, Beijing, Germany*

Insulating rare earth iron garnets (RIG) have drawn great interest in recent years due to their excellent performance in the field of spintronics, with low damping, soft ferromagnetic behavior and, magnetic and angular momentum compensation points. However for device applications, one would need a combination of stable spin structures and efficient electrical manipulation and both can be achieved by spin-orbit effects so that the combination is often termed spin-orbitronics. To obtain stable spin structures, chiral exchange interactions, such as the Dzyaloshinskii-Moriya interaction (DMI) can be employed. We use ultra-thin RIG films with perpendicular magnetic anisotropy (PMA) where efficient electrical switching [1] was observed. In our work, we grow high quality TmIG and GdIG [2] films by pulsed laser deposition. We first study the chiral DMI induced in thin film GGG/TmIG/Pt heterostructures [3]. We find for the first time a clear scaling of the DMI with the inverse of the TmIG layer thickness, which demonstrates the interfacial origin of the DMI [3]. We find a surprisingly long decay length so that we can obtain sizeable DMI in insulating TmIG even in >10 nm thick films, which is an order of magnitude larger than found for metallic systems. By direct imaging we find skyrmions and chiral domain walls and we identify the GGG/TmIG interface as the main source of the DMI. As the second step we then manipulate the magnetization and in particular the chiral spin structures by spin-orbit torques. We find that we can move the spin structures all synchronously confirming their chiral nature. Furthermore, switching of single domain particles is achieved for low current densities, down to $2.8*10^{10}$ A/m^2. So overall, we demonstrate that in insulating ferrimagnet based devices the key spin-orbit effects, namely chiral exchange interactions stabilizing skyrmions and efficient spin-orbit torques can be realized thus opening the field of Insulator Spin-Orbitronics.

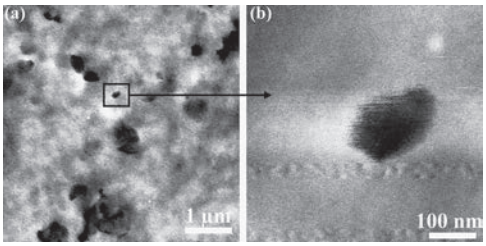
AG-06. Tuning Dzyaloshinskii-Moriya Interaction In Thin Ferrimagnetic CoGd Films to Create Magnetic Skyrmions. *Y. Quessab*[1], J. Xu[1], C.T. Ma[2], W. Zhou[2], G.A. Riley[3], J.M. Shaw[3], H. Nembach[3], J. Poon[2] and A.D. Kent[1] *1. Center for Quantum Phenomena, New York University, New York, NY, United States; 2. Department of Physics, University of Virginia, Charlottesville, VA, United States; 3. Quantum Electromagnetics Division, National Institute of Standards and Technology, Boulder, CO, United States*



Magnetic skyrmions are attractive for spintronic applications, such as racetrack memories, to achieve very high density data storage. A magnetic skyrmion designates a local whirling of the spin configuration with a non-trivial topology. Skyrmions can be stabilized by Dyzaloshinkii-Moriya interactions (DMI) induced by strong spin-orbit coupling in the absence of inversion symmetry. Nearly compensated ferrimagnets with DMI are interesting materials due to their low stray fields and fast spin dynamics that can lead to ultrasmall and ultrafast skyrmions [1, 2]. Yet few studies have investigated *interfacial* (*i*-DMI) in ferrimagnets, which can be tuned to create skyrmions. Here we report a systematic study of the DMI in CoGd thin films as a function of the capping layer and magnetic thickness. We are able to tune the DMI in a range that stabilizes sub-100 nm skyrmions at room temperature in zero field. The *i*-DMI results from the breaking of the inversion symmetry by having different bottom and top interfaces. We studied the interfacial dependence of the DMI by Brillouin light scattering (BLS) as a function of the capping layer composition in Pt/CoGd(5 nm)/$Pt_{1-x}W_x$ (Fig. 1(a)). The samples were prepared by DC magnetron co-sputtering from Co and Gd sources. We found that 10% of W is enough to induce a DMI of about 0.15 mJ m^{-2}. Then we investigated the thickness *(t)* dependence of the DMI in Pt/CoGd(*t*)/(W or Pt) (Fig. 1(b)). The DMI decreases with the CoGd thickness in the asymmetric Pt/CoGd/W stack which confirms the interfacial nature of the DMI. Conversely, the DMI is non-zero even for the symmetric Pt/CoGd/Pt stack, likely due the difference in the nature of top and bottom interfaces, as seen in cross-sectional transmission electron microscopy. Finally, we show that films can have DMI in a range that allows skyrmion nucleation as shown by magnetic force microscopy (Fig. 2).

Our results provide insight into the key parameters to control the DMI in ferrimagnetic films toward achieving ultrasmall and ultrafast skyrmion motion. This research was supported by DARPA awards No. D18AP00009 and R186870004.

AG-07. Strain-induced reversible manipulation of orbital magnetic moments in Ni/Cu multilayers on ferroelectric $BaTiO_3$. *J. Okabayashi*[1], Y. Miura[2] and T. Taniyama[3] *1. Research Center for Spectrochemistry, The University of Tokyo, Tokyo, Japan; 2. National Institute of Material Science, Tsukuba, Japan; 3. Nagoya University, Nagoya, Japan*

The coupling between ferromagnetic and ferroelectric properties has recently attracted considerable attention toward the creation of novel devices using multiferroic controlling of their properties. In particular, the hetero-interfaces in thin films comprising both ferromagnets and electrically polarized materials produce a rich variety of possibilities for creating multifunctional properties. Modulation of interfacial lattice constants by an electric field (*E*) induces interfacial changes in magnetism. The interfacial lattice distortion produces variations in magnetic properties, which are recognized as inverse magneto-striction effects. Moreover, magnetic anisotropy is also tuned by lattice distortions. Recent attempts have been focused on the modulation of the number of charge carriers at the interface between an ultrathin ferromagnetic layer and an oxide-barrier insulator in magnetic tunnel junctions. Other approaches, which are our focus in this study, are based on the interfacial mechanical strain coupling between ferromagnetic and ferroelectric layers using multiferroic hybrid structures. In this study, we focus on thin Ni layers sandwiched by Cu layers exhibit perpendicular magnetic anisotropy (PMA) because of the interfacial tensile strain in the Ni layers. Recently, *E*-control of the magnetic properties of Ni/Cu multilayers on $BaTiO_3$ was achieved; the magnetization was switched from the perpendicular axis to the in-plane easy axis by tuning the lattice distortion through the application of *E* [1]. To understand this relationship and the elastic phenomena from the view point of orbital magnetic moments, we developed a technique by applying an electric field in x-ray magnetic circular dichroism measurements (EXMCD) to clarify the mechanism of the electric-field-induced changes in the magnetic anisotropy of Ni/Cu multilayers on $BaTiO_3$ hetero-structures through lattice distortions. The samples were grown by using ultra-high vacuum molecular beam epitaxy on [100]-oriented $BaTiO_3$ single crystal substrates. The stacked structures are shown in Fig. 1a. The XAS and XMCD measurements for the Ni and Cu *L*-edges were performed at the KEK-PF BL-7A beamline, at room temperature. The EXMCD measurements were performed using the partial fluorescence yield mode. Figure 1b shows the Ni *L*-edge XAS and XMCD spectra by applying an electric field, *E*, of positive bias of 8 kV/cm. Sample surfaces are connected to ground and *E* is applied to the back side of the $BaTiO_3$ substrates. The spectral line shapes of the XAS and XMCD are modulated by *E* in normal incident (NI) case in spite of fixed sample measurement position. By comparing the results with and without *E*, we observed a slight variation in the peak asymmetries between the L_3 and L_2 edges. These results reveal that the orbital moments are modulated by applying *E*, thereby resulting in changes of magnetic anisotropy. The values of spin and orbital moments are estimated to be 0.56 and 0.055 μ_B, respectively, for an electric field of 0 kV/cm, and 0.56 and 0.045 μ_B, respectively, for an electric field of 8 kV/cm. The modulation of the orbital magnetic moments by 0.01 μ_B upon applying *E* is related to the induced lattice distortion of 2% from the $BaTiO_3$ substrates. Moreover, after releasing *E* to zero, spectral line shapes also revert to the pristine state [2]. Therefore, we conclude the reversible changes of orbital magnetic moments is induced by lattice distortion, which is the demonstration of novel orbital-elastic effect.

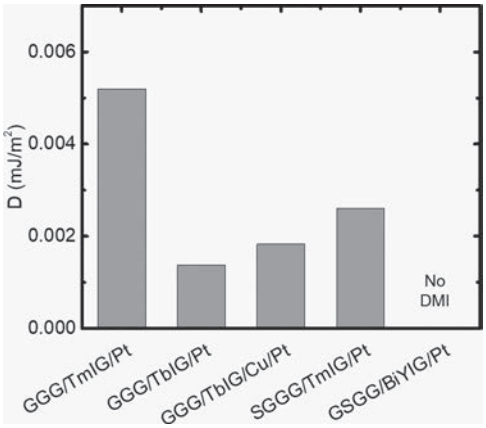
AG-08. Origins of Chiral Exchange Interactions in Centro-Symmetric Magnetic Insulators Arising from Rare-Earth Ions. *L.M. Caretta*[1], E.R. Rosenberg[1], F. Buettner[1], T. Fakhrul[1], P. Gargiani[2], M. Valvidares[2], P. Reddy[1], C. Avci[1], C. Ross[1] and G. Beach[1] *1. MIT, Cambridge, CA, United States; 2. ALBA Synchrotron, Barcelona, Spain*



Chirality plays an essential role in physics and materials science. In magnetic materials, a chiral exchange interaction called the Dzyaloshinskii-Moriya interaction (DMI) can manifest from broken spatial inversion symmetry[1,2]. This discovery has led to the observation of chiral and topological spin textures, such as magnetic skyrmions and chiral domain walls[3–5]. Research has primarily focused on the study of chiral spin textures in metallic ferromagnet thin films with stacking asymmetry, where spin-orbit coupling at a heavy-metal/ferromagnet interface produces an interfacial DMI[4,5]. A broader class of materials, magnetic insulating garnets, have been extensively studied for their technologically desired spintronic properties, such as long magnon diffusion lengths and numerous magneto-optical effects[6,7]. Their low damping and ferrimagnetic properties also make them ripe candidates for high spin texture mobilities and fast spin texture velocities[6,7]. However, the DMI has only recently been observed in rare-earth iron garnet films, and the origins of the DMI are still not clear[8]. Here, we use current-induced domain

wall dynamics to systematically study the origins of the DMI in magnetic insulating garnets. We show that the DMI originates from broken symmetry at the substrate oxide/magnetic oxide and the heavy-metal/magnetic oxide interface. Additionally, we demonstrate a method to control the strength of the DMI by tuning the strain state of the garnet film. Moreover, by studying the rare-earth- and temperature-dependence of the DMI, we find that the DMI necessitates the presence of a rare-earth element in the magnetic insulator, suggesting new means to engineer chirality and ultimately new material and magnetic properties in this ubiquitous class of materials.

AG-09. Robust skyrmion-bubble textures in single $SrRuO_3$ thin films stabilized by magnetic anisotropy. P. Zhang[1], A. Das[1], E. Barts[1], L. Si[2], M. Azhar[1], K. Held[2], M. Mostovoy[1] and *T. Banerjee*[1] *1. University of Groningen, Groningen, Netherlands; 2. Institut für Festkörperphysik, TU Wien, Wien, Austria*

We report on unconventional features in Hall transport in single $SrRuO_3$ thin films, akin to recent reports on topological Hall effect in $SrIrO_3/SrRuO_3$ bilayers [1,2] and ascribed to skyrmions. Unique to our findings are the i) robustness of these features (Fig.1) to the tilting magnetic field vector, manifested in their re-appearance with increasing angle of tilt, for temperatures below the magnetic phase transition and ii) the absence of a heavy metal layer. A systematic study of the magnetic anisotropy in strained $SrRuO_3$ (SRO) thin films grown epitaxially on a mixed surface terminated $SrTiO_3$ (100) (STO) was done using temperature dependence of the magnetization. Our density-functional theory calculation of a SRO/STO superlattice shows that the interface with intermixed RuO_2-TiO_2 lead to an exotic antiferromagnetic coupling, which flips to a high-spin ferromagnetic state under an external magnetic field. A careful analysis of the anomalous Hall resistivity with temperature shows a crossover from intrinsic to extrinsic mechanism and has distinct correlation with the observed unconventional features, ascribed to the topological Hall effect. To understand the mechanism leading to the stabilization of magnetic textures at our tailored interface, with sizeable spin-orbit coupling and in the absence of a strong interfacial Dzyaloshinskii-Moriya interaction, we modelled the magnetic energy incorporating anisotropy and dipolar interactions. We explain the experimental findings by the formation of magnetic bubble domains with skyrmion topology and relatively thick domain walls, using the model in Ref [3]. Further the robustness of the bubble arrays against the rotation of the magnetic field vector, as well as the relatively high critical magnetic fields are found to originate from the complex angular dependence of the magnetic anisotropy energy in $SrRuO_3$ films. [4] Such non-trivial competition between different local and non-local magnetic energies, leading to robust magnetic textures, at our engineered interfaces opens new opportunities for their manipulation with electric fields. Fig.1 : Magnetic field dependence of the Hall resistivity with increasing angle of the magnetic field (inset top panel).

AG-10. Effect of Spatially Modulated Dzyaloshinskii-Moriya Interaction Confinement on the Néel Skyrmions. *S. Bhatti*[1] and S. Piramanayagam[1] *1. School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore*

Magnetic skyrmions have gained intense interest recently due to their abilities of circumventing the defects, small size and required low current for motion[1]. However, skyrmions in a racetrack move in transverse direction towards the edge of the track (due to skyrmion Hall effect). To avoid this detrimental effect, several methods have been proposed[2]. Here, we have proposed a new scheme based on the use of modulated Dzyaloshinskii-Moriya Interaction (DMI) energy by spatially modifying the DMI, which restrict the skyrmion's transverse motion[3]. DMI value was modulated on the edges, which reduces the total skyrmion energy as shown in the fig. 1. In our proposed approach, DMI of the track edges can be tuned locally, by practical approaches such as ion-implantation or compositional modifications that can be easily adapted in a CMOS-friendly manner. By using micromagnetic simulations, we have demonstrated the restriction of skyrmion's transverse motion to avoid the annihilation of the skyrmion. Moreover, the velocity and path of skyrmion can be manoeuvred by varying the current and DMI energy (fig. 2 (a)). Furthermore, we have demonstrated that the size of the skyrmions can be reduced, to some extent, by DMI energy wells' positions (fig. 2(b)). In addition, we have investigated the effect of magnetostatic interaction between the skyrmions in closely spaced neighbouring tracks for high density storage application (fig. 2(c)). Experiments are being carried out at the moment on CoFeB multi-stack, whose results will be presented during the conference.

AG-11. Robustness of Skyrmions in Amorphous GdCo with Interfacial Mixings. *C.T. Ma*[1], B.J. Kirby[2], W. Zhou[1] and J. Poon[1] *1. Physics, University of Virginia, Charlottesville, VA, United States; 2. NIST Center for Neutron Research, National Institute of Standards and Technology, Gaithersburg, MD, United States*

Magnetic skyrmions have been studied extensively for their applications in high-density energy efficient spintronics devices. Recently, ultrathin GdCo films on Pt have been shown to host Néel skyrmions as small as 10 nm [1]. In these materials, skyrmions are stabilized through the interfacial Dzyaloshinskii-Moriya interaction (DMI), which originates from a heavy metal interface. Thus, the interface quality is crucial in stabilizing and transporting skyrmions for device applications. We employed polarized neutron reflectometry (PNR) to investigate the interfacial properties of a W/Pt/GdCo(5 nm)/W/Pt heterostructure deposited on an Si/SiO_2 substrate. Fig. 1 shows temperature-dependent depth profiles determined from measurements taken in an in-plane 3 T field. The GdCo layer exhibits an inhomogeneous magnetization profile at all temperatures. Near the Pt/GdCo interface, a 2 nm region shows a compensation temperature (T_{comp}) of below 50 K. In contrast, away from the interface, T_{comp} of the rest of GdCo is found to be near 250 K. The reduction of T_{comp} likely arises from the intermixing of Pt and GdCo at the interface. With this mixing layer, the robustness of skyrmion in these heterostructures may be compromised. Based on results from PNR, we have simulated a heterostructure of $(GdCo)_{75}Pt_{25}$(2 nm)/GdCo(3 nm) to investigate the effect of the mixing layer on skyrmions in GdCo. We find that skyrmions, as small as 10 nm, remain stable in such magnetic heterostructure. To verify the robustness of these simulated skyrmions, we have utilized tomography as shown in Fig. 2. Columnar distributions of skyrmions are found across the structure. While the robustness and the stability of skyrmions persist with the presence of a mixing layer, further study is needed to investigate the effect on skyrmion's mobility. This work was supported by the DARPA Topological Excitations in Electronics (TEE) program (grant D18AP00009).

AH-01. Epitaxial Integration of Multiferroic $LuFeO_3$ onto a Semiconductor Device Platform. *J. Casamento*[1], P. Dang[3], X. Li[2], H. Lee[2], D. Schlom[1], H.G. Xing[2,1] and D. Jena[2,1] *1. Materials Science Engineering, Cornell University, Ithaca, NY, United States; 2. Electrical and Computer Engineering, Cornell University, Ithaca, NY, United States; 3. Applied Engineering Physics, Cornell University, Ithaca, NY, United States*

The integration of magnetic materials in semiconductor devices is an appealing prospect due to the potential for combining logic and nonvolatile memory. This can be achieved using multiferroic materials with coupled ferromagnetism and ferroelectricity to control electrical polarization with magnetization and vice versa. $LuFeO_3$ (LFO) is an attractive material for this purpose, being a multiferroic material that is ferroelectric below ~1050 K and weakly ferromagnetic below ~150 K[1,2]. Also, room temperature multiferroic behavior has been previously demonstrated in $LuFeO_3$-$LuFe_2O_4$ thin film superlattices[3]. High quality epitaxial growths of LFO by ozone molecular beam epitaxy on GaN (0001) have been achieved, as confirmed by X-ray diffraction (XRD), atomic force microscopy (AFM), and in-situ electron diffraction. XRD shows fringes relating to film thickness and AFM shows LFO surface roughness is less than 0.5 nm on a 2x2 μm scale. Piezoresponse force microscopy suggests that the epitaxial LFO on GaN is ferroelectric at room temperature, with a permanently poled pattern appearing from electrical bias. Hysteresis in seen in vibrating sample magnetometry measurements, indicating that it is ferromagnetic at low temperatures. These results indicate the feasibility of future integration of LFO-based ferroelectric and multiferroic phenomena into III-nitride optoelectronics. This work was supported by the National Science Foundation under Grant Nos. E2CDA ECCS-1740286, and EFMA-1741694 and the Semiconductor Research Corporation as nCORE task 2758. This work was performed in part at user facilities supported by NSF grants MRI-1338010, ECCS-1542081(CNF) and DMR-1719875 (CCMR).

AH-02. $GdFe_{0.8}Ni_{0.2}O_3$ as a new multiferroic compound for low-voltage-driven spintronic devices. K. Chen[1], Y. Huang[1], *S. Chang*[1] and Y. Tseng[1] *1. Materials Science & Engineering, National Chiao Tung University, HSINCHU, Taiwan*

At the forefront of spintronics, electrical (voltage) control of magnetic devices will require novel materials to increase drive current capability, as well as lowering power consumption and promoting operating speed. Multiferroic devices are potential for application of electrical (voltage) controlled devices, owing to coexisting ferroelectric (FE) and magnetic orders in a single phase. Therefore, the idea of making spintronic devices based on multiferroic materials comes very naturally. Unfortunately, development in the field of multiferroics is stagnating due to slow progress in the development of new multiferroic compounds. In this study, we demonstrated the use of sputtering to grow a new multiferroic thin film that features coupled FE and antiferromagnetic (AFM) orders at room temperature. The FE and magnetic orders of the film are very responsive to low applied voltages (+/- 1 volt) and the multiferroic behavior is sensitive to bias polarity. Combining this film with a Co ferromagnetic layer resulted in a heterostructure capable of generating discrete magnetic orders simply by altering the bias magnitude and bias sign. Thus, this material could double the number of available magnetic read-out states within a low voltage regime, which satisfies the requirements for low-power and high-storage technology. Theoretical analysis and experiment results indicate the importance of Ni-dopant in regulating the polarity-dependent multiferroicity of this Gadolinium ferrite system. We believe that the development of such materials could open the door to new spintronic architectures that exploit the local gating of magnetic properties, thereby reducing the energy required for switching while increasing storage capacities.

AH-03. Multilevel Nonvolatile Memory Effect in amorphous SmCo/(011) PMN-PT Heterostructure. *W. Liang*[1,3], J. Liu[1,3], F. Hu[1,3], J. Zhang[2,3], J. Wang[1,3], J. Sun[1,3] and B. Shen[1,3] *1. Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2. Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China; 3. University of Chinese Academy of Sciences, Beijing, China*

Electric field control of magnetism is promising for developing dense, fast, nonvolatile magnetic random access memory with very low energy consumption. A feasible and effective method is using multiferroic materials, especially multiferroic heterostructures, and much progress has been made.[1,2] Among them, soft magnetic and ferrimagnetic materials are often chosen as ferromagnetic layers, while hard magnetic materials, which can bring higher recording density and signal-to-noise ratio, have got little attention. Our recent research indicated that two-state storage can be realized in amorphous hard magnetic SmCo/(011)PMN-PT heterostructure by utilizing the magnetostrictive properties of amorphous SmCo thin film and the polarization switching in PMN-PT substrate.[3] As known, the implementation of multilevel storage is conducive to further improving storage density. From this viewpoint, multilevel storage in amorphous SmCo/(011)PMN-PT heterostructure has been further demonstrated by controlling the polarization switching in PMN-PT substrate. One way is to apply unipolar electric field *E*, another is to apply minor-loop electric field *E*. When unipolar electric fields were cyclically applied, the polarization directions keep rotating on one side of out-plane (011), and will not flip to the other. Even the turning electric field reaches coercive field, the polarization directions lie in-plane of (011), i.e. the 4 possible in-plane <111> directions. As a result, turning electric field makes it possible to realize the multilevel switching of remnant magnetization Mr in amorphous SmCo/(011)PMN-PT heterostructure (Fig. 1a-b). Moreover, minor-loop cyclic electric fields can also produce similar multilevel switching, as shown in Fig. 1c-d. Relative mechanism has been comparably discussed for the both cases. The observed multilevel nonvolatile memory effect in amorphous SmCo/(011) PMN-PT heterostructure promotes the hard magnetic materials to be used in multifunctional information storage and novel spintronic devices.

AH-04. Voltage-Controlled Superconducting Magnetic Quantum Memory. *A. Kenawy*[1,2], M. Milosevic[3], W. Magnus[3] and B. Soree[2] *1. Physics Department, KU Leuven, Leuven, Belgium; 2. imec, Leuven, Belgium; 3. University of Antwerp, Antwerp, Belgium*

Over the past few decades, superconducting circuits have been used to realize various novel electronic devices such as quantum bits, SQUIDs, parametric amplifiers, etc. One domain, however, where superconducting circuits fall short is information storage. Superconducting memories hinge on the quantization of magnetic flux in superconducting loops. Standard implementations store information as magnetic flux quanta in a superconducting loop interrupted by two Josephson junctions (i.e., a SQUID) [1]. However, due to the large inductance required, the size of the SQUID loop is limited to several micrometers, resulting in low-density memory chips. Here, we propose a scalable magnetic memory device consisting of a voltage-biased superconducting loop (e.g., a ring) threaded by a half-quantum flux bias. By numerically solving the time-dependent Ginzburg-Landau equations, we show that, by forming two weak links in the ring, the bias voltage modulates the free-energy barrier between neighboring flux states. Accordingly, by applying a time-dependent bias voltage in the microwave range, one can temporarily reduce the free-energy barrier and harness deterministic phase slips as a writing mechanism to change the number of stored flux quanta. We demonstrate writing speeds in the order of few picoseconds for aluminum nanorings. Since the proposed device does not require a large loop inductance, it can be scaled down, enabling a high-density memory technology.

Physics, Cornell University, Ithaca, NY, United States*

Multiferroic materials with strong magnetoelectric coupling present the possibility of controlling electrical polarization via magnetization switching. This can be applied to semiconductor transistors, where the polarization

switching of the multiferroic can gate the semiconducting channel. Such structures hold promise for combining magnetic memory and digital logic through integrating magnetic materials with semiconductor transistors. $LuFeO_3$ (LFO) is a magnetoelectric multiferroic with ferroelectric ordering below ~1050 K and canted antiferromagnetic ordering below ~150 K [1-3]. After high quality epitaxial growths of LFO onto GaN two-dimensional electron gases (2DEGs) by ozone molecular beam epitaxy, electrical measurements show that the nitride 2DEG survives the growth and is able to couple with LFO's ferroelectric polarization. Furthermore, low-temperature magnetoresistance measurements of the LFO/2DEG stack show a spontaneous change in resistance at certain magnetic fields, alluding to the possibility of changing the LFO's electrical polarization with a magnetic field. Magnetic $Mn_{1-x}Ga_x$ is then grown on top of the LFO to enhance the exchange bias of the structure and improve the possibility of switching electric dipoles with magnetic field. $Bi_{1-x}Sb_x$ / $Mn_{1-x}Ga_x$ spin-orbit torque (SOT) bilayers were recently shown to be a very efficient structure for magnetization switching [4], so combining the SOT bilayers with the LFO/2DEG structure holds promise for creating a field-effect transistor that is controlled by SOT. AH-06. Smart Magnetoelectric Antennas for Magnetic Sensing and Energy Harvesting. *M. Zaeimbashi*[1], M. Nasrollahpour[1], X. Liang[1], H. Chen[1], A. Romano[1], Z. Xu[1], A. Mittal[1], N. Mirchandani[1], G. Jha[1], I. Martos-Repath[1], A. Khalifa[2], M. Onabajo[1], A. Shrivastava[1], S. Cash[2] and N.X. Sun[1] *1. ECE, Northeastern University, Boston, MA, United States; 2. Neurology, Massachusetts General Hospital, Boston, MA, United States*

Recent progress in the field of magnetoelectric (ME) materials have led to ultra-compact ME antennas with size of 2-3 order of magnitude smaller than that of conventional state-of-the-art compact antennas [1]. These miniaturized antennas could be suitable for Medical Implant Communications Service (MICS), in particular for wireless brain monitoring. A wireless implantable device should be able to perform multiple tasks in order to effectively monitor an individual's condition. For instance, a wireless implantable device should harvest their required energy in order to power their circuitry systems. In addition, the implant needs to record the body's information such as magnetic or electric fields in order to successfully track the changes the body. Finally, the implant should transmit the recorded data to the external antenna or device. In this work we're presenting an ultra-compact and smart magnetoelectric antenna that can single-handedly perform all three above-mentioned tasks: energy harvesting, magnetic field sensing, and data communication. This complimentary combination makes ME antennas suitable for brain implantation where magnetic field recording is required to monitor the brain functionality. Fig. 1 shows the optical microscope image of fabricated ME antenna with AlN/FeGaB thin-film structure. AlN acts as a piezo-material and FeGaB as a magneostrictive material. Proposed antenna has three parallel ME element, each with the size of 50×250 μm^2. Fig. 2a shows the architecture of energy harvesting setup. Fig. 2b shows the ME antenna concept and its functionality in receiving (energy harvesting) mode. Fig. 2c shows the S11 of ME antenna showing the resonant frequency of 2.25GHz. Fig. 2d shows the harvesting voltage from ME antenna, showing an induced voltage of 2.13mV when ME antenna is in presence of a 4.5nT RF magnetic field. Fig. 3a shows the ME antenna's phase response in magnetic sensing mode. Here, ME antenna is in presence of a 1kHz magnetic field with 6.6μT strength. Fig. 3b is the zoomed-in version of Fig. 3a and shows the 1kHz phase peak which corresponds to the 6.6μT magnetic field under measurement. The limit of detection of this antenna is 917pT.

Integrated magnetoelectrics have been demonstrated to enable voltage control of magnetism, or vice versa, and have great potential for magnetic field sensors, antennas and magnetoelectric random access memories. Dr. Nian Sun has been playing a pioneering role in integrated magnetoelectrics. In this talk, he will cover the most recent progress on new integrated magnetoelectric NEMS (nanoelectromechanical system) based sensors and antennas. He will cover magnetoelectric materials, and their applications in different devices, including: novel ultra-compact RF NEMS acoustic magnetoelectric antennas immune from ground plane effect with $< l_0/100$ in size, self-biased operation and ground plane immunity; and ultra-sensitive RF NEMS magnetoelectric magnetometers with ultra-low noise for DC and AC magnetic fields sensing. These novel magnetoelectric sensors show great promise in compact, lightweight and power efficient sensors, radars, communication systems, biomedical devices, IoT, etc.

AH-08. Room-Temperature Voltage Control of Magnetism in Sr(Co,Fe)Ox Thin Films. *S. Ning*[1] and C. Ross[1] *1. Department of Materials Science and Engineering, MIT, Cambridge, MA, United States*

Although remarkable advances have been made in current-induced magnetic switching, the voltage control of the magnetic properties is drawing considerable attention as it can further reduce the switching power by using an electric field instead of a current. Several strategies have been developed for voltage control of magnetism, but are impeded by challenges such as the weak magnetoelectric (ME) coupling in single-phase multiferroic materials or ferroelectric/magnetic composites, and the thickness limitation and low Curie temperature of electrically gated ferromagnetic metals or semiconductors. Recently, magneto-ionic effects (voltage-driven ionic migration) has been used to manipulate the coercivity, exchange bias and magnetic anisotropy, but easy on-off switching of magnetism at room-temperature (RT) is still elusive. We demonstrate RT voltage-controlled magnetism switching in Sr(Co,Fe)Ox, (SCFO, $2.5<x<3$) thin films of thickness 50-150 nm produced by PLD on $SrTiO_3$. Via ionic liquid (IL) gating, oxygen ions can be inserted into or extracted from the films, leading to a reversible change of oxygen stoichiometry and valence states of Co and Fe ions, as well as a structural change between an oxygen-deficient phase (brownmillerite, BM) and a fully oxidized phase (perovskite, P) evident from in situ XRD analysis. The oxygen-deficient BM-SCFO is a G-type antiferromagnet with negligible net magnetization. A robust RT ferromagnetism is observed in the fully oxidized P-SCFO produced by the intercalation of oxygen ions through IL gating with a bias of -2 V. This behavior is absent in both parent materials ($SrCoO_x$ and $SrFeO_x$). The RT magnetization varies with Co/Fe ratio and is maximum (~100 emu/cm^3) at a ratio of Co/Fe = 1/1. When gating with a bias of +2 V, the magnetism rapidly vanishes in a few minutes with the structure gradually back to the BM phase due to the deintercalation of oxygen ions. The magnetic changes upon IL gating are reversible over multiple cycles. Our work makes it possible to utilize the oxygen migration driven by IL gating in SCFO thin films to realize reversible non-volatile switching of magnetism at RT, and provides a new direction for the RT electrical manipulation of magnetic properties.

AH-09. Magneto-Ionic Control of Exchange Bias in Gd/NiCoO. P. Murray[1], *C.J. Jensen*[2], A. Quintana[2], J. Zhang[3], X. Zhang[3] and K. Liu[2,1] *1. Physics Department, University of California, Davis, Davis, CA, United States; 2. Physics Department, Georgetown University, Washington, DC, United States; 3. King Abdullah University of Science & Technology, Thuwal, Saudi Arabia*

The presence of the interface-sensitive exchange bias effect in getter-metal / antiferromagnet (AF) oxide systems offers an ideal platform to probe the nature of the interfaces and to electrically control the exchange bias itself. As exchange bias is prominently featured in spin-valve type of spintronic devices that enables the control of magnetic configurations, magneto-ionic control of exchange bias may lead to substantially more energy-efficient switching using an electric field. We have investigated magneto-ionic control of exchange bias in Gd/NiCoO films. As a result of the O^{2-} ion migration at the interface, the multilayer structure is transformed into Gd/NiCo/NiCoO. Since the bulk Gd Curie temperature is at 292K, thus at room temperature the ferromagnetic (FM) signal observed in the as-grown sample is due to the redox-reduced NiCo at the Gd/NiCoO interface, similar to that seen in earlier studies of the GdFe/NiCoO system utilizing a ferrimagnet GdFe [1]. Upon field cooling, the hysteresis loop becomes shifted, with a significant exchange bias of ~ 280 Oe. The magnitude of the exchange bias depends on the thickness of the interfacial layer and of the AF layer. Interestingly, the exchange bias is enhanced by up to 15% in a bias electric field. Scanning transmission electron microscopy (STEM) directly reveals ion-migration-induced chemical segregation and microstructural disorder. Electron energy loss spectroscopy (EELS) shows that upon field cooling, the interfacial region become Ni-rich; this chemical segregation becomes more dramatic after voltage biasing. The observed enhancement of exchange bias under voltage gating may be related to the disorder-induced changes to the effective FM thickness at the interface, and the reduction of the FM NiCo moment, consistent with Malozemoff's random field model. This work has been supported by the NSF (DMR-1610060 and ECCS-1611424) and the nCORE-SMART Center.

AH-10. Magneto-Ionic Control of Coercivity and Exchange Bias using Voltage-Tunable FeO_x/Fe Surface Layers. *J. Zehner*[1], R. Huhnstock[2], S. Oswald[1], S. Schneider[1], I. Soldatov[1], R. Schäfer[1], A. Ehresmann[2], K. Nielsch[1], D. Holzinger[2] and K. Leistner[1] *1. IFW Dresden, Dresden, Germany; 2. Institute of Physics, University of Kassel, Kassel, Germany*

Voltage-triggered ionic motion and redox reactions achieved by electrolytic gating of metal nanostructures enable large and non-volatile magnetic changes at room temperature.[1-3] This magneto-ionic control is highly interesting for novel energy efficient spintronic, actuation, and neuromorphic computing devices. So far, magneto-ionic mechanism are mainly used to control anisotropy and magnetization in magnetic layers with a thickness of a few monolayers or nanometers. In the present study, magneto-ionic effects on coercivity and exchange bias are demonstrated for sputtered and natively oxidized FeOx/Fe films with a thickness of up to 13 nm. Two systems are studied: (I) FeOx/Fe films with a uniaxial in-plane magnetic anisotropy on a Au layer (Figure 1) and (II) exchange bias FeOx/Fe films on an antiferromagnetic IrMn layer. In these systems, reversible oxidation and reduction reactions occur in the FeOx/Fe films at a low voltage of < 1 V in a liquid electrolyte. In the FeOx/Fe/Au films, this change in oxidation state induces large changes in coercivity, remanence, and magnetic domain size, and it makes voltage-induced 180° switching of magnetization possible at a small bias field. For the FeOx/Fe/IrMn systems, large changes in the exchange bias field are achieved (Figure 2).[4] The magnetic changes are revealed by in situ Kerr microscopy. The change of oxidation state and an associated thickness change of the iron oxide and Fe layers are proposed as the underlying mechanisms. This mechanism is proven by X-ray Photoelectron spectroscopy and transmission electron microscopy and it is consistent with a model for the exchange bias. Nonvolatility is achieved as the reduction proceeds at the buried FeOx/Fe interface, leaving the remaining oxide as a protective layer. In addition, a lateral voltage-controlled patterning of the exchange bias fields and magnetic domain state is demonstrated.[4] This versatile magneto-ionic control paves a new route for the development of future electrically controlled magnetic devices and for the design of exchange bias systems in general.

Over the last decades, a flurry of research has focused on the electrical control of magnetism. Magnetoelectric effects can be accomplished by different mechanisms,[1] for example magneto-ionics, which relies on the migration of ions (e.g. oxygen) driven by an electric field, as an effective approach for controlling the oxidation-reduction processes of a ferromagnetic material.[2,3] In this manner, magnetic properties can be easily manipulated by voltage taking advantage of ion diffusion through the ferromagnetic material. Large magneto-ionic effects in heterostructured films consisting of mesoporous Co–Pt films conformally coated with insulating oxide nanolayers are demonstrated. Mesoporous Co–Pt films, prepared by electrodeposition, are coated with Al_2O_3 and HfO_2 by atomic layer deposition (ALD) with the aim to promote voltage-driven ion migration during electrolyte-gating. Magnetic moment at saturation (m_S) and the coercivity (H_C) of Co–Pt are significantly manipulated after biasing either with negative or positive voltages. The application of a negative voltage decreases H_C and increases m_S, whereas positive voltage causes the reverse effect (increase in H_C and decrease in m_S). The same trends were observed in all heterostructures, i.e., uncoated Co–Pt, Co–Pt/Al_2O_3 and Co–Pt/HfO_2 films. Interestingly, the largest magneto-electric effects were obtained for Co–Pt/HfO_2 heterostructured films at negative voltages with an increase of m_S up to 76% and a decrease of H_C by 58%. The observed magnetoelectric changes arise from a reversible oxygen ion migration across the Co–Pt/oxide layer interface, resulting in variations of the Co oxidation state in the nanoporous Co–Pt film. The variations markedly depend on the nature of the ALD nanocoating deposited onto the underlying Co–Pt film, where HfO_2 acts as an oxygen getter layer, thereby triggering magneto-ionic effects at negative voltages, and Al_2O_3 works as oxygen donor layer, thus promoting effects at positive voltages. Hence, our work shows that the combination of a mesoporous magnetic alloy and a skin-like insulating oxide nanocoating is an appealing approach to enhance magneto-ionic effects and decrease power consumption in electrolyte-gated magneto-ionic devices.

AH-12. Ionic chain size dependence of the low-field magneto-ionic response of ionic liquid/polymer composites. L. Fernandes[1], *E. Fernandez-Martin*[1], D.M. Correia[2,3] and S. Lanceros[1] *1. BCMaterials - Basque Center for Materials, Applications and Nanostructures, Leioa, Spain; 2. Departamento de Química, Universidade de Trás-os-Montes e Alto Douro, Vila Real, Portugal; 3. Departamento de Física, Faculdade de Ciências, Universidade do Minho, Braga, Portugal*

Magnetoelectric (ME) materials provide coupling between ferroelectric and magnetic orders, the coexistence of magnetization and electric polarization in the same material allowing an additional degree of freedom in the design of novel devices such as sensors, actuators, and multistate memory components. This work focus in obtaining a new type of ME response induced when magnetic ionic liquids (MILs) are introduced into a porous polymer matrix. This response is related to the ionic movement rather than to dipole variations, which we will denote it as magneto-ionic (MI) response. MILs are typically produced by the incorporation of a paramagnetic component into either the cation or anion in the IL structure, avoiding the need to include magnetic nanoparticles within the composite [1]. MILs combined with piezoelectric polymers, such as, poly(vinylidene fluoride) (PVDF) [2], represent thus a new class of electroactive smart materials with suitable magnetic, electric, mechanical and electromechanical properties for various applications [3]. These materials possess high response and therefore are suitable for low magnetic field sensing devices [4]. This work presents the effect of the ionic liquid chain size on the magnetic and MI response of the composites. The responsive composites based in imidazolium tetrachloroferrate ILs with different chain lengths ([$C_x$mim][$FeCl_4$])/PVDF x=2,4,8 and 14) were prepared by solvent casting with a concentration of MIL of 20 % wt. Figure 1 shows the magnetic hysteresis loops of the different ionic liquids displaying an increase of the paramagnetic response as the chain length increases. The electric response to ac magnetic fields with no dc magnetic has been obtained up to 100 kHz with a maximum ac field of 0.6 Oe (Figure 2) showing that the electrical response for a given frequency to the ac field is linear and decreases with increasing chain length.

AH-13. Large Magnetoelectric Effect in Nanoporous Iron Oxide Thin Films Driven by Magneto-Ionics. S. Robbennolt[1], *A. Nicolenco*[1], P.M. Fernandez[1], S. Aufftet[2], V. Baltz[2], E. Pellicer[1], E. Menéndez[1] and J. Sort[1,3] *1. Physics, Autonomous University of Barcelona, Bellaterra, Spain; 2. SPINTEC, Univ. Grenoble Alpes/CNRS/INAC-CEA, Grenoble, France; 3. Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain*

Voltage control of the magnetic properties of oxide thin films is highly appealing to enhance energy efficiency in miniaturized spintronic and magnetoelectric devices [1]. The Iron oxide system is of particular interest because Iron is cheap and environmentally-friendly and there are multiple Iron oxide phases that are stable at room temperature which all have distinct magnetic properties [2,3]. Herein, magnetoelectric effects in electrolyte-gated nanoporous iron oxide films (FeO_x) are investigated. Highly porous films were prepared by the evaporation-induced self-assembly of sol-gel precursors with a sacrificial block copolymer template. For comparison, films with less porosity but analogous crystallographic structure were also prepared using an identical procedure without the polymer template. The magnetoelectric properties of the films were investigated by recording magnetic moment *vs.* applied magnetic field loops as a function of applied voltage. An electrochemical cell is used to apply electric fields *in situ*, i.e., while the magnetic properties of the films are being measured. The templated (highly porous) films showed a very large magnetoelectric response with a maximum increase in magnetic moment at saturation by a factor of 13 and a noticeable two-fold increase of coercivity after applying –50 V [4]. The non-templated films also exhibited a pronounced increase of magnetic moment at saturation by a factor of 4, although the coercivity remained unaffected over the same voltage range. Magnetoelectric effects in these latter films were found to be fully reversible in the voltage window ±10 V. The observed changes in magnetic properties are concluded to be magneto-ionically driven with oxygen ion exchange between the iron oxide and the liquid electrolyte, as evidenced from Raman and X-ray photoelectron spectroscopy experiments.

Engineering Department, University of Naples "Parthenope", Naples, Italy*

Energy-efficient switching of magnetization is a central problem in nonvolatile magnetic storage and magnetic neuromorphic computing. In the past two decades, several efficient methods of magnetic switching were demonstrated including spin torque, magneto-electric, and microwave-assisted switching mechanisms. Here we experimentally show that alternating spin torque can strongly increase the rate of thermally-activated magnetic switching of the free layer in a nanoscale magnetic tunnel junction [1]. We present analytical and numerical calculations that explain these experimental findings and reveal the crucial role played by low dimensional magnetic chaos near saddle equilibria in enhancement of the switching rate. We study the effect of ac spin torque on magnetization reversal in a nanoscale ferromagnet with biaxial magnetic anisotropy (predominant easy plane with a weaker in-plane uniaxial anisotropy). The nanomagnet is a 1.8 nm thick $Co_{60}Fe_{20}B_{20}$ ellipse with lateral dimensions of 50 x 75 nm^2 that is the free layer in a magnetic tunnel junction (MTJ). The nanomagnet is sufficiently small to support a single-domain ground state and is superparamagnetic at room temperature. Switching of the free layer magnetization results in change of the MTJ resistance via tunneling magneto-resistance (TMR) [2]. We monitor stochastic switching of the nanomagnet via random telegraph noise (RTN) resistance measurements as a function of ac spin torque amplitude, as illustrated in Fig. 1. The RTN switchign rate as a function of microwave power applied to the MTJ is shown in Fig. 1 for several ac spin torque frequencies. All these frequencies lie below the ferromagnetic resonance (FMR) frequency of the free layer (5.1 GHz). This figure reveals a well-pronounced threshold character of the switching rate in spin torque amplitude proportional to the applied ac voltage. Fig. 2 shows the threshold ac drive voltage as a function of the drive frequency. The points are experimental data and the solid line is the zero-temperature theoretical prediction for the onset of chaotic dynamics [1]. The ac-driven chaotic dynamics having a threshold character is predicted to arise in this system when magnetization is near the top of the energy barrier separating the two energy wells of uniaxial anisotropy [3], [4]. In a band of energies near the top of the barrier, chaotic trajectories bring magnetization across the barrier and thereby induce magnetization switching. Fig. 2 reveals that the analytic theory of chaotic dynamics is in good agreement with experiment in the frequency range from 1 to 4 GHz. In the 4-6 GHz regime, the resonant absorption of energy due to FMR leads to an additional reduction in the energy barrier [5]. In the sub-1 GHz regime, the increase in Neel-Brown switching rate arises from adiabatic enhancement of the amplitude of thermal fluctuations of magnetization by spin torque. This work shows that ac spin torque driven chaos can facilitate thermally-assisted switching of magnetization in an MTJ, which provides a new path towards energy-efficient magnetic memory based on thermally stable MTJs. Additionally, MTJs with superparamagnetic free layers are employed in neuromorphic and reservoir computing schemes. Our results show that low-dimensional chaos provides tunability of switching rates in such systems, and therefore, may lead to computing schemes that use both stochasticity and deterministic chaos.

AI-02. Narrow Total Linewidths in Low-Damping Epitaxial $Fe_{1-x}V_x$ Thin Films. *D.A. Smith*[1], Y. Lim[1], M. Clavel[2], M. Hudait[2] and S. Emori[1] *1. Physics, Virginia Tech, Blacksburg, VA, United States; 2. Electrical Engineering, Virginia Tech, Blacksburg, VA, United States*

To induce spin-torque precession of the magnetization with low threshold current densities, it is desirable to have ferromagnetic metals that possess low damping (narrow resonance linewidths) and low saturation magnetization. A commonly used material in spintronic devices, Fe, already has low Gilbert damping but high saturation magnetization. Alloying Fe with Co [1] allows the damping to decrease to record low values in metallic films but further increases the saturation magnetization. Previous theoretical [2] and experimental studies [3-5] have suggested that alloying Fe with V decreases both damping and saturation magnetization although realization of narrow total linewidths has remained elusive. In this study, we have grown high-quality epitaxial $Fe_{1-x}V_x$ thin films with narrow linewidths by cosputtering on MgO and $MgAl_2O_4$ substrates. The Gilbert damping parameter α and saturation magnetization M_{sat} for each sample are quantified using broadband ferromagnetic resonance (FMR) and vibrating sample magnometry, respectively. In contrast to prior experiments [5] that showed broad FMR linewidths (e.g. $\Delta H_{pp} \approx 40$ Oe at f = 17 GHz), our samples show significantly narrower total linewidths (e.g. $\Delta H_{pp} \approx 22$ Oe at f = 17 GHz, see Fig. 1). This reduction in linewidth is achieved by annealing the substrates at elevated temperatures prior to deposition, allowing for higher quality films and enabling the combination of low Gilbert damping and low inhomogeneous linewidth broadening ΔH_0, as shown in Fig. 2. Compared to epitaxial Fe samples deposited under similar conditions, we see a reduction in both the Gilbert damping and saturation magnetization by as much as ≈20% for $Fe_{80}V_{20}$. Our findings point to FeV as an attractive ferromagnetic alloy for energy-efficient spintronic devices.

The reduced symmetry originating at the interface of ultra-thin films has a profound influence on the magnetization dynamics. Instead of a scalar damping parameter it leads to a damping tensor, which reflects the symmetry of the confined device, also known as anisotropic damping [1]. Our M^3 code [2] incorporates a damping tensor instead of a scalar damping parameter in the Landau-Lifshitz-Gilbert (LLG) equation [3, 4]. In our study, the damping tensor reflects the symmetry of a thin film structure with exchange bias. The rotational anisotropy contribution to the damping tensor reflects the crystal symmetry of the thin film whereas the orientational anisotropy contribution implies that components of the damping tensor depend on the direction of the magnetization. To understand the observed angular dependence of the damping in previous experimental paper [5, 6], we carried out micromagnetic calculations to simulate ferromagnetic resonance experiments. In micromagnetic simulations an external magnetic field is applied along various angles with respect to the exchange bias direction and in addition a small perpendicular field pulse is utilized to probe the magnetization dynamics. The frequency linewidth at various fields for different in-plane angles are determined by Fast Fourier Transform (FFT) of the recorded magnetizations. As shown in Fig. 1, fully micromagnetic linewidth data is fitted to determine the effective damping parameter α_{FMR}. These α_{FMR} reflect the symmetry of the damping tensor as demonstrated in Fig. 2. Our simulations explain the uniaxial and unidirectional anisotropy observed in experimental results [5, 6].[7]

AI-04. Gilbert damping constant of NiMnSb half-Heusler alloy film with varying annealing temperature. *R. Mandal*[1], Z. Wen[1], T. Kubota[2,3], K. Takanashi[2,3] and Y. Takahashi[1] *1. Research Center for Spintronics and Magnetics Materials, National Institute for Materials Science, Tsukuba, Japan; 2. Institute for Materials Research, Tohoku University, Sendai, Japan; 3. Center for Spintronics Research Network, Tohoku University, Sendai, Japan*

Half-metallic Heusler alloys are primitive candidates for application in spintronic devices, such as magnetoresistive random access memory[1], current-perpendicular-to-plane giant magnetoresistance read heads for hard disk drives[2] for their high spin polarization and large magnetoresistance ratio. Compared to full Heusler alloys, half-Heusler alloys show large bandgap which helps to suppress thermal activation of electrons that could be advantageous for high-performance magnetoresistive devices. Epitaxially grown NiMnSb (NMS)[3] is a well-known candidate with all-potential properties for such applications. To further investigate the possibilities of this material for application in spintronic devices, the estimation of Gilbert damping (α) is necessary. Herein we report the estimation of α as a function of annealing temperature (T_{annl}) and structural ordering using time-resolved magneto-optical kerr effect (TRMOKE) microscope[4]. MgO-substrate/Cr(30 nm)/Ag(40 nm)/NMS(30 nm)/Al(1.5 nm) films were annealed from room temperature to 673 K. Out-of-plane X-ray diffraction patterns were measured for all the samples and NMS (002) and (004) superlattice peaks were clearly observed in all cases. With enhancement of T_{annl} the NMS (111) peak appears which ensures the formation of $C1_b$ type ordering. Figures 1 (a) and (b) show the maxima in degrees of order at T_{annl} = 573 K for both $B2$- and $C1_b$-type structures respectively and then drop again. To evaluate the α as a function of T_{annl}, the resonance frequency (f_r) was measured using TRMOKE microscope. Using the linearized LLG equation[5] α was estimated. The value of α (Fig. 1 (c)) decreases with T_{annl} and reaches a minimum value of 0.008 at T_{annl} = 573K where the degrees of order show maxima and then again increases, indicating that the degrees of order of samples have strong correlation with Gilbert damping. Therefore, we conclude the 30 nm thick NiMnSb thin film with T_{annl} =573K exhibited highly ordered structure and low magnetic damping showing favorable criteria for application in spintronic devices.

AI-05. Time-retarded damping and magnetic inertia in the Landau-Lifshitz-Gilbert equation self-consistently coupled to electronic time-dependent nonequilibrium Green functions. *U. Bajpai*[1] and B.K. Nikolić[1] *1. Physics and Astronomy, University of Delaware, Newark, DE, United States*

The conventional Landau-Lifshitz-Gilbert (LLG) equation is a widely used tool to describe the dynamics of local magnetic moments, viewed as classical vectors of fixed length, with their change assumed to take place

simultaneously with the cause. Here we demonstrate that recently developed [M. D. Petrović *et al.*, Phys. Rev. Appl. 10, 054038 (2018)] self-consistent coupling of the LLG equation to a time-dependent quantum-mechanical description of electrons—where nonequilibrium spin density from time-dependent nonequilibrium Green function (TDNEGF) calculations is inserted within a torque term into the LLG equation while local magnetic moments evolved by the LLG equation introduce time-dependent potential in the quantum Hamiltonian of electrons—microscopically generates time-retarded damping in the LLG equation described by a memory kernel that is also spatially dependent. For sufficiently slow dynamics of local magnetic moments on the memory time scale, the kernel can be expanded into power series to extract the Gilbert damping (proportional to the first time derivative of magnetization) and magnetic inertia (proportional to the second time derivative of magnetization) terms whose parameters, however, are *time-dependent* in contrast to time-independent parameters used in the conventional LLG equation. We use examples of single or multiple local magnetic moments precessing in an external magnetic field, as well as field-driven motion of a magnetic domain wall (DW), to quantify the difference in their time evolution computed from the conventional LLG equation versus the TDNEGF+LLG quantum-classical hybrid approach. The faster DW motion predicted by the TDNEGF+LLG approach reveals that important quantum effects, stemming essentially from a finite amount of time that it takes for a conduction electron spin to react to the motion of classical local magnetic moments, are missing from conventional classical micromagnetics simulations. We also demonstrate a large discrepancy between the TDNEGF+LLG-computed numerically exact and, therefore, nonperturbative result for charge current pumped by a moving DW and the same quantity computed by a perturbative spin motive force formula combined with the conventional LLG equation.

Confirming the origin of Gilbert damping by experiment has remained a challenge for many decades. This is the case even for some of the simplest ferromagnetic metals, such as pure Fe. Here, we experimentally identify Gilbert damping that increases with decreasing electronic scattering in thin films of BCC Fe. We directly compare the temperature dependence of Gilbert damping and electronic transport in pristine epitaxial films (Figure 1). Our observation of conductivity-like damping, which cannot be accounted for by classical eddy current loss, is in excellent quantitative agreement with theoretical predictions of Gilbert damping due to intraband scattering [1,2], as shown in Figure 2. These results resolve the longstanding question since the 1970s [3,4] about the role of intraband scattering in Gilbert damping in pure ferromagnetic metals. Furthermore, our experimental confirmation that clean ferromagnetic metals exhibit higher intrinsic damping (spin decoherence) at low temperatures may have important implications for designing magnetic media in quantum information applications. AI-07. Intrinsic damping of FeRh thin films. *G.A. Riley*[1,2], M.L. Schneider[1], H. Nembach[1], J.M. Shaw[1], J. Lauzier[3], J. de la Venta[3] and O. Eriksson[4] *1. Quantum Electromagnetics Division, National Institute of Standards and Technology, Boulder, CO, United States; 2. Center for Memory and Recording Research, University of California-San Diego, La Jolla, CA, United States; 3. Physics, Colorado State University, Fort Collins, CO, United States; 4. Department of Physics and Astronomy, Uppsala University, Uppsala, Sweden*

Thin film alloys of FeRh exhibit a large magnetoresistance (MR) effect due to a first order structural phase transition at temperatures near room temperature [1]. During the transition, the magnetization changes from an antiferromagnetic (AF) to a ferromagnetic (F) state and is accompanied by up to 50% change in electrical resistivity [2]. However, the physical mechanism for this transition driven MR is still being explored. A recent model based on density functional theory (DFT) calculations indicate that the large changes in resistivity result from a difference in electronic structure between the F

and AF states as well as increase in amplitude of spin fluctuations [2]. DFT calculations also predict a low damping for FeRh. Vector-network-analyzer ferromagnetic resonance (VNA-FMR) measurements in the perpendicular geometry were performed on FeRh thin films of two thicknesses: t=15 nm and 20 nm. The FeRh films were grown by dc magnetron sputtering on MgO (001) single crystal substrates and were capped with 3 nm of Al. The AF-F transition temperature was determined from magnetometry measurements. Prior to the FMR measurements the samples were heated to 390 K to ensure that the samples are in the ferromagnetic state. Damping was then determined from the slope of the measured linewidth for a range of temperatures above the transition temperature. The temperature-dependent magnetization was used to determine the radiative damping which was subtracted to determine the intrinsic damping following Ref. [3]. Figure 1 shows that the intrinsic damping is higher for the thin film, $\alpha = 3.26 \pm 0.14$, compared with $\alpha = 1.99 \pm 0.11$ for the thick film. The out-of-plane anisotropy, shown in Fig. 2, is considerably larger for the thin film as expected. These results offer a more comprehensive experimental picture of dissipative processes that occur in FeRh thin films to compare with forthcoming theoretical models. This work was supported by DOE award DE-SC0018237.

AI-08. Anisotropic Gilbert Damping in Sputtered $Fe_{0.7}Ga_{0.3}$ Films and Correlation with Crystal Structure. *W. Peria*[1], H. Yu[2], S. Lee[2], J.G. Barriocanal[3], I. Takeuchi[2] and P.A. Crowell[1] *1. School of Physics and Astronomy, University of Minnesota, Minneapolis, MN, United States; 2. Department of Materials Science and Engineering, University of Maryland, College Park, MD, United States; 3. Characterization Facility, University of Minnesota, Minneapolis, MN, United States*

The ability to engineer Gilbert damping is important for spintronics because it governs the switching efficiency in current-induced switching applications as well as the rate of spin relaxation, which plays an important role in magnetic storage applications. Certain compositions of FeGa alloys are known to have large magnetostriction coefficients, which is a valuable property for applications which rely on magnetomechanical transducers. We have measured ferromagnetic resonance linewidths of 30 nm $Fe_{0.7}Ga_{0.3}$/SiO_2/Si(001) (room temperature deposition) with field applied in-plane and out-of-plane (see figure). The in-plane linewidths show a nonlinear frequency dependence which is characteristic of two-magnon scattering. We fit the in-plane data using the model of McMichael and Krivosik [1] and obtain a Gilbert damping of 0.014, which agrees with a linear fit to the data above 20 GHz. We measure the Gilbert damping to be 0.0038 with the field applied out-of-plane, and therefore observe a Gilbert damping anisotropy of approximately a factor of 4. Furthermore, the anisotropy is reduced when the deposition temperature is increased to 200°C, which suggests a straightforward way of tuning the Gilbert damping. The defect correlation length obtained from the two-magnon fitting is in excellent agreement with the grain diameter measured from atomic force microscopy and the coherence length obtained from wide-angle x-ray diffraction (XRD). We show the existence of nanoprecipitates of epitaxial Fe_3Ga, which are known to enhance the magnetostriction in Galfenol ($Fe_{0.81}Ga_{0.19}$) [2]. These nanoprecipitates also show tetragonal distortion in XRD, which has recently been reported to cause anisotropic Gilbert damping in $Co_{0.5}Fe_{0.5}$ [3]. We conclude by positing structural distortions as the cause of the anisotropic damping.

AI-09. Choking nonlocal magnetic damping in exchange-biased ferromagnets. *T. Moriyama*[1], K. Oda[1] and T. Ono[1] *1. Kyoto University, Uji, Japan*

The Gilbert damping constant, α, is one of the important parameters characterizing the magnetization dynamics. It influences the switching speed of the magnetization and also determines the threshold current for various spin-torque-related phenomena [1]. It is, however, one of the least experimentally controllable magnetic parameters. Recently, we have revisited

the mechanism of the non-local damping with the exchange biased ferromagnet (FM)/antiferromagnet (AFM) multilayers and showed that the non-local damping was influenced by the Néel order in the AFM [2]. These results indeed offer a control of the magnetic damping by the magnetic order in the adjacent AFM. In this work, we particularly investigated the temperature dependence of the non-local damping in the exchange biased AFM/FM multilayer. α was characterized for the magnetization pointing along the exchange bias (EB) direction and against the EB direction by ferromagnetic resonance at elevated temperatures. Figure 1 (a) shows the temperature dependence of α in Pt (5nm)/FeMn (t_{FeMn} = 0 and 20nm)/FeNi (4nm). While α for t_{FeMn} = 0 nm slightly increases with the temperature, α for t_{FeMn} = 20 nm drastically decreases with increasing temperature. We also found that α measured against the EB is always greater than that measured along the EB. As shown in Fig. 1 (b), the difference (Δα) is linearly correlated with the strength of the EB, which is consistent with our previous observation [2]. The results essentially indicate that the non-local damping can be controlled by the adjacent antiferromagnet and its temperature dependent exchange bias. We also point out that such a strong temperature dependent damping may be very beneficial for spintronic applications involving a Joule heating upon the operation [3].

AI-10. Effect of Temperature on the Magnetization Dynamics of Amorphous Co-Fe-B Thin Films with Various Thicknesses. *Y. Endo*[1,2], H. Tanaka[1], T. Nguyen[2,3], H. Sato[2,3], S. Ikeda[2,4] and T. Endoh[2,3]
1. Electrical Engineering, Tohoku University, Sendai, Japan; 2. CSIS, Tohoku University, Sendai, Japan; 3. CIES, Tohoku University, Sendai, Japan; 4. CSRN, Tohoku University, Sendai, Japan

The magnetization dynamics in amorphous Co-Fe-B thin films has been studied intensively for the rapid development of spintronics devices such as MRAM, spin-torque oscillator, spin-logic and so on. In particular, a Gilbert damping constant (α), which describes the strength of damping torque, is one of the key parameters to understand the dynamics. However, details about the effect of temperature on α in these thin films are not understood fully. Herein we evaluate α at various temperatures of amorphous Co-Fe-B thin films with the thicknesses of 5, 10, and 15 nm by a broadband ferromagnetic resonance (FMR) measurement technique, and discuss the effect of temperature on α in these films in detail. The effective saturation magnetization ($4\pi M_{s,eff}$), the inhomogeneous field ($\Delta H(0)$) and α were estimated by analyzing FMR spectra of each film at various temperature, and were plotted in Fig. 1 as a function of temperature. For each film thickness, $4\pi M_{s,eff}$ slightly increases as the temperature decreases, while its value for the thickness of 5 nm becomes lower than those for the thickness of 10 and 15 nm. The reason for this difference might be due to the enhancement of the surface anisotropy with the decreases of film thickness. In contrast, regardless of the film thickness, $\Delta H(0)$ and α slightly increase as the temperature decreases and markedly increase at the temperature below 150 K, which might be proportional to the wave number dependent electrical conductivity[1]. Additionally, in case of the film thickness of 5 nm, the increment of α for the temperature becomes larger, which might be ascribed to the magnetic inhomogeneity such as the anisotropy dispersion. Therefore, these results suggest that the tendency of damping in each Co-Fe-B film for temperature is mainly consistent with the behavior of damping expected by intra-band transition. AI-11. Engineering Magnetic Properties via Strain in Europium Iron Garnet Thin Films. V.H. Ortiz[1], B. Arkook[1], J. Li[1], W. Yuan[1], *I. Barsukov*[1] and J. Shi[1] *1. Physics and Astronomy, University of California, Riverside, Riverside, CA, United States*

Ferrimagnetic insulators play an important role in spintronics research. Among ferrimagnetic insulators, rare earth iron garnets (REIGs) have a plethora of attributes desirable for practical applications. Controlled growth of epitaxial REIG thin films offers a unique opportunity to control their magnetic properties such as magnetic anisotropy and Gilbert damping [1][2][3]. In this work, we grow atomically flat europium iron garnet (EuIG) thin films by pulsed laser deposition. Employing various (111) garnet substrates and by varying film thickness from 10 to 50 nm, we control the strain from compressive to tensile regime, which is characterized using X-ray diffraction. We carry out angle- and frequency-dependent ferromagnetic resonance measurements and find a significant second-order perpendicular magnetic anisotropy in films with large compressive strain. While inhomogeneous linewidth increases with increasing strain, we find the Gilbert damping to be nearly constant (~ 10^{-2}). The results advance our understanding of spin dynamics in ferrimagnetic insulators and provide insights for material synthesis and engineering for various spintronics applications This work was supported as part of SHINES, an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences under Award SC0012670.

AI-12. Ferrimagnetic domain wall dynamics driven by Spin Orbit Torques revealed by in-plane fields through the compensation points in GdFeCo. *E. Haltz*[1*], J. Sampaio[1], R. Weil[1], S. Krishnia[1], L. Berges[1] and A. Mougin[1] *1. Laboratoire de Physique des Solides, Orsay, France*

To improve the efficiency of the manipulation of magnetic textures using spin torques, materials such as rare earth-transition metal ferrimagnetic alloys [1] are promising due to their tuneable magnetic properties (via temperature or chemical composition) [2]. At so-called compensation points (CPs), either magnetisation (at T_{MC}) or angular momentum (at T_{AC}) vanishes modifying the classic behaviour [3]. However, a full understanding of the magnetic dynamics at these CPs, including the determination of T_{AC}, still lacks. Domain wall motion (DWM) induced by current pulses (25ns) is studied in a 10μm wire made from co-evaporated $GdFeCo_{(5nm)}$ amorphous thin-film with perpendicular magnetic anisotropy and Pt covered[2]. Combining in-plane field and current J, the dynamics of the DW crossing CPs are probed within two approaches by Kerr microscopy. In a zero-field approach, the DW moves along J revealing a Spin Orbit Torque (SOT) process [4]. The velocity is very high (up to 700 m/s) [3]. However, the non-monotonous behaviour indicates Joule heating revealed by peaks of the domain wall mobility and assigned to TAC. We propose a second approach measuring the DWM driven by current under transverse in-plane field Hy. Moving a DW is related to tilting its internal magnetization [4] which is disclosed under Hy: Hy affects the magnetization angle, bringing it closer or farther to the Néel configuration, changing the SOT efficiency and increasing or decreasing the macroscopic velocity of DWM. The figure shows Δμ=v(+Hy)-v(-Hy)/J for different J and temperature T. The sign of Δμ directly reveals the internal DW magnetisation angle. Two sign changes occur, evidencing T_{MC} and T_{AC}. At T_{MC}, the dominant sublattice changes and the action of Hy reverses which by turn changes the angle. At T_{AC}, the tilt associated to the DWM reverses. Δμ reveals these changes very clearly. This approach relying on the application of a transverse field gives a T_{AC} value consistent with the mobility but based on intrinsic properties of the DW and not affected by the pinning.

AI-13. Magnetic damping of non-collinear synthetic antiferromagnets probed by time-resolved magneto-optical Kerr effect. *A. Kamimaki*[1,2], S. Iihama[2,3], T. Taniguchi[4] and S. Mizukami[2,3] *1. Department of Applied Physics, Tohoku University, Japan, Sendai, Japan; 2. WPI-AIMR, Tohoku University, Japan, Sendai, Japan; 3. CSRN, Tohoku University, Japan, Sendai, Japan; 4. Spintronics Research Center, AIST, Tsukuba, Japan*

Antiferromagnet is the one of the important topics of current spintronics. In particular, synthetic antiferromagnet (SAF) is expected to be used for memory devices because of the tunability of its net magnetizations [1]. Considering magnetization dynamics in SAF, there are two magnetic resonances corresponding to an acoustic (AC) and optical (OP) mode. Besides them, a dynamic exchange coupling due to the spin-pumping should be discussed [2-5]. Previous study showed magnetization damping using microwave technique for SAFs in case of collinear magnetization configuration [5]. From an application point of view, it is also desired to examine magnetization damping in case of non-collinear magnetization configuration. In this work, we investigated two resonance modes for SAF in non-collinear magnetization configuration using all-optical means, and discussed the effect of dynamic exchange coupling on magnetic damping [6]. The stacking structure of SAF was Si/SiO_2 (subs.)/Ta(3)/CoFeB(3)/Ru(0.4)/CoFeB(3)/Ta (3) (thickness in nm). The samples were prepared by a magnetron sputtering. In the all-optical time-resolved magneto-optical Kerr effect (TRMOKE) measurements, a fluence of the pump was 1.5 mJ/cm^2 and an applied magnetic field angle was approximately 10° with respect to the film normal. Fig. 1 shows the typical TRMOKE results. The oscillations for

AC and OP modes were extracted by a fitting. Fig. 2 shows the effective damping for both modes obtained from the fitting. The solid and broken curves show the calculated results with and without the spin-pumping at the Ru/CoFeB interface, and the these results were well agreed with the experiments. It was clarified that the dynamic exchange coupling in SAF increases the effective damping only for the OP mode. A. Kamimaki thanks to the Graduate Programs of Spintronics at Tohoku University. AP-01. Thermoreflectance Measurement of the Spin Peltier Effect.
T. Yamazaki[1], R. Iguchi[2], T. Ohkubo[2], H. Nagano[1] and K. Uchida[2]
1. Nagoya University, Nagoya, Japan; 2. National Institute for Materials Science, Tsukuba, Japan

In recent years, "spin caloritronics", a fusion research field of correlation physics between heat and spin transport, has developed rapidly since the spin Seebeck effect was observed [1]. The spin Peltier effect (SPE) [2,3], the reciprocal phenomenon of the spin Seebeck effect, is referred to as the conversion of spin current into heat current in paramagnetic metal (PM)/ ferromagnetic insulator (FI) junction systems. In previous reports [3,4], the thermographic method is used and revealed that the SPE induces characteristic temperature modulation, where it is localized near the junction interfaces and approaches the steady state very rapidly (expected to be less than 1 ms [4]). While the experimental determination of temporal response is necessary for understanding the physical origin of the SPE and also for designing possible devices utilizing the SPE, no experimental results are obtained so far because of the low temporal resolution of the thermographic method (>1 ms), used in the previous studies. In this work, we demonstrate that the thermoreflectance method realizes the SPE measurement with high temporal resolution. Here, the thermoreflectance method determines the temperature through the reflectivity of the material. Following the previous thermographic studies, we employed this method in the frequency domain with the lock-in detection technique, i.e. the lock-in thermoreflectance (LITR) [5]. In our LITR measurement, the SPE is driven by the application of a charge current to the paramagnetic layer in the junction system, which induces a spin current via the charge-to-spin conversion (spin Hall effect [6]) in the paramagnetic layer (Fig. 1). The SPE-induced temperature change synced with the spin-current injection is extracted by monitoring the reflected intensity of the irradiated CW light (Fig. 2). As shown in Fig. 2, the lock-in detection enables exclusive detection of the SPE-induced temperature modulation, separated from that of Joule heating. We succeeded the SPE measurements by LITR under high lock-in frequency (up to 1 MHz) and determined its temporal response time.

AP-02. Electrical detection of spin Nernst effect using lateral spin valve structures. *R. Matsuda*[1], R. Suko[1], D. Ito[1] and T. Kimura[1,2] *1. Depertment of Physics, Kyushu University, Fukuoka, Japan; 2. Research Center for Quantum Nano-Spin Science, Fukuoka, Japan*

Recent developments of spintronics and spin-caloritronics indicate that a longitudinal heat current produces the transverse spin current owing to the spin-orbit interaction. This is known as spin Nernst effect[1,2,3] (SNE), which is a kind of spin-heat conversion. Several research groups reported the observation of SNE independently and found the similar tendency. In these experiments, they adapt multi-layered structures to perform the efficient spin injection and detection. However, in such layered structures, undesired signals originating from the ferromagnetic proximity effect[4] were superimposed on the SNE and make it difficult to analyze the actual SNE signal. To eliminate the influence of the magnetic proximity effect, we here develop the SNE devices based on lateral spin valve structures. Figure 1 shows the schematic illustration of the fabricated device for SNE. Here, Pt and CoFeAl wires are bridged by a Cu strip. As schematically shown in Fig. 1, the temperature gradient normal to the heavy metal/Cu junction was produced by the Joule heating in the heave metal. Owing to SNE, the transverse spin current is injected into the Cu strip through the side surface

of the Pt wire. The injected spin current can be electrically detected by a CoFeAl electrodes. By changing the magnetization direction of the CoFeAl, a rectangular-shape spin signal will be expected. Figure 2(a) shows the field dependence of the electric signal induced in the CoFeAl electrode. A rectangular shape signal was clearly observed, implying the electrical detection of the SNE of the Pt. To obtain more definite evidence, we also perform the similar experiment by using Ta wire. As seen in Fig.2(b), a clear rectangular shape signal is observed also in the Ta device. In the spin Hall effect, the sign of the spin Hall angle for Ta is opposite to that for Pt[5]. However, in the present experiment, we do not observe the sign reversal in the Ta. Although the reason is not clear at the moment, we may have to take into account the anomalous Nernst effect in the CoFeAl electrode.

AP-03. Spin diffusion length and polarization of ferromagnetic metals measured by a spin-absorption technique in lateral spin valves.
G. Zahnd[1], *S. Ghosh*[1], L. Vila[1], V. Pham[1], M. Cosset-Cheneau[1], W. Lim[1], A. Brenac[1], P. Laczkowski[1], A. Marty[1] and J. Attané[1] *1. University of Grenoble Alpes, CEA, CNRS, INP-G, IRIG-Spintec, Grenoble, France*

Recent advances in spinorbitronics have evidenced the need for new characterization techniques. Parameters such as the damping, the polarization, the spin diffusion length, the Dzyaloshinskii-Moriya interaction (DMI) or the spin Hall angle are key factors in understanding and controlling various mechanisms: spin transfer torque [1], spin texture due to DMI [2], or charge-to-spin conversion based on spin-orbit coupling effects at Rashba interfaces [3], in the bulk of spin Hall effect (SHE) materials [4], or in surface states of topological insulators [5]. We present measurements of pure spin current absorption on lateral spin valves. By varying the width of the absorber we demonstrate that spin current absorption measurements enable one to characterize efficiently the spin transport properties of ferromagnetic elements. The analytical model used to describe the measurement takes into account the polarization of the absorber. The analysis of the measurements thus allows the determination of the polarization and the spin diffusion length of a studied material independently, contrary to most experiments based on lateral spin valves where those values are entangled. We report the spin transport parameters of some of the most important materials used in spin-orbitronics ($Co_{60}Fe_{40}$, $Ni_{81}Fe_{19}$, Co, Pt, and Ta), at room and low (10 K) temperatures. The obtained spin-dependent transport parameters are relatively close to values found in the literature for Pt [6], CoFe [7], NiFe [8], and Ta. We find a very low spin diffusion length for Ta (2 nm), quite low for NiFe, CoFe, and Pt (5.3, 6, and 3.8 nm, at room temperature, respectively). In contrast, the spin diffusion length of Co is found to be on the order of 10 nm at room temperature, smaller than in previous reports.

AP-04. Observation of the spin-dependent Peltier effect in lateral spin valve. *R. Suko*[1], R. Matsuda[1], D. Ito[1] and T. Kimura[1,2] *1. Dep. Physics, Kyushu University, Fukuoka, Japan; 2. Quantum Spin Research Center of Kyushu Univ., Fukuoka, Japan*

The discovery of the thermally excited spin current promoted the research on the conversion between the spin and heat, so called as spin caloritronics. As an opposite phenomena, the spin-current induced heating and cooling effect, namely the spin(-dependent) Peltier effect, has been reported by several groups very recently. In the reports, they used a complicated nanostructures lateral and vertical hybrid nanostructures or specially developed thermometer in order to detect the tiny signal. If the efficiency of the spin-heat conversion is sufficiently large, one can observe the spin-dependent Peltier effect (SDPE) more simply. Here, we demonstrated a relatively simple way for detecting the spin-dependent Peltier effect using a conventional lateral spin valve. Figure 1 shows the SEM image of the lateral spin valve used for the present study. Here, we adapt the CoFeAl (CFA), which has a large spin-dependent Seebek coefficient, indicating an efficient SDPE. The pure spin current generated from CFA1 flow through Cu1 and is effectively absorbed into the CoFeAl 2. The absorbed spin current produces the heat current which heat or cool the CFA2. The temperature change of the CFA2 due to the SDPE can detected as the Seebeck voltage between CFA2 and Cu2. Figure 2 shows a representative nonlocal signal measured at 20 K. A spin-valve like signal due to the SPE with the magnitude of 30nV was clearly obtained. From the change of the resistance, one can estimate the temperature change due to SDPE as 0.5mK. In the presentation, we will reports SDPE for other ferromagnetic metals and their temperature dependence.

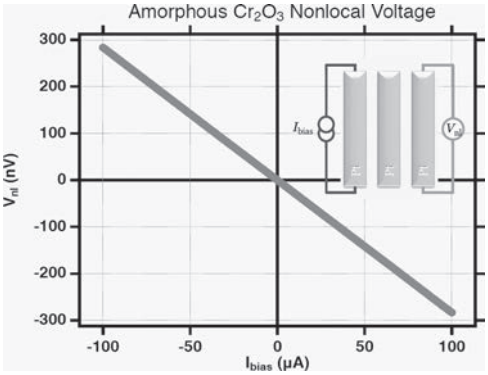
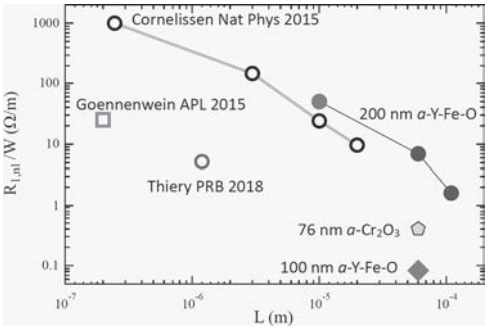
AP-05. Non-Reciprocal Spin Pumping in Asymmetric Magnetic Trilayers. *M. Pereiro*[1], Y. Pogoryelov[1], S. Jana[1], A. Kumar[2], S. Akansel[2], M. Ranjbar[3], D. Thonig[1], D. Primetzhofer[1], P. Svedlindh[2], J. Åkerman[3], O. Eriksson[1], O. Karis[1] and D.A. Arena[4] *1. Department of Physics and Astronomy, Uppsala University, Uppsala, Sweden; 2. Department of Engineering Sciences, Uppsala University, Uppsala, Sweden; 3. Department of Physics, University of Gothenburg, Gothenburg, Sweden; 4. Department of Physics, University of South Florida, Tampa, FL, United States*

In magnetic trilayer systems, spin pumping is generally addressed as a reciprocal mechanism characterized by one unique spin mixing conductance common to both interfaces. However, this assumption is questionable in cases where different types of interfaces are present in the material. Here, we present a general theory for analyzing spin pumping in cases with more than one unique interface. The theory is applied to analyze layer-resolved ferromagnetic resonance experiments on the trilayer system $Ni_{20}Fe_{80}$/Ru/$Fe_{49}Co_{49}V_2$ where the Ru spacer thickness is varied to tune the indirect exchange coupling. The results show that the spin pumping in trilayer systems with dissimilar magnetic layers is non-reciprocal. Our findings have importance on dynamics of spintronic devices based on magnetic multilayer materials.



(Color online) Trilayer system composed of Permalloy (1) and Permendur (2) layers separated by a layer of Ruthenium. On the right-bottom of the figure the coordinate system used for the analytical derivations is shown. The blue arrow represents the precession of the spin in the y-z plane used in the model while the black arrow indicates the direction of the external magnetic field. The sphere represents the locus of constant magnetization length while II stands for the plane tangential to the surface of the sphere. The red-yellow arrows indicate the static (α_{ii}) and dynamic (α_{ij}) spin pumping dampings due to the currents flowing in and out of the layers. The thickness of the magnetic layers is represented by d_1 and d_2.

AP-06. Spin Transport in Disordered Magnetic Insulators. *L.A. Hernandez*[1], M. Roos[1], D.J. Wesenberg[1] and B.L. Zink[1] *1. Physics and Astronomy, The University of Denver, Denver, CO, United States*



Much work has been done to explore spin transport through crystalline magnetic materials [1], yet recent work has shown that long range magnetic order is not a requirement for spin transport through insulators such as amorphous yttrium iron oxide (*a*-$Y_3Fe_5O_{12}$) [2]. Magnetic insulators are of special interest for applications in devices that use spin-based logic [3], and in this work we present the observation of spin transport in amorphous chromium oxide (*a*-Cr_2O_3), and the continued work on *a*-$Y_3Fe_5O_{12}$. Platinum leads inject spin current via the spin hall effect (SHE) and detect a non-local voltage (V_{nl}) via the inverse spin hall effect (ISHE) and the guard rail method is employed to mitigate electric charge leakage [4]. Results of 100 and 200 nm *a*-$Y_3Fe_5O_{12}$, and 76 nm *a*-Cr_2O_3 show a negative slope of the nonlocal voltage vs. injection current at 300 K, confirming the detection of a spin current via ISHE. Temperature dependence of *a*-$Y_3Fe_5O_{12}$ shows the onset of V_{nl} ~ 230 K corresponding with a feature in the magnetization. This gives more insight into the mechanisms of spin transport through

disordered magnetic insulators due to externally excited evanescent spin wave modes [5, 6]. Comparing the nonlocal spin transport of these disordered magnetic insulators with their crystalline counterparts shows that they are just as efficient at transporting spin angular momentum.

AQ-01. Comparison on the ΔE effect in $Fe_{87}Ga_{13}$ alloy by doping Dy and Tb. *H.W. Chang*[1], S.U. Jen[2], D. Tseng[3], W. Cheng[4], W. Chang[1] and C. Ouyang[5] *1. National Chung Cheng University, Chia-Yi, Taiwan; 2. Academia Sinica, Taipei, Taiwan; 3. Tunghai University, Taichung, Taiwan; 4. NTUST, Taipei, Taiwan; 5. National Tsing Hua University, Hsinchu, Taiwan*

Fe-Ga alloys have attracted increasing attention due to good mechanical properties and large saturation magnetostriction (λ_s) at low magnetic field for the potential applications at acoustic sensors and magnetoelastic devices and sensors [1]. λ_s of Fe-Ga alloy is reported to be significantly increased by adding small amounts of Tb [2]. However, the worse ductility for $Fe_{100-z}Ga_z$ alloys with high Ga content e.g. z = 19-27 may limit the applications even though large magnetostriction is obtained [1-2]. Distinct from the previous literatures, more ductile Ga-lean $Fe_{87}Ga_{13}$ master alloy is adopted in this work. R-doping effects on the mechanical properties including Young's modulus (E) at magnetic field (H), that is ΔE effect, magnetic properties, magnetostriction, and magneto-mechanical coupling of quenched $Fe_{86.8}Ga_{13}R_{0.2}$ alloys prepared by induction melting (R=Tb and Dy) are studied. $\Delta E_s/E_0$ effect of $Fe_{87}Ga_{13}$ alloy is 6%, and it is significantly enhanced to 12% by doping 0.2% Dy, but reduced to 4.5% for Tb-doped alloy. The magnetostrictive sensitivity (dλ/dH) with R is similar to that of ΔE with R. For $Fe_{86.8}Ga_{13}R_{0.2}$ alloys, $\Delta E_s/E_0$ is proportional to the square of the magneto-mechanical coupling factor (K^2), theoretically calculated in term of permeability (μ), dλ/dH. Most importantly, strong ΔE effect or K due to high dλ/dH for $Fe_{86.8}Ga_{13}Dy_{0.2}$ alloy favors for applications. Large ΔE effect or magneto-mechanical coupling is considered to correlate to modified phase constitution by doping Dy. For Tb-doped alloy, increased λ_s might be related to the increase of Ga content in the matrix due to the appearance of minor Tb_2Fe_{17} phase. The decreased dλ/dH might result from increased coercivity and decreased μ because of the induction of Tb_2Fe_{17} phase and result in reduced ΔE effect and K. The findings of this work provide an effective pathway of enhancing the ΔE effect for Galfenol alloys.

AQ-02. Extended X-ray Absorption Fine Structure Spectroscopy for Flexible Spintronics. *S. Ota*[1,2], T. Hirai[1,2], T. Ina[3], T. Koyama[2,4] and D. Chiba[2,4] *1. Applied Physics, The University of Tokyo, Bunkyo, Japan; 2. The Institute of Scientific and Industrial Research, Osaka University, Ibaraki, Japan; 3. Japan Synchrotron Radiation Research Institute, Sayo, Japan; 4. Center for Spintronics Research Network at Osaka University, Toyonaka, Japan*

Adding flexibility to spintronic devices yields new functions [1]. Flexible electronic devices generally aim to be immune to an external strain, whereas flexible spintronic devices can make use of sensitivity to the external strain via the magnetoelastic effect [2-4]. Interestingly, reversible change in a magnetic anisotropy of ferromagnetic thin films formed on a flexible substrate has been realized even when stretch-induced tensile strain in the substrate exceeds 1%. However, under such a large strain, a strain transfer from the substrate is unobvious. To determine directly the change in an atomic distance under applying tensile strain, we conducted the extended X-ray absorption fine structure (EXAFS) spectroscopy of a Co film on a polyethylene naphthalate substrate. Figure 1 shows radial distribution functions of a 7-nm-thick Co obtained by EXAFS. In the EXAFS measurement, polarization of the X-ray is parallel to the tensile strain, where the spectrum mainly reflects an atomic structure in the tensile direction. Here, a peak for the nearest neighbor atoms clearly shifts. Atomic distance change of 0.3% at 1.6% substrate strain is determined by fitting analysis. The large difference between the atomic distance change and the substrate strain can be explained by a calculation assuming that the Co has an fcc(111)-oriented polycrystalline structure. The calculation expects 0.45% atomic distance change at 1.6% substrate strain if the substrate strain is perfectly transferred to the Co film. Thus, the EXAFS result is ~30% smaller than the perfect-transfer condition, most likely because of the reduced strain transfer. We also note that the effective magnetoelastic constant (*B*) similarly decreases when the Co thickness is 7 nm (Fig. 2) [3]. The authors thank K. Ochi, M. Suzuki, T. Nakamura, T. Namazu, R. Nishino and M. Kawasaki for useful discussion and technical help. This work was partly supported by the JSPS KAKENHI (Grant No. JP17J03125) and Spintronics Research Network of Japan.

AQ-03. Controlling Acoustic Waves using Magnetoelastic Fano Resonances. *O. Latcham*[1], Y. Gusieva[2], A. Shytov[1], O. Gorobets[2] and V.V. Kruglyak[1] *1. University of Exeter, Exeter, United Kingdom; 2. Igor Sikorsky Kyiv Polytechnic Institute, Kyiv, Ukraine*

Magneto-elastic coupling between acoustic waves and magnetic procession may allow one to combine the low loss of acoustic waves and magnetic memory within the same devices. This may provide a route to devices that are more energy efficient than purely acoustic or magnetic devices. For instance, one can use acoustic waves as a signal carrier and then use their scattering from a magnetic inclusion as a means of control. Here, we explore theoretically how the strength of the magneto-elastic Fano resonance in the scattering of acoustic waves from an isolated magnetic slab (Fig.1) can be enhanced.[1] We find that the scattering strength is determined by the ratio of the linewidth due to the Gilbert damping and that due to the re-emission of acoustic waves. While the former is a material property, the latter depends on the magnetoelastic coupling strength, the slab width and the incidence angle. We calculate the ratio for different parameters of the slab and use it as a figure of merit by which to compare different magneto-elastic materials. We find that the oblique incidence angle may be used to enhance the resonant scattering (Fig.2) by enabling magneto-elastic coupling to the in-plane component of the elliptically polarized magnetic precession. In particular, an angle of incidence of about 15 degrees (Fig. 2) leads to a twofold increase in the figure of merit as compared to the normal incidence. The scattering strength may be further enhanced due to Bragg scattering in arrays of magneto-elastic slabs, which would thereby form a magnon-phonon crystal.

Acoustic waves are incident at an angle on a thin magnetic slab (M) embedded within a non-magnetic matrix (NM) and are scattered with the transmission and reflection coefficients *T* and *R* respectively.

The frequency dependence of he reflection coefficient from a magnetic slab in the region of the Fano resonance is shown for differenet angles of incidence.

AQ-04. Simulation Design of Magnetic and Thermal Properties of Magnetorheological Elastomer Bushing. *W.M. Kiarie*[1], E.J. Barron III[1], M.D. Bartlett[1] and D.C. Jiles[2] *1. Materials Science and Engineering, Iowa State University, Ames, IA, United States; 2. Electrical and Computer Engineering, Iowa State University, Ames, IA, United States*

This paper presents a model of magnetic and thermal properties of magneto-rheological elastomer (MRE) in a novel design of a Semi-active Suspension Bushing (SSB). MREs are a class of composite materials consisting of soft magnetic particles embedded into a polymer matrix. Under the influence of a magnetic field the MRE is activated causing a change of stiffness in the bulk. Suspension bushings are designed to dampen frequencies that may cause discomfort to the driver. These bushings are considered passive, for they work effectively for a limited range of frequencies as designed. If operated outside these frequencies, they eventually lose their effectiveness. Therefore, SSB is designed such that it adjusts its frequencies accordingly depending on the road surface conditions. For this reason, the ability to controllably change the stiffness of MRE makes it highly desirable for use in SSB. The geometry and the electromagnetic circuit design have strong influences on the magnetic flux density and heat transfer properties. For effective performance of the SSB, high magnetic flux density is needed to effect large changes in stiffness this requires a large multi-turn coil leading to significant amount of heat output that can degrade the MRE. To balance these complexities, a Finite Element Analysis (FEA) is carried out to create a novel SSB, that optimizes the magnetic flux density and decreases the heat generated due to resistive losses. From the analysis, this novel design is observed to have a 24% increment in average magnetic flux density throughout the MRE with uniform radial distribution and a significant decrease in the heat generated.

AQ-05. Modeling and Fabrication of a Thin-Film Magnetorheological Elastomer Composite using Iron (III) Oxide Nanoparticles. *D.A. O'Mahoney*[1], A. El-Ghazaly[2] and J. Bokor[3] *1. Materials Science and Engineering, University of California, Berkeley, Berkeley, CA, United States; 2. Electrical and Computer Engineering, Cornell University, Ithaca, NY, United States; 3. Electrical Engineering and Computer Science, University of California, Berkeley, Berkeley, CA, United States*

Magnetorheological elastomers (MREs) are gaining interest for a number of applications[1-3]. However, little has been done to explore their applications in flexible electronics. This work looks at the possibility of using MREs to create flexible, programmable tactile surfaces with predictable deformation control. We took steps in realizing this goal through finite element modeling and fabrication of an MRE thin film device. The MRE was molded and fabricated on top of a nonmagnetic, flexible substrate, to create areas of compression and tension on opposite sides of the film when exposed to a magnetic field. Local control of the magnetic field was modeled using a surface

array of GdCo nanomagnetic dots (Fig. 1). Magnetic field simulations in COMSOL showed shallow field penetration from the nanodots. Because of this, a thin film elastomer was fabricated using nanoscale iron (III) oxide particles with diameter less than 50 nm. Previously MREs have only been created using micron sized magnetic particles in much thicker films[1-4]. Films with smaller particles have not been studied. The composite was fabricated by spin coating 4" silicon wafers with lift-off resist, followed by 6μm of SU-8 as the flexible substrate. The MRE was made by combining 30% iron (III) oxide nanoparticles and 70% Dowsil 734 by volume. This was spun onto the wafers at varying speeds giving final composite thicknesses between 55μm and 80μm after release from the silicon wafer. Displacement of the film was measured using a varying, external out-of-plane magnetic field. Results (Fig. 2) show vertical deformation of the films, with thinner films producing larger displacement maximizing at 58μm with an applied field of 800 Oe. These findings show that nanosized iron (III) oxide particles in an MRE produce measurable deformation and can be used in creating thin MRE films. The technique of spin coating an MRE on top of an SU-8 substrate proved to be successful and COMSOL simulations suggest that the addition of a nonmagnetic layer does not prevent field induced deformation.

AQ-06. Hysteresis-free Highly Magnetostrictive Oxides. *S. Pokharel*[1], Z. Alyousef[1], M. Hassan[1], W. Morgan[1], M. Wuttig[2] and A. Lisfi[1] *1. Physics, Morgan State University, Baltimore, MD, United States; 2. Materials Science and Engineering, University of Maryland, College Park, MD, United States*

Hysteresis-free magnets displaying a large mechanical response under small magnetic fields are of a considerable interest to modern technology [1-2]. Cobalt ferrite can fulfill such requirement since it is distinguished by its large magnetostriction and good chemical stability. However, its moderate magnetization and large hysteresis can limit its technological performance. This research work aims to synthesize new ceramic material in the bulk phase that can exhibit a high magnetization and low anisotropy together with a sizable magnetostriction. The material of interest consists of Zn-doped cobalt ferrite, which is expected to offer the following enhanced properties over pure cobalt ferrite. (1) Doping with Zn can produce a significant increase in the magnetization. (2) The doped ceramic can display nearly hysteresis-free magnetic character while inheriting a large magnetostriction from cobalt ferrite. A series of Zn-doped cobalt ferrite samples was prepared with ball milling. The doped samples with different Zn concentrations were compacted and annealed at different temperatures up to 1500 °C. A good illustration of the enhanced properties is displayed in Fig. 1, which depicts the field dependence of the magnetization and the magnetostriction of Zn-doped cobalt ferrite prepared at 1400 °C. As shown by Fig. 1(a), the saturation magnetization of the Zn-doped sample (86 emu/g) exceeds that of pure single crystal cobalt ferrite (80 emu/g). Additionally, the material displays a reversible magnetic character with high magnetic susceptibility at low field and low saturation field. In term of striction, this doped ceramic exhibits a significantly large mechanical response (150 ppm) at low magnetic field. The detail of this investigation will be presented and discussed under a full study, which corroborates the results of this enhanced doped ceramic.

Field dependence of (a) the magnetization and (b) the magnetostriction of Zn-doped polycrystalline cobalt ferrite prepared at 1400 °C. Both the magnetization and the magnetostrictions are nearly hysteresis free and display high saturation values.

AQ-07. Magneto-optical Studies of Doped Magnetic Shape Memory Heusler alloys. *D. Kral*[1], V. Kopecky[2], L. Beran[1], J. Zemen[3], O. Heczko[2] and M. Veis[1] *1. Institute of Physics, Charles University, Prague, Czechia; 2. Institute of Physics, Academy of Sciences, Prague, Czechia; 3. Faculty of Electrical Engineering, Czech Technical University in Prague, Prague, Czechia*

Magnetic shape memory (MSM) alloys have been in the center of attention of many research groups for the past two decades. The MSM effect causes these extraordinary materials to strain to up to 12% of their original length if a moderate magnetic field (bellow 1 T) is applied[1]. This feature is rather appealing for contactless technology – its possible utilizations include sensorics and active/passive dumping, as well as a number of new paradigms,

such as contactless microfluidic pumps. The remarkable properties of MSM alloys are, however, rather limited by the temperature range in which the MSM effect occurs. Researchers have successfully used doping to widen this range[2], as it has been found that the effect is strongly influenced by changes in electronic structure. However, the exact relationship between the MSM effect and the electronic structure has not yet been found. We have investigated this relationship in a prototype MSM alloy, Ni-Mn-Ga. Electronic transitions manifest themselves in the spectral dependency of the dielectric tensor. Although one may obtain useful information by studying only its diagonal elements, the energies of the intraband transitions are more accurately determined from the off-diagonal parts[3]. In this work we studied bulk samples of Ni-Mn-Ga selectively doped with Fe. We have used spectroscopic ellipsometry along with magneto-optical spectroscopy to reconstruct the spectral dependency of both diagonal (Fig. 1) and off-diagonal (Fig. 2) parts of their dielectric tensor. The spectra have been parametrized using an original oscillator model to obtain energies of electronic transitions in the range from 0.7 to 6.5 eV. Our results are in excellent agreement with ab initio calculations, which proves that the mechanisms governing the operational range of MSM alloys can be easily studied by optical and magneto-optical methods.

AQ-08. Effect of film thickness on static and high frequency magnetic properties of $Fe_{100-x}Ga_x$ films with various Ga composition (x).

Y. Kawabe[1], T. Miyazaki[1,2] and Y. Endo[1,3] *1. Graduate School of Engineering, Tohoku University, Sendai, Japan; 2. Faculty of Engineering, Tohoku University, Sendai, Japan; 3. Center for Science and Innovation Spintronics, Tohoku University, Sendai, Japan*

Recently, much attention have been focused on magnetostrictive materials since their magnetostriction can be tuned easily by tensile stresses, electric fields and magnetic fields. Especially, Fe-Ga (Galfenol) alloys have been of much interest as one of the candidates for these materials because of their large magnetostriction, relative low saturation field, high Curie temperature, and good mechanical properties [1]. Therefore, Fe-Ga films are also studied intensively from both fundamental and application points of view. Previous reports on Fe-Ga films were focused on the effect of Ga composition on their static and high frequency (HF) magnetic properties [2-4]. While, details about the effect of film thickness on their properties are still open question. Herein, to clarify the effect of film thickness on static and HF magnetic properties of $Fe_{100-x}Ga_x$ films with several Ga compositions (x), we investigated their properties of these films in detail. Figure 1 shows change in the saturation magnetostriction (λ_s) and the in-plane effective damping constant ($\alpha_{//}$) in $Fe_{100-x}Ga_x$ films (x = 18.5, 24.9, and 33.4) with the film thickness (t). For every x, the tendency of λ_s for t is almost the same; λ_s increases for t < 30 nm, becomes maximum at t = 30 nm, and further decreases for t > 30 nm. Each value of λ_s becomes lower than those of a Fe-Ga alloy [1] and a polycrystalline Fe-Ga film [2]. In contrast, the relationship between $\alpha_{//}$ and t is the same for each x. In particular, $\alpha_{//}$ becomes maximum at t = 50 nm, and their $\alpha_{//}$ values are approximately 4 – 7 times as high as that of $Ni_{78}Fe_{22}$ films with the low magnetostriction. The reason for this might be due to the contribution of magnetic inhomogeneity such as large anisotropy dispersion, two-magnon scattering and so on. Therefore, it is suggested that both λ_s and $\alpha_{//}$ correlate each other for each x. This work was supported in part by JSPS KAKENHI Grant No. JP17H03226. This work was also supported in part by CIES collaborative research from CIES, Tohoku University, and ASRC in Japan.

AQ-09. Interplay between magnetic domains and antiphase boundaries in Ni-Mn-Ga compound.

O. Heczko[1], L. Straka[1], L. Fekete[1], M. Vronka[1,2] and M. De Graef[2] *1. Magnetic Measurement and Materials, FZU - Institute of Physics CAS, Prague, Czechia; 2. Materials Science and Engineering, Carnegie Mellon University, Pittsburgh, PA, United States*

Heusler Ni-Mn-Ga compound is considered as an example of magnetoelastic multiferroics. The manifestation of the coupling between ferromagnetic and ferroelastic ordering is magnetically induced structural reorientation (MIR). The dramatic consequence of MIR is giant, up to 12% magnetic field induced strain and 90 deg switch of magnetization direction [1]. Moreover, it was shown recently that the increased coercivity provides further functionality [2, 3]. To understand this behavior, we studied the interactions between magnetic domain walls, twin boundaries and antiphase boundaries (APB) using magnetic force microscopy (MFM) and Lorenz TEM. To observe APB by MFM we used newly developed method [4]. Lorenz TEM was used to confirm the MFM observation and to determine the thickness of magnetic domain walls in the presence of APB. Both methods for observation of APB utilize the magnetic contrast arising from different magnetic properties of the boundary and bulk [5]. The magnetic contrast is only way how to observe APB since the conventional TEM methods failed in this material. The example of APB observation is in Fig 1. As the in-plane magnetization crosses randomly distributed APBs the weak magnetic contrast is generated, which is detected by magnetic force microscopy. The contrast from APB is bi-colored and weak compared to single color of magnetic domain wall (also in Fig1) and thus can be easily recognized. With easy magnetization axis perpendicular to surface the APB contrast is inundated by strong contrast arising from magnetic domains. From the detailed analysis follows that most of the magnetic domain walls are pinned on the APBs which agrees well with LTEM observation. Moreover, LTEM indicates that the magnetic domain walls pinned on the APB are much thinner compared to free domain walls [6]. It indicates that the pinning of magnetic domain walls on the APBs can be the main coercivity mechanism in 10M martensite and explain why increased density of APBs strongly enhances the magnetic coercivity [7].

AQ-10. Modeling Low-Frequency Short-Range Mechanical Communication. *M.E. Goforth*[1] and J.P. Domann[1] *1. Biomedical Engineering and Mechanics, Virginia Tech, Blacksburg, WV, United States*

With respect to current methods, communicating at sub-VLF (<3kHz) frequencies is very difficult to achieve due to hardware constraints. Additionally, many applications such as communicating under water and in mines are practically impossible by propagating conventional electromagnetic waves. Conceptually, a device that only alters its surrounding magnetic field would be able to fill this current gap in technology. A model was developed to analyze a macroscale layered composite consisting of an aluminum beam coupled to a layer of magnetoelastic material which is driven at frequency by a piezoelectric layer. This device takes an electric signal to the piezoelectric layer which in turn vibrates the aluminum beam at a prescribed frequency (~1 kHz). The vibrating beam thus strains the magnetoelastic material altering its magnetization which affects the field surrounding the device. The model is on the continuum level which has been built up from the principles of micromagnetics. Since the operating frequencies being considered are "low," the LLG equations cannot be used. Hence, Boltzmann statistics have been used incorporating the magnetocrystalline, magnetoelastic, and Zeeman energies. The numerical FEA model takes prescribed initial conditions and material properties and inputs them into a segregated solver. The state of stress is first determined and this information is fed into the nonlinear constitutive solver. Here, Boltzmann statistics and a function for total energy are used to determine the most probable state of magnetization which determines the state of the surrounding magnetic field. The cycle continues with the state of stress being determined for the next step. The model has compared well to data presented in the literature, as well as inform experiments and prototypes attempting to prove the concept of "mechanical" communications.

AQ-11. EXAFS Analysis of SmFe2 Thin Films with Perpendicular Magnetic Anisotropy for Piezoelectric Magnetic Tunnel Junctions. *Y. Takamura*[1], H. Onozawa[1], S. Urashita[1], M. Tomita[1] and S. Nakagawa[1] *1. Department of Electrical and Electronic Engineering, Tokyo Institute of Technology, Tokyo, Japan*

Perpendicular magnetic tunnel junctions with a giant magnetostrictive free layer whose side wall is covered by piezo-electric materials, piezo-electric tunnel junctions (PE-MTJ) [1], is a promising spin device which overcome an intrinsic dilemma between high thermal stability and reducing critical current density for spin transfer torque magnetization switching. On a magnetization switching operation in PE-MTJs, the piezoelectric part applies pressure to the MTJ so that the magnetic anisotropy in the free layer, meaning energy barrier for magnetization switching, is lowered by inverse-magnetostrictive effect. Thus, the critical current density is dramatically reduced. As the free layer materials, we have been developed negative giant magnetostrictive $SmFe_2$ thin films, and successfully formed $SmFe_2$ thin films with perpendicularly magnetic anisotropy (PMA) by systematic investigation. However, the $SmFe_2$ thin films are amorphous, and thus the origin of the anisotropy is not understood. In this study, we carried out polarized extended X-ray absorption fine structure (EXAFS) measurements on $SmFe_2$ thin films with PMA to investigate the anisotropy in the coordination number. $SmFe_2$ thin films were sputter-deposited on W-buffered quartz substrates and capped with W. The standard condition of a substrate temperature during sputtering and post annealing temperature were 200°C and 500°C respectively. EXAFS measurements were done at a beamline BL-9C in High Energy Accretor Research Organization (KEK). EXAFS signals for Sm-L3 edges were clearly different between perpendicular and in-plane configurations, implying the existence of the difference in the coordination number neighboring a Sm atom in the depth direction and in-plane directions of the $SmFe_2$ films. This anisotropy can be the origin of the magnetic anisotropy and would be useful for further development of high quality giant magnetostrictive materials. This work was supported by JSPS KAKENHI Grant Number 18K18853. This work was performed under the approval of the Photon Factory Program Advisory Committee (Proposal No. 2018P004).

AQ-12. Fabrication and magnetocaloric effect of Ni_2MnGa Heusler alloy nanowires. *Y. Zhang*[1], F. Qin[1], D. Estevez[1] and H. Peng[1] *1. Zhejiang University, Hangzhou, China*

As a type of functional material for multiple devices and sensors, Ni-Mn-Ga Heusler alloy has many attractive characteristics such as magnetic-field-induced strain (MFIS) and magnetocaloric effect (MCE). Much work has been done to prepare and study bulk, films, microwires and powders of Ni-Mn-Ga. It was found that the properties like mechanisms of phase

transition of Ni-Mn-Ga varied as its form changed. Among others, Ni-Mn-Ga nanowires remain to be investigated in terms of their structure and magnetic properties. Experimentally, Ni_2MnGa Heusler alloy nanowires were fabricated using electrospinning method. Optimized calcination and reduction annealing treatments warrant stable and uniform 2:1:1 phase structure which is expected to make vital contribution to magnetic property. The nanowires exhibit a magnetic phase transition between ferromagnetic and paramagnetic state near room temperature, as is in accordance with the mechanism existed in other forms of Ni-Mn-Ga alloys. However, positive slope in Arrott plot indicates that the scale of the magnetic phase transition is second order on contrary to most Ni-Mn-Ga bulk alloys. Moreover, due to the peculiarity of preparing method which results in small sum of residual antiferromagnetic oxides of transition metals, competition between ferromagnetic and antiferromagnetic phases is believed to lead to thermodynamic irreversibility at relatively low temperatures, as revealed by splitting feature observed from zero-field-cooled (ZFC) & field-cooled (FC) curves. For the interest of finding out the magnetocaloric effect of these Ni_2MnGa nanowires, the isothermal entropy change ($-\Delta S_m$) was calculated to be 0.35 J/(kgK), which is comparable to that of some Heusler alloy microwires, powders and films. It is worth noticing that the nanowires possess a fairly large working temperature range (T_{FWHW}) of 170 K which is much larger than that of many crystalline magnetocaloric materials; this could be attributed to the variety of subsystems caused by size distribution and composition fluctuation, which is outstanding at the nanoscale.

Heusler alloys can present magnetocaloric effect (MCE) [1,2], ferromagnetic shape-memory effect, half-metallic behaviour, and even superconductivity [1]. The conventional preparation method of Heusler alloys is arc-melting, followed by prolonged high temperature annealing [1,2]. However, recently rapidly quenching technique has been successfully employed for the Heusler-type ribbons and wires preparation [3,4]. This technological advance is of fundamental importance since most the proposed applications require miniaturized of Heusler-type materials [2-4]. The origin of high MCE effect of Heusler alloys is usually related to the first-order phase transition. However, the magnetic hysteresis that appears for first-order phase transitions may reduce the actual efficiency of the cooling process. Therefore, studies of the materials exhibiting the second-order phase transitions with a broader peak in the magnetic entropy change have attracted attention [5]. We present our last results on the tuning of the second-order phase transitions in Heusler-type NiMnGa glass—coated microwires prepared using Taylor-Ulitovsky method by annealing at temperatures ranging from 550 up to 750 ^oC. As-prepared Ni-Mn-Ga microwires exhibit a very weak magnetization at room temperature. However, annealed samples present ferromagnetic behaviour and second-order phase transition at nearly room temperatures. Additionally, both temperature dependence of magnetization, *M(T)*, as well as the corresponding Curie temperature, T_c, are considerably affected by the annealing conditions (annealing temperature and duration). Mixing of glass-coated microwires annealed at different conditions within the same bunch allows tuning of *M(T)* dependence and hence obtain broader second-order phase transition (see Fig). As discussed elsewhere [5] such expanding the temperature range over which a significant magnetic entropy change can be obtained is beneficial for the improvement of the refrigerant capacity. Observed *M(T)* and T_c dependence on annealing conditions has been discussed considering the relaxation of internal stresses distributed in complex way within the microwires.

Temperature dependencies of magnetization of NiMnGa microwires.

AQ-14. Substitution effects on the magnetic phase transition and magnetocaloric effects in nanolaminated $AlFe_2B_2$ alloys. Y. Yan[1], T. Chen[2], *J. Chen*[3], Y. Yang[1], P. Jia[1], W. Cui[1,2] and Q. Wang[1] *1. Northeastern University, Shenyang, China; 2. Lanzhou University of Technology, Lanzhou, China; 3. Institute Of Electronics, CAS, Beijing, China*

Recently, a kind of novel transition-metal boride, called as MAB phase, possesses a general formulae of $(MB_2)_nMAl$ (n = 1, 2, 3) and layered crystal structure. M can be Cr, Mn, Co elements. But only for M = Fe, AlFe2B2 is ferromagnetic with phase transition temperature ranged between 280 ~ 320 K[1]. Due to the second-order nature, no hysteresis is desired and some attentions are paid to explore it as emerging magnetocaloric materials. In this work, the substitution effects of C for B and Ti, V for Fe have been studied. All alloys were prepared by arc-melting. The as-prepared ingots were annealed at 800ºC for 4 days followed by quenching into iced water. Structures and magnetic properties are studied by Bruker diffractometer and cryogenic VSM. The XRD patterns of AlFe2B2-xCx, AlFe2-yTiyB2 and AlFe2-zVzB2 show that the single-phase can be formed for x≤0.1, y<0.1 and z <0.1. More substitution leads into the impurities. The thermal magnetization curves of AlFe2B2-xCx alloys are shown in Fig. 1. The FM-PM phase transition occurs at 283K. With increased C substitution, the Tc is gradually increased. However, the almost flat M-T curve is observed for x=0.3 due to the decomposition of main $AlFe_2(B,C)_2$ phase. By minor Ti and V substitution for Fe, the T_c is decreased to 280 K due to magnetic dilution. Increased substitution does not further lead into decreased T_c due to the possible substitution limitation. All isothermal magnetization curves are reversible, indicating the second-order nature. The delta S is maximized at their respective T_c. Under the field of 7 T, delta Smax is 6.4 Jkg-1K-1. More C substitution leads into decreased delta Smax to 4 Jkg-1K-1 in $AlFe_2B_{1.9}C_{0.1}$, 4.8 Jkg-1K-1 in AlFe1.9Ti0.1B2 and 5 Jkg-1K-1 in AlFe1.9V0.1B2, due to the decreased magnetization.

AQ-15. Lattice entropy change evaluated based on Debye approximation for $LaFe_{13-x}Si_x$ magnetocaloric materials. *Z. Yu*[1,2], J. Hao[1,3], F. Hu[1,2], J. Wang[1,2], J. He[3], J. Sun[1,2] and B. Shen[1,2] *1. Beijing National Laboratory for Condensed Matter Physics & State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2. School of Physical Sciences, University of Chinese Academy of Sciences, Beijing, China; 3. Division of Functional Material Research, Central Iron and Steel Research Institute, Beijing, China*

$La(Fe,Si)_{13}$-based materials have attracted many attentions since their discovery for giant magnetocaloric effect (MCE)[1,2]. The typical feature of $LaFe_{13-x}Si_x$ with first-order phase transition is the concurrent magnetic and lattice transitions. However, the lattice entropy change is usually difficult to measure. Gschneidner et al. found a relationship between the lattice entropy change and the lattice deformation (ΔV/V), which is given by $\delta[\Delta V/V(\%)]/\delta[\Delta S_{latt}]=0.08$(J/kgK)[3]. Yet, this empirical relationship is a rough approximation ignoring the specific Grüneisen parameter and Debye temperature, which affect the accurate evaluation of lattice entropy. Here, we report lattice entropy change evaluated based on Debye approximation for $LaFe_{13-x}Si_x$. Fig.1a displays the lattice parameter as a function of temperature for $LaFe_{13-x}Si_x$ with various Si concentrations. One can notice that the sharpness and the amount of lattice change around T_C become steeper and larger with the phase transition evolution from second-order to first-order. Fig.1b shows the calculated lattice entropy as a function of temperature after deducting the general contribution from lattice vibration. One can notice that the change of lattice entropy across phase transition can be as much as ΔS_{Latt} ~11.2 J/kg K for the $LaFe_{13-x}Si_x$ with x=1.2, and the ΔS_{Latt} increases linearly with decreasing Si content x (inset of Fig. 1b). We also measured the total entropy change ΔS_{Tot} across phase transition from heat flow curve using DSC instrument, and found the numerical value of ΔS_{Tot} increases from 2.4 to 28.3 J/kg K as Si content decreases from x=2.2 to 1.2 (Fig. 1c). For the materials with x=1.2, the ΔS_{Latt} accounts ~39% of ΔS_{Tot}. In addition, we also comparably measured the magnetic entropy change using the so-called normal and loop methods based on Maxwell relationship for the first-order compound with x=1.3[4]. The normal and loop methods can give consistent results in the process of descending magnetic field (Fig. 1d). The entropy change (~27.5 J/kg K) driven by 5 T almost reaches the total ΔS_{Tot} across phase transition.

AQ-17. Magnetostructural Phase Transitions and Magnetocaloric Effects in Sb Doped MnCoGe. *A. Aryal*[1], I. Dubenko[1], S. Talapatra[1], S. Stadler[2] and N. Ali[1] *1. Physics, Southern Illinois University, Carbondale, IL, United States; 2. Physics and Astronomy, Louisiana State University, Baton Rouge, LA, United States*

The effect of Sb doping on the structural, magnetic and magnetocaloric properties of the $Mn_{1-x}Sb_xCoGe$ system ($0 \le x \le 0.04$) have been investigated by room temperature X-ray diffraction, differential scanning calorimetry (DSC), and magnetization measurements. A change in crystal structure from orthorhombic to hexagonal was observed in the room temperature XRD data with increasing Sb concentration. Doping Sb for Mn in $Mn_{1-x}Sb_xCoGe$ results in a decrease in the martensitic transition temperature T_M. For the concentration range $0 \le x \le 0.015$, T_M was found to coincide with the ferromagnetic transition temperature (T_C), resulting in a first-order magnetostructural transition (MST) from paramagnetic hexagonal phase to ferromagnetic (FM) orthorhombic phase near room temperature. A drastic decrease in T_M by ~ 177 K relative to parent compound was found for x = 0.02. As T_M decreased below T_C (~ 268 K) of hexagonal phase a MST from FM hexagonal to FM orthorhombic phase was observed for compound with x = 0.02. Maximum values of magnetic entropy change in the vicinity of MST were found to be about 14.0 $Jkg^{-1}K^{-1}$, 10 $Jkg^{-1}K^{-1}$ and 8.5 $Jkg^{-1}K^{-1}$ for x = 0.01, 0.015 and 0.02, respectively, for ΔH = 5T. The large values of the ΔS_M at the first-order MST illustrates the potential of $Mn_{1-x}Sb_xCoGe$ compounds to be used in magnetic cooling technology. In this work $Ni_{45}Co_5Mn_{(37-x)}In_{(13+x)}$ alloys (x= 0, 0.4) were prepared using induction arc melting under argon atmosphere and their crystal structure, magnetostructural transitions, microstructures, magnetic, and magnetocaloric properties were systematically studied. The attributes of magnetostructural coupling have an important role in the magnetic behavior of these magnetofunctional alloys. This research exhibits that a strong magnetostructural coupling can be achieved over a wide temperature range in this alloy family. The M(H) and M(T) were measured under different fields and temperatures for the synthesized samples. The area between ascending and descending M(H) loops were calculated to study the hysteresis losses and to minimize their effect on the overestimation error of magnetic entropy change and relative cooling power. The effect of varying stoichiometry composition and applied magnetic field on the Curie temperature, magnetostructural transitions, magnetic and magnetocaloric properties and relative cooling power were studied. The impediment hysteresis losses of these alloys that have a first order phase transmission were considered to eliminate the overestimation of the magnetic entropy change using Maxwell's relations [1]. It's shown that by increasing the applied field the peak of entropy change curves shifts to lower temperatures. Additionally, a small variation in the stoichiometry composition broadens the magnetic entropy change curve and shifts the critical temperatures by about 36 K to around room temperature. Furthermore, the magnetization change accompanying the martensitic transformation is greatly improved, resulting in a large magnetic entropy change of 31 $Jkg^{-1}K^{-1}$ under 5 T across the magnetostructural transformation which is much higher than the values reported for other Ni-Mn rich alloys in literature. The broadened and higher peak of the entropy change curves produced a significantly high relative cooling power in $Ni_{45}Co_5Mn_{36.6}In_{13.4}$ (488 JKg^{-1}) and $Ni_{45}Co_5Mn_{37}In_{13}$ (317 JKg^{-1}) under 5 T applied field. These results are especially promising in finding high-performance magnetocaloric material for magnetic refrigeration systems [2-4].

AQ-19. Magnetostructural transition and large magnetocaloric effect in transition metal-based multicomponent alloy with Ni_2In-type crystal structure. *A. Biswas*[1], A.K. Pathak[1], Y. Mudryk[1], V. Balema[1] and V.K. Pecharsky[1,2] *1. Ames Laboratory of US DOE, Ames, IA, United States; 2. Materials Science and Engineering, Iowa State University, Ames, IA, United States*

The coupling between structural and magnetic transitions in magnetic materials is paramount for a plethora of functional properties of materials including shape memory effect, barocaloric effect (BCE) and magnetocaloric effect (MCE). Recently, several Mn-containing compounds with the general formulae Mn*TX* (*T* = transition metal *X* = p-block element) have been reorted to exhibit magneto-structural transitions (MST)[1-3]. Generally, stoichiometric Mn*TX* alloys undergo martensitic structural transitions between the low-temperature TiNiSi-type orthorhombic and the high-temperature Ni_2In-type hexagonal phases in their paramagnetic states. Same materials also exhibit second-order magnetic transitions adopting different magnetic structures in various temperature regions depending on the composition. For example, MnNiSi has a structural transition around T_t ~ 1200 K, which is followed by a paramagnetic to ferromagnetic (FM) transition at T_C ~ 622 K[1]. By substituting Fe and Cr in Mn-site and Al in Si-site, we demonstrated that these two transitions can be coupled near room temperature, e.g., in $Mn_{0.4}Cr_{0.1}Fe_{0.5}NiSi_{0.94}Al_{0.06}$, resulting in an MST. Such coupling is rather uncommon among Mn*TX* alloys that do not contain expensive p-block elements, such as Ge or Ga. The Cr, Mn, and Al-substituted MnNiSi alloy exhibits large MCE with magnetic entropy change DS_M = -11 J/ Kg K at 2 T in the vicinity of its MST at ~270 K, which is comparable with other potential magnetocaloric materials[4]. Our results reveal a new potential magnetocaloric material, which is free from non-abundant elements, and is prepared by a simple, one-step arc-melting process. AR-01. Phase modification and coercivity improvement of melt spun $LaCo_5$ ribbons by Ti, Zr, or Hf substitution. *H.W. Chang*[1], Y. Guo[1], W. Chang[1], Y. Wong[1] and C. Shaw[2] *1. National Chung Cheng University, Chia-Yi, Taiwan; 2. Superrite Electronics Co. Ltd., Taipei, Taiwan*

Since the price surge of critical RE elements in 2011, it is significant to explore the RE-free or other abundant RE-containing permanent magnetic materials. La, one of the most abundant RE elements, is much cheaper than Nd, Pr, Sm, and Y due to its less usage. Unlike $SmCo_5$ alloy, $LaCo_5$ has not been attracted much attention due to the easy formation of impurity phases, such as $LaCo_{13}$ (1:13), La_5Co_{19} (5:19) and La_2Co_7 (2:7), despite its good magnetically intrinsic properties. The study related to the magnetic properties of $LaCo_5$ alloys so far is rare, and only ball-milling and mechanochemical synthesis to prepare $LaCo_5$ alloys are available. In this work, melt spinning is adopted to prepare $LaCo_5$-based ribbons, and the magnetic properties, crystal structure and microstructure of $LaCo_{5-x}M_x$ ribbons (M= Ti, Zr, and Hf; x=0.05-0.1) spun at 40 m/s are explored. Very low ${}_iH_c$ =0.8 kOe is obtained for $LaCo_5$ ribbon. Nevertheless, permanent magnetic properties of $LaCo_5$ ribbons are significantly enhanced by Ti, Zr, and Hf substitution for Co. The ${}_iH_c$ of the as spun ribbons is increased to 2.7-9.0 kOe for M=Ti, 5.2-8.1 kOe for M=Zr, and 4.8-9.0 kOe for M= Hf, respectively. The 2:7 and 1:13 phases diminished by M substitution with x=0.05, and almost suppressed for x=0.1 reveal that Ti, Zr, or Hf substitution is effective in suppressing the formation of impurity phases, stabilizing 1:5 phase, and accordingly enhancing the coercivity of the ribbons. XRD result analyzed by Rietveld refinement indicates that M tends to occupy 3g sites in 1:5 structure and the lattice constants are slightly changed. The occupancy of M at 3g sites may improve magnetocrystalline anisotropy field and thus contribute to coercivity enhancement and slight decrease in Curie temperature. M-doping is also helpful in refining the grain size from 100-150 nm to 30-50 nm and contributes to remarkable improvements of ${}_iH_c$ and the squareness of demagnetization curve. Besides, the coercivity of $LaCo_{5-x}M_x$ ribbons is mainly dominated by nucleation mechanism. Summarized with the above results, the suppressed impurity phase, the modified phase constitution, and the refined microstructure with M substitution significantly enhance coercivity of melt spun $LaCo_5$ ribbon.

AR-02. Structure factor and 3d - valence electron concentration considerations towards stabilization of the $SmFe_{5-y}Co_yNi_z$ phases using the high entropy alloy concept: special case $SmFe_3CoNi$. *D. Niarchos*[1,2], M. Gjoka[1], V. Psycharis[1] and E. Devlin[1] *1. Department of Materials Science, INN, NCSR "Demokritos", Athens, Greece; 2. AMEN-Technologies, Athens, Greece*

Although RCo5 (R=Rare-Earth) alloys with the CaCu5-type structure are stable and can be processed to make magnets withe nergy products in the range of 20-25MGOe, their Fe-rich counterparts with the same structure in bulk form are thermodynamically unstable [1].The energy of formation for the series $SmTM_5$ (TM=Fe, Co,Ni) is related to the number of 3d electrons in the system: the more 3d electrons, the more stable is the compound [2,3]. For example $SmNi_5$ is very stable, $SmCo_5$ less stable, and $SmFe_5$ unstable (positive energy of formation) as is seen in Fig. 1a. Given that the structure factors R_{Sm} and R_{TM} are almost the same across the $SmTM_5$ (TM=Fe, Co,Ni) series, the 3d electron concentration and the valence electron concentration are the important parameters for the stability of Fe-rich phases. In such structures the rare earth occupies the 1a site while the transition metal ions occupy two crystallographically different sites, 2c and 3g, in the space group P6/mmm, as shown in Fig. 1b. Previous efforts to substitute Co with Fe slightly improved the magnetization but the substitution is limited to less than 10 % [4]. In this work we will present data based on the high entropy alloy concept of the transition metals Fe_3Co-(Ni,Cu) [5]. In Fig. 2 we summarise our approach to creating $SmFe_3Co$-(Ni,Cu) by considering the heat of formation and the valence concentration of the stable compounds $SmNi_5$, $SmCo_5$ and $SmCu_5$, which, together with the structure factor, lead to the series $SmFe_3\{Co_{1-x}(Ni,Cu)_x\}$. A long anneal is needed to allow the diffusion of Co, Ni and Cu elements to occupy the remaining 2c sites, Fig. 1b. Crystallographic and magnetization data will be presented, which show a promising new magnetic material for permanent magnet applications. AR-03. Effect of B on the Magnetic Properties for Sm-Fe-Co Thin Films. *Y. Tamazawa*[1], M. Kambayashi[2], G. Saito[1], M. Doi[1] and T. Shima[1] *1. Graduate School of Engineering, Tohoku Gakuin University, Tagajo, Japan; 2. Department of Electronic Engineering, Tohoku Gakuin University, Tagajo, Japan*

RFe$_{12}$ compounds with the tetragonal ThMn$_{12}$-type structure have been reported [1-4] and they are expected to show outstanding magnetic properties better than Nd-Fe-B sintered magnets, since RFe$_{12}$ compounds possess high saturation magnetization M_s and large magnetocrystalline anisotropy K_u. Recent study revealed that the addition of a light element nitrogen to the RFe$_{12}$ compounds can improve the magnetic properties by changing the average interatomic distances between Fe and Fe [5]. However, the influence of other light elements on the structure and magnetic properties of Sm(Fe, Co)$_{12}$ compounds has not been reported. In this study, Sm (Fe$_{0.8}$Co$_{0.2}$)$_{12}$B thin films with various B content and film thicknesses have been fabricated and their structure and magnetic properties have been investigated. The samples were prepared by using ultrahigh vacuum magnetron sputtering system with base pressure of less than 1.0×10^{-8} Pa. A V underlayer of 20 nm was deposited onto the MgO (100) single crystal substrate at T_s = 325 °C. Then, the Sm$_{11.3}$(Fe$_{0.8}$Co$_{0.2}$)$_{88.7}$B layer of 5 to 200 nm was deposited. The amount of B to the Sm$_{11.3}$(Fe$_{0.8}$Co$_{0.2}$)$_{88.7}$B layer was varied from 0 to 9 %. Finally, the V cap layer of 10 nm was deposited for the prevention of oxidation. The structural analysis was performed by the X-ray diffraction (XRD) and grazing incident X-ray diffraction (GIXD) with Cu-Kα radiation. The magnetization curves were measured by using a superconducting quantum interference device (SQUID) magnetometer in the magnetic fields up to ±70 kOe. The film composition was determined by an energy dispersive X-ray spectroscopy (EDX). All the measurements were performed at room temperature. From XRD patterns, the peak position of (002) and (004) from ThMn$_{12}$ phase was shifted to higher angle with increasing B content. From magnetization curves, H_c as high as 9.4 kOe was obtained in the Sm$_{11.3}$(Fe$_{0.8}$Co$_{0.2}$)$_{88.7}$B (100 nm) thin film when the amount of B addition is 5 at.%. Effect of the amount of B and film thickness on the crystal structure and magnetic properties for Sm(Fe, Co)$_{12}$ compounds will be discussed at the conference.

AR-04. Magnetic properties of Sm(Fe,Zr)$_3$ melt-spun ribbons. T. Saito[1], T. Horita[1] and *Y. Ogawa*[1] *1. Chiba Institute of Technology, Narashino, Japan*

The SmFe$_3$ phase is a ferromagnetic phase with a rhombohedral structure [1-3]. It has been reported that the specimens with the SmFe$_3$-type phase exhibited coercivity and the coercivity of the SmFe$_3$-type phase can be improved by the small addition of zirconium (Zr) [4,5]. In order to examine the effects of Zr addition to the SmFe$_3$ phase, several Sm(Fe,Zr)$_3$ melt-spun ribbons were prepared in this study. The relationships between the structures and magnetic properties of the Sm(Fe,Zr)$_3$ melt-spun ribbons are examined. (Sm$_{1-x}$Zr$_x$)Fe$_3$ (x = 0–0.4) alloy ingots were prepared by induction melting under an argon atmosphere. The alloy ingots were induction melted and then ejected through an orifice with argon onto a copper wheel rotating at a surface velocity of 40 ms^{-1}. The melt-spun ribbons were annealed under an argon atmosphere at 773-1273 K for 1 h. The as-quenched melt-spun ribbons consisted of either fully or partly of the amorphous phase and showed low coercivity values. Heat treatment of the melt-spun ribbons resulted in the formation of the (Sm,Zr)Fe$_3$ phase. Figure 1 shows the dependence of the coercivity of the (Sm$_{1-x}$Zr$_x$)Fe$_3$ (x = 0–0.4) melt-spun ribbons on the annealing temperature. The coercivity of the melt-spun ribbons was drastically increased by heat treatment. The coercivity of the SmFe$_3$ melt-spun ribbon showed the maximum value when it was annealed at 973 K, while that of the (Sm$_{0.7}$Zr$_{0.3}$)Fe$_3$ melt-spun ribbon reached its maximum when annealed at 1173 K. The highest coercivity of 11.3 kOe was achieved in the (Sm$_{0.7}$Zr$_{0.3}$)Fe$_3$ melt-spun ribbon annealed at 1173 K.

AR-05. Production of anisotropic SmFe$_3$ magnets by hot deformation. *Y. Ogawa*[1], T. Saito[1] and D. Nishio-Hamane[2] *1. Chiba Institute of Technology, Narashino, Japan; 2. Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan*

It has been reported that the SmFe$_3$ phase is a ferromagnetic phase with a rhombohedral structure and that it is magnetically anisotropic [1–3]. Thus, the SmFe$_3$ phase can be considered as a possible candidate for permanent magnets if anisotropic magnets can be produced. In the case of Nd-Fe-B magnets, anisotropic Nd-Fe-B magnets have been produced by either the sintering of Nd-Fe-B powder or hot deformation of hot-pressed Nd-Fe-B magnets. The objective of the present study was to produce anisotropic SmFe$_3$ magnets by the hot deformation of hot-pressed SmFe$_3$ magnets.

The structures and magnetic properties of the hot-deformed $SmFe_3$ magnets are discussed. $SmFe_3$ alloy ingots were prepared by induction melting in an argon atmosphere. The alloy ingots were were induction melted and then ejected through an orifice with argon onto a copper wheel rotating at a surface velocity of 40 ms^{-1}. The melt-spun ribbons were comminuted into powders and then hot-pressed in a vacuum at 823 K under a pressure of 100 MPa by the spark plasma sintering (SPS) method. Hot deformation of the hot-pressed $SmFe_3$ magnets was performed in a vacuum at 973–1073 K under a pressure of ~200 MPa by the SPS method. X-ray diffraction and thermomagnetic studies revealed that the hot-deformed $SmFe_3$ magnet consisted of the $SmFe_3$ phase. Figure 1 shows the hysteresis loops of the $SmFe_3$ magnets hot-deformed at 1023 K, measured parallel and perpendicularly to the pressing direction. The magnetic anisotropy of the hot-deformed $SmFe_3$ magnets was confirmed by the existence of a higher remanence in the parallel direction than in the perpendicular direction. This indicates that anisotropic $SmFe_3$ magnets were successfully produced by the hot deformation of hot-pressed $SmFe_3$ magnets.

AR-06. Synthesis of $SmFe_5$ intermetallic compound. *T. Saito*[1] and D. Nishio-Hamane[2] *1. Chiba Institute of Technology, Narashino, Japan; 2. Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan*

Many efforts are being made to obtain new permanent magnet materials. One of the most promising candidates is the $SmFe_5$ phase, which has a hexagonal structure like that of the well-known $SmCo_5$ magnet. The $SmFe_5$ phase is a metastable phase and its formation has been reported only in sputtered films. It has been reported that the $SmFe_5$ phase can be stabilized by the addition of zirconium or titanium [1–3]. However, the addition of a nonmagnetic element results in a reduction of the saturation magnetization of the $SmFe_5$ phase. Since the formation of several metastable phases has been reported in binary Sm-Fe alloys [4], the $SmFe_5$ phase might be able to be produced by a rapid solidification process such as melt-spinning. The purpose of this study was to seek the possibility of producing binary Sm-Fe alloys with the $SmFe_5$ phase by optimizing the annealing conditions of rapidly quenched melt-spun ribbons. The relationship between the structures and magnetic properties of the Sm-Fe melt-spun ribbons is discussed. The $SmFe_5$ intermetallic compound was synthesized by the melt-spinning technique and subsequent annealing, as follows. $SmFe_5$ alloy ingots were prepared by induction melting under an argon atmosphere. The molten alloy ingots were then ejected through an orifice with argon onto a copper wheel rotating at a surface velocity of 40 ms^{-1}. The melt-spun ribbons obtained from this process were annealed under an argon atmosphere at 773–1273 K for 1 h. The specimens were examined by an X-ray diffraction (XRD) system, transmission electron microscope (TEM), and vibrating sample magnetometer (VSM). The TEM study revealed that the as-rapidly quenched $SmFe_5$ melt-spun ribbon consisted of nano-sized $SmFe_5$ grains. Subsequent annealing resulted in the crystal growth of the $SmFe_5$ grains. The optimally annealed $SmFe_5$ melt-spun ribbon exhibited a coercivity exceeding 1 kOe. Figure 1 shows a TEM micrograph of the $SmFe_5$ melt-spun ribbon annealed at 1073 K. The annealed specimen consisted of fine $SmFe_5$ grains of around 100 nm in diameter.

AR-07. Effect of Secondary Aging On Magnetic Properties of 2:17 SmCo Commercial Magnet. *Z. Xie*[1], D. Zhang[1], H. Zhang[1], W. Liu[1], Q. Wu[1], Q. Lu[1], Y. Li[1], Z. Ma[1] and M. Yue[1] *1. College of Materials Science and Engineering, Beijing University of Technology, Beijing, China*

Aging process has very important effect on coercivity of 2:17 SmComagnet. However, the effect of secondary aging on SmCo magnet need be further clarified. In this paper, the 2:17 SmCo commercial magnet (named 32L) was aged again, and the relationship between the coercivity and microstructure are studied. Fig. 1(a) shows the demagnetization curves of 32 L magnet before (black line) and after (red line) secondary aging. The coercivity of secondary aging magnet has been greatly improved from 9.83 kOe to 30.61 kOe after the secondary aging. The initial magnetization curves of the magnet were investigated, as shown in Fig. 1(b). Before the secondary aging, the magnet shows one step magnetization process, indicating that there is no pinning site against magnetic domain wall motion. However, after the secondary aging, the initial magnetization curve rise slowly below 3T magnetic field, which indicate stronger pinning force against magnetic domain wall motions [1]. From the first derivative curves shown in the inset of the figure, the corresponding pinning field are 6.97 kOe and 33.21 kOe, respectively. It shows that after the secondary aging, the pinning field is responsible for the enhancement of coercivity. The EPMA results of the magnet indicate that the Cu-lean grain boundary region is obvious in the secondary aging magnet. The secondary aging changes the distribution of Cu element in the magnet with low coercivity, and increases the strength of the pinning field, which is beneficial to the improvement of coercivity.

Danube University Krems, Krems an der Donau, Austria

Through atomistic simulation, we investigated how pressure affects the melting point of the $NdFe_{12}$ structure theorised by Miyake et al.[1], and recently grown epitaxially by Hirayama et al.[2]. Material constants from the literature, were used to fit Morse potentials using a genetic algorithm code and the General Utility Lattice Program (GULP), before running two-phase solid-liquid coexistence simulations in LAMMPS at various temperatures and pressures. Morse potentials for the interaction between identical atoms were fit to the material constants of the pure elemental forms of neodymium and iron (Table.1). In order to fit the final neodymium-iron potential two reference structures Nd_2Fe_{17}[3], and $NdFe_{12}$[2]were used, however as these structures have not been studied as thoroughly, only their lattice constants, comparative cohesive energies per atom, and a reasonable estimate of a similar young's modulus to $Nd_2Fe_{14}B$ are used for parameter fitting. An iterative process was used to fit the potentials, which varied the Morse potentials base parameters via random single percentage point scaling, and interchanging of similar parameters – known as *mutation*, and *cross-breeding* respectively. Each potential's absolute percentage difference from the expected values is calculated, and then scaled by a weighting function before being summed to give the *fitness* of the potential. The algorithm converges to a solution by discarding the potentials of poor *fitness* at the end of each iteration. We find the melting temperatures of neodymium and iron to be ~1700K, and ~3000K, overestimated by a factor 1.32, and 1.66 respectively (Fig.1). In expectation of the Fe-Fe interaction dominated $NdFe_{12}$ having a similar scaling to that of elemental iron, we predict a melting temperatures of ~1220K at ambient pressure, rising up to ~1270K at 500MPa. Further investigation will require the development of MEAM potentials for the current binary, and future ternary phases, using for example titanium and cobalt.

AR-09. Fabrication of Permanent Magnet by 3D Printng Technique. *M. Lee*[1], Y. Choi[1], N. Tran[1], J. Ahn[1] and B. Lee[1] *1. Department of Physics and Oxide Research Center, Hankuk University of Foreign Studies, Yongin, The Republic of Korea*

Alnico magnets, which are made of alloy components of elements such as iron, nickel, cobalt and aluminum, do not exert strong magnetic force but are stable at high temperature of 650 degree celcius. It is alsoAlnico magnet is a permanent magnet with constant demand for applications such as in speakers, microphone and amplifier due to its superior hardness that are not damaged by strong impact. However, the molding cast used in the fabrication process must take into account the production period and cost., and the The shape of the permanent magnet is limited by the limitations of the shape of the molding cast. We This study present proposed a method for rapid production of high quality magnetic alloy by stacking metal pattern Less than a millimeter using 3D printer of laser cladding method. The laser is CW CO2 CO_2 laser and are maintained at an output of 400W. Purchased A purchased high purity alloy powder has an average size of 50-150um and can be molded into two or more types of powder. Metal powder is injected with inert gas at a rate of 4g/min to prevent oxidation during work, thus making high purity alloys and removing the need for vacuum system. The composition ratio of the injected powder and alloy powder was confirmed to be almost identical through XRF. The alloy produced was separated into two phases (magnetic phase and non-magnetic phase) through high temperature heat treatment, and the magnetic phase produced magnetic anisotropy by magnetic heat treatment. The microstructure was checked through SEM, and the magnetic properties were measured with VSM to compared the

permanent magnet properties with the actual alnico magnet. Permanent magnets made of laser cladding have properties similar to those of the actual alnico magnets, and the advantages of whichthat they can be easily molded can beand used in various industries.

AR-10. Unquenched Orbital Magnetic Moment in M-type Hexaferrites by Non-isovalent Substitution. *J. Kim*[1] and Y. Koh[2] *1. CALDES, Institute for Basic Science, Pohang, The Republic of Korea; 2. Max-Plank Korean Initiative, Pohang, The Republic of Korea*

The hard magnetic property of M-type hexaferrites are originated basically from the uniaxial crystal structure of magnetoplumbite and there have been a lot of works to enhance the property by modifying the magentic crystalline anisotropy energy or local spin magnetic moments through substituting varieties of cations for Sr and Fe sites. Smaller ionic size of La^{3+} induces a structural transition at low temperature and the excess charges from them can increase the ratio of Fe^{2+} ions with smaller spin magnetic moment in the antiparallel sites. The substituted Co ions for Fe sites have smaller local magnetic moments than Fe ions and their uneven distribution in differerent local sites is expected to change the magnetization too. In this work, we have measured X-ray absorption spectroscopy and X-ray magnetic circular dichroism on a series of M type Sr hexaferrites which have different substitution ratios of La and Co. They directly show that the Fe^{2+} are formed by the La and Co substitution and they are localized mostly at O_h sites. Also, we will show that the local symmetry distortion at O_h sites taken by Fe^{2+} induces a large unquenched orbital magnetic moment at the Fe^{2+} sites.

AR-11. Effect of Lanthanum Substitution on Magnetic Properties of $Ba_{4-x}La_xNi_2Fe_{36}O_{60}$ Hexaferrite. *X. Jiang*[1], X. Liu[1], T. Shen[1], Z. Yu[1], K. Sun[1], C. Wu[1] and R. Guo[1] *1. School of Materials and Energy, University of Electronic Science and Technology of China, Chengdu, China*

Hexagonal ferrites with c-axis texture have high magnetocrystalline anisotropy field (H_a). It it is benefit for achieving the ferrites with high remenence ratio (M_r/M_s) and coercivity (H_c), which are promising for implementing self-biased microwave ferrite devices [1,2]. U-type hexagonal ferrite has lower anisotropy field than that of M-type hexagonal ferrite [3]. It indicates that the U-type ferrite may have lower ferromagnetic linewidth (ΔH) which is benefit for reducing the insertion loss of the ferrite devices, but the lower anisotropy field of U-type hexagonal ferrite may give rise to the lower coercivity which is undesired. Lanthanum substitution was adopted to improve the remenence ratio and coercivity of U-type ferrites in the presented abstract. The La-substituted polycrystalline $Ba_{4-x}La_xNi_2Fe_{36}O_{60}$ (x=0.0-0.3) hexaferrites were prepared by a conventional ceramic method and wet magnetic field pressing with an external magnetic field of 2000 Oe. Effects of lanthanum substitution on magnetic properties of the sintered samples were investigated. Microstructures were examined using a scanning electron microscopy (SEM) shown in Fig. 1. The SEM picture shows that the grains align well along the external magnetic field. Saturation magnetization ($4\pi M_s$), remenence ratio, and coercivity were measured by a vibrating sample magnetometer (VSM) exhibited in Table 1. $4\pi M_s$ almost keeps changeless with the increase in x and it is appropriate for Ku-band ferrite devices, while M_r/M_s goes up obviously. La substitution increases the anisotropy constant (K_1) because of the change of the delocalized electrons [4]. The increasing in K_1 helps the grains align along the external field and improve the M_r/M_s. Coercivity also increases when x is 0.1. Anisotropy constant was also calculated by the intersection of magnetization curve (M-H) of easy axis (c-axis) and hard axis direction. K_1 increases obviously with the increase in x. Then anisotropy field goes up accordingly. It can be concluded that K_1 and H_a improves the c-axis orientation.

AR-12. Magnetic Properties of Mn substituted Strontium Ferrite Powders synthesized by the Molten Salt Method. *M. Kim*[1], H. Lee[1] and J. Kim[1] *1. Materials Science and Chemical Engineering, Hanyang University, Ansan-si, The Republic of Korea*

Hexagonal M-type ferrite magnets have been used in multiple applications such as motors, sensors, and etc. Because of their excellent high temperature stability and corrosion resistance, the M-type magnets have been widely used in severe operation conditions [1]. In particular, magnetic sensors in motors are strongly required to reduce their size and to enhance their accuracy. This indicates that M-type ferrite powders must be controlled to have a homogeneous structure with enhanced magnetic properties. In this study, the shape and size of ferrite powders were controlled by the molten salt method and changes in the coercivity were obtained by Mn substitution of strontium ferrite [2]. In order to obtain homogeneous mixtures, $SrCO_3$, Mn_2O_3, α-Fe_2O_3 and NaCl powders were mixed by ball milling at 300 rpm for 24 hr. These raw materials were calcined at various conditions using an alumina crucible in a box furnace under a heating rate of 10°C/min and a O_2 blowing rate of 3L/min. After the calcination, these synthesized powders were furnace cooled and washed with distilled water to remove residual NaCl powders and then dried in an oven at 60°C for 24 hr. The microstructures of fabricated ferrite powders were analyzed by a SEM and an XRD using CuKα radiation. The magnetic properties were measured by a VSM under 25 kOe. Figure 1 shows the morphology changes depending on the calcination condition. As shown in the figure 1, the two step calcination is an effective method to obtain homogenous morphology of the powders. Figure 2 shows the VSM results of fabricated strontium ferrite powders with different Mn concentrations. As shown in the figure 2, the coercivity of the strontium ferrites increases sharply with increasing the Mn concentration. These results show that the Mn substitution of strontium ferrite and the two step calcination process effectively improve the magnetic properties of strontium ferrite powders and are expected to be further improved by optimization of the calcination conditions [3].

AR-13. Effect of molten salt assisted calcination process in $SrFe_{12-x}Al_xO_{19}$ hexaferrite. *T.P. Poudel*[1], J. Mohapatra[2], D. Guragain[1], S. Yoon[3], D. Neupane[1], J. Liu[2] and S.R. Mishra[1] *1. University of Memphis, Memphis, TN, United States; 2. University of Texas at Arlington, Arlington, TX, United States; 3. Gunsan National Univeristy, Gunsan, The Republic of Korea*

Among ferrite families, M-type hexagonal ferrite, SrFe 12 O 19 (SrM) have great attraction due to their superior physical and chemical properties. SrM has applications from permanent magnet to electromagnetic wave absorber. Various strategies and synthesis technique have been used to prepare SrM viz. solid-state ball milling technique, hydrothermal technique, ceramics method, sol-gel, auto-combustion technique, co-precipitation method, and molten salt assisted method. Among these different techniques, the auto-combustion technique has been favored. However, agglomeration of particles has been often noticed with the auto-combustion technique, which affects the magnetic properties of SrM. We purpose a novel modified auto-combustion-molten salt technique for the synthesis of highly dispersed SrM nanoparticles. auto-combustion technique. As synthesized powder was mixed with NaCl thoroughly, and later heatedat 1100 o C for twelve hours. The calcined powder was thoroughly washed with methanol solution to obtain a highly dispersed SrM plate-like nanoparticles. We have prepared SrFe 12-x Al x O 19 with x= 0, 1, 2, 3, and 4. The structural and magnetic properties of molten-salt assisted SrM particles were compared with SrM synthesized via conventional auto-combustion technique, using XRD, FTIR, SEM, and VSM. The molten salt assisted powder showed plate-like morphology with an average size of 665 nm and thickness 86 nm (for x = 4). The surface area measured showed that molten salt assisted samples having a comparatively higher surface area of 25.15 m 2 /g for x = 4 samples vs. auto-combustion synthesized sample (14.67 m 2 /g). A reduction in magnetization (10.2 emu/g, for x = 4) and remanence (5.29 emu/g, x = 4), while enhancement in coercivity (20240 Oe, for x = 4) molten salt sample was observed when compared to that of samples prepared using auto-combustion technique only (Ms ~ 12 emu/g, Hc ~ 14888 Oe, and Mr~6.5 emu/g for x = 4). The EDX analysis shows that there is a presence of Na (0.1 atomic percentage) and Cl (0.4 atomic percentage) content in Molten salt assisted x = 4 samples. The molten salt assisted auto combustion technique could be a promising technique for applications requiring highly dispersed SrM nanoparticles.

AR-14. Effects of In^{3+} site occupancy on the magnetic properties of M-type strontium hexaferrite. C. Kim[2], B. Kim[1] and *S. Yoon*[1] *1. Department of Physics, Gunsan National University, Gunsan, The Republic of Korea; 2. Department of Physics, Kookmin University, Seoul, The Republic of Korea*

Effects of non-magnetic indium substitution on magnetic properties of M-type Strontium hexaferrites has been studied by first-principle calculation and crystallographic and magnetic measurements. The Indium doped samples $SrFe_{12-x}In_xO_{19}$ (x=0.25, 0.5, 0.75, 1.0) have been prepared by the auto-combustion method using metal nitrates and citric acid, followed by annealing at 1100 °C for 12 hours. Electron microscopy shows that the samples have hexagonal plate-like shape with the particle size ranging from 500~1000 nm and that the apparent size decrease with addition of indium. Lattice parameters show linear increase with increasing indium content, meaning the uniform solid solution is formed throughout the doping range (Fig 1). Figure 2 depicts the variations of saturation magnetization M_S and the coercivity H_C with indium content x obtained from room temperature VSM measurement. Whereas the H_C decreased monotonically with indium addition, the M_S first increase until x=0.5 reaching maximum but decrease thereafter. Effective magnetic anisotropy constants *K* are calculated as well from hysteresis curves using the law of approach to saturation method, and are 3.79×10^5, 3.70×10^5, 2.95×10^5, and 2.87×10^5 J/m^3 for x= 0.25, 0.5, 0.75 and 1.0, respectively. In view of the fact that 12k and 4f substitutions give rise to positive and negative contributions to M_S, this behavior strongly suggests that 12k site occupancy is more dominant when x>0.5. At the early stage of substitution, indium ions preferentially replace Fe^{3+} ions at $4f_2$ site [1]. However, if the occupation probability of the 12k site is almost equal, it can be anticipated that the two tendencies of site occupancy can compete at higher doping level. Density functional theory calculation has been performed to identify the possible substitution site of indium in accordance with experimental reports. The calculation found strong competition among different site occupations, which will be discussed in detail. Mossbauer spectra also show gradual decrease in $4f_2$ intensity, in support of the above conjecture.

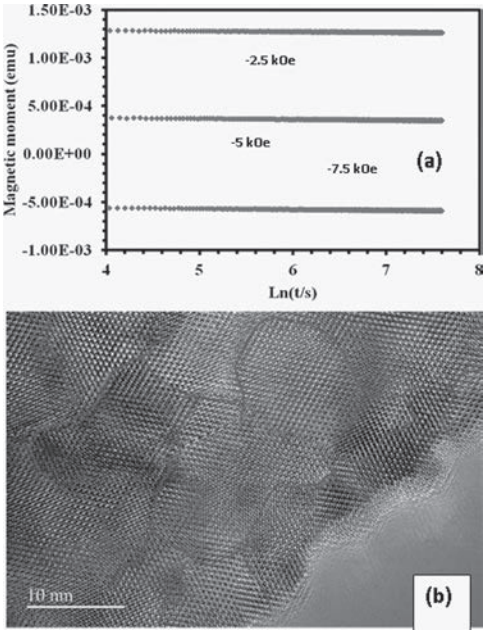
AR-15. Effect of perpendicular magnetic field assisted compaction on the magnetic and magnetostrictive properties of Cobalt Ferrite. *S. Indla*[1], G. Thotakura[2], A. Chelvane[3], T.V. Jayaraman[2] and D. Das[1] *1. School of Engineering Sciences and Technology, University of Hyderabad India, Hyderabad, India; 2. Mechanical Engineering, University of Michigan, Dearborn, MI, United States; 3. Advanced Magnetic Group, Defense Metallurgical Research Laboratory, Hyderabad, India*



Polycrystalline $CoFe_2O_4$ powder was synthesized by combustion method followed by calcination [1]. Phase pure $CoFe_2O_4$ powder was pressed into pellets in a uniaxial hydraulic press under two different conditions: magnetic-field assisted pressing (MP) and normal pressing (NP) [2]. In the former, a magnetic field of 1 T is applied perpendicular to the applied pressure. Sintering of the green pellets at 1350°C for 12 h resulted in sintered pellets having ~80% of the theoretical density. X-ray diffraction revealed the presence of single phase cubic spinel structure in the sintered pellet while the scanning electron micrographs (SEM) of the as-sintered pellet showed the presence of micron-sized (~4 μm) ferrite grains. Magnetometry revealed that no significant change in magnetic properties, such as coercivity (43 kA/m for NP vs. 44 kA/m for MP), remanence (20 Am^2/kg and 19 Am^2/kg for NP and MP, respectively), and saturation magnetization (83 Am^2/kg for NP vs. 81 Am^2/kg for MP), between the two conditions. The magnetostriction was measured on a cubic pellet (~8 mm) with the strain gauge (350 Ohm) mounted on the flat surface of the pellet. Nearly 25% improvement in magnetostriction (168 ppm for MP vs. 134 ppm for NP sample) and 17% improvement in strain sensitivity (0.48×10^{-9} m/A to 0.56×10^{-9} m/A) were observed in the magnetic field assisted compacted sample compared to that compacted in the absence of a magnetic field.

AR-16. Magnetic Relaxation Process in Perpendicular Anisotropy Heterostructures. *Z. Alyousef*[1], M. Hassan[1], S. Pokharel[1], W. Morgan[1], M. Wuttig[2] and A. Lisfi[1] *1. Physics, Morgan State University, Baltimore, MD, United States; 2. Materials Science and Engineering, University of Maryland, College Park, MD, United States*

The increasing interest over magnetic media with perpendicular anisotropy is driven by fundamental science and technological demands such as data storage. Perpendicular magnetic media with small grains size and narrow switching field distribution have demonstrated their superior performance of high recording capacities. However, the media magnetic stability is compromised by the reduction of the grain size due to the thermal switching driven by the competition between thermal and magnetic anisotropy energies [1]. Cobalt ferrite is a promising ceramic for overcoming this problem due its large anisotropy that can be generated through its giant magnetostriction combined with epitaxial strain. In this paper, we elucidate the thermal stability of epitaxial $CoFe_2O_4$ hetero-structures with a large perpendicular anisotropy. The $CoFe_2O_4$ films were deposited by pulsed laser deposition from a polycrystalline target on (100) MgO substrate. The epitaxial nature of the films was confirmed through X-ray diffraction and transmission electron microscopy analyses. Magnetic relaxation measurements were performed with VSM under two different methods. (1) Direct measurement of the magnetization time dependence at constant applied magnetic field. (2) Measurement of hysteresis loops at different sweep rates of applied magnetic field in the range of 10-5000 Oe/s. As depicted by Fig. 1 (a) the time dependence measurements reveal a logarithmic decay of the magnetization over time and small magnetic viscosity weakly dependent on the external applied field. The investigation results will be presented and discussed based on the structural domains resulting from the epitaxy (Fig. 1(b)), the demagnetizing field imposed by the measurement geometry, the thermally activated irreversible process and the magnetization reversal mechanism in these epitaxial hetero-structures.

AR-17. Strong dependence of exchange coupling on soft phase magnetization in hard/soft nanocomposites. *C. Pahwa*[1] and P. Sharma[1]
1. School of Physics & Materials Science, Thapar Institute of Engineering & Technology, Patiala, India

Existence of interfacial exchange coupling at nanoscale between high and low anisotropic ferrite can be exploited for tunable microwave devices. $BaFe_{12}O_{19}$ with high FMR (~35GHz) is extensively used in microwave devices upto W band. On contrary, spinel ferrites with low FMR frequency limit its application below 3 GHz [1]. To widen the operable frequency range; a composite ferrites could be an alternate for various microwave device applications. It is well reported, that nanoscale processing of composite ferrite show interfacial exchange coupling among the phases, and their effect on magnetic properties is vastly investigated [2]. However, role of different magnetization of soft ferrite and magnetic spin interaction across the interface in exchange-coupled system is one of the strong regime to investigate. In the present work, exchange-coupled nanocomposite with different magnetization of soft phase has been prepared. We observed strong dependence of exchange coupling on the magnetization of soft phase. The effect of exchange-coupling on magnetic and microwave properties was studied. Fig. 1 shows soft phase magnetization drastically affect the magnetization of exchange- coupled composite, which vastly deviates from theoretically calculated values. Interestingly, large difference between the magnetization of soft and hard phase provides better interfacial coupling. Fig. 2 depicts coupling dependent reflection losses in K_u-band, the multiple peaks in composite may paved the way for tunable microwave applications.

AS-01. Exploring magnetic resonance with a compass. *D. Nelson*[1], E. Cookson[1], M. Anderson[1], D. McKinney[2] and I. Barsukov[1] *1. Physics and Astronomy, UC Riverside, Riverside, CA, United States; 2. Santa Rosa Academy, Menifee, CA, United States*

Magnetic resonance plays an important role in today's science, engineering, and medical diagnostics. Learning and teaching magnetic resonance is challenging since it requires advanced knowledge of condensed matter physics and quantum mechanics. Driven by the need to popularize this technologically impactful phenomenon, we develop an inexpensive table-top demonstration experiment. It unveils the magnetic resonance of a hand-held compass in the magnetic fields of a permanent magnet. The setup provides an immediate visualization of the underlying physical concepts and allows for their translation to broad student audiences. This work was supported by the National Science Foundation under Grant No. ECCS-1810541.

AS-02. Magnetic Fields Web Series: Engaging Middle School Students in STEM. *P. Pena Martin*[1], J. Isberg[1], E. Ertekin[1,3], V. Lorenz[1,2] and N. Mason[1,2] *1. Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 2. Department of Physics, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 3. Department of Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, United States*

Web based media can make scientific content accessible to audiences far beyond the scientific community. We created a web series called "Magnetic Fields" that aims to introduce materials science, particularly concepts related to magnetism, and promote themes more general to STEM fields, such as persistence and the scientific process, through use of characters and a story geared towards a middle school audience. The goal is to build and maintain interest in science at an age where this tends to drop off. The four-episode arc follows a group of high school characters as they encounter a strange new material during a class field trip to a laboratory. The series is directed by John Isberg, with professional actors making up most of the cast. The series was initiated by scientists in the Illinois MRSEC, and the storyline was developed in collaboration with MRSEC students and faculty. The episodes were released in May 2019 through Youtube. We report on the process of creating this series, response to it upon release, and discussion of its use as an educational tool. The authors acknowledge primary support of the NSF through the University of Illinois at Urbana-Champaign Materials Research Science and Engineering Center DMR-1720633.

AS-03. In-class experiments with smart phones for teaching upper-level electricity and magnetism. A. Davidson[1], A. Ranjan[2] and *X. Fan*[1] *1. Physics and Astronomy, University of Denver, Denver, CO, United States; 2. Cherry Creek High School, Greenwood Village, CO, United States*

Interactive-engagement method such as studio physics [1, 2], has demonstrated higher learning gains than traditional lecturing in intro-level physics classes. However, there have been limited applications in upper-level classes, such as Electricity and Magnetism (E&M), possibly because experiments on E&M topics can be too costly and sophisticated to be carried out in the classroom. Smart phone, which is equipped with magnetic field sensors, radio signal detectors and light sensors, provides a convenient platform for carrying out E&M-related experiments. In this poster, we will present three examples of the implementation of smart-phone-based studio physics in an E&M class for Physics majors: (1) Detection of earth magnetic field inclination; (2) quantifying skin depth of aluminum foil with cellphone tower signals; and (3) Measurement of Brewster's angle. Besides sensitive sensors, smart phone also has computational power, which can be explored to further expand the breadth and depth of the smart-phone-based studio physics. Due to the wide accessibility of smart phones and the simplicity of experimental setup, we expect this teaching technique can be easily transferred to other institutes in the world.

AS-04. The Use of Virtue Modules in Physics Lab Teaching. *W. Zhang*[1], R. Bidthanapally[1], T. Sebastian[2], Y. Xiong[1,3], H. Qu[3] and J. Sklenar[4]
1. Physics Department, Oakland University, Rochester, MI, United States; 2. THATec Innovation GmbH, Mannheim, Germany; 3. Electronic and Computer Engineering, Oakland University, Rochester, MI, United States; 4. Physics Department, Wayne State University, Detroit, MI, United States

Lab sessions in physics education connect the fundamental concepts to practical examples and are effective measures of the students' understanding and reasoning through ultimate real-world tests. Many topics in condensed matter physics are known to be challenging to convey in both lectures and labs. In addition, these topics are usually resource demanding, which has been one of the challenging issues. Here, we introduce and demonstrate the use of virtue lab modules for teaching physics labs and for effectively integrating research and education. Experiments that are relevant to magnetism and spintronics include, but not limited to, spin current detecting, microwave energy harvesting, and spin-based thermoelectric effects. An important highlight of these modules is the highly-interactive laboratory learning platform. In the class, each piece of experimental hardware (e.g. electrometers, oscilloscopes, etc) will be paired with a computer-based virtual module. The individual modules mimic the hardware, which the students can use to become familiar with the hardware, acquire real-time feedback, and visualize the data acquisition dynamics, on-demand and risk-free. The virtual component is also helpful for demonstrating delicate, shared hardware in class, without risk of damaging the actual instrumentation. These individual components are connected to a central operating system and the experiment can be re-programmed by simple coding and user-interfaced commands [1]. Work at Oakland University is supported by NSF DMR-1808892.

AT-01. Comparative Study of Magnetic Properties of Fe_3O_4 Nanoparticles Produced by Pulsed Laser Deposition and Chemical Route.
W.S. Torres[1], N.R. Huaman[2], R. Bini[3], M.d. Santos[4], L.F. Cótica[3] and *D.L. Rocco[1,4] 1. Física, Universidade Federal Fluminese, Niterói, Brazil; 2. Centro Brasileiro de Pesquisas Físicas, Rio de Janeiro, Brazil; 3. Física, Universidade Estadual de Maringá, Maringá, Brazil; 4. Formação Geral, Centro Federal de Educação Tecnológica de Minas Gerais, Timóteo, Brazil*

Magnetite (Fe_3O_4) nanoparticles (NPs) have being intensely studied due to their semi-metallic nature, high Néel temperature (~850 K) and expected 100% spin polarization at room temperature. These properties make then a suitable candidate for spintronics sensors, as well biomedical applications[1]. It is well known that the NPs magnetic properties of this material are strongly dependent on the way they are synthesized and the substrate utilized[2]. Thus, our goal in this work was to prepare NPs of Fe_3O_4 using pulsed laser deposition (PLD) technique and to compare theirs structural and magnetic properties with the Fe_3O_4 NPs produced by a chemical route (CR) [3,4]. To PLD approach we starts from an iron target made by arc melting and using the wavelengths (λ) of 532 and 1064 nm with beam energy of 300 and 600 mJ, respectively, work pressure (argon) of 1.3 mbar. Transmission Electron Microscopy (TEM) revealed the formation of spherical NPs with core/shell morphology (Fig1) and with diameter of (8 ± 4) nm (1064 nm) and (16 ± 5) nm (= 532 nm). The as deposited NPs were exposed to air for 5 days, in order to oxidize them, and after that thermally treated at 600°C for 1 hour in order to accelerate the diffusion of oxygen through the material. X-ray diffraction technique with Rietveld's method was used to quantify the phases, and the percentages obtained were: 58% of Fe_3O_4 and 42% of α-Fe (532 nm) and 85% of Fe_3O_4 and 15% of α-Fe (1064 nm). Measurements of AC magnetization in different frequencies were carried out for the thermal treated NPs and these results were compared to the ones of Fe_3O_4 NPs synthesized by CR in which 100% of Fe_3O_4 was obtained. With the curves of the real part of magnetization versus temperature we got an estimation of the NPs blocking temperature (T_B) as being 257.6, 220.3 and 195.8 K for the ones obtained by CR, deposited with 532 and 1064 nm, respectively. As T_B is proportional to the medium diameter of the NP, we can see that the NPs deposited with 1064 nm have a diameter smaller than the ones deposited with 532 nm, which is in agreement with TEM image.

AT-02. Inverse magnetocaloric effect of densely packed ferromagnetic nanoparticles clusters.
C.M. Souza[1], L.L. Oliveira[2], *A.L. Dantas*[2] and A.S. Carriço[1] *1. Department of Physics, Federal University of Rio Grande do Norte, Natal, Brazil; 2. Department of Science and Technology, State University of Rio Grande do Norte, Natal, Brazil*

We present a theoretical discussion of the inverse magnetocaloric effect (IMCE) of clusters of ferromagnetic nanoparticles uniformly packed in ellipsoidal clusters. We apply the theoretical model to Gd nanoparticles with diameters in the 30 nm – 200 nm range, arranged in micrometer-sized clusters. The magnetocaloric effect (MCE) is strongly affected by the nanoparticles dipolar interaction, which leads to an up-shift of the Curie temperature and the values of temperature for the peaks in the isothermal entropy variations. We show that by switching off an external magnetic field of moderate strength the isothermal entropy variation of high-packing density nanoparticles clusters shows a double peak structure, with opposite signs, around the Curie temperature. The IMCE below the Curie temperature is due to the nucleation of the dipolar antiferromagnetic state (DAFS) and depends on the values of the packing density and the nanoparticles diameter, as well as the external field strength. We have found, for instance, that a 0.98 eccentricity cluster with a 2.37 μm major axis, holding 795 Gd nanoparticles with 30 nm diameter, packed with a density of 2.1 x 10^{15} nanoparticles/cm^3, shows a normal MCE, with no signature of dipolar effects, with ΔS=0.33 J/(mol K), at a temperature of T=294 K, in response to switching off a 0.5 T external magnetic field, as in bulk Gd. Using 60 nm diameter nanoparticles, the entropy variation displays a double-peak, as shown in Fig.1, with ΔS=-0.044 J/(mol K), at T_-=309 K and ΔS=0.097 J/(mol K), at T_+=317 K. At T_- the negative entropy change is due to the formation of a DAFS. For H_{ext}=0.5 T, the local field at most of the nanoparticles is smaller than the local field in the absence of the external magnetic field. Thus, when you switch off the external field, at most particles the local field increases, leading to a negative ΔS peak.

Isothermal entropy variation of a 0.98 eccentricity cluster with a 2.37 mm major axis, holding 795 Gd nanoparticles with 60 nm diameter, packed with a density of 2.1 x 10^{15} nanoparticles/cm^3, corresponding to switching off a 0.5 T external magnetic field.

AT-03. *In-situ* Alignment of Filament-based 3D Printed Magnetic Materials. *A. Sarkar*[1], S.M. A.[1], M. Paranthaman[2], M. Kramer[1], T. Lograsso[1], C. Haase[1] and I.C. Nlebedim[1] *1. AMES Laboratory, Ames, IA, United States; 2. Oak Ridge National Laboratory, Oak Ridge, TN, United States*

With the trend for rapid prototyping of parts and systems, additive manufacturing process like three-dimensional (3D) printing can advance the fabrication of shape-specific architectures for anisotropic permanent magnets involving expensive and critical rare-earth elements[1,2]. Although *in-situ* alignment will open new horizons for manufacturing of complex permanent magnets, integration of alignment systems into 3D printing processes is still a challenge. We will present a mechanism to address this challenge accomplished by integration of bonded magnet production, 3D printing, finite element modeling and system development. We have developed a mechanism to align magnetic materials using fused filament 3D printer with a novel magnetic field source architecture. The work addresses opportunities to integrate magnetic field into 3D printing process in order to enable printing, and alignment of anisotropic permanent magnets, without requiring further processing. The principle behind the analysis is rotation of magnetic particles in a molten matrix under low magnetic field. The alignment architecture was designed and optimized for weight and applied field. An in-depth finite element modeling and CAD was performed followed by prototyping of the magnetic field source. Magnetization vs. field measurements of extruded and printed Sm-Co in PLA polymer magnets, with and without alignment, confirmed alignment of magnetic particles. This process can be used for any permanent magnet composition or hybrid magnets. The work presents a benchmark for application of *in-situ* magnetic alignment of 3D printed bonded magnets in industrial and commercial applications. This work is supported by the Critical Materials Institute (CMI), an Energy Innovation Hub funded by the U.S. Department of Energy (DOE), Office of Energy Efficiency and Renewable Energy, Advanced Manufacturing Office. Ames Laboratory is operated for the U.S. Department of Energy by Iowa State University of Science and Technology under Contract No. DE-AC02-07CH11358. Authors are thankful to Electron Energy Corporation for providing the Sm-Co grinding swarfs used for this work.

AT-04. Modulation of static and dynamic properties of Co_2MnAl Nanowires through deposition parameters. M. Sharma[1], A. Das[1] and *B.K. Kuanr*[1] *1. Special Centre for Nanoscience, Jawaharlal Nehru University, New Delhi, India*

Full heusler alloys have emerged as a fascinating multifunctional material due to its excellent magnetic and electrical properties which can lead to potential applications in spintronics, thermoelectric, ferromagnetic shape memory and superconductors [1]. Recently a lot of research has been focused on bulk and thin film heusler alloys, however, very few reports studied the one-dimensional heusler alloy nanowires [2]. In the present work, Co_2MnAl heusler alloy nanowires have been successfully fabricated in anodic alumina templates using simple and low-cost electrodeposition technique at room temperature. We investigated the role of deposition parameters such as pH value of the electrolyte and deposition potential on the structural and magnetic properties of Co_2MnAl nanowires. It is observed that the crystallinity improves with the increase of pH value and optimized around pH=3.0. The XRD confirms the formation of B2 crystal type heusler alloys which is further verified by high-resolution transmission electron microscopy. The static magnetic properties revealed that the saturation magnetization, squareness, coercivity and uniaxial anisotropy of the nanowires increase with the increase in pH value. The highest remanent squareness of 76% is observed for pH=2.9. The dynamic measurements of heusler alloy nanowires have been studied by ferromagnetic resonance technique using the flip-chip method in the field-sweep mode at different applied frequencies ranging from 20-40 GHz. It is observed that the resonance field increases linearly with the increase in frequency for all samples. Further, the resonance field decreases to 35% with the increase of pH value of electrolyte, resulting in an increase in the effective field.

AT-05. Magnetic and catalytic properties of Co_xNi_{1-x} nanowires. J. Elkins[1], *J. Mohapatra*[1], M. Xing[1], J. Beatty[1] and J. Liu[1] *1. Department of Physics, University of Texas at Arlington, Arlington, TX, United States*

Many binary alloy systems have tunable properties and phase structures upon adjusting their compositions. CoNi is one of such systems that will change from hcp to fcc structure after the Ni content surpasses the threshold.

Therefore, it would be interesting to track the changes in the properties of CoNi nanoparticles as the amount of Ni reaches and surpasses the hcp/fcc threshold. CoNi bimetallic nanoparticles with varying Co:Ni concentrations were synthesized via a solvothermal approach. The changes in phase structure, morphology, magnetic properties, and catalytic hydrogenation were studied as the Ni content was increased. According to the XRD measurements, as the Ni content increased, the nanowires shifted from hcp to fcc structure, with nearly pure fcc at 50:50 Co:Ni ratio. Magnetic measurements show that as the Ni content is increased, the H_C and M_S decrease as shown in Figure 1. Contrary to the magnetic trend, the catalytic activity of the nanowires increases upon increasing Ni content. The addition of a thin Pt film sputtered on top of the CoNi films further increased the current density for hydrogen evolution reaction.

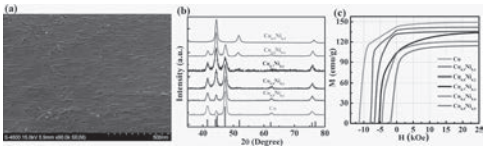

Figure 1. (a) Scanning electron microscope (SEM) micrographs of the aligned $Co_{0.9}Ni_{0.1}$ nanowire assemblies. (b) XRD patterns for Co_xNi_{1-x} (x = 0, 0.1, 0.2, 0.3, 0.4, and 0.5) alloys (c) Demagnetization measurements at room temperature of the aligned Co_xNi_{1-x} NWs assemblies.

AT-06. Effects of surface spin disorder on the magnetic properties of $CoFe_2O_4$ nanoparticles. *J. Mohapatra*[1], J. Beatty[1], J. Elkins[1], M. Xing[1] and J. Liu[1] *1. Department of Physics, University of Texas at Arlington, Arlington, TX, United States*

The effects of surface spin disorder are studied on the magnetic properties of two groups of $CoFe_2O_4$ nanoparticles with average size of 3.5 nm and 10 nm, respectively. Magnetization curves showed that the magnetic moment of the 3.5 nm $CoFe_2O_4$ nanoparticles (29 emu/g) is much smaller than the bulk materials (82 emu/g), whereas the 10 nm $CoFe_2O_4$ nanoparticle (75 emu/g) is comparable to the bulk value. The low magnetization in former case is attributed to the higher surface spin disorder. More importantly, the zero-field cooled and field-cooled magnetization loops of the 3.5 nm $CoFe_2O_4$ nanoparticles exhibited very high coercivity (27 kOe) and irreversible behavior even at a high field of 90 kOe (Figure 1a-b). Further, the measured training behavior indicates that the 3.5 nm $CoFe_2O_4$ nanoparticles have highly frustrated surface spins that rearrange much more slowly than the interior spins. On the other hand, the blocking behavior of 10 nm $CoFe_2O_4$ nanoparticles measured at various field strengths (50-5000 Oe) shows a strong dependence on the applied magnetic field (H_{app}). As the H_{app} is increased, the blocking temperature is found to be shifted to lower temperatures, a peculiar characteristic of super-spinglass systems (Figure 1c-d). Our experimental results demonstrate the origin of spinglass-like phenomenon at two different size scales.

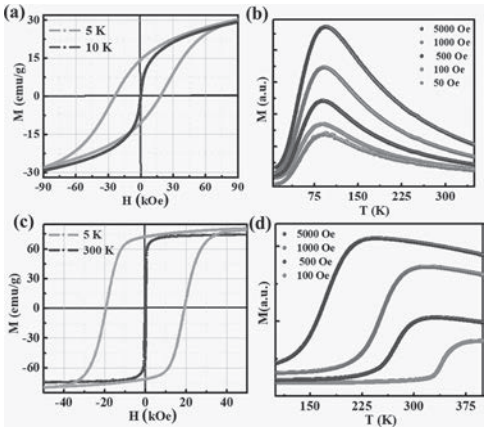

Figure 1. (a, c) Room temperature (300 K) and low temperature (5 K) hysteresis curves and (b, d) zero-filed-cooled magnetization curves of 3.5 nm and 10 nm $CoFe_2O_4$ nanoparticles, respectively.

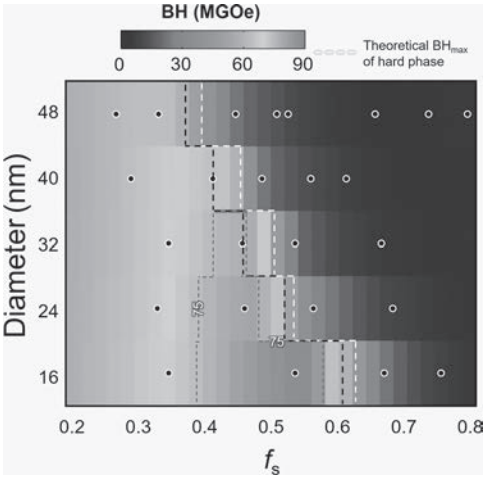
AT-07. Designing Cobalt Nanowire Arrays. *J.G. Giuliani*[1], A. Galindo[1], J. Reyes[1] and K. Nash[1] *1. Physics, University of Texas at San Antonio, San Antonio, TX, United States*



Cobalt (Co) is a popular element particularly for its magnetic properties, which makes it an ideal candidate for a variety of magnetic storage devices. More specifically, perpendicular magnetic storage devices (PMD) can benefit from cobalt's strong crystal anisotropy. However to achieve a viable device it is necessary to learn how to control the anisotropy orientation which has been the subject of much research. One such method of research is the use of self-supported anodic aluminum oxide-template-assisted electrochemical deposition (AAO-ED) to create ordered arrays of Co nanowires. This method allows for the tailoring of many aspects of the nanowires including the length, diameter, and the interwire distance by varying the AAO growth conditions. Also, by using various ED parameters it has been reported that the crystal structure can be altered from face-centered-cubic (FCC) to hexagonally-close-packed (HCP). Utilizing both the AAO and ED methods it should be possible to create nanowires with the correct crystal anisotropy for the use in PMD however; this remains a formidable challenge to achieve because of two main limitations. One limitation is that when the AAO self-supported templates are removed, the nanowires are left in a disordered state. The second heavily debated limitation is delineating the critical ED conditions in which to grow the nanowires to produce the desired crystal anisotropy. In this work, we introduce a variation of the AAO-ED technique, along with various ED growth conditions to synthesize Co nanowires. The ED growth condition parameters include pH, external magnetic fields, and substrate materials. Confirmation of the Co nanowire structures and their magnetic properties are confirmed with X-Ray Diffraction, scanning electron microscopy, focused ion beam milling, and with a vibrating-sample magnetometer. Overall this work demonstrates that these techniques allow for the synthesis of Co nanowires with specific crystal anisotropies to be directly synthesized onto almost any surface and subsequently retain the nanowire order even after the AAO has been removed which is ideal for the implementation into PMD devices.

AT-08. The Practical Energy Product of Cylindrical Core/shell Consist of Soft- and Hard-magnetic Materials. *N. Kim*[1], H. Han[1], S. Lee[1] and K. Lee[1] *1. School of Materials Science and Engineering, Ulsan National Institute of Science and Technology (UNIST), Ulsan, The Republic of Korea*

The exchange-coupled soft-and hard-magnet has been considered as a good candidate for a future high-efficient permanent magnet since it can acquire high saturation magnetization and high coercivity from soft- and hard-magnets, respectively. However, to achieve such an ideal advantage from both magnets, very rigorous design of structures and mixing ratio are required. To do this, various types of exchange-coupled magnet has been investigated including multi-layer, mixture, core/shell structures. The cylindrical core/shell structure are particularly advantageous owing to large interface and versatility at controlling compositions and a demagnetization factor by dimensions. Since the energy product corresponds to the energy stored in the stray field produced by the magnet itself, it should be measured from demagnetizing field, H_d and the flux density, B at the remanent state. In this study, we investigate the energy product of the cylindrical core/shell structure, which do not mean the maximum energy product estimated from a hysteresis loop for a single aspect ratio, but the energy product considering H_d of the system at the remanent state by using micromagnetic simulations. As a model system, we adopted cylindrical core/shell structure composed of the soft-magnetic shell and the hard-magnetic core. To estimate the energy product, the hysteresis loops were calculated by applying external magnetic field along with easy axis and H_d and B. The results reveal that the energy product basically depends on the ratio but the dimension of the whole system contribute dominantly in the high energy product range. By optimizing the dimension and the ratio, the energy product can reach to very high value of 90 MGOe. We finally expanded this model to iterative array structure of the cylindrical core/shell.

Soc., vol. 28, no. 5, pp. 205–211, 2018.

The phase diagram of the energy product according to the ratio of the soft-magnetic shell and the diameters of the hard-magnetic core. The energy product is plotted as black dots, and its color is linearly interpolated in each diameter. The black and white dashed line indicates that the calculated nucleation field is zero and the theoretical maximum energy product of the hard phase.

AT-09. Magnetic coupling of cementite nanoparticles within double-wall carbon nanotubes. W. Nieto[1], J. Chimborazo[2], A. Briones-Leon[2], O. Domanov[2], H. Shiozawa[2], T. Pichler[2], P. Ayala[2] and *D. Niebieskikwiat*[1] *1. Departamento de Física, Universidad San Francisco de Quito, Quito, Ecuador; 2. Faculty of Physics, University of Vienna, Vienna, Austria*

Studying the novelty of magnetism in carbon nanotubes is still intriguing and it has not been completely explored, despite a number of promising technological applications. In this study, we focus on the magnetic properties of bundles of double-walled, metallic carbon nanotubes with encapsulated cementite (Fe_3C) nanoparticles of ~3 nm in length inside their hollow core. These nanoparticles are not unintentional impurities, but have been deliberately introduced to fill the nanotubes with ferromagnetic material. Results of VSM magnetometry of the filled nanotubes give an anisotropy constant of ~$3x10^6$ erg/cm^3, much larger than the anisotropy of free cementite nanoparticles, indicating a strong magnetic coupling of the nanoparticles with the nanotubes. On the other hand, the calculated activation volume for magnetization reversal, of ~400 nm^3, shows that around 300 nanoparticles of cementite are mutually coupled through the conduction electrons of the nanotubes. Considering a spin diffusion length of 130 nm along the direction of the nanotubes, the activation volume suggests that magnetic coupling also occurs between neighboring nanotubes in the direction perpendicular to their axis, with a perpendicular magnetic correlation length of ~5-6 nm, i.e. involving four parallel nanotubes.

AT-10. Electrophoretic Deposition of Iron-Oxide Nanoparticles to Achieve Thick Nickel/Iron-Oxide Magnetic Nanocomposite Films. *S.C. Mills*[1], C.S. Smith[2], D.P. Arnold[2] and J. Andrew[1] *1. Materials Science and Engineering, University of Florida, Gainesville, FL, United States; 2. Electrical and Computer Engineering, University of Florida, Gainesville, FL, United States*

It is desirable to fabricate on-chip power components with both low loss and high magnetic saturation, which are typically not achievable with single-phase ferromagnetic materials. Magnetic nanocomposites fabricated from a low loss magnetic phase (e.g. ferrite) and a high magnetic saturation phase (e.g. nickel) can exhibit hybrid magnetic properties. To provide useful magnetic energy storage and power handling, thick (tens of microns) nanocomposites are needed [1,2]. Electro-infiltration—a process that electroplates a magnetic metal through a porous layer of nanoparticles—has

the potential to fabricate thick nanocomposites [3]. For the formation of a nanoparticle layer, solution-based methods, such as drop-casting, suffer a lack of control over film thickness and quality. Electrophoretic deposition (EPD), a method that deposits charged particles in colloidal suspensions via electrophoresis, can fabricate thicker magnetic nanoparticle films than other methods [4]. In this work, EPD is shown to be a viable option for assembling iron oxide nanoparticles into a mold, which can be subsequently electro-infiltrated with nickel to fabricate the final nanocomposite (~4.8 μm in thickness). The deposited films are imaged via scanning electron microscopy and energy dispersive x-ray spectroscopy to qualitatively observe the infiltration of the nickel between the iron oxide nanoparticles (Fig. 1). Further confirmation of successful composite formation is performed via vibrating sample magnetometry, showing the saturation magnetization value of the film (~473 kA/m) falls between that of the iron oxide nanoparticles (~280 kA/m) and the nickel (~515 kA/m) (Fig. 2). These results demonstrate the potential of EPD to fabricate electro-infiltrated magnetic nanocomposite films.

AU-01. Anomalous magnetic behavior in $Ni_{80}Cr_{20}$ nanoparticles prepared by electric explosion method of wire. *S. Vishvakarma*[2], S. Veeturi[2], P. Ranjan[1] and R. Sarathi[1] *1. Electrical Engineering, Indian Institute of Technology Madras, Chennai, India; 2. Physics, Indian Institute of Technology Madras, Chennai, India*

The remarkable magnetic properties observed in nanoparticles (NPs) that are different from their bulk counterparts. This is attributed to a complex interplay between finite size effect [1]. In the past considerable interest has been shown in the application of nickel–chromium (Ni–Cr) alloy NPs in for ferro-fluids and hyperthermia. The $Ni_{80}Cr_{20}$ NPs synthesized by physical and chemical methods, exhibited contrasting magnetic properties [2-4] i.e, NPs prepared by mechanical alloying exhibited ferromagnetism at room temperature compared to their non-magnetic bulk counterparts. It was suggested that the Cr-segregation in NiCr NPs results in ferromagnetic character and this is also supported by the Monte-Carlo simulations [4]. These observations suggest that the magnetic properties also depend on the synthesis process [2-4]. Therefore, in the present investigation we have synthesized $Ni_{80}Cr_{20}$ fine particles by electric explosion of wire. By varying the process conditions we have synthesized fine particles with different size distributions by wire explosion method (WEM) from commercially purchased Nichrome ($Ni_{80}Cr_{20}$) wire of 0.4 mm diameter. As prepared particles are of spherical shape and exhibit pure FCC phase (Fig.1). The samples prepared with different process conditions are termed as S1 and S2 respectively. Zero field cooled (ZFC) and field cooled (FC) magnetization curves suggest the presence of magnetic disorder and susceptibility does not follow Curie-Weiss behavior. The maximum observed in ZFC at T= 25K and sharp rise in FC curve is the signatures of presence of spin glass behavior (Fig.2). Although magnetic isotherm at T=5K showed coercivity for S1 and S2 samples 150 Oe and 80 Oe respectively, no spontaneous magnetization is observed. This rules out the possibility of AFM and weak ferromagnetic order. These observations are in contradiction to that of particles prepared by mechanical alloying. These anomalous magnetic properties will be discussed in details along with microstructure.

AU-02. Magnetic spinel ferrite materials as high efficient and easily retrievable visible photocatalysts. Y. Jia[1] and *C. Liu*[1] *1. Physics, Hankuk University of Foreign Studies, Yongin, The Republic of Korea*

The development of efficient photocatalysts are now considered as one of the few approaches to solve the energy and environmental crisis around the world. Spinel ferrite materials, due to their suitable bandgap energy, have been increasingly investigated recently as promising photocatalysts under wide ranged solar light irradiation. The room temperature magnetization makes it possible to re-collect the spinel ferrite-based photocatalysts easily by using a normal magnet, which is a very important advantage as compared to non-magnetic photocatalyst. In this work, we plan to present our research research results on design and preparation of spinel ferrite-based photocatalyst with high efficiency in water system cleaning and CO2 reduction. A hydrothermal synthesis procedure was developed to prepare ferrite nanoparticles with good crystallinity and quite uniform size distribution. Non-metal element (N, S) doping was investigated to further adjust the bandgap energy for more efficient solar light absorption. The optical and photoelectrical characterizations will be present to evidence the desired properties for photocatalyst applications [1,2]. In addition, hetergeneous photocatalysts were also designed and prepared to enhance the light absorption and the separation of photo-generated electrons and holes. ferrite/TiO2, and ferrite/g-C3N4

composites were investigated in details for their photocatalystic applications in water system cleaning (CTC degradation, MO decomposition, etc), and showed relatively high efficiency due to the effective charge transfer across the interfaces of the composite materials [3,4]. Finally, we will also present our results in applying ferrite-composites for photocatalytic CO2 reduction. Their retrievability and stability in recycled usage will also be discussed. The results presented in this work are believed to provide important insights for developing novel photocatalysts based on spinel ferrite materials.

AU-03. Tailoring the energy product of cylindrical core-shell FePt@ $CoFe_2$ and FePt@Fe nanoparticles. Y.S. Santos[1], *L.L. Oliveira*[1], R.M. Souza[2], M.S. Nunes[3], A.L. Dantas[1] and A.S. Carriço[2] *1. Department of Science and Technology, State University of Rio Grande do Norte, Natal, Brazil; 2. Department of Physics, Federal University of Rio Grande do Norte, Natal, Brazil; 3. Department of Physics, State University of Rio Grande do Norte, Natal, Brazil*

We report a theoretical discussion of the impact core-shell composition on the maximum energy product (BH_{max}) of cylindrical core-shell FePt@$CoFe_2$ and FePt@Fe nanoparticles, with the magnetization along the cylindrical axis. For strong ferromagnetic core-shell interface exchange energy interaction, BH_{max} increases with the shell thickness. However, beyond a critical value of the shell thickness, BH_{max} turns a monotonically decreasing function of the shell thickness. The core-shell dipolar interaction favors the early alignment of the shell magnetization with the external field, in the demagnetization quadrant. Fe has a larger value of the exchange stiffness energy (25 x 10^{-12} J/m) than $CoFe_2$ (1.9 x 10^{-12} J/m). Thus, the exchange energy cost for a twist in the shell magnetization from aligned to the core magnetization to the direction opposite to the core magnetization at the shell surface, as required by the dipolar field, is larger in the FePt@Fe nanoparticles than in the FePt@ $CoFe_2$ nanoparticles. Thus, the critical shell thickness for Fe is larger than that of $CoFe_2$. We have found, for instance, that a 30 nm height and 7 nm FePt diameter core FePt@Fe nanoparticle, has the BH_{max} optimized for a 4 nm thick Fe shell. The FePt(7 nm)@Fe(4 nm) nanoparticle, for a magnetic field of H=-9 kOe, where the BH_{max} is reached, has the core and shell ferromagnetically coupled at the maximum value of the core-shell magnetization. For the same value of the magnetic field, a FePt(7 nm)@$CoFe_2$(4 nm) has the shell magnetization opposite to the core magnetization, with a large drop of the core-shell magnetization and the value of the BH_{max}. Thus, although having a smaller magnetization (M_s=1711 emu/cm^3) than $CoFe_2$(M_s=1887 emu/cm^3), Fe is the choice material for the shell, leading to a larger value of the BH_{max}. We have found, for instance, that a 30 nm height FePt(7 nm)@ Fe(4 nm) nanoparticle has a BH_{max} of 763.5 KJ/m^3, which is 88% larger than that of the FePt core (406.75 KJ/m^3). Also, with the same values of the FePt core diameter, and core-shell height, the best composition for a FePt@ $CoFe_2$ nanoparticle corresponds to a 2nm thick $CoFe_2$ shell, with a BH_{max} of 622.5 KJ/m^3.

AU-04. Compositional dependence of structural and magnetic properties of $Ga_{2-x}Fe_xO_3$ nanoparticles. *T. Han*[1] and T. Chen[1] *1. Department of Applied Physics, National University of Kaohsiung, Kaohsiung, Taiwan*

The $Ga_{2-x}Fe_xO_3$ (GF_xO) compound, is a quite interesting material due to simultaneous exhibit magnetic and electric orderings [1,2]. However, the physical properties of GF_xO at reduced grain sizes remain underexplored due to the challenges associated with their synthesis with a proper control over the crystalline phase. In addition, the effect of the Fe/Ga ratio on the magnetic properties of the nanosized GF_xO system has not yet been completely established. In this work, therefore, we prepare a series of GF_xO nanoparticles with $0.8 \leq x \leq 1.2$ using the sol-gel method to systematically study the effect of the Fe/Ga ratio on their structural and magnetic properties. All the samples of GF_xO with $0.8 \leq x \leq 1.2$ have been characterized by the powder XRD measurements and Rietveld refinements. All the observed peaks can be indexed by reflections of the $Pc2_1n$ orthorhombic structure of GF_xO, and no impurity phase was found. The determined lattice parameters are found to display a monotonic increase with the Fe content x. Composition of the GF_xO nanoparticles was confirmed by energy dispersive X-ray spectra. The evolution of the Néel temperature (T_N) of GF_xO samples versus their Fe-content (x) is given in Fig.1. It is found that with increasing Fe-content, up to 1.2, the T_N increases from 279 to 350 K. Moreover, the magnetic hysteresis curves measured below T_N exhibit two-phase-like magnetic behavior consisting of soft and hard magnetic phases. The results could be explained by the site-disorder of the cations in GF_xO nanoparticles.

AU-05. Controlling domain wall chirality by combining hard and soft magnetic materials in planar nanostructures with wire-ring morphology. *R. Corona*[1,3], S. Castillo[2,3], J. Escrig[1,3] and D. Altbir[1,3] *1. Física, Universidad de Santiago de Chile, Santiago, Chile; 2. Departamento de Ingenieria, Universidad Autonoma de Chile, Santiago, Chile; 3. CEDENNA, Santiago, Chile*

The study of the magnetization reversal process in ferromagnetic nanostructures continues attracting the attention of the scientific community due to several applications based on domain walls (DWs) and their dynamics [1-3]. Vortex domain walls exhibit a certain chirality that it is important to control for the use in potential technological applications. Gao *et al.* [4] studied a series of permalloy nanowires with an antisymmetric notch, concluding that the DW can keep or change its chirality, as it passes through a notch, depending on the geometric parameters of the system. Following these ideas, in this work we explore using micromagnetic simulations, a wire-ring structure, where we have alternated hard (cobalt) and soft (permalloy) magnetic materials. This wire-ring structure has been previously proposed by Corona *et al.* [5] for the nucleation of multiple DWs. The authors found that for thick rings, the magnetization reversal process began in the ring, while for thin rings, the process starts at the end of the wire with uniform width. However, the reversion process at the interface between the ring and the wire was not studied in detail and, in addition, only single material nanostructures were considered. In this work, we consider another variable and use materials with different coercivities for the ring and the wires. Our results evidence that, depending on the geometry, it is possible to control the DW chirality when it goes through the ring section. Therefore, this system can be used as a device that controls the chirality of the domain wall. Acknowledgments: The authors acknowledge financial support from Fondecyt 1160198 and 11170858, and Financiamiento Basal para Centros Científicos y Tecnológicos de Excelencia (CEDENNA), under project FB0807.

AU-06. Domain wall motion and coupled electron hopping relaxation in nanostructured magnetite. *R. Das*[1,2], V. Kalappattil[2], M. Phan[2] and H. Srikanth[2] *1. Faculty of Materials Science and Engineering, Phenikaa University, Hanoi, Vietnam; 2. Department of Physics, University of South Florida, Tampa, FL, United States*

Magnetite (Fe_3O_4) nanoparticles are not only promising for biomedical applications but also an excellent model for the study of nanomagnetism. Since most of the synthesis methods gave poorly crystalline, off stoichiometric Fe_3O_4 nanoparticles, the particle size dependence of Verwey transition has just recently been studied [1,2]. The low-temperature magnetic state of magnetite has remained a matter of debate till date, due to the presence of microtwinning in the monoclinic phase of Fe_3O_4 single crystals, which causes problem in neutron diffraction [3]. Most research on Fe_3O_4 was focused on the electric and magnetic properties near Verwey transition. There have been only a few reports on the low temperature (below 50 K) features, like Fe^{+2} ions electron relaxation. Kronmüller *et al*. observed two anomalies at ~25 and ~50 K in single crystals of Fe_3O_4 and attributed it to the relaxation of Fe^{+2} extra electrons [4]. However, no consensus has been reached on the origin of these anomalies. A clear understanding of the low temperature anomalies and the nature of Verwey transition in Fe_3O_4 nanoparticles is currently lacking, mainly due to the poor crystallinity of nanoparticles synthesized. In this study, we demonstrate that the low temperature anomalies observed in highly crystalline, stoichiometric Fe_3O_4 nanorods are associated with the coupled electron hopping relaxation process and domain wall motion. Both DC and AC susceptibility showed the presence of a hump around 35 K, which is associated with the relaxation of the Fe^{+2} extra electrons. Radio-frequency transverse susceptibility (TS) measurements indicated a noticeable increase in anisotropy field below ~ 25 K, which is attributed to the rearrangement of Fe^{+2} electrons in the octahedral site. TS measurements also revealed the domain wall freezing below ~ 35 K. A corroboration of DC, AC and TS susceptibility measurements has shed light on the complex nature of the low temperature anomalies in nanostructured magnetite.

AU-07. Effect of particle size variation on structural, magnetic and transport properties of Sol-gel derived nanocrystalline $La_{0.15}Pr_{0.45}Ca_{0.40}MnO_3$ perovskite manganites. *D. Raghav*[1], H.K. Singh[2] and G.D. Varma[3] *1. Physics, I.I.T. Roorkee, Roorkee, India; 2. CSIR NPL, New Delhi, India; 3. Physics, I.I.T. Roorkee, Roorkee, India*

In the present work we have investigated the effect of particle size on the structural, magnetic and transport properties of $La_{0.15}Pr_{0.45}Ca_{0.40}MnO_3$ system. $La_{0.15}Pr_{0.45}Ca_{0.40}MnO_3$ (LPC) materials have been synthesized using Sol-gel method and sintered at different temperature to get the samples of different particle sizes. Phase pureness of the synthesized samples has been confirmed by Retiveld refinement of the powder X- Ray diffraction (XRD) data, which authenticates orthorhombic structure with *Pnma* space group. All three lattice constants (a, b and c), bond lengths and bond angles increase with increasing particle size. The magnetization measurements (H@100 Oe) as a function of temperature exhibit paramagnetic (PM) to ferromagnetic (FM) transition and also bring out the hysteresis between the field cooled cooling (FCC) and field cooled warming (FCW) magnetization curves due to the coexistence of ferromagnetic (FM) and antiferromagnetic (AFM) phase [Fig. 1(a)]. Moreover, the divergence between the zero field cooled (ZFC) and FCW magnetization decreases with increasing particle size. The isothermal magnetization loops confirm the increase in the FM component at higher particle size at low temperature (5K) [fig.1(b)]. The temperature dependent resistivity measurements of all samples in zero magnetic field show no insulator to metal transition for the samples sintered at lower temperatures, but the sample sintered at higher temperature shows the metal to insulator transition. The data of resistivity have been fitted by using variable range hopping model (VRH). Characteristic temperature (T_0), localization length ($1/\alpha$) and average hopping distance (R) have been calculated by using this model. X-ray photoemission spectra of Mn2p and Mn2s core-level confirm dual valence state of Mn (Mn^{3+} and Mn^{4+}), which are responsible for the magnetic behaviour of LPCMO system. The detail correlation between the transport and observed magnetic properties of sintered LPCMO samples will be described and discussed in this paper.

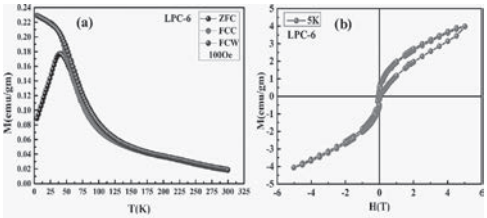

Fig. 1.- (a) Zero-field-cooled (ZFC), Field cooled cooling (FCC) and Field Cooled warming (FCW) Magnetization vs Temperature (M-T) measurements have been shown at 100 Oe magnetic field for LPC-6 nanocrystals. (b) Magnetic field versus magnetization (M-H) hysteresis curves for LPC- 6 sample at 5 K.

AU-08. Evaluation of magnetic properties in ferromagnetic martensite particle using type 304 stainless steel wire. *K. Kinoshita*[1] *1. Department of energy conversion science, Kyoto university, Kyoto, Japan*

Austenitic stainless steel, including type 304 stainless steel (SUS 304), is an interesting material as a magnetic composite because of the generation of ferromagnetic martensite particles upon plastic deformation. We developed a magnetic composite model for SUS 304, which is able to qualitatively express the permeability property [1]. However, the analysis results did not quantitatively agree with the experimental results. Miura et al. showed that a coercivity (H_c) of SUS 304 increased and then decreased with increasing martensite fraction [2]. This result suggests that the quantitative difference between the experimental and analysis result may be because we did not consider the possibility that the magnetization curve of the single martensite particle changed as its size and morphology varied. We need to confirm the hypothesis by measuring the magnetization curve for a single martensite particle; however, this is difficult because of the size and shape distributions of martensite particles. In this study, we attempted to weaken the effect of the distribution of martensite particles on the magnetization curve by decreasing the number of crystal grains per unit area using SUS 304 wires. The magnetization curve for the SUS 304 wires with an applied plastic tensile strain from 10 %–30% was measured using a squid magnet flux meter. Fig.1 shows the relationship between the plastic tensile strain and martensite fraction obtained by the saturation magnetization method. The martensite fraction for a wire diameter of 0.8 mm grew exponentially with increasing plastic tensile strain, and the behavior was the same as the results of the bulk material [3],[4]. However, for the wire diameter of 0.4 mm, the martensite fraction linearly increased, and this value was approximately 2/3 smaller than for the wire diameter of 0.8 mm. From the relationship between the H_c and the martensite fraction shown in Fig.2, the H_c increased and then converged. The variance of H_c per unit martensite fraction was larger for the wire diameter of 0.4 mm in which the number of grains was smaller.

AU-09. Size-induced Enhancement of Room Temperature Magnetic Memory Effect in Fe-doped NiO Nanoparticles. *A.C. Gandhi*[1] and S.Y. Wu[1] *1. Department of Physics, National Dong Hwa University, Hualien, Taiwan*

In this study, we explore the role of size effect on the room temperature magnetic memory effect[1-3] from hydrothermally synthesized $Ni_{1-x}Fe_xO$ NPs (having a similar structure as NiO confirmed from synchrotron radiation X-ray diffraction)[4]. The effect of thermal treatment from 400°C to 800°C leads to increase of grain size from 8 to 35 nm (NiO) and 9 to 57 nm (1% Fe), suggesting Fe-doping has enhanced the crystal growth. A lattice expansion and microstrain are obtained from 8 nm NiO attributed to nickel vacancy defect and the effect of 1% Fe-doping (9 nm) resulted in further lattice expansion with reduced microstrain. On the further increase of grain size, lattice parameter approached to NiO bulk value of 4.177Å, whereas microstrain to zero. Above findings suggest that the dopant Fe^{3+} ions to move from ordered Ni^{2+} substitutional lattice sites to more disordered regions, such as surface regions. This dopant migration begins around ~500°C (27 nm) and is accompanied by suppression of disordered surface spins, and a corresponding enhancement in *n* with grain size suggests a relative increase of interparticle interaction possibly because of migration of dopant ions on the surface of NPs (Fig.1(a)). The value of *n* is obtained after analyzing time-dependent relaxation of magnetization M(t) at 300 K using $W(t)=t^{-n}$ ($W(t)=-(d/dt)\ln M(t)$).[5] The effect of interparticle interaction and broad size distribution in 1% sample leads to drastic enhancement in T_B from 140 K to far above 400 K with the increase of grain size from 9 nm to 57 nm (Fig.1(b)). An enhanced RT memory effect with grain size can be noted from Fig.2. Furthermore, both the spontaneous exchange bias (EB) field and coercivity drop with the increase of grain size. Our findings suggest that $Ni_{1-x}Fe_xO$ NPs system differs from a typical EB system. The thermal treatment at higher temperature might have resulted in the formation of interacting inverted core-shell type structure of $Ni_{1-x}Fe_xO$ NPs such that higher amount of Fe^{3+} ions are residing on the surface of NPs having a compensated AF-core.

AU-10. Néel Relaxation Time and Blocking Temperature for Nanoparticle Magnetization as a Function of Static Applied Field.
C.R. Chalifour[1], N.R. Anderson[1], T.M. Crawford[2] and K. Livesey[1]
1. UCCS Biofrontiers Center and Department of Physics, University of Colorado Colorado Springs, Colorado Springs, CO, United States; 2. Department of Physics and Astronomy, SmartState Center for Experimental Nanoscale Physics, University of South Carolina, Columbia, SC, United States

The blocking temperature of a system of magnetic nanoparticles corresponds to the temperature separating ferromagnetic and superparamagnetic behavior. This quantity occurs at an inflection point in zero field cooled (ZFC) magnetization curves [1,2] and allows one to estimate the energy barrier for magnetization reversal. The blocking temperature is not a single temperature but rather a "blocking region" exists [1,2], arising from the stochastic behavior of magnetization reversal over a barrier [1,3]. The field-independent Néel-Arrhenius equation for the magnetization relaxation time $\tau_{NA}=\tau_0 e^{KV/kT}$, describes this stochastic behavior, where the characteristic attempt time τ_0 is taken as a constant on the order of nanoseconds [2], *KV* is the anisotropy energy barrier, and *kT* is the thermal energy. However, this form is inherently flawed because it does not consider that both the attempt time and barrier height can be altered by an applied field. We use a Néel relaxation time that depends on externally applied static fields, as found by Brown [4,5], and calculate its consequences on ZFC and field-cooled (FC) curves [1]. We examine the case of an assembly of noninteracting magnetic nanoparticles with easy axes aligned parallel to the applied field, show that the analytic model reduces to the expected result in the limiting case of zero applied field, and that the ZFC peak shifts to *lower* temperatures as a larger field is applied. This is shown in the figure where just a 50 Oe field shifts the ZFC peak down (red, dashed line) compared to the case where the field-dependence of is ignored (solid, black line). Our analytic results are in excellent agreement with results of numerical Landau-Lifshitz-Gilbert simulations. We have run the model with the addition of poly-disperse particle sizes and will discuss its implication on the interpretation of experimental results.

Ciencias Básicas, Universidad Central de Chile, Santiago, Chile*

In this work, changes in hysteretic behavior for magnetic multilayer thin films with perpendicular magnetic anisotropy (PMA) under the influence of superparamagnetic nanoparticles are presented. Firstly, Si/[Pd(1.5nm)Co(0.3nm)] x10/Pd(2nm) magnetic thin films were fabricated by sputtering machine over a silicon substrate. Subsequently, $CoFe_2O_4$ nanoparticles (nps) were prepared using a stainless-steel reaction kettle with a Teflon-liner (20 ml) and were dispersed in hexane and stored at 4°C for further characterization and use. The magnetic characterization was carried out using an Alternate Gradient Force magnetometer. For the magnetic film, it is possible to observe the typical square behavior for thin film whit PMA. With 118 mg (each 10ml) of nps over the thin magnetic film, we observe a complete change in the magnetic behavior in both, remnant magnetization and coercivity. It is also possible to note a waist in the loop, which may be due to a chiral reversion process in film induced by the interaction with nps. The change in the main features of the hysteresis loop generates a great possibility of novel applications.

AU-13. Room temperature ferromagnetic behaviour in Dy^{3+} doped dilute magnetic semiconductor nanoparticles. *S. Jindal*[1] and P. Sharma[2] *1. School of Physics and Material Science, Thapar Institute of Engineering and Technology, Patiala, India; 2. School of Physics and Material Science, Thapar Institute of Engineering and Technology, Patiala, India*

II-VI dilute magnetic semiconductors are promising material for application in electronics. Currently a great deal of attention is being focused on adding spin degree-of-freedom into semiconductor to create a new area of solid-state electronics, called spintronics [1]. Such materials need to be good semiconductors for easy integration in typical integrated circuits with high sensitivity to the spin orientation. The major material challenge is to magnetize and stabilize semiconductors with room temperature ferromagnetic ordering without significantly affecting the physical properties of semiconductors. Cadmium sulfide (CdS) is one of the promising II-VI semiconductor due to its inherent property of direct band gap of 2.42 eV and in green spectral range [2, 3]. Rare-earth (RE) elements play an important role in many functional materials and exhibit interesting magnetic and optoelectronic properties. Due to their highly localized 4f electrons, the direct f-f interactions between the neighbouring rare-earth atoms are very weak. This produces larger magnetic moments in 4f REs than 3d transition metals. Most of the earlier works on dilute magnetic semiconductor (DMS) were focused on TM doped ZnS, CdS. Since REs have higher magnetic moment than TMs, we expect to achieve higher magnetization with a few percentages of RE doping. In the present work, $Cd_{1-x}Dy_xS$ (x = 0.00, 0.05, 0.10 and 0.15) nanoparticles were synthesized by hydrothermal technique. The room temperature (*RT)* magnetic hysteresis loops of synthesized nanoparticles are shown in Fig.1. The magnetization increases upto x = 0.10, and then decreases. This increase in magnetization may due to the formation of various defects or vacancies with doping [4]. Fig.2 shows UV- visible absorption spectra with Tauc's plot of $Cd_{1-x}Dy_xS$ nanoparticles. The optical bandgap (E_g) enhances from 2.43 eV (x = 0.00) to 2.55 eV for x = 0.10. Further, for higher doping content E_g decreases. This blue shift in optical bandgap with doping can be attributed to the quantum confinement effect.

Temperature affects every physical system, chemical reaction, and biological process. A new method, magnetic nanothermometry, is being explored to measure temperature throughout a volume. This method uses large changes in magnetization as function of temperature, which cannot be obtained with current magnetic nano-objects (MNO). To get a large magnetization change we have examined the magnetic properties of RE-doped Fe_3O_4 (RE = Eu, Gd, Er) MNO. Samples were synthesized by co-precipitation. For the doped material, RE^{+3} were chosen in order to replace the Fe^{+3} in the $(Fe^{+2})(Fe^{+3})_2O_4$ structure. Structural characterization was performed by X-ray diffraction and transmission electron microscopy. Hyperfine interaction parameters as a function of temperature (300 K to 873 K) were obtained by perturbed angular g-g correlation (PAC) spectroscopy using $^{111}In(^{111}Cd)$ as probe nuclei. To fit the PAC spectra, the ^{111}Cd probes were considered to occupy three sites: tetrahedral, octahedral, and a third site where the probes are located at the nanoparticle surface [1]. The hyperfine magnetic field B_{hf} was calculated using the Larmor equation, and its behavior as a function of temperature follows a Brillouin-type transition. For example, the Curie temperature (T_C) obtained for 5% Er-doped was approx. 846 K (FIG. 1), which is higher than the expected T_C for pure Fe_3O_4 (approx. 722 K) [2]. Magnetization as a function of temperature shows a 70 % change in magnetization around 100 K for Er-doped Fe_3O_4 (FIG.2), which is an improvement in temperature on pure Fe_3O_4 (below 50 K) [3]. Current work is focused on correlating the temperature range in which the magnetization change occurs and determining if it depends on the dopant element.

Instituto de Física, Universidade de São Paulo, São Paulo, Brazil*

The use of nanoparticles coated with different materials have been studied by many researchers to improve the quality of nanomaterials for biomedical applications such as controlled drug delivery, image contrast and treatment of cancer by magnetic hyperthermia [1]. In this work, we used oils extracted from ucuúba (Virola surinamensis), bacaba (Oenocarpus bacaba Mart.) and açaí (Euterpe oleracea Mart.) to coat Fe_3O_4 nanoparticles. The ucuúba, bacaba and açaí are native trees of the Amazon forest, whose oils are rich in fatty acids, such as lauric, myristic, steatic, oleic, palmitic, and linoleic acid, with different proportions. These pure oils, free of solvents, were obtained by the extraction method with carbon dioxide in the supercritical state [2], and then added during the synthesis process of iron oxide nanoparticles by thermal decomposition method [3]. The results of X-ray diffraction confirmed the formation of Fe_3O_4 single phase. The average size around 3 nm and spherical morphology of the magnetite nanoparticles was determined by transmission electron microscopy. The study of magnetic properties revealed a saturation magnetization (Ms) enhancement and high values of the anisotropy constant for Fe_3O_4 samples when coated with açaí (91.4 emu.g^{-1}; 4.6 10^5 J.m^{-3}) and ucuúba (80.6 emu.g^{-1}; 9.3 10^5 J.m^{-3}) oils, which present a large percentage of saturated total fatty acid. The results indicate that nanoparticles with sizes smaller than around 5 nm present Ms values as high as those found in bulk Fe_3O_4 and higher than those usually obtained for nanoparticles coated with oleic acid [4]. The neutron activation analysis (NAA) nuclear technique was used to determine with high accuracy the mass of Fe in the Fe_3O_4 core of nanoparticles in order to normalize the magnetization values [5]. These results show that natural oils have a great potential to produce stable and quality nanoparticles as compared with conventional coated.

AV-01. Ultrasound-Velocity Measurements in Spin-Frustrated Cobaltite $CoTi_2O_5$. *K. Takayanagi*[1], T. Watanabe[1], F. Kirschner[2], D. Prabhakaran[2], S. Blundell[2] and Y. Hara[3] *1. Nihon University, Tokyo, Japan; 2. Oxford University, Oxford, United Kingdom; 3. National Institute of Technology, Ibaraki College, Hitachinaka, Japan*

Orthorhombic cobaltite $CoTi_2O_5$ is considered to be a low-dimensional frustrated antiferromagnet with T_N = 26 K, which consists of magnetic Co^{2+} chains running along the crystal *a* axis [1]. For this compound, the experimentally-determined antiferromagnetic order below T_N is incompatible with the orthorhombic crystal structure above T_N [1]. Thus, in $CoTi_2O_5$, it is considered that, although the structural transition has not been experimentally observed so far, a spin-driven lattice distortion should coincide with the antiferromagnetic ordering at T_N, where the spin-lattice coupling lowers the crystal symmetry resulting in the release of frustration. Such a so-called spin-Jahn-Teller transition has experimentally been identified only in cubic chromite spinels ACr_2O_4 (A = Zn and Mg), where the magnetic Cr^{3+} ions form three-dimensional sublattice of corner sharing tetrahedra (pyrochlore lattice) [2]. For the verification of the spin Jahn-Teller effect in the low-dimensional antiferromagnet $CoTi_2O_5$, we perform ultrasound velocity measurements in the single-crystalline sample. The ultrasound velocity measurements have been proven to be a powerful tool for the study of spin-lattice-coupling-driven phenomena in the frustrated magnets [2,3,4]. Figures 1 and 2 respectively show temperature dependence of shear elastic moduli C_{55} and C_{66} in the orthorhombic $CoTi_2O_5$, which are respectively obtained by measuring the velocity of transverse ultrasound with propagation $k||a$ and polarization $u||c$, and that with $k||a$ and $u||b$. Both C_{55} and C_{66} exhibit monotonic hardening upon cooling, as is usually observed in solids [5]. Additionally, C_{66} exhibits a discontinuous change at $T_N \sim 26$ K as shown in the inset to Fig. 2. In the presentation in the conference, we report the experimental results in all the symmetrically-independent elastic moduli in the orthorhombic $CoTi_2O_5$.

AV-02. Magnetic properties and the planer Hall effect of CoFeMnSi films. *K. Yamada*[1,2], T. Kimura[1], K. Elphick[2] and A. Hirohata[2] *1. Department of Physics, Kyushu University, Fukuoka, Japan; 2. Department of Electronic Engineering, University of York, York, United Kingdom*

Recently, a spin gapless semiconductor (SGS) attracts increasing attention because SGS has high resistivity, high spin polarization and a Dirac electron system. L. Bainsla *et al.* have reported the signature of SGS in a bulk CoFeMnSi(CFMS) crystal [1)]. H. R. Fu *et al.* have then reported an anomalous Hall effect in epitaxial CFMS thin films [2)]. On the other hand, a planer Hall effect (PHE) is useful for magnetic sensors as the PHE strongly depends on the direction of a magnetic field. In this presentation, we will report the PHE and magnetic properties of CFMS thin films. We prepared the films consisting of Ta (5)/Ru (5)/CFMS (20)/Ta (5) and Ru (5)/CFMS (10)/Ta (5) (thickness in nm) on Si substrates by high vacuum sputtering. At first, we measured the temperature T dependence of the conventional Hall effect introducing a magnetic field perpendicular to the film plane using an AC lock-in method. The Hall coefficient is found to increase with decreasing measurement temperature. This behavior shows that obtained films are semiconductor-like. Next, we measured the magnetic field H dependence of transverse magnetoresistance introducing a magnetic field horizontal to the film at T = 6 and 300K. The experimental configuration is shown in the inset of Fig 1(a). The magnetic field dependence of transverse resistance R_{XY} is shown in Fig 1(a), while the angle θ dependence of R_{XY} is shown in Fig 1(b). Here, the magnetic resistivity ρ_{XY} due to PHE is described as $\rho_{XY} = (\rho_{\perp}-\rho_{//}) \sin(2\theta)/2$ where $\rho_{\perp}$ and $\rho_{//}$ are the resistivity under magnetic fields applied transverse and parallel to the current, respectively. It is well known that two origins for PHE exist. One is an spin-orbit interaction due to the intrinsic magnetization and another is breaking of time reversal symmetry in Dirac electron systems [3)]. We found that PHE of CFMS films is not induced by the Dirac electrons but by their intrinsic magnetization as evidenced by the presence of hysteretic magnetic behavior. Such films can be useful from the viewpoints of fundamental physics and sensor applications.

AV-03. Enhanced Room Temperature Ferromagnetism in MoS_2 by N Plasma Treatment. *B. Wang*[1], D. Zhang[1], H. Wang[1], H. Zhao[1], R. Liu[2], Q. Li[1], S. Zhou[3], L. Sun[2], J. Du[2] and Q. Xu[1] *1. School of Physics, Southeast University, Nanjing, China; 2. School of Physics, Nanjing University, Nanjing, China; 3. Institute of Ion Beam Physics and Materials Research, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany*

MoS_2 is a typical two-dimensional material of unique properties, which has important applications in semiconducting devices [1]. The introduction of ferromagnetism in MoS_2 may further extend its applications in spintronics. MoS_2 powders were prepared by hydrothermal method. N plasma was introuduced into a vacuum chamber with RF power of 100 W at N_2 pressure of 10 Pa for various durations at room temperature to treat MoS_2 powders. The morphologies of MoS_2 change little after the N plasma treatment. X-ray diffraction patterns and Raman spectra confirm the 2H structure, with little variation with increasing N plasma treatment time. The wavenumber difference of more than 24.5 cm^{-1} between E^1_{2g} and A_{1g} peaks indicates the thick layer structure [2]. X-ray photoelectron spectroscopy confirms the adsorption of N after the N plasma treatment, and higher valence state of Mo than +4 due to the bonding with N. The magnetic measurements show weak room temperature ferromagnetism of the as-prepared MoS_2 with saturated magnetization of only 1.13 memu/g after the subtraction of high field linear background, as shown in Fig. 1(a). With increasing the N plasma treatment time, the magnetization shows negligible variation. A sudden increase of saturated magnetization to 3.5 memu/g is achieved after the N plasma treatment for 30 min, shown in Fig. 1(b). However, the saturated magnetization drastically decreases with further increasing N plasma treatment time. To exclude the possible experimental errors, we repeated the experiment, and similar results were obtained. This indicates that the room temperature ferromagnetism can only be enhanced in a narrow period of N plasma treatment. First principle calculation has been performed to calculate the possible origin of ferromagnetism, and shows that only the chemical adsorbed N ions on S ions may form conjugated π bonds with adjacent Mo ions to have total magnetization of 0.75 m_B (inset of Fig. 1(b)), contributing to the observed room temperature ferromagnetism.

AV-04. Substitution Effects on Magnetism of Laves-Phase Iron Compound $ZrFe_2$. *T. Suzuki*[1], Y. Fukushima[1], Y. Takei[1] and T. Watanabe[1] *1. Department of Physics. College of Science and Technology, Nihon University, Tokyo, Japan*

Transition-metal Laves-phase compounds AB_2 (B = transition-metal element) exhibit a variety of electron-correlation-driven novel phenomena such as the emergence of heavy-fermionic behavior in Sc-doped YMn_2 ($(Y_{1-x}Sc_x)Mn_2$) [1,2], and ferromagnetic quantum criticality in nonstoichiometric $NbFe_2$ ($Nb_{1-x}Fe_{2+x}$) [3,4]. Laves-phase iron compound $ZrFe_2$ is a metallic ferromagnet with $T_C \sim 620$ K [5], where Fe 3*d* electrons are expected to dominate the physical properties. This compound has C15-type cubic Laves-phase crystal structure, which contains Fe sublattice of corner-sharing tetrahedra (pyrochlore lattice). For the exploration of electron-correlation-driven phenomena, we study element substitution effects on the magnetism of $ZrFe_2$ by investigating structural, magnetic, and electrical properties of mixed crystals $Zr_{1-x}Fe_{2+x}$, $Zr(Fe_{1-x}B_x)_2$ (B = Mn and Co), and $(Zr_{1-x}A_x)Fe_2$ (A = Y, Nb, Ti, and Hf). Figures 1 and 2 respectively show temperature dependence of zero-field-cooled (ZFC) and field-cooled (FC) magnetic susceptibilities in polycrystalline $Zr(Fe_{1-x}Mn_x)_2$ and $Zr(Fe_{1-x}Co_x)_2$ ($x = 0.4 \sim 0.7$). We note here that, according to X-ray diffraction experiments at room temperature in these samples, $Zr(Fe_{1-x}Mn_x)_2$ with $x = 0.4 \sim 0.7$ crystallizes in C14-type hexagonal Laves-phase structure, while $Zr(Fe_{1-x}Co_x)_2$ with $x = 0.4 \sim 0.7$ crystallizes in C15-type cubic Laves-phase structure. From Figs. 1 and 2, it is evident that, for $ZrFe_2$, the ferromagnetic order is suppressed by substitution of Mn or Co for Fe. In the presentation in the conference, we report the experimental results in polycrystalline $Zr_{1-x}Fe_{2+x}$, $Zr(Fe_{1-x}B_x)_2$ (B = Mn and Co), and $(Zr_{1-x}A_x)Fe_2$ (A = Y, Nb, Ti, and Hf) in detail.

AV-05. Spin Wave Excitation in the Kitaev Honycomb Magnet α-$RuCl_3$.
S. Ji[1], S. Do[2], D. Voneshen[3] and K. Choi[4] *1. Neutron Science Center, Korea Atomic Energy Research Institute, Daejeon, The Republic of Korea; 2. Max Planck POSTECH, Pohang, The Republic of Korea; 3. ISIS Facility, Rutherford Appleton Laboratory, Didcot, United Kingdom; 4. Physics, Chung-Ang University, Seoul, The Republic of Korea*

Recently, α-$RuCl_3$ has been hailed as a promising candidate for the 2-dimensional Kitaev honeycomb model[1]. Due to its proximity to the Kitaev quantum spin liquid state[2,3], the compound simultaneously shows a broad continuum-like spin excitation and spin-wave modes from antiferromagnetically ordered spins. In this presentation, we provide a complete picture of magnetic excitation in α-$RuCl_3$. By using inelastic neutron scattering measurements with high resolution, we obtained clear spin wave excitations distinguishable from a broad continuum excitation. Our spin wave theory analysis with higher-order expansion not only identifies the spin wave modes by a minimal spin exchange model Hamiltonian but also suggests coexistence of fractional spin exictations and magnons in the compound. Furthermore, we present the magnetic field dependence of spin excitation and discuss about the possible field-induced quantum spin liquid state.

AV-06. Fabrication of noncentrosymmetric Nb/V/Ta superlattice and its superconductivity.
F. Ando[1], D. Kan[1], S. Nakamura[2], M. Naritsuka[2], Y. Kasahara[2], Y. Shiota[1], T. Moriyama[1], Y. Shimakawa[1], Y. Matsuda[2] and T. Ono[1] *1. Institute for Chemical Research, Kyoto University, Uji, Japan; 2. Department of Physics, Kyoto university, Kyoto, Japan*

Spin-orbit interaction (SOI) has recently been attracting intense attentions in the various fields of solid state physics, such as spintronics, topological matter, and unconventional superconductivity. In case of superconductors, the SOI with broken inversion symmetry significantly forbids the conventional classification of Cooper pairs and a mixed spin singlet-triplet state is expected to be realized [1]. There have been several reports of superconductors where the crystalline structure lacks a center of inversion, such as $CePt_3Si$ [2], $CeRhSi_3$ [3], and UIr [4]. Then, we can expect that an unconventional superconductivity can be explored in an artificial superlattice without inversion symmetry. In the present work, we show the crystal growth and conductivity of *ABC*-type superlattice [Nb/V/Ta] as a new platform to investigate an unconventional superconductivity. Nb, V, and Ta are all commonly-used superconducting elements and have body-centered cubic lattice structure. The $[Nb\ (t\ nm)/V\ (t\ nm)/Ta\ (t\ nm)]_n$ (n = 20/t and 40/t) superlattices were sputtered onto MgO(100) substrates at 750 degree. At first, we investigated the interfacial morphology and crystalline structure. Figure 1 shows the measured and calculated X-ray reflection curves for the superlattice (t = 1.0). Two noticeable Bragg peaks directly indicate that 2.8-nm-thick Nb/V/Ta multi-layers are periodically deposited with highly sharp interfaces. In addition, we confirmed the epitaxial growth of the superlattice by the combination of RHEED and X-ray diffraction. Finally, the electric resistivities were measured at low temperature as shown in figure 2. The inset of the figure is a photomicrograph of the processed film with the measurement configuration. It was found that the superlattices exhibited superconducting transitions [5]. In the presentation, we will discuss more details about the superconducting properties including critical magnetic fields.

AV-07. Substitution Effects on Magnetism of Spin-Frustrated Chromite and Ferrite Spinels.
K. Miura[1], Y. Koga[1], Y. Sugaya[1] and T. Watanabe[1] *1. Department of Physics, Nihon University, Tokyo, Japan*

Chromite spinel $CdCr_2O_4$ and ferrite spinel $CdFe_2O_4$ are considered to be typical spin-frustrated magnets, where orbital-inactive magnetic ions of Cr^{3+} ($3d^3$) with spin S = 3/2 and Fe^{3+} ($3d^5$) with S = 5/2 respectively form the sublattice of corner sharing tetrahedra (pyrochlore lattice). $CdCr_2O_4$ with the Weiss temperature Θ_W ~ -70 K exhibits an antiferromagnetic transition at T_N ~ 8 K in coincidence with the cubic-to-tetragonal lattice distortion [1,2]. On the other hand, for $CdFe_2O_4$ with Θ_W ~ -53 K, although the magnetic susceptibility exhibits an antiferromagnetic-transition-like anomaly at ~ 13 K, the

neutron scattering experiments revealed the absence of long-range magnetic order down to low temperature (1.5 K) [3]. We study substitution effects on the frustrated magnetism of $CdCr_2O_4$ and $CdFe_2O_4$ by investigating structural and magnetic properties of mixed crystals $Cd(Cr_{1-x}Fe_x)_2O_4$, $Cd(Cr_{1-x}B_x)_2O_4$ (B = V and Mn), and $Cd(Fe_{1-x}B_x)_2O_4$ (B = Mn and Co). Figure 1 shows temperature dependence of zero-field-cooled (ZFC) and field-cooled (FC) magnetic susceptibilities in polycrystalline $Cd(Cr_{1-x}Fe_x)_2O_4$. While $CdCr_2O_4$ (x = 0) exhibits an antiferromagnetic transition at T_N ~ 10 K, the mixed-crystal samples exhibit spin-glass-like behavior below ~ 10 K. Temperature dependence of ZFC and FC magnetic susceptibilities in $Cd(Cr_{1-x}Mn_x)_2O_4$ is shown in Fig. 2. The emergence of a ferromagnetic order in $Cd(Cr_{1-x}Mn_x)_2O_4$ with x = 0.4 ~ 0.7 is discovered, which should be driven by the substitution of e_g-orbital-active Mn^{3+} ($3d^4$) with S = 2 for orbital-inactive Cr^{3+} ($3d^3$) with S = 3/2. In the presentation in the conference, we report the experimental results in polycrystalline $Cd(Cr_{1-x}Fe_x)_2O_4$, $Cd(Cr_{1-x}B_x)_2O_4$ (B = V and Mn), and $Cd(Fe_{1-x}B_x)_2O_4$ (B = Mn and Co) in detail.

AV-08. Superconductivity and magnetism of $Eu_{1-x}La_xFeAsF_{1-y}$. *S. Totsuka*[1], S. Demura[1] and Y. Takano[1] *1. Department of Physics, Nihon University, Tokyo, Japan*

After the discovery of superconductivity at 26 K in $LaFeAsO_{0.89}F_{0.11}$ [1], the isostructural superconducting compounds $Sr_{1-x}R_xFeAsF$ (R = rare earths) are found in 2009 [2]. This superconductivity is due to the electron doping. However, the superconductivity is not appeared by the F deficiency in $SrFeAsF_{1-y}$, irrespective of a same electron doping. We have previously investigated effects of the F deficiency in superconducting $Sr_{1-x}R_xFeAsF_{1-y}$ and found that T_C decreases with increasing y [3]. While Eu ion is divalent in EuFeAsF [4], it is trivalent in EuFeAsO [5]. The valence of Eu ion is sensitive to the chemical environment. In order to study the valence of Eu ion in $Eu_{1-x}R_xFeAsF_{1-y}$, we have prepared $Eu_{1-x}La_xFeAsF_{1-y}$, and investigated their electrical and magnetic properties. All samples were prepared by the solid state reaction. Stoichiometric amounts of raw materials FeF_2, EuAs, La, Fe and As were weighted, mixed and pressed into bars in Ar atmosphere. They were heated at 773 K for 5 h, and 1173 K for 60 h in an evacuated quartz tube. EuFeAsF is almost single phase and several impurity phases increase with increasing x and y. While the lattice constant a is unchanged for all samples, the lattice constant c decreases with the increase of x and y. Figure 1 shows the temperature dependence of the magnetic susceptibility (χ - T) of EuFeAsF. It obeys a Curie law. The absolute value is smaller than Eu^{2+} free ion value. There are two possibilities; one is a mixing of Eu^{2+} and Eu^{3+} ions, and the other is an antiferromagnetic interaction between Eu^{2+} ions. While the former can not reproduce the experimental result, the latter with the Weiss temperature of 5.5 K fits it. In χ - T curve of Eu_{1-x} La_xFeAsF, the hump considered to be due to a ferromagnetic impurity is observed in addition to the shifted Eu^{2+} ion value above x = 0.45. It increases with increasing x. Similar hump is observed in $Eu_{0.6}$ $La_{0.4}FeAsF_{1-y}$. Figure 2 shows $T_C - (x, y)$ phase diagram of $Eu_{1-x}La_xFeAsF_{1-y}$. Superconductivity is observed between x = 0.4 and 0.6. The highest T_C is about 37 K at x = 0.4, and T_C decreases with increasing y.

AV-09. Effects of Zn-Site Magnetic Substitution in Frustrated Chromite Spinel $ZnCr_2O_4$. *F. Tsujimura*[1] and T. Watanabe[1] *1. Department of Physics, College of Sience and Tecnology, Nihon University, Tokyo, Japan*

Chromite spinel $ZnCr_2O_4$ is a typical frustrated magnet, where the magnetic Cr^{3+} ions form the sublattice of corner sharing tetrahedra (pyrochlore lattice). This compound exhibits an antiferromagnetic transition in coincidence with the cubic-to-tetragonal structural contraction at T_N ~ 13 K, which is much lower than the Weiss temperature θ_W ~ -390 K [1]. For $ZnCr_2O_4$, it is considered that the spin-lattice coupling lowers the crystal symmetry resulting in the release of frustration, which is called spin Jahn-Teller effect [2,3]. We study effects of Zn-site magnetic substitution on the spin Jahn-Teller order of $ZnCr_2O_4$ by investigating structural and magnetic properties of mixed crystals $(Zn_{1-x}A_x)Cr_2O_4$ (A = Mn, Fe, Co, and Cu). For $ZnCr_2O_4$, it was previously reported that the small-amount nonmagnetic substitution of the Zn-site sensitively suppresses the spin Jahn-Teller order, resulting in the emergence of spin-glass-like behavior [4,5]. Figure 1 shows temperature dependence of zero-field-cooled (ZFC) and field-cooled (FC) magnetic susceptibilities in polycrystalline $(Zn_{1-x}A_x)Cr_2O_4$ (A = Mn, Fe, Co, and Cu) with x = 0.1. All the samples exhibit Curie-Weiss behavior at high temperatures above ~ 150 K (not shown). At low temperatures below ~10 K, the A = Mn, Co, and Cu samples exhibit the ZFC-FC hysteresis, indicating the emergence of spin-glass-like behavior. Additionally, the magnetic susceptibility of the A = Mn sample is rapidly enhanced upon cooling from ~ 30 K down to ~10 K. For the A = Fe sample, the magnetic susceptibility exhibits the ZFC-FC hysteresis below ~ 130 K. Figure 2 shows temperature dependence of ZFC and FC magnetic susceptibilities in polycrystalline $(Zn_{1-x}Mn_x)Cr_2O_4$ with x = 0 ~ 0.1. It is evident that the antiferromagnetic order (spin Jahn-Teller order) is sensitively suppressed by Mn substitution, resulting in the emergence of spin-glass-like behavior.

AV-10. Complex high field phase of the Kondo-lattice $CeRhIn_5$ unveiled by NMR. G. Lesseux[1], H. Sakai[2], Y. Tokunaga[2], S. Kambe[2], P. Kuhns[3], A. Reyes[3], J. Thompson[4], P. Pagliuso[1] and *R.R. Urbano*[1] *1. DEQ, State University of Campinas, Campinas, Brazil; 2. Advanced Science Research Center, Japan Atomic Energy Agency, Tokai, Japan; 3. National High Magnetic Field Laboratory, Tallahassee, FL, United States; 4. Los Alamos National Laboratory, Los Alamos, NM, United States*

Magnetic fields around B*~30T is proven to induce significant changes in the Fermi surface of the Kondo-lattice compound $CeRhIn_5$ as revealed by various macroscopic probes [1-4]. Although there is an increasing number of experimental signatures of a field-induced singularity emerging at B*, there is a lack of microscopic evidences for such a singularity due to inherent experimental challenges. Here, we report low temperature and high field ^{115}In Nuclear Magnetic Resonance (NMR) measurements of a high quality $CeRhIn_5$ single crystal through B*. Upon increasing the applied magnetic field along the c-axis at 0.5K, although a line broadening at high fields, no remarkable change of the planar In(1) signal was observed in the entire field range to 45T. Also, the formal Knight shift K′(1) was found to be virtally constant for all measured fields except at B* when it displays a dramatic discontinuity. Our results are the first microscopic evidences for the emergence of the singulatiry found at 30T. The interpretation is based on a scenario where a field-induced mixing of the crystal electric fields (CEF) energy levels is a key ingredient for the enhancement of hybridization between the Ce 4f and the conduction electrons c.e. resulting in a greater itinerant character of the f-electrons above B*. This ultimately may lead to a quantum critical point predominantly itinerant at B~50T in $CeRhIn_5$.

AV-11. Realization of Various Weyl Semimetal Phases in Topoelectrical Circuit Models. *S. Rafi-Ul-Islam*[1], Z. Siu[1] and M.B. Jalil[1] *1. Electrical and Computer Engineering, National University of Singapore, Singapore*

We present an effective method to realize various Weyl semimetals (WSM) phases in three-dimensional topoelectrical (TE) circuit lattices composed of inductors and capacitors (Figs. 1a and 1b). The Laplacian of its admittance matrix at resonant frequency is given by L_{Weyl} (k)=i ω_r [(c_{Az}+c_{Bz}) cos k_z σ_o-(c_1+c_2 cos k_x + 2c_y cos k_y)σ_x - c_2 sin k_x σ_y -(c_{Az}-c_{Bz}) cos k_z σ_z] (1) where,ω_r, c_is and L_is are the resonant frequency, and coupling capacitances and inductances [1] respectively. Eq. 1 yields two pairs of Weyl points (WPs) located at (π, ± arccos((c_2-c_1)/2c_y), ±π/2) in *k* space. A capacitive (inductive) coupling between two B sublattice nodes along the z direction will cause the tilt strength (c_{Az}+c_{Bz}) to be greater (less) than the effective velocity term (c_{Az}-c_{Bz}) around the WP, giving rise to a pair of Type II (Type I) WPs shown in Fig. 1d (Fig. 1c). The Type-I and Type-II WSMs have closed elliptical and open hyperbolic iso-admittance contours (IAC) respectively (Fig. 2a and Fig. 2b). We calculated the impedance between two nodes by using the circuit Green's function [2], and classified the two Weyl phases by the impedance spectrum at resonance. Type-I WSMs show impedance peaks in the vicinity of WPs only (Fig. 2c), while Type-II WSMs exhibit many secondary peaks (Fig. 2d). This impedance behaviour is analogous to the vanishing and non-vanishing density of states at the WPs in the two WSM phases respectively. The experimental accessibility of TE circuit models makes it a ready platform for the study of novel transport phenomena in WSM-based nanodevices [3].

AV-12. Impurity effect of quantum spin trimer system $Na_2(Cu_{1-x}Ni_x)_3Ge_4O_{12}$. *R. Toma*[1] and Y. Yasui[1] *1. Physics, Meiji University, Kawasaki, Japan*

The quantum spin trimer system $Na_2Cu_3Ge_4O_{12}$ has the one-dimensional array of Cu_3O_8 trimers formed of edge-sharing three CuO_4 square planes which have Cu at center of square planes in Fig.1 [1]. The exchange interactions between Cu^{2+} spins, J_1, J_2 and J_3 were reported by analyzing magnetic susceptibility data and specific heat one [2]. The nearest-neighbor exchange coupling J_1 (J_1/k_B = 30 ± 20 K, antiferromagnetic) and the second-neighbor one J_2 (J_2/k_B = 340 ± 20 K) were reported by employing the isolated S = 1/2 Heisenberg trimer model above 70 K. In the low temperature region, two spins of the edge in the Cu_3O_8 trimer forms a nonmagnetic singlet by strong antiferromagnetic interaction J_2, and the spin left in the center of the Cu_3O_8 trimer forms one-dimensional chains by the exchange interaction J_3 (J_3/k_B = 18 ± 1 K) between the trimers, which was evaluated by S = 1/2 uniform Heisenberg chain model. $Na_2Cu_3Ge_4O_{12}$ exhibits antiferromagnetic transition at T_N = 2 K accompanied with ferroelectric transition (multiferroic phenomenon) [2]. In order to investigate the magnetic dynamics of the present system, we have studied impurity effect on magnetic susceptibility and specific heat of $Na_2(Cu_{1-x}Ni_x)_3Ge_4O_{12}$, where spin S = 1/2 of Cu^{2+} ions is replaced by S = 1 of Ni^{2+} ions. From the analyses of the specific heat and magnetic susceptibility, J_1 and J_2 are affected heavily by replacing Ni^{2+} ions with Cu^{2+} ions. On the other hand, J_3 and transition temperature T_N are had little effect by Ni-doping. We have observed the magnetic specific heat components newly appear at around 12 K by Ni-doping. In the presentation, we discuss the magnetic dynamics of $Na_2Cu_3Ge_4O_{12}$ by analyzing the magnetic susceptibility and specific heat data of the Ni-doping system.

[1]Mo *et al.*;Iong.Chem.45,3478-3480,(2006). [2] Yasui *et al.*;J.Appl. Phys.115, 17E125, (2014).

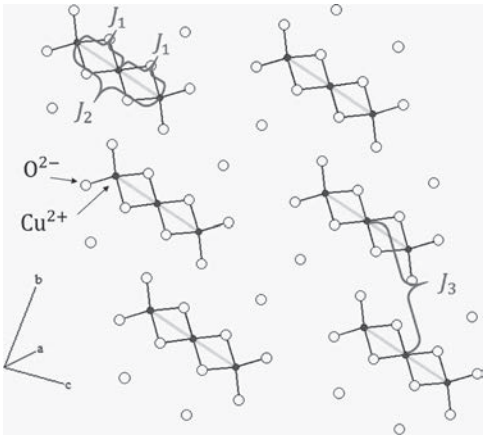

Fig.1 Schematics structure of $Na_2Cu_3Ge_4O_{12}$ cut into a plane of Cu_3O_8 trimers formed of edge-sharing three CuO_4 square planes [1]. The exchange coupling J_1, J_2 and J_3 are defined.

AV-13. Magnetic Properties of Frustrated Quantum Spin Chain System $Rb_2(Cu_{1-x}M_x)_2Mo_3O_{12}$ (M=Zn, Ni). *Y. Yasui*[1], Y. Okubo[1], S. Kittaka[2] and T. Sakakibara[2] *1. Physics, Meiji University, Kawasaki, Japan; 2. Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan*

We have investigated magnetic properties of the frustrated quasi-one-dimensional quantum spin system $Rb_2(Cu_{1-x}M_x)_2Mo_3O_{12}$ (M=Ni, Zn)., which are formed of edge-sharing CuO_4 square planes called as CuO_2 ribbon chains. The spin systems with the CuO_2 ribbon chains attract much attention, because the competition between the nearest-neighbor exchange interaction J_1 and the second neighbor interaction J_2 often induce the anomalous physical properties and exotic quantum states. Authors' group found that $Rb_2Cu_2Mo_3O_{12}$ exhibits the magnetic field induced ferroelectric transitions at $T_c \sim 8$ K [1]. The magnetic ground state of $Rb_2Cu_2Mo_3O_{12}$ is found to be non-magnetic state, which is the first example of non-magnetic ground state for CuO_2 ribbon chain systems [2]. Here, we have prepared several polycrystalline samples of partially substituted Zn^{2+} (S=0) or Ni^{2+} (S=1) to the Cu^{2+} (S=1/2) ions of $Rb_2Cu_2Mo_3O_{12}$. Measurements of the magnetic susceptibility (χ) and specific heat have been carried out for the spin systems, in order to understand the physics of non-magnetic state through the impurity effect on magnetic properties. For $Rb_2Cu_2Mo_3O_{12}$, the $\chi - T$ curve has a broad maximum at peak temperature $T_{max} \sim 13.5$K due to grow the antiferromagnetic short range ordering. With increasing Zn- or Ni- concentration, the values of T_{max} systematically decrease, and antiferromagnetic short range ordering is suppressed. The magnetic specific heat (C_{mag}) is evaluated by using specific heat data of a non-magnetic system $Rb_2Mg_2Mo_3O_{12}$. The $C_{mag}/T - T$ curve of x=0 has broad peak at ~ 8K. By the Zn- or Ni- doping, the broad peak of the $C_{mag}/T - T$ curve significantly is suppressed. Impurity effects of the Zn-doping on the magnetic properties have been found to be stronger than that of Ni-doping. For $Rb_2Cu_2Mo_3O_{12}$ below ~2 K, a dome-shape magnetic ordering phase exists in H-T phase diagram at the region of H_c (= 2.3 T) ≤ H < 13 T. By the Zn- or Ni- doping of x=0.01, temperature values of the phase boundary become higher than that of x=0, and the dome-shape magnetic ordering phase becomes stable. We present various magnetic properties of $Rb_2(Cu_{1-x}M_x)_2Mo_3O_{12}$ (M=Ni, Zn).

[1] Y. Yasui *et al*.: J. Appl. Phys. 113, 17D910 (2013). [2] Y. Yasui *et al*.: JPS Conf. Proc. 3, 014014 (2014).

AV-14. Magnetic properties of $Ba_3Co_{1-x}Ca_xRu_2O_9$. *A. Nagaya*[1], A. Horie[1], Y. Yasui[2], T.D. Yamamoto[3] and I. Terasaki[3] *1. Meiji University, Kawasaki, Japan; 2. Meiji University, Kawasaki, Japan; 3. Nagoya University, Nagoya, Japan*

We have measured magnetic susceptibility and specific heat on polycrystalline samples of $Ba_3Co_{1-x}Ca_xRu_2O_9$. The compounds with the general formula $Ba_3MRu_2O_9$ (M = Co, Ca, and Zn) have the Ru_2O_9 dimers, made from face-shared RuO_6 octahedra, connected with corner-shared MO_6 octahedra to form triangular lattice in the ab-plane. The magnetic ground states of the compounds are varied by the species of M. In $Ba_3CoRu_2O_9$, it is reported that Co^{2+} ($3d^7$) and Ru^{5+} ($4d^3$) ions have local spin and both spin systems exhibit an antiferromagnetic transition at $T_N \sim 100$ K [1]. On the other hand, the ground state of $Ba_3CaRu_2O_9$ is a non-magnetic state, because the Ru_2O_9 dimers are in the non-magnetic singlet state [2]. Recently, a novel type of spin liquid behavior has been reported in $Ba_3ZnRu_2O_9$ [3]. We have controlled the magnetic ground state from an antiferromagnetic order to non-magnetic state by making a solid solution system $Ba_3Co_{1-x}Ca_xRu_2O_9$. Measurements of the magnetic susceptibility and specific heat have been carried out on several polycrystalline samples of $Ba_3Co_{1-x}Ca_xRu_2O_9$. With increasing x, an antiferromagnetic transition temperature T_N decreases such as $T_N = 73$ K ($x = 0.3$), and 50 K ($x = 0.5$). The magnetic ground state of the spin systems is changed to a spin-glass state at around $x \sim 0.55$, where spin-glass transition temperature $T_{sp} = 26$ K ($x = 0.6$), and 6 K ($x = 0.8$). In the region of $x > 0.9$, the spin systems are found to have a non-magnetic ground state. We have also studied spin states of Co^{2+} ($3d^7$) and Ru^{5+} ($4d^3$) ions of $Ba_3Co_{1-x}Ca_xRu_2O_9$ by analyzing the magnetic specific heat and magnetic entropy. In the presentation, we discuss the magnetic properties and spin states of $Ba_3Co_{1-x}Ca_xRu_2O_9$.

Antiferromagnetic (AFM) spintronics has drawn significant attention recently due to its potential for low power consumption information storage and processing [1,2]. NiO is one of the most common AFM oxides, and becomes a fascinating candidate for investigating many novel spin-dependent phenomena in AFMs, such as spin Hall magnetoresistance, enhanced spin current transmission, THz magnons, and AFM switching by the spin-orbit-torque. All those spin-dependent transport properties should be closely correlated with the electronic structure of NiO, which has been paid little attention especially in ultrathin film range. In this contribution, we experimentally studied the electronic band structure of NiO films epitaxied on Ag(001). Utilizing the spin-polarized low energy electron microscopy in Lawrence-Berkeley National Laboratory, we measured the electron reflectivity as a function of NiO film thickness and electron energy. We found that the electron reflectivity oscillates systematically with electron energy and film thickness. Our experimental data can be well described by the phase accumulation model, which can be used to derive the band dispersion along the direction in the energy range of 3-8 eV and 12-20 eV above the Fermi surface. We also found that the electron reflectivity shows the weak quantum interference effect in CoO/Ag(001) system. Our work demonstrates the electron quantum interference effect inside the AFM thin films, which might provide further understandings of novel effects in the field of AFM spintronics.

AV-16. Strong Coupling of a Ferromagnetic Sphere to a High-Tc Superconducting CPW Resonator. *I.W. Haygood*[1,2], E. Edwards[3,1], M. Pufall[1] and W.H. Rippard[1] *1. 687, NIST, Boulder, CO, United States; 2. Physics, University of Colorado - Boulder, Boulder, CO, United States; 3. IBM, Albany, NY, United States*

Hybrid quantum systems based on microwave cavity resonators and collective spin excitations in ferrimagnetic YIG structures have recently been explored at both room temperature and in the quantum limit [1]. These systems typically consist of a YIG element, often a mm-scale sphere, which couples to the RF magnetic field of a microwave cavity leading to level repulsion between the microwave cavity mode and the magnetostatic modes in the ferromagnet. These hybrid systems have been shown as possible candidates for use as quantum memories [2], microwave to optical transducers [3], single magnon detectors [4], and even parametric amplifiers[5]. Here we will present our work demonstrating coupling of a YIG sphere mounted to a ceramic rod coupled to a coplanar waveguide (CPW) resonator at 4 K. The system presented has the unique capability to tune the coupling to both the microwave and the coupling between the cavity and the YIG sphere. This allows us to access the strong-coupling, weak-coupling, magnetically-induced transparency, and Purcell regimes. We then discuss our plans to develop planar chip-based systems to scale the system by an order of magnitude. Finally, we will discuss how hybrid magnon-polariton systems coupled to a qubit can be used for fundamental magnetic measurements.

AV-17. Electron Correlation Effects and Magneto-Optical Property of Yttrium Iron Garnet. *H. Nakashima*[1], A.M. Pradipto[1], T. Akiyama[1], T. Ito[1] and K. Nakamura[1] *1. Physics engineering, Mie university, Tsu city, Japan*

Magneto-optical properties of YIG and other iron garnets have already been widely studied experimentally and envisaged in applications such as magneto-optical sensors. Theoretical first-principles approach has become an effective tool to investigate the electronic, magnetic and magneto-optical properties, however, only few theoretical reports are available due to the complexity of crystal structure and to the strong electron correlation for d-electrons. We have employed the constrained density functional theory (DFT) approach with linear response theory1) to calculate the Hubbard model parameter Ueff for the DFT+U treatment of the strong correlation. This method evaluates the Ueff values numerically by eliciting the difference in the second derivatives of the total energies of both the interacting and non-interacting electronic system. Calculations were performed by using the generalized gradient approximation2) to the DFT as implemented in the full-potential linearized augmented plane wave method3). A bcc unit cell of YIG (space group Ia-3d) contains a total of 160 atoms and, in our calculations, the lattice constant has been fixed to the experimental value (a=12.376 Å)4). There are two inequivalent Fe ion positions in YIG, i.e. those having octahedral and tetrahedral coordinations of oxygens, denoted here as FeO and FeT, respectively. In the present work, we have calculated the Ueff values to be 9.8 eV for FeO and 9.1 eV for FeT. We have applied the obtained Ueff values for the calculations of the electronic and magnetic properties and confirmed the validity of the Ueff value by comparing the band gap character with experimental observations. The spin magnetic moments of Fe atoms are 3.63 μB for FeO and -3.55 μB for FeT in the GGA calculation, while in the GGA+U calculation, they are 4.27 μB for FeO and -4.16 μB for FeT. We have calculated the complex dielectric function and magneto-optical Kerr effect (MOKE). Although the calculated dielectric function showed a difference compared to the experimental report, the overall MOKE spectra feature compares reasonably well with experiments. Further discussion on the discrepancy for our result of optical absorption as compared with experimental one will be presented.

AV-18. Delithiated $Fe_{1-x}Mg_xPO_4$ cathode materials: structural, magnetic, and Mössbauer studies. *H. Choi*[1], J. Kim[1] and C. Kim[1] *1. Department of Physics, Kookmin University, Seoul, The Republic of Korea*

Lithium-ion deficient $Fe_{1-x}Mg_xPO_4$ is a promising cathode material for batteries because of Mg ion is not electrochemically active. $Fe_{1-x}Mg_xPO_4$ (x = 0.01, 0.05, and 0.1) are synthesized by two-step method, which involves combining the solid-state reaction method and the chemical lithium deintercalation method. From the XRD analysis results, the crystal structure of $Fe_{1-x}Mg_xPO_4$ was an orthorhombic structure with *Pnma* space group. The magnetic properties of the sample were determined from vibrating sample magnetometer (VSM) and Mösssbauer spectroscopy, including their magnetic interactions, transition metal oxidation states, and structural ordering. The magnetic susceptibility (χ) of $Fe_{1-x}Mg_xPO_4$ was measured using VSM at temperatures from 4 to 290 K. Typical antiferromagnetic behavior can be found in the below Néel temperature (T_N). The magnetic parameters of $Fe_{1-x}Mg_xPO_4$ calculated from the fitted inverse susceptibility curves χ^{-1}(T). The T_N and curie constant decreases with increasing Mg content, which is consistent with the weakening of the antiferromagnetic exchange and a lower effective total magnetic moment after Mg substitution. Furthermore, for $Fe_{1-x}Mg_xPO_4$, the value of effective moment (μ_{eff}) decreases as expected with increasing Mg content. This can be explained the crystallographically strong deformation of $Fe(Mg)O_6$ octahedra. Mössbauer spectroscopy measurements at various temperatures were performed. The spectra at room temperature was fitted with one doublet, which having the isomer shift (δ) = 0.32–0.43 mm/s (Fe^{3+}). The large electric quadrupole splitting (1.46–1.92 mm/s) value is explained by the asymmetric local environment of the Fe atom. Below the T_N, the spectra of $Fe_{1-x}Mg_xPO_4$ were analyzed the eight resonance absorption lines (including two relatively small intensities). We can be obtained the mechanisms of the processes associated with lithium deintercalation in compounds based on LiMPO$_4$/MPO$_4$ from Mössbauer spectroscopy data.

AW-01. Magnetoresistive Imaging of Magnetic Bubbles, Skyrmions, and Skyrmion Fabric. *I. Kao*[1], B. Parks[1] and S. Majetich[1] *1. Physics, Carnegie Mellon University, Pittsburgh, PA, United States*

Skyrmions have been proposed for use in racetrack memory,[1] where individual bits pass by a magnetoresistive electrode. There has been tremendous progress in imaging skyrmions,[2-4] and recent success using the Hall effect for sensing,[5] though the change in Hall resistance is a fraction of a mΩ. There is still a need for detection methods that could be incorporated into a memory device. Tunnel junctions have limitations to measure non-collinear spin textures, because the tunnel magnetoresistance (TMR) reflects the average over the area of the fixed layer electrode. Here we describe the use of tunnel magnetoresistance with a magnetic point contact that is small compared to the skyrmion diameter. To test this technique, the same regions of magnetic bubbles, skyrmions, or skyrmion fabric samples were imaged by magnetic force microscopy (MFM) in non-contact mode, and by conductive atomic force microscopy (CAFM) in contact mode. MFM detects a frequency shift due to the vertical magnetic force due to the fringe field of the sample, while CAFM measures tunnel magnetoresistance (TMR). The spin textures inferred from the images for the two methods are compared. The multilayer stack was Ta(3)Pt(10)$[Co(0.2)Ni(0.6)]_{20}$Pt(1)AlO_x(1) deposited by magnetron sputtering, where the numbers in parentheses are the film thicknesses in nanometers. From MFM, we saw magnetic bubbles enlarge and merge to form stripe domains at the nucleation field, while shrink and vanish in the single domain at the saturation field. In the MFM image (Fig.1), violet indicates a repulsive force where the moments of the tip and sample are antiparallel (AP), while blue indicates attraction due to parallel (P) moments. In the CAFM image (Fig.2) of tunnel current, red indicates low current (high resistance) expected for AP moments, while violet indicates high current (low resistance) expected for P moments. The images obtained at the same location show strong correlations. An MgO wedge sample was prepared to optimize the tunnel barrier thickness, and asymmetric skyrmion stacks are investigated, along with in-plane magnetized contacts for detection of skyrmion chirality.

AW-02. Realization of Ferro- and Ferri-magnetic skyrmions in Pt/Co/X based systems. *T. Lin*[1], S. Poellath[2], H. Liu[3], T. Xing[1], Z. Wang[1], Y. Sun[1], B. Ji[1], Y. Wu[3], J. Shen[3], C. Back[4] and N. Lei[1] *1. Beihang University, Beijing, China; 2. Universität Regensburg, Regensburg, Germany; 3. Fudan University, Shanghai, China; 4. Technische Universität München, Garching, Germany*

Magnetic skyrmions have attracted great attention and have been considered as potential candidates for next generation spintronics based memory and logics. To overcome some obstacles for future application of magnetic skyrmions, we designed various Pt/Co/X systems and experimentally realized skyrmions in them. To achieve skyrmion motion with high efficiency, we will introduce the study of Ferro-magnetic skyrmions in Pt/Co/W systems with large spin orbit coupling [1]. Besides skyrmion motion efficiency, skyrmion Hall effect is another obstacle for skyrmion-based applications. Facing this problem, we will show our experimental work on Ferri-magnetic Pt/Co/Tb multilayer skyrmion systems, which is promising to alleviate the skyrmion Hall effect. In addition, the temperature dependence of our Ferri-magnetic skyrmions is analyzed, in which the physical mechanism is preliminarily studied and discussed. Our realization of magnetic skyrmions

in different Pt/Co/X multilayer structures may provide alternative candidates to achieve highly efficient skyrmion motion and skyrmion-based applications.

AW-03. Ultrafast nucleation and manipulation of antiferromagnetic skyrmion chains in nanotrack. *K. Khan*[1], N. Sisodia[1] and P.K. Muduli[1]
1. Physics, IIT Delhi, New Delhi, India

Chiral structures like skyrmions are promising candidates for future spintronic devices as they offer the advantage of ultra-dense storage and low power consumption [1,2]. To stabilize such chiral structures, Dzyaloshinskii-Moriya interaction (DMI) an antisymmetric magnetic exchange interaction is needed [3,4]. DMI can occur in some bulk magnetic materials with broken inversion symmetry or thin films of ferromagnetic/heavy metal (FM/HM) bilayer having strong spin-orbit coupling at the interface [5]. Both FM and antiferromagnetic (AFM) skyrmion can be translated by spin transfer torque via spin Hall effect. A disadvantage of FM skyrmion is skyrmion Hall effect (SkHE), which leads to an additional transverse motion (along the nanotrack width) of the skyrmion which can eventually lead to skyrmion destruction at the nanotrack edge. Recently, it has been reported, that AFM skyrmion can be translated along the nanotrack without SkHE due to zero topological charge [6]. In this work, by using micromagnetic simulation [9], we show an ultrafast nucleation and manipulation of AFM skyrmion by locally injecting a inplane spin polarized current. Recently it is reported that a single AFM skyrmion can be nucleated[8], by injecting 2 ns long out of plane spin polarized current pulse ($j = 5\times10^{13}$ Am^{-2}). Here, we use a 1 ns short dc inplane spin polarized current ($j = 5\times10^{13}$ Am^{-2}) in both AFM and FM layer, which nucleate a chain of seven AFM skyrmions in AFM layer, but there is no signature of FM skyrmion in FM layer as shown in Fig 1a. Interestingly, in Fig 1 (b) these chain of AFM skyrmions are also translated due to repulsion from newly created AFM skyrmion. In Fig 1 (c), we show the velocity of 1st nucleated AFM skyrmion which attains a steady state with a very high velocity of ~450 m/s after 0.2 ns. Our findings shows a potential way to create an AFM skyrmion chain and translate them with a constant velocity for racetrack based memory devices.

Physic Department E21, Technical University of Munich, Garching, Germany*

Magnetic skyrmions are topologically protected chiral spin textures. Most skyrmion structures studied in today's research are stabilized by the Dzyaloshinskii-Moriya interaction [1]. Topologically similar spin structures have been observed in ferrimagnetic Fe/Gd multilayers stabilized by the competition between exchange, long-range dipolar, and domain wall energy [2,3]. In this work, Fe(Co)/Gd multilayers were deposited by magnetron sputtering at room temperature with up to 80 bilayers and varying individual layer thicknesses. The magnetic moment of the 3d-transition metals and the Gd layers are coupled antiparallel with the Gd moment being dominant over the whole temperature range. First, the structural properties of the films were investigated by X-ray reflectivity measurements and cross-section transmission electron microscopy. Both suggest a highly intermixed system still revealing a periodic modulation in composition along the growth direction. However, a co-sputtered homogeneous alloy with the same overall composition does not show the formation of non-trivial magnetic structures. The static magnetic properties were studied dependent on composition, magnetic field, and temperature by SQUID-VSM magnetometry, Lorentz transmission microscopy (LTEM), and magnetic force microscopy (MFM). The system shows a decrease in out-of-plane magnetic anisotropy and an increase in the magnetic moment for thicker Gd layers which leads to a shift of the stability range of the skyrmion phase to higher temperatures. The formation of skyrmions and bubbles was directly observed via field dependent MFM [Fig. 1] and LTEM [Fig.2]. The size of the observed spin objects is in the range of 100 nm. Additionally, the dynamic response of the spin textures was investigated by VNA ferromagnetic resonance measurements. With out-of-plane applied fields, we observed rich spectra containing spin wave excitations for skyrmions and stripe domains similar to [4].

AW-05. Energetics, equilibrium shape and topology of skyrmions stabilized by the anisotropic Dzyaloshinskii-Moriya interaction in thin films with C_{2v} symmetry. *M.D. Kitcher*[1], T. Mewes[2], C.K. Mewes[3], M. De Graef[1] and V. Sokalski[1] *1. Materials Science and Engineering, Carnegie Mellon University, Pittsburgh, PA, United States; 2. Physics, University of Alabama, Tuscaloosa, AL, United States; 3. Physics and Astronomy/MINT, University of Alabama, Tuscaloosa, AL, United States*

2D C_{2V} magnetic systems exhibit both Rashba (D_R) and Dresselhaus (D_D) tensorial forms of the Dzyaloshinskii-Moriya interaction (DMI) according to the spin-orbit couplings present [1]. Equivalently, Moriya's rules, as applied to C_{2V} planes, do not uniquely choose the orientation of the DM vector, which is also modulated by the unit cell's asymmetry [2]. Overall, DMI is thus nominally anisotropic and hybridized, potentially stabilizing antiskyrmions as well as elliptical and Bloch-Néel (mixed) skyrmions as shown by [2] and [3]. Moreover, DMI character (i.e., $||D_R|| / ||D_D||$) and the unit cell's aspect ratio correlate to the DM vector's orientation. Ascertaining the existence and tunability of [anti]skyrmions in such systems is of technological interest and would elucidate the nature of DMI. This work models the equilibrium shape and internal wall magnetization of bubble domains (skyrmions being the limiting cases) in thin films with C_{2v} symmetry, using the Wulff construction and a domain wall (DW) energy dependent on the strength and character of DMI [3]. We show that for sufficiently strong DMI with no applied field, specific DM vector orientations stabilize antiskyrmions, while elliptical and/or mixed skyrmions are favored otherwise. An applied field was found to break the C_{2v} symmetry and stabilize domain shapes resembling ovals, teardrops and Reuleaux triangles. Relations between the domain shape, the unit cell's aspect ratio and the DM vector's orientation are discussed. Additionally, the effects of the DW's highly anisotropic energy on its elasticity and mobility will be reported. These findings are compared to micromagnetic simulations implemented within the M[3] package. Preliminary structural and magnetic measurements are introduced for a tunable C_{2v} thin film comprised of Si/Ag/Pt/Co (110) multilayers which we propose as an archetype for mirroring the optimal properties obtained from the above calculations.

In two-dimensional systems, the magnetic skyrmion has an integer topological charge Q, defined by $Q \equiv \int dA\ m.(\partial_x m \times \partial_y m)$. This nonzero Q makes magnetic skyrmions distinct from topologically trivial spin states with Q=0. Because of the topological effect, the magnetic skyrmion is expected to exhibit a high stability and to move fast at a low current [1], offering intriguing possibilities for the skyrmion to be used as information carrier in memory, logic, and oscillator devices. For device applications of magnetic skyrmions, it is important to understand the skyrmion Hall effect: a bending of skyrmion motion with respect to the direction of the driving force. Previous studies have focused on how to vanish the skyrmion Hall effect [2], because it can cause skyrmion annihilation and thus information loss. In this work, we take a different view from previous studies: we exploit the skyrmion Hall effect for device application, instead of vanishing it. We numerically study how spatially inhomogeneous Dzyaloshinskii-Moriya interaction (DMI) affects the transverse motion of a magnetic skyrmion. We find that when a magnetic skyrmion enters from a region with a DMI to another region with a different DMI δ_D, it exhibits very large transverse motion of which deflection angle and symmetry are distinct from the previously reported skyrmion Hall effect [3]. This unconventional skyrmion Hall effect is found to originate from an effective equilibrium spin-orbit-like torque due to the inhomogeneity of DMI [4]. By exploiting this large transverse motion of which direction and magnitude can be controlled by the DMI difference δ_D, we propose a skyrmion field-effect transistor based on the gate-controlled DMI, which was demonstrated in a recent experiment [5]. In the presentation, we show that the proposed skyrmion field-effect transistor can have the multibit states classified by the skyrmion position which is controllable by the magnitude and sign of the gate voltage.

AW-07. Skyrmions-Based Ultra-Low Power Electric-Field-Controlled Reconfigurable (SUPER) Logic Gate. Z. Zhang[1,2], Y. Zhu[1,2], *Y. Zhang*[1], K. Zhang[1], J. Nan[1], Z. Zheng[1], J. Wang[1], G. Wang[1], Y. Zhang[1,2] and W. Zhao[1] *1. Fert Beijing Research Institute, BDBC, School of Microelectronics, Beihang University, Beijing, China; 2. School of Electronics and Information Engineering, Beihang University, Beijing, China*

As a kind of topologically protected spin textures, skyrmions have been regarded as an excellent candidate for developing high-density, low-power memory and logic devices [1-4]. Unfortunately, owing to the presence of the skyrmion-Hall (Sky-Hall) effect and low motion velocity, the application of skyrmion-based device has been hindered. Compared with skyrmions in ferromagnetic (FM) materials, skyrmions in near-compensated ferrimagnetic (FIM) materials have higher motion velocity and negligible Sky-Hall angle [5-8]. This provides a brighter prospect of skyrmions for computing applications. In this paper, we propose a FIM skyrmion-based ultra-low power reconfigurable (SUPER) logic gate. By leveraging electric-field-controlled magnetic anisotropy (EFCMA) effect and skyrmion-skyrmion (Sky-Sky) interaction, various logic functions, such as AND, OR, XOR, NOT, etc., can be realized. Fig. 1 illustrates the schematic of the proposed SUPER logic gate. In order to propagate skyrmions via SOT effect, a driving current is injected into the heavy metal (HM) layer. Three voltage gates on the FIM film are used to control the trace of skyrmions to implement the logic operations. We also demonstrate the implementation of logic operations with simulation. As shown in Fig. 2(a)-(b), when "Vc1" is off and "Vc2" is on, AND logic operation can be achieved. If the input is (0,0), (0,1) or (1,0), there is no skyrmion arriving at the output MTJ, which gives the output '0'. If the input is (1,1), the cooperation of the driving current and the Sky-Sky interaction between the two skyrmions adds a new term of force on the skyrmions, which makes them bypass this gate and arrive at the output MTJ. The output is then '1'. Similarly, we also carry out other logical operations in this gate.

AW-08. Manipulating Spin Chirality of Magnetic Skyrmion Bubbles by In-Plane Reversed Magnetic Fields in MnNiGa Magnet. *B. Ding*[1,2], J. Cui[1,2], H. Li[1,2], E. Liu[1,3], G. Wu[1], Y. Yao[1] and W. Wang[1,3] *1. Institute of Physics, Beijing, China; 2. University of Chinese Academy of Sciences, Beijing, China; 3. Songshan Lake Materials Laboratory, Dongguan, China*

Skyrmions, the particle-like topologically stable spin textures, are usually stabilized by the Dzyaloshinskii-Moriya interaction (DMI) in the noncentrosymmetric crystals but can also been identified in centrosymmetric magnets with uniaxial magnetic anisotropy. The dynamics of magnetic skyrmion and its response dynamics to external stimuli are important topics for the manipulation of skyrmions, indispensable for practical applications in spintronics. Contrary to DMI-stabilized skyrmions with a fixed chirality, skyrmion bubbles (SKBs) in centrosymmetric magnets possess two degrees of freedom, i.e., vorticity and helicity [1], making them suitable to manipulate spin chirality and topological texture through stimuli. In our previous work, the field free biskyrmion bubbles have been explored in centrosymmetric hexagonal MnNiGa alloys at room temperature via appropriate field cooling (FC) procedure [2-3]. In this work, motivated by the above-mentioned method, the generation of zero-filed skyrmion bubble lattice was obtained in $(Mn_{1-x}Ni_x)_{65}Ga_{35}$ (x=0.45). Furthermore, we report on the manipulated spin chirality of the field free SKBs at room temperature and observation of a collective effect of SKBs chirality reversal after applied with the in-plane magnetic field shown in Fig.1. Combining with quantitative analyses of micromagnetic simulation and data of LTEM, we have found that the controllable symmetry breaking of the SKB arising from thickness variation provide an ability to manipulate the collective behavior of the spin chirality with small external fields, leading to a promising application in nonvolatile spintronic devices for magnetic skyrmions.

Magnetic skyrmions are topologically stabilized spin textures particularly suitable for next generation spintronics devices, like the skyrmion-based racetrack memory. Recent studies confirmed the current-driven skyrmion dynamics in ultrathin ferromagnets [1]. However, the topological Magnus effect leads to a transverse motion of ferromagnetic skyrmions due to their non-zero topological charge [1]. Antiferromagnetically exchange-coupled skyrmions or compensated ferrimagnets could suppress this effect owing to an overall zero topological charge [2]. Especially at the angular momentum compensation temperature skyrmions dynamics is predicted to be collinear with the current [3]. We here explore ferrimagnets, such as GdFeCo multilayers where perpendicular anisotropy can be obtained for much thicker layers than for simple ferromagnets. Furthermore the compensation temperature can be tuned over a wide range by changing the deposition. Finally we show demonstrate at the spin reorientation transition worm domains as well as magnetic skyrmions can be observed.

Magnetic skyrmions are emerging as key elements of unconventional operations having unique properties such as small size and low current manipulation [1]. Very recently, it has been proposed to use skyrmions for unconventional applications, such as skyrmion based reshuffle for probabilistic computing [2,3] and reservoir computing [4–6]. In this work, we show how magnetic skyrmions can be useful in the solution of the shortest path optimization problem. In particular, the underlying physics is the same as memristive networks [7], where the inputs of the problem are the current and voltage distributions. On the contrary, the solution of the problem is achieved by using the final spatial distribution of the skyrmions, which behave similarly to real ant colonies when seeking the shortest path to food, but driven by a physical energy landscape. The capability of skyrmions to move on interconnected grids along complex trajectories [1] is the key feature which makes skyrmions the only candidate over other magnetic solitons, e.g. domain walls and vortex, to be used in this category of optimization problems. We analyze the skyrmion motion in a complex 2-dimensional synthetic antiferromagnetic system (Fig. 1). We compute the spatial distribution of the current by supposing to supply voltage between the terminals 1 and 2 (Fig. 1). We continuously nucleate a single skyrmion in correspondence of terminal 1, and then shift it by the spin-Hall effect. Each new skyrmion introduced into the system goes through the same path, as real ants follow the path with a larger amount of pheromone. After 130 ns, the best solution emerges (Fig. 1) and can be read by using state-of-the-art imaging techniques, such as MFM, STXM and MOKE.

In recent years, a number of spectacular advances have demonstrated the existence, not only of magnetic skyrmions, but also their ordering into a skyrmion lattice (SL). The potential of skyrmions as high- density, low-power, data-storage and logic devices is driving their exploration. Skyrmions are topological spin textures stabilized by the competition between the antisymmetric Dzyaloshinskii-Moriya interaction (DMI) and the symmetric exchange interaction. The emergence of a Bloch-type SL phase has been observed in several magnetic materials with a chiral structure close to the paramagnetic to helical magnetically-ordered phase boundary. The formation of Néel-type skyrmions in bulk crystals with polar C_{nv} symmetry was only recently observed in $VOSe_2O_5$ [1], GaV_4S_8 [2,3], and GaV_4Se_8 [4]. Here, we present the results of a muon-spin rotation (μ^+SR) investigation of skyrmion-hosting materials GaV_4S_8 and GaV_4Se_8 and intermediate compounds from the $GaV_4S_{8-y}Se_y$ series, with y = 2 and 4 [5]. We present measurements in the longitudinal field (LF), transverse field (TF), and zero-field (ZF) geometries, allowing access to static and dynamic local magnetic properties. While GaV_4S_8 and GaV_4Se_8 are very similar in exhibiting a SL phase, we show that their magnetic behaviour is quite different. This is likely attributable to subtle (but significant) differences in the electronic ground states of the two systems. We find that the intermediate compounds with y = 2 and 4 do not undergo a transition to a state of long-range magnetic order, but instead show a glassy freezing of dynamics as the temperature is reduced. Our LF μ+SR measurements reveal that the skyrmion phases in GaV_4S_8 and GaV_4Se_8 give rise to emergent dynamics on the muon (microsecond) time scale, reflecting the slowing of magnetic fluctuations perpendicular to the applied field. In GaV_4S_8 these dynamics are observed over the temperature and field range where the SL was observed in single crystals. For GaV_4Se_8, the observed dynamics are more limited in their extent in the H–T phase diagram than the reported extent of the SL. It is thus plausible that the SL region of GaV_4Se_8 is less extensive than previously suggested.

Ferromagnetic (FM) skyrmion has been one of the most striking topological forms which are applied in spintronics devices such as spin transfer torque nano-oscillators (STNOs)[1]. Spin-transfer torque and Dzyaloshinskii-Moriya interaction (DMI) enable the movement of skyrmion on the nanodisk. However, Magnus force is far greater than boundary force, which will lead to the annihilation of skyrmion or staying at the central part on the nanodisk. This occurrence severely reduces the performance of STNOs. In recent research, voltage has shown the influence on the perpendicular magnetic anisotropy, known as voltage-controlled magnetic anisotropy (VCMA)[2, 3]. This effect can be explained as[4]: $K_{uv}=K_u+\theta V_b$, so the anisotropy coefficient can be modified by manipulating applied voltage. In order to effectively solve the problem above, we have designed a composited structure model shown in Fig.1, where the voltage gate is on the bottom FM layer. It proposes two anisotropy areas with different anisotropy coefficients in the inner area and outer area respectively. When K_{uv} of the inner area becomes larger than the K_u of the outer area to some extent, the inner area will show the repulsive force to the skyrmion. We hope to use this repulsive force to offset the magnus effect so that it can prevent skyrmion move to the central point of the nanodisk, making skyrmions move along the edge of the inner circular. The trajectory of skyrmion's motion of $K_{uv}=1.4\times10^6$ J/m^3 is illustrated in Fig. 2(a), We adopt Object Oriented Micromagnetic Framework (OOMMF)[5] for simulation and the typical parameters are as follows[6]: θ=0.02, DMI=4.0 mJ m^{-2}, A=15.0×10^{12} J/m, K=0.8×10^6 J/m^3, M_S=580×10^3 A/m, α=0.5, r=10 nm and R=80 nm. Assuming the voltage as a certain range from 0 to 100V. Fig. 2(b) shows that in a certain range of stable motion, with the increase of the K_{uv}, the frequency of oscillator will drop. Our results provide a promising method to modulate the frequency of STNOs by VCMA.

Magnetic skyrmions are topologically-protected magnetization textures characterized by a non-trivial topology [1]. Skyrmions are usually obtained in presence of the DMI, arising in systems lacking or breaking the inversion symmetry [1]. Recently, a growing interest have been devoted to magnetic multilayers [2–4], where tiny "hybrid skyrmions" can be stabilized at room temperature in absence of DMI. Such "hybrid skyrmions" are characterized by a thickness-dependent reorientation of their domain wall chirality and the equilibrium configuration depends on the interplay between dipolar interactions and DMI. In addition, theoretical studies have pointed out that SHE-driven skyrmion motion in these multilayers is characterized by a skyrmion Hall angle (SHA) dependent on the value of the DMI and/or on the number of repetitions of the ferromagnetic layer [3,5]. Therefore, by proper designing the IDMI and/or the number of repetitions, it is possible to achieve a zero SHA. Here, we micromagnetically investigate a squared 500x500nm^2 multilayer characterized by different 20 ferromagnetic repetitions, similarly to experimental studies [6]. At zero DMI, when the dipolar interactions are the dominant energy term, the hybrid skyrmion has a chirality going from an outward Néel skyrmion in the top layer to a Bloch skyrmion in the middle layer and to an inward Néel skyrmion in the bottom layer. On the other hand, when the DMI is increased, the Bloch skyrmion is shifted towards the upper layers, until, beyond a threshold DMI value, a pure Néel skyrmion is obtained along the whole thickness [3,4], as observed in Figure 1. We have also performed micromagnetic simulations as a function of the number of ferromagnetic repetitions, finding similar outcome. Our results are in agreement with recent experimental measurements [4]. Magnetic skyrmions are envisioned as carriers of information in racetrack storage devices of the future [1]. Their non-trivial real-space topology brings about great stability but also the skyrmion Hall effect: When skyrmions are driven by currents, they are deflected towards the edge of the racetrack where they annihilate. Even in perfectly clean samples the skyrmions can only creep along the edge at limited velocities before they disappear [2]. Over the recent years, several alternative carriers of information have been proposed, which do not exhibit a skyrmion Hall effect, for example antiferromagnetic skyrmions [3,4], skyrmioniums [5], antiskyrmions [6], and skyrmions with a modulated in-plane magnetization [7]. However, the controlled generation of these particles still lacks experimental realization. Since the generation of Néel skyrmions is well understood, one is desired to find methods for suppressing the skyrmion Hall effect also for these particles. Here [2], we consider a ferromagnet on a heavy-metal layer, what leads to the stabilization of Néel skyrmions, which can be driven via spin-orbit torques. Instead of a conventional heavy metal like Pt we use a lower symmetric material, which allows for an injection of spins partially oriented along the racetrack direction [8]; cf. Fig. 1. We show by analytical considerations and micromagnetic simulations that the deflection angle decreases in this case and derive the condition for complete suppression of the skyrmion Hall effect [2]. Consequently, the skyrmion moves in the middle of the racetrack at velocities similar to those proposed for antiferromagnetic skyrmions [3]; cf. Fig. 2.

Universidad de Santiago de Chile, Santiago, Chile*

In this work, and by means of analytical calculations and micromagnetic simulations, we explore the effect of the magnetostatic field generated by a magnetic cylindrical tip on the stability of skyrmions. Our results show that the interaction energy between the tip and the skyrmion plays a fundamental role in the stabilization of Néel skyrmions confined in nanodisks, allowing its nucleation and annihilation, and also providing precise control of its size and polarity. The magnetostatic field created by the tip can be used to control the polarity, chirality, and size of the core of the skyrmion, or create an almost homogeneous magnetic state, which is a particular case of a skyrmion with a core radius larger than the radius of the dot. The different states can be achieved by varying the distance between the tip and the dot, as shown in Fig. 1. Our analytical results show a good agreement with micromagnetic simulations and, as a highlighted result, we can show that from static energy calculations we can explain the dynamics associated with changes in the magnetostatic interaction. Based on our results, we propose a very simple and cyclic method to nucleate and annihilate skyrmions, as well as to control their polarity and chirality. This proposal could open new possibilities for logic devices taking advantage of all the degrees of freedom that skyrmionic textures have [1].

This paper reports polarized beam small angle neutron scattering results on nanoparticle MnSi, illustrating the influence of restricted geometry on the formation of skyrmions. The nanoparticle films are produced by a cluster-deposition sputtering technique and show excellent uniformity of particle sizes with a deviation of around 20%. For this study 17.7 nm particle were chosen for which extensive magnetization and structural characterization has been performed. The magnetization data show anomalies in the magnetic susceptibility over limited temperature and applied field ranges that are characteristic of the formation of the skyrmion spin state [1]. The skyrmion effects are expected to be strongest near the Curie temperature where the Dzyaloshinshkii-Moriya interaction is dominant. For 17.7 nm nanoparticles sharp spikes appear in the magnetic susceptibility in fields of 70 Oe to 150 Oe in the temperature range 25 K to about 43 K (Tc = 39 K). At fields or temperatures significantly higher or lower than these ranges, no characteristic anomalies appear. For the neutron experiments, 75 K measurements (background) and 35 K measurements were compared over a Q-range of 0.03 nm^{-1} to 1.20 nm^{-1}. Measurements at 150 Oe showed no magnetic difference in temperature, while fields of 80 Oe and 100 Oe showed a temperature-dependent magnetic signal with shape similar to that of a 17 nm nanoparticle. Polarization analysis of the neutron spin further reveals signatures in both the non spin-flip and spin-flip channels, the latter of which is indicative of magnetic scattering from spins with components perpendicular to the applied field. These results will be analyzed in the context of the expected scatting associated with skyrmion formation.

Recently, there has been considerable interest in the physics of magnetic skyrmions and the materials in which they are hosted due to their potential uses in spintronic devices [1]. Magnetic skyrmions are topological magnetic spin structures that were originally identified in materials belonging to the B20 class but have recently been found in other non-centrosymmetric materials [2]. Multiferroic GaV_4S_8 and GaV_4Se_8 have been shown to host Néel type skyrmions [3,4]. These two materials are isostructural forming in a low temperature *R*3*m* non-centrosymmetric space group but exhibit very different magnetic phase diagrams at low temperatures. In GaV_4S_8 and GaV_4Se_8 the magnetocrystalline anisotropies favour the formation of skyrmion magnetic spin textures constrained to particular crystallographic axis. We have undertaken investigations of several intermediate compositions of $GaV_4S_{8-y}Se_y$ to try to identify variations in magnetic behaviour across the series, in an attempt to investigate the possibility of observing skyrmions in the intermediate phases. Phase-pure polycrystalline solid-solutions have been successfully synthesized of the $GaV_4S_{8-y}Se_y$ ($0 \le y \le 8$) family and high-quality single crystals grown using the chemical vapour transport technique. We present the results of our detailed investigations of the crystal and magnetic structures of this series of materials as both powders and single crystals, using x-ray as well as neutron diffraction techniques (Figs. 1 & 2). These results are further supported by *dc* and *ac* magnetic susceptibility, and heat capacity measurements within the series.

AW-18. Unidirectional Manipulation of Magnetic Skyrmion Transmission via Asymmetric Modulation of Potential Energy Barrier. *D. Jung*[1], H. Han[1], N. Kim[1] and K. Lee[1] *1. School of Mechanical and Advanced Materials Engineering, Ulsan National Institute of Science and Technology (UNIST), Ulsan, The Republic of Korea*

Magnetic skyrmion is a self-localized chiral spin configuration with a topological protection, which holds promise as a digital information carrier in the future spintronics devices due to its advantages such as a nanoscale size, a topological stability, and a facile current-driven motion [1-3]. To realize competitive skyrmion-based devices, it is essential to understand interactions between the skyrmion and boundaries of devices. However, until now the potential energy of a skyrmion by general geometric boundaries has not been fully understood except for simple model in the limited situation such as one-dimensional ultrathin nanostrips or cylindrical dots [4-6]. In this work, we develop a methodology in determining the general potential energy of a skyrmion in a patterned thin films with arbitrary shape. We thus demonstrate that a current-driven skyrmion propagation can be unidirectionally manipulated (see FIG. 1) by forming asymmetrical potential energy profile through an asymmetric shape of device. Using a simple model based on the collective coordinates for skyrmion's motion, we reveal underlying physics of the dependence of the boundary force and spin-torque parameters on the manipulation of skyrmion dynamics. This work provides a fundamental

understanding of skyrmion's dynamics upon boundaries of devices as well as an efficient way to design skyrmion-based logic device such as a diode element by manipulating potential energies through the device shape.

AW-19. Manipulation of magnetic skyrmions in a locally modified synthetic antiferromagnetic racetrack. R. Loreto[1], X. Zhang[2], Y. Zhou[2], M. Esawa[3] and *C.I. Levartoski de Araujo*[1] *1. Physics, Universidade Federal de Viçosa, Viçosa, Brazil; 2. The Chinese University of Hong Kong, Shenzhen, China; 3. University of Tokyo, Tokyo, Japan*

With the recent proposition of skyrmion utilization in racetrack memories at room temperature, skyrmionics has become a very attractive field. However, for the stability of skyrmions, it is essential to incorporate the Dzyaloshinskii–Moriya interaction (DMI) and the out-of-plane magnetic field into the system. In those skyrmion-based racetrack memories, the information encoded by skyrmions may be destroyed due to the skyrmion Hall effect in ferromagnetic racetracks, which can be surmounted by using alternative topological textures as skyrmionion [1] or resonant magnetic soliton [2]. Another approach would be the utilization of synthetic antiferromagnetic racetracks [3]. Hence, the manipulation of skyrmions in synthetic antiferromagnetic racetracks is important for practical applications. Here, we computationally study the interaction between a pair of skyrmions and a locally modified region in a synthetic antiferromagnetic racetrack, where the perpendicular magnetic anisotropy or thickness is locally adjusted to be different from that of the rest region of the racetrack. The skyrmion pair moves through the track with small pulse of current as demonstrated in Figure 1a. After currents switch of it is found that the skyrmions can be attracted, repelled, and even trapped by the locally modified region in a controllable manner (Figure 1b and 1c). Besides, we demonstrate that the skyrmion location can be precisely determined by the locally modified region. The possible manipulation of skyrmions by utilizing locally modified regions in a synthetic antiferromagnetic racetrack may be useful for future skyrmion-based applications.

AW-20. Writing Skyrmions with a Magnetic Dipole. D. Garanin[1], *D. Capic*[1], S. Zhang[2], X. Zhang[2] and E. Chudnovsky[1] *1. CUNY Graduate Center at Lehman College, Bronx, NY, United States; 2. PSE, KAUST, Thuwal, Saudi Arabia*

In our already published paper, we demonstrate numerically on large spin lattices that one can write skyrmions in a thin magnetic film with a magnetic force microscope (MFM) modeled as a magnetic dipole of a few tens of nanometer in size. Nucleation of non-chiral skyrmions as well as chiral skyrmions formed by the Dzyaloshinskii-Moriya interaction has been investigated. Analytical model is developed that agrees with numerical results. It is shown that skyrmions can be written though a number of scenarios that depend on the experimental technique and parameters of the system. In one scenario, that branches into subscenarios of different topology, the magnetic dipole on approaching the film creates a skyrmion-antiskyrmion pair. As the dipole moves closer to the film it induces collapse of the antiskyrmion and creation of a non-zero topological charge due to the remaining skyrmion. In a different scenario the dipole moving parallel to the film nucleates a skyrmion at the boundary and then drags it inside the film. Possible implementations of these methods for writing topologically protected information in a magnetic film are discussed. This is an already published paper so I am not submitting it for publication at the conference; I would just like to present the findings.

Ion-based manipulation of magnetic materials provides a promising route to electrically-controlled magnetism, of interest from both fundamental and device perspectives. Electrolytes such as ionic liquids and gels play a key role, through the foundational electric double layer transistor (EDLT) (Fig. 1). In EDLTs, massive capacitances (up to 100 μF/cm^2) enable induction of interfacial charge carrier densities up to 10^{15} cm^{-2} at just a few volts, *i.e.*, significant fractions of an electron/hole per unit cell in most materials. This is sufficient to induce and control electronic/magnetic order, properties, and phase transitions, generating great interest. Challenges remain, however, including understanding mechanisms, ultimate capabilities, and the universality of the approach [1]. In particular, it is now well established that both electrostatic and electrochemical gating mechanisms occur in EDLTs (Fig. 1), redox-based response in oxides providing a prominent example [1]. In this presentation I will review our recent work using epitaxial perovskite cobaltite thin films as model systems to understand mechanisms and capabilities of electrolyte gating for control of magnetism [2-5]. Through development of *operando* tools such as synchrotron X-ray diffraction (SXRD) [3] and polarized neutron reflectometry (PNR) [3,5], gate bias polarity asymmetry was first elucidated in these systems. In essence, positive gate voltages are found to induce oxygen vacancies (V_O), assisted by low enthalpy of formation and high diffusivity, while negative gate voltages favour electrostatic hole accumulation due to the thermodynamic stability of V_O [2,3]. Studies on other perovskite oxides have enabled separation of the influence of V_O formation enthalpy and diffusivity, highlighting the importance of the latter, and pointing to a potential route to understand and predict electrostatic *vs*. electerochemical response in electrolyte-gated oxides [1,6]. Electrical control of ferromagnetism in cobaltites was then achieved *via* both electrostatic [2,5] and electrochemical [2,3] mechanisms. Most recently, validating a theoretical prediction [4], optimization of *electrostatic* control of Curie temperature (T_C) has been achieved by gate-induced percolation from a nanoscopic magnetic cluster state (Fig. 2), confirmed by *operando* PNR [5]. Electrical control of T_C over a 150 K window was thus demonstrated, establishing new records for both *electrostatic* electrolyte gating, and complex oxide materials [5]. If time allows I will briefly show new results establishing that ferromagnetism can be electrically induced in EDLTs even from a *diamagnetic* starting point. Work supported by the NSF MRSEC and the DOE Center for Quantum Materials (specifically neutron scattering).

Manipulating magnetism with voltage has an enormous potential to boost energy efficiency in nanoscale device applications[1,2]. Recent works have indicated that voltage-driven ionic motion and related chemical reactions at or near magnetic interfaces (i.e., "magneto-ionic" effects) can enable considerable reversible, non-volatile changes of the magnetic properties, such as anisotropy direction, coercivity, domain wall pinning, exchange bias, spin reorientation, or magnetization. Thus, low-power voltage-reprogrammable magnetic materials are coming within reach and they may transform magnetics-based nanotechnologies. We have recently demonstrated the possibility to induce room temperature voltage-driven anionic and cationic motion of oxygen and cobalt, respectively, in a single 100 nm-thick polycrystalline paramagnetic Co_3O_4 dense film by electrolyte-gating. This effect results in controlled transitions from fully non-magnetic (paramagnetic) to ferromagnetic states[3]. Negative biasing (–10 V) reduces Co_3O_4 to Co, resulting in ferromagnetism, whereas, upon positive voltages, the process can be completely reversed, oxidizing Co back to Co_3O_4. The amount of Co and, thus, the induced ferromagnetism scales with time and the applied bias. Part of the induced ferromagnetism is permanent, but can be fully erased by applying positive voltages. The effect is self-sustained in the sense that no external oxygen acceptor/donor layers are required to obtain the desired effects. The presence of defects, such as oxygen and cobalt vacancies and grain boundaries (as evidenced by electron microscopy and positron annihilation spectroscopy), promote ion migration at room temperature, in absence of heat assistance, contrary to most previous works from the literature. Magneto-ionic effects have been also observed in electrolyte-gated nanoporous cobalt-ferrite[4] and Fe-oxide[5] films prepared by evaporation-induced self assembly combined with dip coating. By applying a negative voltage, cobalt ferrite becomes partially reduced, leading to an increase in magnetic moment at saturation of 15% and reduction in coercivity between 5-28%, depending on the voltage applied. These changes are mainly non-volatile but can be later reversed with a positive voltage to recover the initial properties. Similar studies, done on analogous films without the induced nanoporosity, reveal that the effects were much smaller, underscoring the importance of nanoporosity in our system. In the case of nanoporous Fe-oxide films, a maximum increase in magnetic moment at saturation by a factor of 13 and a noticeable (two-fold) increase of coercivity (after applying –50 V) were observed. Raman and X-ray photoelectron spectroscopy experiments again revealed the key role played by controlled oxygen ion migration in these effects[5]. All these results could have an imminent and strong economic impact in a wide range of technological fields, such as energy-efficient spintronic devices, magnetic sensors, magnetic actuators or magnetic memories.

BA-03. Magneto-Ionic Control of Magnetism in Thin Ferromagnetic Films. *G. Beach*[1] *1. Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, MA, United States*

Voltage control of magnetism has the potential to substantially reduce power consumption in spintronic devices, while offering new functionalities through field-effect operation. Magneto-electric coupling has usually been achieved using complex oxides such as ferroelectrics, piezoelectrics, or multiferroics. Here, I describe an alternative approach known as magneto-ionic switching [1,2], which relies on solid-state electrical gating of a mobile ionic species to modulate the properties of a thin ferromagnetic film. First, I will review our initial discoveries of voltage control of magnetism through solid-state electrochemical switching of the interfacial oxidation state [1-3] in thin metallic ferromagnets. In ultrathin ferromagnet/oxide bilayers, perpendicular magnetic anisotropy (PMA) arises from interfacial hybridization between the ferromagnetic 3d and oxygen 2p orbitals. By using GdOx as a gate oxide with high oxygen ion mobility, I show that O^{2-} can be reversibly displaced at a Co/GdOx interface with a small gate voltage, leading to unprecedented large, non-volatile changes to interfacial PMA by > 0.75 erg/cm^2 [3]. High-resolution cross-sectional transmission electron microscopy (TEM) and in-situ electron energy-loss spectroscopy (EELS) during bias application [2] directly reveals the reversible redox reaction taking place at the Co/GdO_x interface. By optimizing the device structure and geometry, I show that these effects can be achieved with switching times down to <100 microseconds [2], and can be integrated into devices [1,3] that can be gated locally to realize memory and logic functionalities. In the second part of the talk, I focus on our recent discovery [4] that magnetic anisotropy can be reversibly and nondestructively toggled at room temperature with a small gate voltage through H^+ pumping in all-solid-state heterostructures, eliminating the irreversibility and structural degradation that occurs in oxygen redox-based structures. I show that H_2O hydrolysis in ambient atmosphere catalyzed by a rare-earth oxide/noble metal interface can serve as a solid-state proton pump that enables nondestructive magnetic property gating with a modest voltage. We demonstrate reversible 90^o magnetization switching in a thin Co film at room temperature by either inserting H^+ at its interface with an oxide or loading hydrogen into an adjacent heavy metal layer. The mechanism permits both unipolar toggle switching and nonvolatile state retention, with no discernible irreversibility in magnetic properties of the ferromagnet after >2000 cycles. Moreover, since heavy metals like Pt and Pd that exhibit strong spin-orbit coupling are also well-known hydrogen storage materials that can be driven between a metal and metal-hydride phase, a host of spin-orbit induced phenomena at heavy-metal/ferromagnetic interfaces becomes accessible to voltage gating despite the fact that electric fields cannot be applied directly.

Magneto-ionic approaches for modifying ion distributions in metal/oxide heterostructures offer exciting prospects to control material properties. Much of the progress so far has been limited to metal/oxide interfaces. Our recent studies show that such magneto-ionic effect, even though

initiated at metal/oxide interfaces, can extend deep into the rest of the oxide films and drastically tailor their physical properties, including antiferromagnetism [1-2], ferromagnetism [3,4] and superconductivity [5]. In studies of antiferromagnetic (AF) NiCoO, we have demonstrated a controllable positive exchange bias in GdFe/NiCoO due to redox-driven oxygen migration [1], and that the oxygen migration across the interface can be reversibly driven by an electric field [2]. More recently, we have observed an electrically enhanced exchange bias in Gd/NiCoO due to the magneto-ionic effect. A thin Gd capping layer deposited onto AF NiCoO initiates a solid-state redox reaction which reduces the oxide to ferromagnetic NiCo in a thin interfacial region. Upon field cooling, the hysteresis loop becomes exchange biased, demonstrating interfacial coupling between the NiCo and the remaining oxide. After electrically biasing the interface, driving O^{2-} ions towards the Gd layer, a ~15% enhancement of the exchange bias is observed, which can be reset by a subsequent field-cooling procedure (Fig.1). In studies of cuprates, we show a simple, scalable approach to tailor superconductivity in 100nm thick $YBa_2Cu_3O_{7-\delta}$ (YBCO) films via a chemically-driven ionic migration mechanism [5]. Using a thin Gd capping layer of up to 20 nm deposited onto 100 nm thick epitaxial YBCO films, oxygen is found to leach from deep within the YBCO. Progressive reduction of the superconducting transition is observed, with complete suppression possible for a sufficiently thick Gd layer (Fig. 2). These effects arise from the combined impact of redox-driven electron doping and modification of the YBCO microstructure due to oxygen migration and depletion. Our findings demonstrate an effective solid-state ionic approach to control a wide variety of magnetic functionalities, where the interface induced effect can go well into the quasi-bulk regime, opening up possibilities for electric gating. Complex oxide heterostructures provide access to emergent functional and structural phases which are not present in the bulk constituent materials. Controlling ionic distribution and stoichiometry in complex oxide heterostructures has been utilized to significantly alter and tune the electronic, magnetic, and structural properties. Recently, deposition of a strong oxygen getter on top of an oxide thin film has emerged as a novel way to tailor oxygen stoichiometry and nanoscale functional properties [1-4]. However, the role played by nanoscale morphology, i.e. phase separation and defects in these oxide thin films and heterostructures remains largely unknown. In this talk, I will focus on Gd/$La_{0.67}Sr_{0.33}CoO_3$ (LSCO) heterostructures due to their high oxygen ion conductivity, as well as coupled magnetic and electronic properties of LSCO, which are strongly dependent on the oxygen stoichiometry. This combination of properties enable the ionic control of the functional properties of LSCO thin films through the presence of oxygen getter layers such as Gd. We utilize x-ray nanodiffraction to directly image the nanoscale morphology of LSCO thin films as they are progressively transformed from the equilibrium perovskite phase to the metastable brownmillerite (BM) phase with increasing Gd thickness. Our studies show the coexistence of perovskite and BM phases with a critical oxygen vacancy concentration threshold which leads to the formation of extended BM filaments. Strain maps reveal that the perovskite phase changes from compressive to tensile strain on opposite sides of a BM filament. Our studies provide an unprecedented nanoscale survey of the phase separation in the cobaltites and shed light on the formation of the metastable BM phase

Antiferromagnets have potential to be the next building blocks of spintronic devices, thanks to the resonance frequencies in the THz regime, the absence of stray magnetic fields and the resulting resilience against external magnetic fields. These particular properties might enable ultrafast operation combined with high packing density, while spin transport in this class of materials is of interest for spin-logic based devices and was recently demonstrated to be possible over distances of 40 μm. [1] We have previously probed the spin transport properties of thermal magnons in crystalline epitaxial NiO(001) thin films [2], and found that the electrical reading of the magnetic moments is possible via spin Hall magnetoresistance (SMR) [3]. Here we show that one can electrically switch the orientation of the antiferromagnetic Néel vector via current pulses in the same system, without any ferromagnetic element. The switching of the antiferromagnetic moments is probed electrically (Fig. 1) and by direct imaging via x-ray magnetic linear dichroism – photo-emitted electron microscopy (Fig. 2). Both non-deterministic switching below the current threshold and deterministic switching above the current threshold are observed. We explain our results with a theoretical model involving spin torques acting directly on the domain walls and a ponder-omotive force that drives the antiferromagnetic domain walls. Resistance changes not related to the magnetic order are also induced by high density current pulses, as seen in a control sample with Pt only, which have to be considered to correlate the measured transverse resistance to the orienta-tion of the Néel vector. This writing method exploiting spin torques acting on antiferromagnetic materials can be used to realize antiferromagnetic memory elements with Hall cross shape, where combined electrical reading and writing operations are possible. [4,5] See also Ref. [6] (under revision).

BB-02. Néel order variation in IrMn/CoFeB bilayer indicated by combined electrical and spectroscopic approach. *Y. Huang*[1], C. Yang[2], H. Wu[3], X. Che[3], K. Wang[3], C. Lai[2] and Y. Tseng[1] *1. National Chiao Tung University, Hsin-Chu, Taiwan; 2. National Tsing Hua University, Hsin-Chu, Taiwan; 3. University of California, Los Angles, Los Angles, CA, United States*

Perpendicular magnetization exchange-biased via the interfacial coupling with an adjacent antiferromagnet (AFM) serves as a key to realize the external field-free spin-orbit torque (SOT) switching. Currently, some AFM-based SOT devices have been reported that the AFM order would be modified through the spintronic effect [1][2][3]. This work investigates the

variation of AFM order in terms of anisotropic magneto-resistance effect (AMR) and x-ray linear magnetic dichroism (XMLD) in a Ta(2)/IrMn(5)/CoFeB(1.2)/MgO(2)/Ta(2) Hall bar device, where the thickness is in nanometer. The AHE measurement shows clear perpendicular Hex as Fig. 1(a). By varying the perpendicular magnetic field (Hz), we found a significant change on the longitudinal resistance (Rxx) of the Hall bar (Fig. 1(b)), where the low/high Rxx state was responsible for the Hz of +30 Oe/-30 Oe, respectively. This phenomenon is absent in the AFM-free device, suggesting the significant AMR effect arising from the tailorable AFM order upon varying Hz. To get a deeper insight into the AFM order, we perform the XMLD at Mn $L_{2,3}$ edge with a fixed linearly polarized X-ray and varied Hz (absorption difference, μ_{+Hz}-μ_{-Hz}). A clear XMLD feature is observed at Mn L_3 edge, suggesting the AFM order is capable of rotating with different Hz. The combined AMR and XMLD information reconstruct spin structure at the IrMn/CoFeB interface, which could be magnetically manipulated for the advanced AFM-based spintronic applications.

BB-03. Reliable Electrical Switching of Tri-State Antiferromagnetic Néel Order in *a*-Fe_2O_3 Epitaxial Films. *Y. Cheng*[1], S. Yu[1], M. Zhu[2], J. Hwang[2] and F. Yang[1] *1. Department of Physics, The Ohio State University, Columbus, OH, United States; 2. Department of Materials Science and Engineering, The Ohio State University, Columbus, OH, United States*

The ability to manipulate antiferromagnetic (AF) moments is a key requirement for the emerging field of antiferromagnetic spintronics. Electrical switching of bi-state AF moments has been demonstrated in metallic AFs, CuMnAs and Mn_2Au [1-4]. Recently, current-induced "saw-tooth" shaped Hall resistance was reported in Pt/NiO bilayers [5-8], while its mechanism is under debate. Here, we report the first demonstration of convincing, non-decaying, step-like electrical switching of tri-state Néel order in Pt/*a*-Fe_2O_3 bilayers (See Fig.1). Our experimental data shows the switching behavior of *a*-Fe_2O_3 Néel order among three stable states, which can be detected by the change of Hall resistance ΔR_{xy} through spin Hall anomalous Hall effect (SH-AHE). We also show that the observed "saw-tooth" Hall resistance is due to an artifact of Pt, not AF switching, while the signature of AF switching is step-like Hall signals (See Fig.2). Together with the Monte-Carlo simulations, we reveal the clear mechanism of AF Néel order switching and explain why only the first current pulse switches the Néel order. This demonstration of electrical control of magnetic moments in AF insulator (AFI) films will greatly expand the scope of AF spintronics by leveraging the large family of AFIs.

BB-04. Anisotropic Magnetoresistance and Nontrivial Spin Magnetoresistance in Pt/α-Fe_2O_3 Bilayers: Evidence for Magnetic Proximity Effect. *S. Yu*[1], Y. Cheng[1], A.S. Ahmed[1], M. Zhu[1], J. Hwang[1] and F. Yang[1] *1. The Ohio State University, Columbus, OH, United States*

Recently antiferromagnetic insulators(AFM) play an import role in spintronic research including the spin superfluid [1] and long distance spin transport [2]. However, magnetic proximity effect (MPE) has not been conclusively observed in antiferromagnet based systems. In this work, we observed anomalous Hall effect and anisotropic magnetoresistance in angular dependent magnetoresistance (ADMR) measurements in Pt on antiferromagnetic (AF) α-Fe2O3(0001) epitaxial thin films at 10 K, which provide evidence for the MPE[3]. The Néel order of α-Fe2O3 and the induced magnetization in Pt show a unique ADMR compared with all other FM and AF systems. In γ-scan of ADMR at 10 K, a sharp peak is observed when H is perpendicular to film (γ = 0° and 180°) at H = 1-14 T and the peak becomes narrower as H increases while the peak magnitude remains essentially the same. A macrospin response model is established and can explain the AF spin configuration and all main ADMR features in the Pt/α-Fe2O3 bilayers. This work was supported primarily the U.S. Department of Energy (DOE) under Grant No. DE-SC0001304 and partially supported by the Center for Emergent Materials, an NSF MRSEC, under Grant No. DMR-1420451

BB-05. Spin-Torque Induced Electrical Switching of Antiferromagnetic MnN. *M. Dunz*[1], T. Matalla-Wagner[1] and M. Meinert[1] *1. Center for Spinelectronic Materials and Devices, Department of Physics, Bielefeld University, Bielefeld, Germany*

Recently, it was shown that switching of magnetic moments via spin-orbit torque is possible in epitaxial films of antiferromagnetic NiO [1]. A spin-polarized current is generated in adjacent Pt layers and exerts a torque on the moments in the antiferromagnetic film. Here, we report on spin-torque induced switching of magnetic moments in polycrystalline films of antiferromagnetic MnN [2]. Ta (6 nm) / MnN (t_{MnN}) / Pt (4 nm) layer stacks are prepared via (reactive) sputter deposition at room temperature and patterned to star-shaped structures [3]. In Fig. 1, a typical measurement cycle is shown. First, current pulse bursts are sent through one of the pulse lines (red area) and the planar Hall resistance is measured after every burst. Afterwards, the antiferromagnet is left to relax for 10 minutes (grey area). Then, the same number of current bursts is sent through the orthogonal pulse line (blue area), leading to a reversion of the Hall resistance, again followed by relaxation. As can be seen in Fig. 1, the process is fully reversible. To investigate temperature and thickness dependence of the switching, samples with t_{MnN} = 6 nm and t_{MnN} = 9 nm are measured over a broad temperature range. Fig. 2 shows the switching efficiency of the first burst R_e [3] in dependence on the sample temperature T_S for both thicknesses. Higher T_S are needed to reach a certain efficiency in the thicker film as a result of increased anisotropy energy. Overall, R_e clearly increases with increasing T_S in both samples. The relaxation time constant decreases with increasing T_S and the switching efficiency is increased with increased current density. This is in line with the thermal activation model developed for Néel-order spin-orbit torque switching in CuMnAs [3] and Mn_2Au [4].

BB-06. Terahertz detector based on an antiferromagnetic spin-Hall oscillator. *V. Puliafito*[1], I. Medlej[2], I. Lisenkov[3], M. Carpentieri[4], B. Azzerboni[1], A.N. Slavin[5] and G. Finocchio[1] *1. University of Messina, Messina, Italy; 2. Lebanese University, Hadeth Beirut, Lebanon; 3. Winchester Technologies LLC, Boston, MA, United States; 4. Politecnico di Bari, Bari, Italy; 5. Oakland University, Rochester, MI, United States*

Spintronic devices based on antiferromagnetic materials work in the THz-frequency range, and are attracting a lot of attention from the scientific community [1-2]. In this field of research, a full micromagnetic framework for studying magnetization dynamics of antiferromagnets (AFMs), in particular under the influence of spin-orbit-torques, has been developed and compared successfully with analytical models [3]. The magnetization dynamics of current-driven AFMs is described as dynamics of two exchange-coupled sub-lattices by solving two Landau-Lifshitz-Gilbert equations including a torque term due to the spin-Hall effect. The exchange coupling of the sub-lattices includes the inhomogeneous intra-lattice, the homogeneous inter-lattice, and the inhomogeneous inter-lattice contributions. Within this micromagnetic framework, we perfomed modeling of an AFM spin-Hall oscillator [3,4]. In our numerical study, the oscillator consists of an AFM layer (40x40x5 nm^3) having a uniaxial anisotropy and coupled to a layer of a heavy metal. The AFM dynamics is described as precession of two coupled sub-lattice magnetizations m_1 and m_2 around the polarization p of the spin-Hall current, and may show a hysteretic behavior. The frequency of the generated signal shows a blue-shift with the increase of the applied current, from hundreds of GHz up to several THz, as expected [3]. In particular, the AFM oscillator demonstrates an interesting behavior in the sub-threshold regime. We studied the AFM resonance frequency (AFMR) of the oscillator, which defines the spectral "gap" of the device, as a function of different parameters. The most important result is that the AFMR frequency decreases with the increase of the direct electric current applied to the heavy metal, and converges to the self-oscillation frequency at and above the threshold current. This result, which agrees with a previous analytical model, demonstrates the possibility to use the sub-threshold oscillator as a current-tunable signal detector of a resonance type in the THz frequency range.

BB-07. Magnetoresitance Studies of the Tetragonal CuMnAs Single Crystal. J. Volny[1], K. Vyborny[2], D. Wagenknecht[1], E. Duverger-Nédellec[1], R. Colman[1] and *K. Uhlirova*[1] *1. Department of Condensed Matter Physics, Charles University, Prague, Czechia; 2. Department of Spintronics and Nanoelectronics, Institute of Physics AS CR, Prague, Czechia*

Emerging field of antiferromagnetic (AFM) spintronics is drawing a lot of attention due to promising applications in storage devices [1]. One of the promising materials is an AFM metal CuMnAs. Its transport properties have been mostly studied on thin films. So far the main focus has been on spin-orbit torque, allowing for a selective manipulation of magnetic moments in the AFM [2]. This amounts to an effective writing of information. As a method for readout, anisotropic magnetoresistance (AMR) is being used (although little explored), giving different readout signals for two orthogonal orientation of magnetic moments. In this work, we explore resistivity and AMR in a geometry which overcomes the limitations of thin films. To this end, we have prepared a transport device out of a bulk single crystal grain (small) of tetragonal CuMnAs [3] using Focused Ion Beam micromachining. This technique, allowing for precise control over sample geometry, lets us measure resisitivity along arbitrary crystallographic direction. For the first time, we report temperature dependence of both in-plane and out-of-plane resistivity, uncovering large structural transport anisotropy between both principal crystallographic axes. This is further discussed in context of *ab initio* calculations assuming various types of impurities in our samples. The AMR measurement in magnetic field B with rotation of the sample around c-axis (out-of-plane direction) shows only moderate response (~0.1 %) to B with saturation at around 6 T. In the first approximation, we could describe the dependence of the change of resistivity on the direction of B as $\Delta\rho(\theta) \sim \cos(2\theta)$ where θ is the angle between a-axis and B. However, we observe a tilt of the peaks towards higher θ for temperatures above 300 K and to the lower θ for temperatures under 300 K. This behaviour is discussed by means of the Stoner–Wohlfarth model for AFM suggesting an uniaxial magnetic anisotropy not pointing along any principal crystallographic axis. In addition, the calculated AMR values tend to be larger than experimental data, suggesting multidomain character of the sample.

BB-08. Theory of Spin-Current-Induced Auto-Oscillations in a Biaxial Antiferromagnet. *A. Parthasarathy*[1], E. Cogulu[2], A.D. Kent[2] and S. Rakheja[1] *1. Department of Electrical and Computer Engineering, New York University, Brooklyn, NY, United States; 2. Center for Quantum Phenomena, Department of Physics, New York University, New York, NY, United States*

In antiferromagnetic materials with biaxial crystal symmetry, injection of a spin current polarized perpendicular to the Néel order can excite steady-state precession [1]. This phenomenon may be used to generate either a coherent signal [2] or a Dirac-delta-like impulses [3] at terahertz frequencies. Recent works have established that in the macrospin limit the spin-current dynamics of the Néel vector is equivalent to a classical damped pendulum in gravity forced with a constant torque, and have studied the problem numerically [1,3]. However, a general formulation of the problem and its analytic solutions are lacking. Based on the dynamics of a damped-driven pendulum [4] and its nonlinear dynamics, we explore the two-dimensional parameter space of spin-torque and Gilbert damping to determine the regimes of periodic and stationary solutions (see Fig. 1), and find the expression for the homoclinic bifurcation. Transient analytic solutions for the frequency of oscillation are determined in the limits of small and large damping; in the general case, we find a scaling function for the steady-state frequency (see Fig. 2). The results are analyzed in context of material properties of biaxial antiferromagnets such as NiO, CuMnAs, MnPt. We also propose experiments that can detect spin oscillations in antiferromagnets, such as by slowing down the dynamics by exploiting the hysteretic behavior: that sustaining the oscillations requires a lower current than initiating it. *This work was supported in part by the Semiconductor Research Corporation (SRC) and the National Science Foundation (NSF) through ECCS 1740136. BB-09. Electrical detection of Néel vector of a uniaxial antiferromagnetic insulator. *J. Li*[1], W. Yuan[1], M. Lohmann[1] and J. Shi[1] *1. Department of Physics and Astronomy, University of California, Riverside, Riverside, CA, United States*

Antiferromagnetic (AFM) materials may find novel spintronic applications thanks to their numerous interesting attributes: robustness against magnetic field perturbations, absence of stray fields, and ultrafast spin dynamics (1). However, one of the challenges in antiferromagnetic spintronics is that it is difficult to control and probe AFM spin order experimentally due to the lack of net magnetic moment. Here we report an electrical detection of the Néel order of antiferromagnetic insulator Cr_2O_3 (both crystal and epitaxial film) through magnetoresistance (MR) of normal metal (NM) layer deposited on top of Cr_2O_3. The Cr_2O_3 thin films are grown on Al_2O_3(11-20) substrate by pulsed laser deposition (PLD) and are characterized by reflection high-energy electron diffraction (RHEED), X-ray diffraction (XRD), and atomic force microscopy. We control the AFM Néel order of Cr_2O_3 by sweeping the external magnetic field at different orientations, and MR changes are observed during the spin-flop (SF) transition and continuous rotation of the Néel order. The MR variation as a function of magnetic field strength can be well understood by relative orientations between the AFM Néel order and current directions. We find that the MR is very sensitive to the interface properties. The MR of Pt changes sign after we etch the surface of Cr_2O_3 with argon-beam prior to the deposition of the Pt layer. And more interestingly, SF-induced MR jumps are not only observed in heavy metals such as Pt, Pd, and Ta, but also in light metal such as Cu on the etched Cr_2O_3. Our results suggest the interfacial spin-dependent scattering of conduction electrons from the AFM Néel order or the uncompensated interfacial magnetic moment plays an essential role in determining MR of AFM/NM. Furthermore, we demonstrate that the SF-induced MR jump can be used to track SF-field up to 300 K, which provides important information about exchange interaction and uniaxial anisotropy in Cr_2O_3. This work was supported as part of the SHINES, an Energy Frontier Research Center funded by the US Department of Energy, Office of Science, Basic Energy Sciences under Award No. SC0012670.

BB-10. Imaging Antiferromagnetic Domains in Nickel-oxide Thin Films by Magneto-optical Voigt Effect. *J. Xu*[1], C. Zhou[1], M. Jia[1], D. Shi[1], C. Liu[1], H. Chen[1], G. Chen[2], G. Zhang[3], Y. Liang[3], J. Li[4], W. Zhang[5] and Y. Wu[1] *1. Fudan University, Shanghai, China; 2. University of California, Davis, Davis, CA, United States; 3. Dalian Institute of Chemical Physics, Chinese Academy of Sciences, Dalian, China; 4. Shanghai Synchrotron Radiation Facility, Shanghai, China; 5. Oakland University, Rochester, MI, United States*

The emerging field of antiferromagnetic (AFM) spintronics is believed one of the most promising contenders for future energy-efficient, high-speed, robust information storage and processing [1-2]. However, the absence of a net magnetization in AFMs renders conventional magnetometry ineffective, which cast a great challenge in accessing their magnetic properties especially at the microscopic scale. To date, the photoemission electron microscopy (PEEM) based on X-ray magnetic linear dichroism effect (XMLD) [3] remains the most commonly adopted technique to study the AFM domains. Such a technique is not widely accessible and is difficult to be incorporated simultaneously with state-of-the-art magneto-transport measurements. In this contribution, we demonstrate the magneto-optical detection of antiferromagnetic domains in a collinear AFM thin film, i.e. NiO grown on MgO (001) substrate, utilizing the Voigt effect combined with a tabletop, magneto-optical microscopy technique. A large Voigt rotation up to 60 mdeg at room temperature can be observed for a 20-nm-thick NiO(001) film. By directly imaging the domain patterns, we are able to investigate the evolutions of domain configuration systematically under different thicknesses and temperatures. The XMLD-PEEM measurements confirm the AFM origin of the measured Voigt contrast. We elucidated on the surface spin-canting structure of NiO on MgO(001), and found that the AFM NiO spins are only partially tilted outward from the surface with a tilting angle of ~10°. As a tabletop technique, our approach to image the AFM domains utilizing the magneto-optic Voigt effect is considerably more accessible than user facility instruments such as XMLD-PEEM, and can also be made adaptable with

external magnetic fields or electric currents, which is extremely important in future experiments involving electric- and magnetic-field driven AFM dynamics and switching.

BB-11. Current-driven phase transition in a gradient-doped FeRh nanopillar: spin injection-triggered phase transformation and memristivity. R.C. Temple[1], J. Massey[1], T. Almeida[2], M. Rosamond[3], E. Linfield[3], K. Fallon[2], D. McGrouther[2], T. Moore[1], S. McVitie[2] and *C.H. Marrows[1] 1. School of Physics and Astronomy, University of Leeds, Leeds, United Kingdom; 2. School of Physics and Astronomy, University of Glasgow, Glasgow, United Kingdom; 3. School of Electronic and Electrical Engineering, University of Leeds, Leeds, United Kingdom*

FeRh has a first order antiferromagnetic (AF) to ferromagnetic (FM) transition at about 370 K in bulk. The transition temperature can be manipulated through magnetic field, strain, chemical doping and spin-polarised currents [1]. Due to this high versatility the material has been extensively investigated in recent years for its potential technological applications in heat-assisted magnetic recording [2], antiferromagnetic memory resistors [3] and electric field control of magnetic order [4]. We have recently shown that the transition is retained in islands patterned to few 100 nm dimensions [5] and that the use of a doping gradient can give a simple form of phase coexistence where the film separates into slabs with AF and FM order [6], separated by a planar phase boundary. We have fabricated few 100 nm diameter gradient doped devices through which electrical current can be driven vertically through the phase boundary (see Fig. 1). Since the AF phase has a substantially higher resistivity than the FM phase, the pillar resistance—comprising the series resistance of the two slabs—can be used as a proxy for the phase boundary position within the pillar. Driving current pulses (typically of 1 μs duration and ~10^{11} A/m^2 density) through the phase boundary results in a brief change in resistance due to Joule heating before the resistance relaxes to a new level that has shifted depending on the current flow direction (see Fig. 2). Trains of current pulses containing a few tens of mC of charge shift the resistance of the pillar by a few mΩ. The shift direction is consistent with the microscopic mechanism being spin injection from or into the FM phase slab that triggers the phase transition in a few nm wide region next to the phase boundary [7]. This represents memristive behavior, with potential application as artificial synapses in spintronic neuromorphic circuits.

Utilization of antiferromagnets (AFMs) as functional components has opened new directions for next-generation low-power spintronic architectures [1-7]. A major roadblock concerns electrical recording of information in AFM devices without auxiliary ferromagnets. Previous investigations demonstrated the utilization of Néel spin-orbit torques (SOTs) [4,5] and/or interfacial SOTs in AFM-insulator/heavy metal (HM) [6,7] as a viable route for electrical manipulation. The realization of AFM devices using these materials is, however, limited by material choice and epitaxial structure constraints. Here, we demonstrate electrical writing in Mn-based polycrystalline metallic AFM/HM structures by spin-orbit torques (SOTs). The multilayer film with Si sub./buffer/PtMn(10)/Pt(5)/Ru(1) (AFM/HM, hereafter) (in nm) is grown by sputtering and patterned into star-shaped devices. Electrical writing is achieved by sourcing pulsed currents (I_{Write^1} and I_{Write^0}) along orthogonal directions while read-out was achieved by measuring transverse Hall resistance R_{Hall} (Fig. 1(a),(b)). Figure 2 shows the results of electrical writing for different current amplitudes. A combination of electrical measurements with X-ray magnetic imaging on identical structures shows

reorientation of antiferromagnetic Néel vector upon application of I_{Write}^{1} and/or I_{Write}^{0}. The present experimental results demonstrate the prospect of metallic AFMs for next generation antiferromagnetic spintronic architectures. BB-13. Tailorable Néel order via spin-orbit torque and the effect on field-free switching. *C. Yang*[1] and C. Lai[2] *1. Material Science and Engineering, National Tsing Hua University, Hsing Chu, Taiwan; 2. Material Science and Engineering, National Tsing Hua University, Hsing Chu, Taiwan*

As a modified structure of spin-orbit torque (SOT) device based on ferromagnet/heavy metal (FM/HM) bilayer, an antiferromagnet (AFM) adjacent to FM was currently regarded as a route toward to the application of field-free SOT switching due to the exchange bias (Hex) at FM/AFM interface (*1, 2*). In this study, we magnetically reconstruct the interface of Co/IrMn in a Pt/Co/IrMn Hall-cross device. In terms of Hex, anisotropic magneto-resistance, and X-ray linear dichroism (XMLD), a global Néel order modification driven by SOT effect has been found with a preferred orientation (anti)parallel to the electrical current we applied for SOT (Fig. 1(a)) and was tailorable while rotating the input current geometry (Fig. 1(b)). This modification on IrMn spin established an in-plane bias field of approximately 15 Oe at Co/IrMn interface, which enabled the partial Co switching being field-free. This nature was further investigated by means of engineering the interface of Co/IrMn with Ru dusting. The reduction of Hex in the Ru-dusted device showed great consistency with the reduction on the switchable component achieved by field-free manner. This work gives an insight into the manipulation of AFM state in HM/FM/AFM trilayer for field-free switching and advanced AFM-based spintronics.

Antiferromagnet-based memories offer new potential capabilities such as picosecond time scale switching [1], immunity to magnetic fields, and the potential to realize high-density memory arrays due to the vanishing bit-to-bit dipole interactions. Electric control of the AFM order has been previously demonstrated in epitaxially grown AFMs with broken inversion symmetry such as CuMnAs [2, 3], and Mn_2Au, and in insulating NiO interfaced with a Pt layer [5,6]. In this work, we investigate current-induced switching in micrometer-scale circular memory bits based on the metallic antiferromagnet PtMn, which is already widely used as part of the pinned layer in in-plane magnetic tunnel junctions manufactured on CMOS. The device consists of a pillar of PtMn with thickness < 10 nm, grown by room-temperature sputter deposition on top of a heavy metal layer, i.e. Pt, which provides a spin current able to switch the AFM state. The device shows reversible switching in response to currents applied to the Pt layer, with opposite current polarities achieving opposite switching directions in the PtMn. The switching current density is ~2 MA/cm^2. We show that the switching process is essentially unaffected by external fields up to 16 T, and is robust over a wide temperature range. We also investigate the switching process by micromagnetic simulations, which shed light on the current-controlled domain structure of the device and the role of different torque terms in the switching process. Our results pave the way towards practical antiferromagnetic memories integrated on silicon.

BB-15. Non-Spin Torque Origin of Current-Induced Switching in an Antiferromagnet Insulator/Pt Bilayer Film. *P. Zhang*[1] and L. Liu[1]
1. Massachusetts Institute of Technology, Cambridge, MA, United States

Electrical control and detection of magnetic ordering inside antiferromagnets has attracted considerable interests, for the potential advantages in operating speed and device densities [1]. In contrast to ferromagnet, where the current induced torque on magnetic moments was first established and quantified via comparison with magnetic field's influence [2], the investigation on the spin torque mechanism in antiferromagnets represents a greater challenge, due to the lack of an independent method for controlling Néel vectors. Here by utilizing an antiferromagnetic insulator with Dzyaloshinskii-Moriya interaction [3], α-Fe_2O_3, we show that the Néel vector can be conveniently controlled with the application of a moderate external magnetic field, which is further used to examine the current induced magnetic dynamics. We find that the switching criteria employed in many of the previous studies -- the sawtooth feature in resistance or Hall resistance change is not necessarily related to the reorientation of Néel order. By further comparing the current and field-induced Néel vector tilting and through a systematic scaling study, we reveal the important role of magnetoelastic effect in current induced switching of this antiferromagnet. The spin torque effect induced switching, which is expected to be smaller and has the opposite sign as the magnetoelastic effect in our experiment, remains yet to be demonstrated.

Three-terminal spintronic devices based on the manipulation of a nanomagnet through spin-orbit torques[1] (SOT) are prospective candidates for high-speed cache memory. They are non-volatile, have essentially infinite endurance, and can operate at high speeds with low error rates[2]. However, their switching process is limited by an incubation time which is typical when the initial magnetization is collinear to the spin polarization. When the magnetization easy axis lies perpendicular to the spin polarization, switching is possible but requires an external field[3]. In this work, we demonstrate the use of non-uniform micromagnetic states to perform field-free deterministic switching. By employing this scheme, it becomes possible to control the magnetization switching direction for the same current polarity. We use this property to illustrate a potential nanomagnetic logic device. Lastly, we also explore the use of W(O) as an SOT generator and confirm its -50% spin Hall angle reported previously in a separate study[4].

For spin-orbit torque (SOT) switching of a perpendicular magnet, an in-plane field is required for breaking the symmetry[1]. Although schemes have been demonstrated in external-field-free SOT switching of a perpendicular layer[2–4], practically integrating them with perpendicular MTJs (p-MTJs) still appears to be challenging. We have previously demonstrated field-free SOT switching of a perpendicular magnet via using an Ir layer for generating both SOTs and a steady exchange coupling in-plane field coupling with a synthetic antiferromagnetic structure (SAF)[5]. Here we report the experimental demonstration of its integration with p-MTJ devices, showing robust SOT writing of p-MTJs with size ranging from 500 nm to sub-50 nm, free of requirement for an external field. The film structure, as shown in Fig. 1(a), is substrate/ IrMn(5)/ Co(2)/ Ru(0.85)/ Co(2)/ Ir (1.35)/ FeCoB (1.2)/ MgO(1.2)/ FeCoB(1.3)/ Ta(0.5)/ [Co(0.4)/ $Pt(1)]_{x3.5}$/ Ru(0.85)/ [Co(0.4)/ $Pt(1)]_{x5.5}$/ Pt(7) (unit in nm). After deposition, the film is annealed at 300 ^{0}C for 10 min with a 5000 Oe magnetic field applied along -x direction. Fig. 1(b) shows the hysteresis loops of the film, exhibiting strong perpendicular anisotropy of the MTJ. The film is then patterned into three-terminal devices (Fig. 2(a)) for current-induced switching experiments. In Fig. 2 (b), we obtain well-defined switching of the p-MTJ at zero external field, as indicated by the sharp changes in MTJ resistance. With varying the pulse width (Fig. 2(c)), we observe that the switching current remains almost constant for pulse width from 5 μs down to 100 ns and starts to increase sharply with pulses shorter than 100 ns. Fig. 2(d) shows the effect of MTJ size on the threshold current. It can be seen that the threshold current is essentially constant for size greater than 150 nm and only slightly elevates at smaller MTJ size (down to 50 nm). Combined micromagnetic modeling providing physical insights will be presented in the talk.

BC-03. Ultrafast and energy-efficient spin–orbit torque switching in compensated ferrimagnets. *K. Cai*[1], Z. Zhu[1], J.M. Lee[1], R. Mishra[1], L. Ren[1], P. He[1], G. Liang[1], K.L. Teo[1] and H. Yang[1] *1. Department of Electrical and Computer Engineering, National University of Singapore, Singapore*

Spintronics aims to develop energy-efficient as well as high-speed magnetic logic and memory devices, and the spin-orbit torque is a promising approach for magnetization manipulation. However, conventional ferromagnetic spin-orbit torque systems have intrinsic limitations in operational speed due to their inherent magnetization dynamics. Alternatively, antiferromagnets and ferrimagnets with antiparallel exchange coupling exhibit faster spin dynamics, which shows the potential to overcome these limitations [1]. Here, we experimentally demonstrate an ultrafast spin–orbit torque induced magnetization switching in Pt/CoGd ferrimagnetic devices through time-domain measurements [2]. We find that the switching time can be easily reduced to the sub-nanosecond regime in ferrimagnets, corresponding to a ~10 times faster speed compared to ferromagnets (as shown in Figure 1a). Moreover, the switching energy efficiency is one to two orders of magnitude higher than that of ferromagnets [3]. In particular, a very high domain wall velocity of ~5.7 km s^{-1} is realized during switching (as shown in Figure 1b), which is in agreement with the analytical modeling and atomistic spin simulations. This work highlights the potential of the ultrafast and energy-efficient ferrimagnet based spin–orbit torque memory and computing applications.

BC-04. Gate-Tunable Inverse Spin Hall Effect in Ultrathin Pt. *S. Dushenko*[1,2] *1. The Institute for Research in Electronics and Applied Physics, University of Maryland, College Park/ National Institute of Standards and Technology, Gaithersburg, MD, United States; 2. Department of Electronic Science and Engineering, Kyoto University, Kyoto, Japan*

We report reversible modulation of up to two orders of magnitude of the inverse spin Hall effect (ISHE) in ultrathin platinum (Pt) using careful control of its thickness and an ionic gating technique.[1] The ISHE enables use of electric and spin currents in the same device, which is crucial for the future integration of spintronics and electronics. The ISHE[2,3] is governed by the spin-orbit interaction and is particularly strong in heavy metals. Due to the spin-orbit interaction, the scattering direction of the carriers depends on their spin direction. Thus, it couples the spin current with the charge current, allowing their interconversion. Following studies by Saitoh *et al*.[4] and Valenzuela *et al*.[5], Pt has become a dominant material choice for spin current detection due to the large ISHE[6] and easy fabrication. There have been many attempts to achieve control over the spin-charge conversion process. However, in contrast to semiconductors and two-dimensional systems, electric gating control over spin-charge conversion in heavy metals was considered out of reach because of high carrier density. In this study, we achieved the largest to date modulation of the metal resistivity in ultrathin Pt film. Such control over the carrier density allowed us to reversibly tune the amplitude of the ISHE in Pt over two orders of magnitude. *I-V* characteristics, ferromagnetic resonance (FMR) and the ISHE measurements were carried out at 250 K on 1.5 nm to 20 nm thick Pt films deposited on a 1.3 μm thick YIG ferrimagnetic layer. The voltage of an ionic gel (DEME-TFSI) top gate was set at room temperature and samples were cooled after the development of the electric double layer in the gel. Spin pumping was used to inject spin current in Pt by exciting FMR in the YIG at 9.12 GHz. Evidence for the ISHE modulation is derived from dramatic changes in the spin-charge conversion voltage, Pt resistance and FMR absorption spectra. Using the ionic gel top gate, the resistance of the Pt film was tuned up to 280% (Fig. 1). In contrast to the microwave absorption spectrum, electromotive force generated via the ISHE was strongly modulated with the application of the gate voltage. To isolate the ISHE from the large resistance changes, we report $I_{ISHE} = V_{ISHE}/R$. In the 2 nm thick Pt sample, the amplitude of the spin-charge conversion current was tuned from the I_{ISHE} = 3.0 nA at the gate voltage V_G = -2 V to I_{ISHE} = 0.1 nA at V_G = 2 V (Fig. 2). In our best sample, we achieve modulation of the V_{ISHE} and I_{ISHE} from 100% at V_G = -2 V down to 0.8% and 1.7%, respectively, at V_G = 2 V. The modulation of the spin-charge conversion current is reversible and reproducible between different measurements of the same sample, as well as between measurements of different samples with the same thickness. Our results can be used in the gate-tunable spin-charge converter devices. For example, it opens an exciting possibility of the gate-controlled spin-orbit torque magnetoresistive random-access memory (SOT-MRAM), where the spin current generated by the spin-charge conversion in heavy metal exerts a torque on the free magnetic layer.

BC-05. Process control of tungsten β-phase window for spin-orbit torques MRAM applications. *K. Vudya Sethu*[1,2], S. Couet[1], J. Swerts[1], B. Soree[1,2], J. De Boeck[1,2], G.S. Kar[1] and K. Garello[1] *1. Imec, Leuven, Belgium; 2. ESAT, KU Leuven, Leuven, Belgium*

Spin-orbit torques (SOT) magnetic random-access memory (SOT-MRAM) is a new class of current based MRAM which is promising for embedded low-level cache applications [1, 2]. However, the critical current density required by SOT switching is presently too large and decreasing it remains a major challenge. A key parameter that influences threshold current for switching is the spin Hall angle (SHA) of the heavy metal used to generate SOT. Among heavy metals, W in beta phase has one of the highest SHA reported in the literature (~-30%) [3]. In imec, using our 300 mm platform, we successfully integrated W-based SOT-MTJ and demonstrated low power and sub-ns performances [4]. However, in our samples, beta-to-alpha transition of W occurs around 4 nm narrowing the process control and accessible thickness range. In addition, this phase transition dramatically reduces to 2 nm when inserting an adhesion layer to avoid stack delamination. Therefore, there is also a need to control and extend the beta phase window. In this presentation we will show that using oxygen and nitrogen (W(O,N)) doping during the sputter deposition of W allows for controlling and maintaining W beta-phase to more than 10 nm (Fig.1). We will next discuss that using this process it is possible to tune the perpendicular magnetic anisotropy (PMA) and we will also show that it remarkably enhances SHA up to -45% in optimized W(O,N) layers, which is one of the highest for W/CoFeB system with PMA free layer. We will conclude by presenting W(O,N)-based MTJ integrated devices properties (Fig.2) and the benefits that optimized W(O,N) layers bring to reduce threshold switching current.

BC-06. Design of an Erasable Spintronics Memory Based on Current-path-dependent Field-free Spin Orbit Torque. H. Zhou[1], Z. Wang[1], Z. Li[1], *C. Wang*[1], B. Wu[1] and W. Zhao[1] *1. Beihang University, Beijing, China*

Emerging spin orbit torque magnetic random access memory (SOT-MRAM) promises to overcome the speed and endurance issues of the spin transfer torque (STT) MRAM [1-2]. However, for the perpendicular-anisotropy SOT-MRAM, an undesirable magnetic field is required to achieve the deterministic switching [3-4]. Recently, we proposed a novel field-free SOT mechanism for the deterministic switching of the perpendicular magnetization [5], where an elliptical perpendicular-anisotropy magnetic tunnel junction (MTJ) is deposited above a heavy metal layer with a tilted long-axis. Two unidirectional currents flowing through different paths can deterministically switch the MTJ to P and AP states (low and high resistance states), respectively. In other words, the switched final state is only dependent on the current path instead of current direction. According to the final state, we call the two current paths P-path and AP-path, respectively (see Fig. 1). Here, based on this proposed SOT mechanism, we present an erasable spintronics memory. Take 4-bit memory as an example, four P-paths are connected to form the erasing channel, while four AP-paths are used as the programming channels (see Fig. 2). Non-volatile data can be written in two steps. In the first step, a reset current is injected into the erasing channel so that the states of four MTJs are all reset to '0' ('Step 1' in Fig. 2). In the second step, another one current is applied to the programming channel corresponding to 'MTJ1'. Then the 'MTJ1' is set to '1' ('Step 2' in Fig. 2). As a result, data '0010' is written into the memory. The switching could be achieved at sub-nanosecond latency and sub-hundred femto-joule energy. Thus our proposed memory is a good candidate for the embedded applications.

Center for Memory and Recording Research, University of California San Diego, La Jolla, CA, United States; 3. IBM TJ Watson Research Center, Yorktown Heights, NY, United States*

Spin orbit torque (SOT) switching devices are promising for faster, more reliable and efficient switching compared to current magnetic memory technologies. However, large-scale fabrication of nano-scale SOT switching devices remains a challenge. Here we report some fabrication considerations of nano-sized, three terminal in-plane SOT switching devices with low switching current density by optimizing ion-beam etching conditions and by inserting Hf interlayers. As shown in figure 1(a), non-linear dependence of the critical switching field with bias current indicates the switching is caused by SOT current. We show that the angle and time of the ion beam etching is critical to avoid defects such as the shunting effect caused by redeposition at the junction pillar sidewall, trench effects around the base of junction pillar caused by reflected ions from the pillar side-wall during high angle etching, and a "big foot" effect caused by the shading of tall junction pillar. The switching behavior of the fabricated junctions is significantly affected by the junction pillar's in-plane aspect ratios due to demagnetization factor change, and by the insertion of Hf spacer interlayers which affects both interface spin-current transparency and interface anisotropy. We succeeded in bringing switching current densities down to 1.7×10^7 A/cm^2 through optimized etching, manipulation of the aspect ratio of the junctions and inserted Hf interlayers. The inserted Hf interlayers decreases 1/3 of the critical current required for switching as shown in figure 1(b). This study gives us a more comprehensive understanding of how to improve the fabrication process for application in mass production. Works at IBM supported by an IBM Summer Intern Program. Work at UCSD supported by Award # DE-SC0019273.

BC-08. Highly Efficient Spin-Orbit Torque Magnetization Switching in a Perpendicularly Magnetized Ferromagnetic-Semiconductor Single Layer: Damping Like Torque and Field Like Torque. *M. Jiang*[1], H. Asahara[1], S. Sato[1], S. Ohya[1,2] and M. Tanaka[1,2] *1. Dept. of Electrical Engineering, The Univ. of Tokyo, Tokyo, Japan; 2. Center for Spintronics Research Network (CSRN), Graduate School of Engineering, The Univ. of Tokyo, Tokyo, Japan*

Spin-orbit torque (SOT) magnetization switching, which is induced by a spin current generated by a charge current, is a promising phenomenon that can be used to improve the performance of magnetoresistive random access memory. In our previous study, we achieved a highly efficient full SOT magnetization reversal in a GaMnAs single layer by applying a very low current density (J_c) of 3.4×10^5 A cm^{-2} [1], which is two orders of magnitude smaller than that required in the conventional SOT systems [2]. According to the Landau–Lifshitz–Gilbert (LLG) equation, the SOT is contributed by two parts; damping like torque (DLT) and field like torque (FLT). By fitting simulated results using the LLG equation to the experimental results, we clarified that the DLT is dominant during the magnetization switching in the 7-nm-thick GaMnAs single layer. Here, we explore the contributions of DLT and FLT by inducing the SOT switching in perpendicularly magnetized GaMnAs single layers with different thicknesses; d = 5 nm, 7 nm, 10 nm, and 15 nm as shown in Fig. 1. In the GaMnAs single layer with d = 5nm, SOT magnetization switching (dominated by DLT) is observed with $J_c = 1.6\times10^5$ A cm^{-2}, which is even smaller than that of our previous paper [1]. With the increase of d, the FLT starts to act on the magnetization switching and competes with the DLT. When d < 15 nm, J_c increases as d increases, which is caused by the enhancement of the contribution of FLT. At d = 15 nm, the switching polarity is totally reversed, indicating that the FLT becomes dominant. This result is understandable, considering that the acting direction of FLT is opposite to that of DLT. Our finding will advance the understanding on the contributions of DLT and FLT during the SOT switching in GaMnAs single layer. BC-09. Toggle Mode Spin-Orbit Torque Driven Perpendicular Magnetic Anisotropy MRAM. *N. Hassan*[1], S.P. Lainez-Garcia[1], F. Garcia-Sanchez[2,3] and J.S. Friedman[1] *1. Electrical & Computer Engineering, The University of Texas at Dallas, Richardson, TX, United States; 2. Istituto Nazionale di Ricerca Metrologica, Torino, Italy; 3. Departamento de Fisica Aplicada, Universidad de Salamanca, Salamanca, Spain*

Spin-orbit torque (SOT) is a high speed and energy efficient writing technology for magnetic random-access memory (MRAM) that prevents device degradation by separating the read-write path [1]. However, orthogonality between the in-plane polarized SOT current and thermally stable perpendicular magnetic anisotropy (PMA) inhibits deterministic MRAM switching. Several approaches have been proposed to break this symmetry, including an in-plane magnetic field [2], deformation of the device structure [3], tilted anisotropy [4], an antiferromagnet–ferromagnet bilayer system [5], and competing spin currents [6]. However, all of these approaches increase the fabrication complexity, are highly sensitive to the SOT current duration and magnitude, or increase the switching energy. We therefore propose toggle PMA SOT-MRAM [7], which exploits the precessional nature [8] of field-like SOT to achieve field-free and energy-efficient switching with a simple structure that is robust to the SOT current magnitude and duration. The structure is a three-terminal magnetic tunnel junction that consists of a heavy metal, free ferromagnet, insulating tunnel barrier, and compensating ferromagnet. A unidirectional SOT current applied through the heavy metal causes the free ferromagnet magnetization to stabilize at an excited steady state after crossing the hard axis plane. Switching off the excitation relaxes the magnetization to the nearest easy axis, thus completing a toggle cycle. Application of the next excitory pulse toggles the magnetization back to its initial state. Micromagnetic simulations demonstrate robust switching, with greater than 50% tolerance to applied SOT current magnitude. This deformation-free structure provides efficient data read-out, and the toggle switching can be leveraged for directional writing through a simple XOR between the current and incoming bits. The proposed device therefore provides a promising solution for compact, highly-efficient, and robust SOT-MRAM with PMA.

BC-10. Materials Requirements of High-Speed and Low-Power Spin-Orbit-Torque Magnetic Random-Access Memory. *X. Li*[1,2], C. Yao[2], M. DC[1], W. Tsai[3], S. Lin[3] and S. Wang[1,2] *1. Materials Science and Engineering, Stanford University, Stanford, CA, United States; 2. Electrical Engineering, Stanford University, Stanford, CA, United States; 3. TSMC, Hsinchu, Taiwan*

As spin-orbit-torque magnetic random-access memory (SOT-MRAM) is being intensively researched as the next-generation ultralow-power and high-speed on-chip cache memory solution [1], it is critical to identify the required materials properties to deliver the desired power and performance mandated by on-chip integration based on two transistor-one magnetic tunnel junction (2T-1MTJ) design. In this presentation, we will first discuss the circuit-level goals for replacing different levels of SRAM cache using SOT-MRAM. Then, array- and device-level materials requirement to achieve the above goals will be described, including the SOT material and the magnetic tunnel junction (MTJ). Last, we will briefly present an outlook of promising approaches to realize high-density 2-terminal SOT-MRAM crossbar architecture [2] and accompanying materials requirements. This work will provide important guidelines for SOT-MRAM materials and device research in the future. In particular, the typical 2 transistor-1 SOT-MTJ cell will be modeled in an effective circuit model as shown in Figure 1. Here, we include the parasitic resistance from the metal electrodes and the SOT layer, as well as the transistor itself. We will both analyze the read and write operation of the SOT-MTJ cell and their respective materials requirement. It is worth noting that a few works [3][4] have already discussed the write current shunting effect due to the ferromagnetic free layer (FL) sitting on top of the SOT layer during write operation as shown in Figure 1(a). However, to fully evaluate what are the best materials properties to be used in a SOT-MRAM cell, the transistors resistance and capacitance are also critical parameters to include. We find that to achieve the lowest power and latency, it is crucial to match the SOT layer material properties, such as resistivity, width, and length to that of the transistor if we consider the SOT efficiency of the material remains unchanged. The authors thanks NSF Center for Energy Efficient Electronics Science (E3S) and TSMC for financial support. This research was supported in part by ASCENT, one of six centers in JUMP, a Semiconductor Research Corporation (SRC) program sponsored by DARPA.

BC-11. Spin-Based Comparator Using Spin Hall Effect Driven Nanomagnets. *S. Wasef*[1], M. Alawein[1], S. Amara[1] and H. Fariborzi[1]
1. CEMSE, KAUST, Jeddah, Saudi Arabia

In this work, we propose a three-terminal magnetic tunnel junction (3T-MTJ) spin-based voltage comparator and a spin circuit model for the same. The proposed device utilizes a (α-β)-W channel (6.2 nm) of size 400 nm 400 nm, and it is represented by a spin Hall effect (SHE) circuit model [1]. One of the reasons of using (α-β)-W to produce transverse pure spin currents is its ability to provide similar spin current density to β-Ta and Pt but with lower resistivity [2]. The MTJ multilayer is comprised of CoFeB (2 nm) (free layer (FL))/MgO (0.6 nm)/CoFeB (5 nm) (reference layer (RL)) as in [3], and the size of the MTJ pillar is 40 nm 120 nm. The SHE, MTJ, and stochastic magnetization dynamics models are coupled in a self-consistent manner as in [4, 5] (Fig. 1(b)). The MTJ model is a representation of its varying conductance G = (GAP + GP)*(1 + P1.P2)*cos(Φ)/2 where P_1 (P_2) is the interface polarization factor of the FL (RL) of the 3T-MTJ calculated using Julliere's model for a TMR of 275% [3], and is the angle between the magnetizations of FL and RL. The operation of the comparator can be divided into two phases: (1) comparison phase, and (2) reset phase. First, the magnetic orientation of the FL is kept parallel to that of the RL. During the comparison phase, two voltage sources are connected to terminals T1 and T2 using clock controlled switches. Depending on the magnitude of the voltage across the SHE layer, a charge current flows and a transverse pure spin current is generated. The magnetic moment of the FL changes when the generated spin current exceeds the critical spin current required for switching [6]. During the reset phase T2 is connected to a 1 V supply and T1 is grounded to switch back the magnetic orientation of the FL to parallel state. A reading voltage of 1 V is used to read the output. Terminal T3 of the 3T-MTJ is connected to two inverters to produce a rail-to-rail output. We obtain a delay of 3.2 ns for a differential voltage of 400 mV (Fig. 2(a)).

The University of Tokyo, Tokyo, Japan*

Spin-orbit torque (SOT) induced magnetization switching in three-terminal magnetic tunnel junctions (MTJs)[1-4] is attracting great interest owing to its potential application for magnetic random access memories. Although there are similarities in the device structure between SOT-MRAM and the conventional spin transfer torque (STT)-MRAM, there remains many issues to be addressed in order for the SOT-based devices to compete with other technologies. We have studied the thermal stability factor (Δ) of three terminal MTJs using current and magnetic field induced magnetization switching. The Δ estimated from current (SOT) induced magnetization switching is studied as a function external bias field (H), duration and amplitude of the current pulse. The inset of Fig. 1(a) shows the device structure, the magnetic easy axis is orthogonal to the current flow direction (the SOT switching scheme is referred to as type-Y in ref. [3]). Figure 1(a) shows the magnetization switching hysteresis curve when current pulses with length of 50 ns and amplitude of V_{pulse} is applied to the W channel. An offset easy-axis field of $H_y \approx +50$ Oe was applied to compensate the dipolar magnetic field. We find symmetric switching for both positive and negative V_{pulse}. Figure 1(b) shows the switching probability with $H_y \approx$ —50 Oe, which favors antiparallel magnetic configuration. The switching probability is fitted using the thermally activated STT switching model with Δ and an intrinsic threshold current I_{c0} as the fitting parameters[5]. We find Δ for positive V_{pulse} is larger than that for negative V_{pulse}. The asymmetric Δ (against the current flow direction) is one of the characteristics we find for the SOT-induced magnetization switching. Details of the SOT-switching mechanism and its relation to the thermal stability factor will be discussed.

BC-13. Reduced thermal variation of perpendicular magnetic anisotropy in magnetically stiffened dual-W composite storage layer for STT-MRAM. *J. Chatterjee*[1], A. Chavant[1], F. Fettar[2], S. Aufftet[1], C. Ducruet[3], I. Joumard[1], L. Vila[1], R. Sousa[1], I. Prejbeanu[1] and B. Dieny[1]
1. Univ. Grenoble Alpes, CEA, CNRS, Grenoble INP, INAC-Spintec, Grenoble, France; 2. Univ. Grenoble Alpes, Inst. NEEL, Grenoble, France; 3. Crocus Technology, Grenoble, France

State-of-the-art spin-transfer-torque magnetic random access memory (STT-MRAM) is based on out-of-plane magnetized magnetic tunnel junctions (pMTJs) which comprise a composite storage layer (CSL) of the form (FeCoB/non-magnetic spacer (Ta, W, Mo etc.)/FeCoB). As STT-MRAM has to operate on a wide range of temperature (e.g. -40°C to 150°C for automotive applications), it is desirable to minimize the thermal variation of the magnetic and transport properties of pMTJs. In this context, we report a novel design of dual-W composite storage layer (dual W-CSL) of the form "FeCoB/W/ferromagnet/W/FeCoB", which brings additional degrees of freedom to further improve the performance of the storage layer and particularly reduce the thermal variation of its properties. A detailed investigation of the thermal variation of magnetic and electrical properties of such dual W-CSLs for various ferromagnet insertions($Fe_{72}Co_8B_{20}$, $Co_{60}Fe_{20}B_{20}$ and Co) characterized by different exchange stiffness is reported. In particular, cobalt insertion between two W laminations significantly enhances the effective perpendicular anisotropy at room temperature compared to that of the conventional CSL (FeCoB/W/FeCoB) and reduces the relative thermal variation of effective perpendicular anisotropy in the range 300 K-400 K, which is shown in Fig. 1. Moreover, as shown in Fig 2(a) and (b), STT-MRAM cells with 80 nm diameters comprising Co inserted dual-W-CSL exhibit in average 15% and 38% higher thermal stability factor (Δ) as well as 26 % and 15% higher tunneling magnetoresistance ratio (TMR) respectively at room temperature and 110 °C than those of conventional CSL. Despite the increase of Δ for the memory cells comprising the Co inserted dual-W-CSL compared to the conventional case, the STT-efficiency (Δ/I_{c0}) of the former cells still remain the same (Fig. 2(c)) which makes this storage layer promising for STT-MRAM applications.

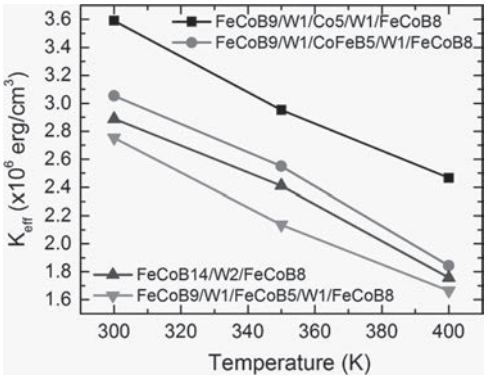

Fig.1 Effective perpendicular anisotropy of different composite storage layers as a function of temperature for 300, 350 and 400 K.

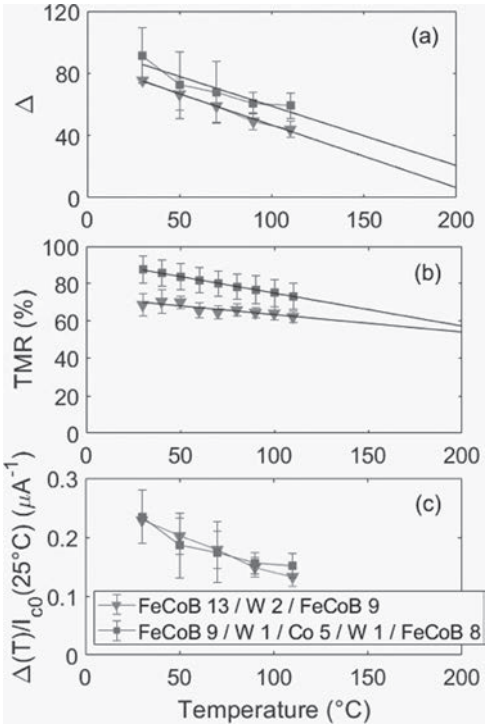

Fig.2 (a) Thermal stability factor (D) (b) TMR and (c) practical STT-efficiency as a function of temperature of the memory cells of 80 nm diameter for conventional CSL and Co laminated dual-W-CSL.

It is known that the dynamics of magnetisation described by the Landau-Lifshits-Gilbert (LLG) equation [1] correctly models the reversal of a magnetic bit and hence the writing of digital information at nanosecond rates. Recently, the LLG equation was reformulated by including a physically correct inertial response [2] which predicts the appearance of spin nutations at a frequency much higher (in the terahertz range, i.e. at sub-picosecond timescales) than the spin precession described by the conventional LLG equation, typically at gigahertz frequencies. Here we show the first direct experimental evidence of inertial spin dynamics in ferromagnetic thin films in the sub terahertz frequency regime. We observed that when a ferromagnetically ordered spin system is driven by intense narrowband terahertz magnetic field pulses of tunable centre frequency, its behavior is similar to the one of a forced oscillator. By analyzing both amplitude and phase of the response, probed with femtosecond magneto-optical Kerr effect, we detect a broad resonance at approximately 0.6 THz, which we ascribe to nutation spin dynamics being driven by the terahertz magnetic field. From the experimental data, we were able to extract the angular momentum relaxation time, which we found to be on the order of 10 ps for three distinct samples with different Gilbert damping constant. Our experimental results are in good agreement with the numerical simulation of LLG equation with the inertial term. This work deepens our understanding of ultrafast magnetism and paves a new way towards controlling magnetism exploiting the nutation resonance.

Physics and Astronomy, University of Minnesota Twin Cities, Minneapolis, MN, United States*

Magnetic memory has recently shifted towards the use of magnetic thin films with large perpendicular magnetic anisotropy (PMA) to simultaneously satisfy the requirements in storage density and thermal stability. Understanding the magnetic switching process and its dependence on the Gilbert damping (α) of materials with large PMA is crucial for developing low-power consumption, ultrafast-switching, and high-thermal stability devices. The need to quantify α of materials with large PMA has resulted in the development of the all-optical ultrafast Time-Resolved Magneto-optical Kerr Effect (TR-MOKE) technique. While TR-MOKE has demonstrated its capability of capturing magnetization dynamics of materials with large PMA at high frequencies and fields, a quantitative analysis regarding the operational optimization of this emerging technique is still lacking. Through the application of a macrospin model based on the Landau-Lifshitz-Gilbert equation, the optimized operational conditions that produce the largest TR-MOKE signals are predicted.

As an experimental verification, we conducted TR-MOKE measurements on a representative sample of a CoFeB PMA thin film to show the excellent agreement of the model prediction with measurements. This analysis results in a better understanding on the external field influence on magnetization precession. With the results from this work and enhanced understanding of TR-MOKE measurements, we then determined the influence of annealing temperature in tungsten (W)-seeded CoFeB stacks. One of the most widely used PMA thin-film stacks is Ta/CoFeB/MgO; however, post-annealing at temperatures exceeding 350 °C leads to the failure of the CoFeB thin film to keep the PMA property. We replaced the Ta seed layer with W and discovered that this stack of W/CoFeB/MgO can sustain annealing temperatures up to 400 °C while still maintaining superb PMA properties and a relatively low Gilbert damping of ~0.02 at room temperature. Due to electronic heating, during the operation of these films in MRAM, it is necessary to understand the relaxation behavior at slightly elevated operational temperatures. For this reason, we also measure the increasing magnetic relaxation at environment temperatures up to 150 °C.

BD-03. Light and THz induced magnetization dynamics in ultrathin PMA garnets. *L. Soumah*[1], S. Bonetti[1], A. Anane[2], V. Unikandanunni[1] and D. Polley[1] *1. Stockholm University, Stockholm, Sweden; 2. Universite Paris Sud CNRS Thales, Palaiseau, France*

Since the 60's, magnetic garnets have been the reference materials in terms of magnetization dynamics, due to their extremely low magnetic damping[1]. In those magnetic insulators, dynamics can be triggered differently: RF excitation, DC charge current (using spintronics phenomena[2]) or femtosecond-long light pulses[3–5]. Light-induced Ferromagnetic Resonance (FMR) precession can be observed on ferromagnetic garnets using λ=400 to 1300 nm pump. Femtosecond light pulses trigger magnetization dynamics through either impulsive (Inverse Cotton Mouton Effect[5] or Inverse Faraday Effect[4]) or displacive mechanisms (such as Photo-Induced Magnetic Anisotropy[3]). If light in the visible and near-infrared range is the most common way to induce magnetization dynamics, it is also possible to use the field from ultrafast terahertz (THz) light to obtain magnetization precession or demagnetization in metals[6,7]. However, THz induced magnetization dynamics in insulators remains an unexplored subject. Here, we investigate the magnetization dynamics induced by radiation of different wavelength, and hence possibly different light-matter interaction phenomena, in nanometer-thick $Bi_{0.3}Y_{2.7}Fe_5O_{12}$ films. Those films present high Faraday rotation coefficient, perpendicular magnetic anisotropy and low magnetic damping[8], and are thus ideal candidates for light-based pump-probe experiments. In those ultrathin films we induce magnetization dynamics using 400 nm light circularly and linearly polarized light (Figure 1 (a) and (b)) to establish the different processes involved into dynamics at those wavelengths. We also explore the potential of strong THz field pulses to generate magnetization dynamics in those films. Comparing the two excitation process mechanisms we draw conclusion on the most efficient approach.

We present a comprehensive analysis of the magnetization dynamics of single magnetotactic bacteria of the types: a) Magnetospirillum Gryphiswaldense MSR-1 and b) Magnetospirillum Magnetotacticum MS-1 with individual chains of magnetite nanoparticles (particle diameter: a): 30 nm, b): 50 nm – 60 nm). The spectra of angular dependent ferromagnetic resonance (FMR) measurements at room temperature of single (multisegmented) nanoparticle chains show multiple angular dependent resonance lines originating from single particles and particle segments of the chain. A uniaxial shape anisotropy of the single chains with an easy axis along the chain axis is revealed. Formation of magnonic band gaps and band deformations are visible due to complex phase relationships in the dipolar coupled particle chain. These properties strongly depend on the arrangement of the nanoparticles in the chain and can be tailored by modifying the genetic code of the bacteria for use in applications e. g. magnonic logic devices. The complementary micromagnetic simulations are in good agreement to the experimental results, revealing the exact origin of the resonance lines. [1] A new approach to identify the origin of the resonances experimentally has been performed by using the element specific method of scanning transmission X-Ray microscopy ferromagnetic resonance (STXM-FMR) [2, 3], providing a lateral resolution down to 30 nm and a time resolution in the picosecond regime. First results at room temperature measured at the Fe L3-edge are shown, revealing a resonance response of a segment of a double segmented nanoparticle chain in a single wild type bacterium Magnetospirillum Magnetotacticum. The phenomenon of sub-picosecond demagnetization [1] has fascinated the magnetism community for the last two decades. Recently it was demonstrated that angular momentum from the spin system can be transferred to the lattice at ultrafast timescales via the microscopic version of the Einstein–de Haas effect [2]. The recovery of the spin order was suggested to happen via the Elliott-Yafet spin-flip scattering model [3]. Surprisingly though, there does not yet exist systematic studies on possible anisotropic demagnetization effects in epitaxial model systems, which would allow for probing the role of orientational spin-lattice coupling. We performed ultrafast demagnetization measurements on epitaxial hcp-cobalt thin film with the c-axis in the plane of the film by pumping the sample with 400-nm radiation and probing the magneto-optic effects in the longitudinal MOKE geometry using 800-nm radiation. The in-plane magnetic anisotropy of the sample enabled us to measure the demagnetization dynamics along two different directions, namely along the easy axis and at 45 degrees between the easy and hard axis (Fig. 1). Along these two directions, we observed a difference in the spin relaxation time. As shown in Fig. 2, the spin relaxation is systematically faster in the 45 degrees axis direction compared to the easy axis of magnetization, with only negligible (within the error bars) difference in the demagnetization magnitude and rate for the two different orientations. Repeated measurements with different relative polarization of both pump and probe show consistent evidence. The observed effect could be related to the anisotropic electron-phonon coupling in cobalt [4]. Our results emphasize the importance of the lattice symmetry in ultrafast demagnetization dynamics. Work at UCSD supported by the DOE award #DE-SC0018237.

The excitation of ferromagnetic material with an ultrashort laser pulse quench the magnetic moment rapidly on sub-picosecond timescales also called ultrafast magnetization, is one of the hot topics in modern magnetism[1]. For the last two decades, extensive efforts have been made to understand the origin of this ultrafast demagnetization[2,3,4]. The magneto-optical response of Fe and Ni is studied experimentally and theoretically during ultrafast demagnetization. We have performed pump-probe experiments in the transverse magneto-optical Kerr effect (T-MOKE) geometry using photon energies (40 to 72 eV) that cover the M-absorption edges of Fe and Ni. The asymmetry was calculated by measuring the reflection of light for two different magnetization directions of the sample. The observed variation of the magnetic asymmetry in the range of photon energies implies that the relation between magnetic asymmetry and sample magnetization is more complex than generally assumed[5]. Density functional theory (DFT) was used to calculate the magneto-optical response of different magnetic excitations: long-wavelength magnons, short wavelength magnons, and Stoner excitations. In case of Fe, the band structure is quite sensitive to the magnetic excitation, which results in the breakdown of the proportionality between the magnetization and magnetic asymmetry at and away from the resonance. Our modeling also reveals that during remagnetization Fe is to a reasonable approximation described by magnons, even though small non-linear contributions could indicate some degree of Stoner excitations as well. For Ni, the calculated asymmetry is not very sensitive to different magnetic excitations. However, due to the large magnetic asymmetry found for Ni experimentally, there is non-linearity in the relationship between asymmetry and the off-diagonal component of the dielectric tensor that underestimates the demagnetization by 12%. Our experimental and theoretical results emphasize the need for considering a coupling between asymmetry and magnetization that is more complex than a simple linear relationship and that is crucial for the microscopic interpretation of ultrafast magnetization experiments.

A profound concept in theoretical modelling is the separation of time scales in different reservoirs, for instance spin and lattice. However, in magnetocaloric [1] and multiferroic [2] materials such a reservoir separation is not feasible because of comparable exchange energies. Thus, a proper description combining the instantaneous dynamics of both, spin and lattice degrees of freedom, but also a deep understanding about the dynamical exchange mechanism between the reserviors are required. We will present our electronic structure approach of combined atomistic spin-lattice dynamics. Here, we apply our self-consistent, constrained, first-principles Tight Binding method, allowing us to calculate forces/torques without mapping to any particular effective Hamiltonian model. In particular for the spin degree-of-freedom it was shown [3] that this mapping is not feasible. Applying multiparameter perturbation theory to a disordered state in spin and lattice, we still are able to obtain 'parameters' in an effective bilinear spin-lattice Hamiltonian. This allows to compare ab-initio forces/torques with those obtained from an effective Hamiltonian, making a crucial statement about the validity of the classical spin-lattice model discussed in Ref. [4]. The current proposed self-consistent method will be applied to bulk Stoner magnets and low-dimensional systems. We reveal a significant discrepancies away from the bilinear model in both spin and lattice, especially under disorder. For instance, the hitherto assumed constant spin-spin exchange drastically varies strongly in time. Furthermore, indications for a dynamical anisotropic exchange interaction mediated by lattice vibration is exposed. Our approach will give, one hand, a new insight on exchange phenomena in a multi-reservoir system and, on the other hand, allows to study spin-lattice driven phenomena from a new first-principles perspective.

BD-08. Terahertz induced Demagnetization in Magnetic Multilayers. *D. Polley*[1], K. Neeraj[1], V. Unikandanunni[1], S. Urazhdin[3] and S. Bonetti[1,2] *1. Department of Physics, Stockholm University, Stockholm, Sweden; 2. Department of Molecular Sciences and Nanosystems, Ca' Foscari University of Venice, Venice, Italy; 3. Department of Physics, Emory University, Atlanta, GA, United States*

In the last few years, strong table-top terahertz (THz) sources have been efficiently used to investigate spin-dynamics in different types of magnetic systems [1-3]. For metallic ferromagnets, defects-induced spin-lattice scattering appears to be more relevant than phonon scattering [1] and the THz-induced demagnetization amplitude is found to be more pronounced in multilayer films (ML) than for in-plane films [3]. Such observations paved the way to investigate the experimental realization of THz-induced 'ballistic switching' [4] in a table-top geometry. Here, we study the THz transport and the THz-induced ultrafast demagnetization dynamics in two ML films namely CoPt and CoNi. The complex conductivity is measured in the frequency range of 0.3-2.5 THz as shown in Fig. 1a, and has been analyzed with the Drude model. The d.c conductivity ($\sigma_{d.c.}$) and the Drude scattering timescale (σ_{Drude}) is smaller for CoPt (as shown in Table 1), due to the presence of the strong spin-orbit scattering element Pt and increased interface-scattering. THz-induced demagnetization spectra shown in Fig. 1b is measured in polar-magneto-optical Kerr effect geometry using strong THz radiation (~ 200 mT, fluence ~ 1 mJ/cm^2). The demagnetization amplitude is 52% larger in CoPt than CoNi and COMSOL simulation [5] confirms that absorbed energy difference alone cannot explain such a large change. The calculated Elliot-Yafet (EY) parameter (α_{EY}) [6] shows enhanced electron-phonon scattering rate in CoPt, which we suggest is due to enhanced spin-orbit coupling and interface scattering. This can explain the higher demagnetization amplitude in CoPt at the same THz field and fluence. The extracted electron-phonon relaxation timescale is slightly faster in CoNi than CoPt as shown in Table 1. The observation of large THz-induced demagnetization and its explanation in terms of enhanced EY scattering might open up efficient ways to induce THz-induced switching in ferromagnetic films.

Institute of Magnetism, Kyiv, Ukraine; 4. Faculty of Engineering and Mathematical Sciences, Physics, The University of Western Australia, Crawley, WA, Australia*

Single-crystal Yttrium Iron Garnet (YIG) is known as a material with the lowest Gilbert damping, which can be decreased or increased in electrically driven YIG/Pt bilayers by transfer of a spin torque from Pt to YIG films [1-3]. However, in the absence of an electric current in the Pt layer, the experimentally determined magnetic relaxation turns to be too high for practical applications [1]. Here, using the ferromagnetic resonance (FMR) technique, we show that the origin of this excessive damping is related to eddy currents induced in the Pt layer by magnetic oscillations excited in YIG film. Furthermore, we demonstrate a way to eliminate this relaxation mechanism. The experiment is performed using two 6.7-μm-thick YIG films grown by liquid phase epitaxy on a 500-μm-thick Gallium Gadolinium Garnet (GGG) substrate. One of the films serves as a reference, on another one YIG surface is covered by a 10 nm Pt layer, deposited by magnetron sputtering. The samples are fixed on the brass wall of a rectangular waveguide connected to an Anritsu vector network analyzer (VNA). The waveguide is placed inside electromagnet is such a way that orthogonal microwave, h_{rf} and magnetizing magnetic, H_0 fields are applied in the YIG film plane (Fig.1). For the reference YIG/GGG sample, the FMR linewidth Δf_{FMR} is independent of whether the sample is faced to the brass by YIG or by GGG side and is about 2.5 MHz. On the contrary, in the case of the Pt/YIG/GGG structure, Δf_{FMR} depends drastically on the fastening of the sample. If GGG is in contact with brass, the Δf_{FMR} increases up to 9.5 MHz. In the case, when Pt contacts the wall, Δf_{FMR} is almost the same as in the reference sample. This behavior can be understood if one attributes the observed Pt-related damping with Ohmic losses of eddy currents induced in a high resistive Pt layer. In such a case, the massive metallic wall electrically shunts the Pt layer and, thus, reduces the eddy current density in Pt. The shunting effect depends on a distance between Pt and the brass wall. The gradual increase of Δf_{FMR} with increase of this distance is clearly visible in Fig. 2. Developed analytical theory supports this explanation.

BD-10. Microscopic Mechanisms of Level Attraction for a Coupled Magnon System in a Microwave Cavity. *I. Proskurin*[1,2], R. Macedo[3] and R.L. Stamps[1] *1. Department of Physics and Astronomy, University of Manitoba, Winnipeg, MB, Canada; 2. Institute of Natural Sciences and Mathematics, Ural Federal University, Ekaterinburg, Russian Federation; 3. School of Physics and Astronomy, University of Glasgow, Glasgow, United Kingdom*

Level attraction was proposed recently as a new universal type of interaction in dynamical nonequilibrium systems. In this regards it is analogous to synchronization of two harmonic oscillators, where one of the oscillators has a negative-mass instability [1,2]. This type of behavior is important in quantum information processing for realization of quantum amplifiers and mode entanglement [2]. Level attraction was recently demonstrated experimentally for cavity magnon-polaritons and interpreted in terms of macroscopic manifestation of the Lenz's effect in a dissipative system [3]. In this work, we consider the microscopic origins of level attraction for a coupled magnon system. By analyzing magnon response functions, we show that, in general, the attractive regime is related to an effective susceptibility of a diamagnetic type. There is a number of microscopic mechanisms that can contribute to this type of susceptibility depending on the type of interactions with another subsystem coupled to magnonic bath. For cavity magnon-polaritons, we analyze the contribution from the inverse Faraday effect and the Aharonov-Casher phase [4]. For the former scenario, we derive the effective susceptibility and the level attraction picture for the geometry shown in the Figure. We also demonstrate that in materials with flowing spin currents there is a relativistic mechanism of level attraction through the Aharonov-Casher effect of the cavity electric field. We estimate the magnitude of this effect and discuss its relevance to materials with Dzyaloshinskii-Moriya interactions. We extend our theory to the resonant absorption of magnons by the Bloch electrons in conducting materials and apply it to the Rashba materials with spin-orbit torques, where we demonstrate the origin of the attractive regime from the antidamping torque, which can be helpful for interpreting the available experimental data in these systems [5].

BD-11. Abnormal anti-crossing dispersion in photon-magnon coupling. *B. Bhoi*[1], B. Kim[1] and S. Kim[1] *1. Department of Materials Science and Engineering, Seoul National University, Seoul, The Republic of Korea*

Understanding and exploiting the interactions of the excited modes in hybrid quantum systems are the keys to achieving the ambitious goal of quantum information processing [1-2]. Therefore, collectively excited modes (i.e., magnons) in ferromagnets, being coupled to elementary excitations of electromagnetic waves (photons), have increasingly been studied in a variety of hybrid systems [3-4]. The interaction (coupling) between the magnon and photon modes is usually demonstrated by showing the modes' splitting near their common resonant frequency within the so-called anti-crossing region or their level repulsion, as described well by a classical model for coupled oscillators and also by a two-level quantum model [4]. Herein, we report the experimental demonstration of an abnormal, opposite anti-crossing dispersion (or level attraction) in a photon-magnon (P-M) coupled system that consists of an Yttrium Iron Garnet film and an inverted pattern of split-ring resonator structure (noted as ISRR) in a planar geometry [5]. It was found that the normal shape of anti-crossing dispersion typically observed in P-M coupling is changed to its opposite anti-crossing shape just by changing the position/orientation of the ISRR's split gap with respect to the microstrip line axis along which ac currents are applied. The characteristic features of the opposite anti-crossing dispersion and its linewidth evolution were scrutinized with the help of analytical derivations based on electromagnetic interactions. We ascribed the observed opposite anti-crossing dispersion to the compensation of both intrinsic damping and coupling-induced damping in the magnon modes. This is achievable by controlling the relative strength and phase of the oscillating magnetic fields generated from the ISRR's split gap and the microstrip feeding line. We provided a phase diagram of the dispersion type in the P-M coupling region according to the strength and phase of the microwave magnetic fields acting on the hybrid system. The position/orientation of an ISRR's split gap provides a robust means of controlling the dispersion shape of anti-crossing and its damping in a P-M coupling, thereby offering more opportunity for advanced microwave-device designs.

The control of the magnetization and/or the magnetization dynamics in a reliable, fast and energy-efficient way is of paramount interest for data storage, manipulation and signal processing. The possible control of magnetization via elastic strains (static and/or dynamic) is one of the promising paths that currently drives intense research activities, leading to the emergence of the so-called "straintronics". This work aims at exploring *both the magnetic and elastic dynamical responses* of magnetostrictive $TbFe_2$/Nb crystalline layered heterostructures, after excitation by femtosecond *laser-induced acoustic pulses*. The combination of ultrafast X ray diffraction (UXRD) with Magneto Optical Kerr Effect (MOKE) measurements permits to probe with time resolution the two degrees of freedom: the strain evolution in the different layers and the associated strain-induced magnetic changes in $TbFe_2$. When the excited $TbFe_2$ is the surface of the sample, a classical symmetric bipolar strain pulse is observed while a decomposition of the transient strain into an asymmetric bipolar and a unipolar pulses occurs when the excited $TbFe_2$ is capped with SiO_2. The inverse magnetostriction due to the unipolar strain pulses leads to a MOKE signal that linearly depends on the strain pulse amplitude measured through UXRD (Fig. 1). Linear chain model simulations accurately predict the timing and shape of UXRD and MOKE signals due to the strain reflections from multiple interfaces in the heterostructure [1]. MOKE thus appears to be a very sensitive probe for the

arrival of the multiple strain echoes at the top of the highly magnetostrictive $TbFe_2$ layer and complements bulk sensitive UXRD that provides quantitative information on strains with unit cell resolution and layer selectivity. The combination of MOKE and UXRD outlines a potential path towards an experimental calibration of the magnetoelastic coefficient for picosecond acoustic pulses, which constitutes an important step towards the manipulation of magnetization in giant magnetostriction materials.

BD-13. Gigahertz Frequency Antiferromagnetic Resonance and Strong Magnon-Magnon Coupling in the Layered Crystal $CrCl_3$. D. MacNeill[1], *J.T. Hou*[2], D. Klein[1], P. Zhang[2], J. Pablo[1] and L. Liu[2] *1. Physics, Massachusetts Institute of Technology, Cambridge, MA, United States; 2. Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, MA, United States*

Antiferromagnetic spintronics is an emerging field with the potential to realize high speed logic and memory devices. Compared to ferromagnetic materials, antiferromagnetic dynamics are less well-understood, partly due to their high instrinsic frequencies that require specialized terahertz techniques to probe. Here, we report broadband microwave absorption spectroscopy of the layered antiferromagnet insulator $CrCl_3$ [1]. We observe a rich structure of resonances arising from quasi-two-dimensional antiferromagnetic dynamics. Due to the weak interlayer magnetic coupling in this material, we are able to observe both optical and acoustic branches of antiferromagnetic resonance in the GHz frequency range and a symmetry-protected crossing between them. By breaking rotational symmetry, we further show that strong magnon-magnon coupling with large tunable gaps can be induced between the two resonant modes. All of these effects are captured with analytical solutions of the Landau-Lifshitz Gilbert equations, and the extracted values of exchange field and saturation magnetization are consistent with magnetometry measurements. Our results provide $CrCl_3$ as a versatile platform for studying antiferromagnetic dynamics with conventional microwave electronics. Furthermore, $CrCl_3$ can be cleaved to produce air-stable films down to the monolayer limit. Using van der Waals assembly, we can combine different magnetic materials to build antiferromagnetic devices and to induce magnon-magnon coupling by breaking sublattice exchange symmetry.

BD-14. Greatly Enhanced Magnetoelastic Excitation of a Single Nanomagnet by Focusing Surface Acoustic Waves. *W. Yang*[1], M. Jaris[1] and H. Schmidt[1] *1. University of California Santa Cruz, Santa Cruz, CA, United States*

Elastic surface waves can significantly influence the magnetization dynamics of nanomagnets [1]. Surface acoustic waves (SAWs) can be optically generated by a nanowire array and used to excite narrow-band magnetization precessions in a single nanomagnet via magneto-elastic (MEL) coupling. This was used for time-resolved measurements of the SAW driven magnetization precession of a single nanomagnet and enabled direct determination of the intrinsic Gilbert damping of the nanomagnet [2]. Here, we demonstrated a dramatic enhancement of the MEL excitation of a single nanomagnet using focused SAWs (FSAWs) (Fig. 1a,b). We show the Kerr signal amplitude is almost 10 times larger than the optically excited (Fig. 1c). The Fourier amplitude of the MEL excitation shows a linear increase with increasing pump fluence (Fig. 1d). Thanks to the robust MEL excitation, we demonstrated for the first time the MEL controlled magnetization dynamics in sub-100nm single nanomagnets. Furthermore, we integrated four sets of nanowires with different pitch (Fig. 2a,b), which enables us to selectively excite magnetization dynamics of any one of four identical single nanomagnets at the corresponding four different resonant fields (Fig. 2c, d). The all-optical technique provides an alternative method of studying intrinsic spin dynamics of individual small nanomagnets, which have important implications for nanoscale spintronic devices and nanoscale magneto-mechanical devices.

BD-15. Controlling the magnon-photon interface via a cavity Fano resonance. J. Gollwitzer[1], L. Bocklage[1,2], R. Röhlsberger[1,2] and *G. Meier*[3,2] *1. Deutsches Elektronen-Synchrotron DESY, Hamburg, Germany; 2. The Hamburg Centre for Ultrafast Imaging, Hamburg, Germany; 3. Max-Planck Institute for the Structure and Dynamics of Matter, Hamburg, Germany*

The interface between photons and magnons has introduced the opportunity to perform quantum information processing in macroscopic systems. So far, strong coupling and Rabi oscillations have been exploited to control the coupling between photons and magnons in microwave cavities (1–3). Here, we present a new scheme to achieve spectral control of magnon-photon coupling via Fano interference. The Fano resonance is controlled via cavity detuning, which acts as the background channel in the Fano picture at sufficiently low coupling. An incoherent term in the Fano picture, normally attributed to decoherence in open quantum systems (4,5), actually arises here due to the coupling of a discrete matter resonance with a resonant cavity mode. Magnon-photon hybridization at higher coupling strengths alters the

Fano phase relations and effects the breakdown of the Fano picture. These results establish spectral Fano control in cavity optomagnonics, which may lead to advances in room temperature quantum information processing.

BE-01. Thermal Gradients and Anomalous Nernst Effects in Membrane-supported Non-Local Spin Valves. R.K. Bennet[1], A. Hojem[1,2] and *B.L. Zink*[1] *1. Physics & Astronomy, University of Denver, Denver, CO, United States; 2. Physics, UC San Diego, La Jolla, CA, United States*

Non-local spin valves (NLSVs) have the unique capability to separate charge and spin currents, and thus are an important tool for both applied and fundamental research in nanomagnetism.[1,2] Previous research shows that changes to the composition of the NLSV substrate can have a marked effect on the background non-local resistance by altering the substrate thermal conductance.[3] Our research demonstrates enhancement of non-local spin resistance by the anomalous Nernst effect (ANE) and dramatically lowered thermal conductance in NLSVs fabricated on Si-N membranes with a thickness of 500 nm.[4,5] In this membrane-supported construction, the thermal gradient is confined to nearly 2 dimensions. We therefore use 2D finite-element modeling of Py/Al NLSVs to present refined values as low as 0.17 for the Nernst coefficient of permalloy at 200 K. This is in good agreement with previously reported values.[6,7] We also discuss the rarely-measured temperature dependence of the Nernst coefficient of permalloy. This membrane-supported construction also leads to additional thermal spin injection effects, such as thermally-assisted electrical spin injection not seen in our bulk Si substrate-supported devices. We model this previously unknown effect as a contribution from phonon momentum interacting with the pure spin current in the Al channel.

BE-02. Sign reversal of anomalous and planar Nernst effects at low temperature for a $C1_b$-type NiMnSb half-Heusler alloy thin film. *H. Sharma*[1,2], *Z.* Wen[3], K. Takanashi[1,4] and M. Mizuguchi[1,2] *1. Institute for Materials Research, Tohoku University, Sendai, Japan; 2. CREST, Japan Science and Technology Agency, Kawaguchi, Japan; 3. National Institute for Materials Science, Tsukuba, Japan; 4. Center for Spintronics Research Network (CSRN), Tohoku University, Sendai, Japan*

The Nernst effect, thermally induced transversal voltage in the direction perpendicular to both the temperature gradient and the magnetization, is a valuable probe for the spin-orbit coupling phenomena in the field of spin caloritoronics [1-6]. The interplay between the anomalous Nernst effect (ANE), planar Nernst effect (PNE), pure spin-current and spin-polarized current generated by a thermal gradient is attracting many researchers. The ANE and PNE can be utilized to investigate the spin-orbit coupling phenomena through the interaction among spin, charge and heat. On the other hand, the $C1_b$-type half-metallic Heusler alloys are of intense research interest because of their exclusive properties due to the semiconducting behavior of the minority band with a gap at the Fermi level and thus leading to 100% spin polarization of conduction electrons [6-8]. This exceptional property may direct distinctive thermoelectric effects in half-metallic Heusler alloys, which augment the interest in the physical properties in the concerned materials. In this contribution, we present a systematic investigation of the ANE, PNE and Seebeck with in-plane applied thermal gradient (see in inset of Fig. 1a) at different temperatures for a $C1_b$-type NiMnSb half-Heusler alloy thin film. A clear reversal behavior of ANE and Seebeck (see in Fig. 1a) is observed at low temperatures ($T \leq 40$ K). In addition, the PNE switches (see Fig. 1b) from its fourfold $\sin\theta\cos\theta$ angular dependence behavior to twofold $\sin\theta$ angular dependence behavior at low temperatures ($T \leq 40$ K). This observed arbitrary behavior of ANE, Seebeck and PNE in $C1_b$-type NiMnSb half-Heusler alloy thin film will be discussed in details.

BE-03. Large anomalous Nernst and Hall effects without magnetization scaling in $Fe_{1-x}Sn_x$ ordered alloy thin films.
M. Mizuguchi[1], H. Sharma[1], Y. Goto[2], A. Maeno[2], T. Nagahama[2], K. Watanabe[3], M. Tsujikawa[3] and M. Shirai[3] *1. Institute for Materials Research, Tohoku University, Sendai, Japan; 2. Graduate School of Engineering, Hokkaido University, Sapporo, Japan; 3. Research Institute of Electrical Communication, Tohoku University, Sendai, Japan*

The anomalous Nernst effect (ANE), one of the thermomagnetic effects studied for a long time, has recently attracted renewed attention. The ANE, which originates from fictitious fields in momentum space, is essential for clarifying the interplay among heat, spin, and charge in magnets[1]. It is indispensable to find the guiding principle to obtain materials with large ANE in order to realize a thermoelectric device based on the ANE. Thus, we have systematically investigated the ANE in ordered alloy thin films[2-4] and found the relation between the magnetic anisotropy and the ANE for the films. Recently, the metastable *B*2-type Fe-Sn alloys have been successfully fabricated by molecular beam epitaxy (MBE)[5]. This material attracts attention because large tunnel magnetoresistance is expected by combining with a MgO burrier layer. In this paper, we report the large ANE and anomalous Hall effect (AHE) in *B*2-type $Fe_{1-x}Sn_x$ ordered alloy films with various Sn composition (x). The films were grown on MgO(100) substrates by MBE. Transverse Seebeck coefficient (S_{xy}) loops and Hall resistivity (r_{xy}) as a function of the magnetic field were measured. For ANE measurements, one side of a sample was heated, and a temperature difference was induced along the long side of a rectangle sample. A magnetic field perpendicular to the sample plane was applied. Figure 1 shows Sn composition dependence of S_{xy} for $Fe_{1-x}Sn_x$ ordered alloy films measured at room temperature. Maximum S_{xy} is about 4 μV / K with x = 30 %. This value is exceedingly larger than ordinary ferromagnetic materials[2-4], and it is revealed that a Sn-doping into Fe site is very effective to enhance ANE of Fe. Surprisingly, the intensity of S_{xy} is not scaled to the saturation magnetization (M_s) of these films because M_s tends to decrease with increasing the Sn composition. This implies that the mechanism of the ANE in *B*2-type $Fe_{1-x}Sn_x$ is not simple and any interesting physics is involved in this phenomenon. Detailed comparison between ANE and AHE, and an insight on electronic structures of this material calculated by ab initio will be also discussed.

BE-04. Light-induced thermal spin current. *Y. Chen*[1] and S. Huang[1] *1. Physics, National Taiwan University, Taipei, Taiwan*

In this work, we investigate the thermal spin current driven by light, including magnonic spin current of the spin Seebeck effect (SSE) and spin-polarized current of the anomalous Nernst effect (ANE) [1]. Unlike heating by electrical means, the light-induced thermal spin current by the SSE (see Fig. 1) and the ANE (see Fig. 2) can be enhanced, reduced, and its sign can even be reversed due to the intrinsic characteristic of the penetrating light. Most importantly, by reversing the direction of the incident light, we are able to qualitatively distinguish the contributions from the interfacial and bulk temperature gradients to the transverse spin accumulation. Most importantly, although the overall spin signals are strongly influenced by the frequency of light, the interfacial and bulk spin Seebeck coefficients are intrinsic and frequency independent. In addition, we observe a nearly instantaneous time response both from the SSE and the ANE during the light excitation, which highlight the importance of spin-to-charge conversion by the spin-orbit coupling for ultrafast spin caloritronics. We demonstrate light offers distinct heating mechanism to develop spintronic and spin caloritronic devices.

BE-05. Magnonic Spin Fluctuation in CuMn. *P. Wu*[1], Y. Tu[1], D. Qu[2], S. Lee[2] and S. Huang[1] *1. National Taiwan University, Taipei, Taiwan; 2. Institute of Physics, Academia Sinica, Taipei, Taiwan*

How to efficiently generate and manipulate spin current is one of the most important topics in the field of spintronics. Recently, strong interest has been focused on the enhancement of spin current by spin fluctuation. Most of the studies use long-range ordered magnetic materials such as ferromagnetic metals or antiferromagnetic insulators. In this work, we utilize $Cu_{1-X}Mn_X$ alloys over the entire composition range to study the influence of spin frustration and spin fluctuation, from antiferromagnetic to spin glass (SG) phase transition. We report the enhancement of the inverse spin Hall effect (ISHE) during spin fluctuation in conducting CuMn alloys by the spin Seebeck effect (SSE) measurement with YIG. By tuning composition in $Cu_{1-x}Mn_x$, the SG transition is systematically changed, as revealed by the blocking temperature (T_b). We demonstrate the ISHE signal can be significantly enhanced with a maximum at peak temperature T_p and subsequently suppressed by spin frozen at low temperature, as shown in Fig. 1. Most importantly, we found temperature dependent SSE signal is strongly influenced by the short-range spin fluctuation and always above its T_b. In addition, the value and the sign of the ISHE voltage vary with composition and correspond to the number of valence electrons. Thus, we provide a compelling and controllable method to significantly enhance the spin current through short-range SG system, which is beneficial for energy efficient spintronic devices.

BE-06. Surface acoustic wave induced DC spin current in spin-orbit heterostructures. *T. Kawada*[1*], M. Kawaguchi[1], T. Funato[2], H. Kohno[2] and M. Hayashi[1,3] *1. Physics, The University of Tokyo, Tokyo, Japan; 2. Physics, Nagoya University, Nagoya, Japan; 3. National Institute for Materials Science, Tsukuba, Japan*

Spin current plays an important role in the field of spintronics. Spin rotation coupling, the interaction between spin angular momentum and mechanical rotation, is attracting significant interest as a source of spin current. The Rayleigh-type surface acoustic wave can produce lattice rotation in the radio-frequency range, allowing large spin-rotation coupling[1]. Recently, it has been shown that surface acoustic waves can generate spin current even in nonmagnetic metals with weak spin-orbit coupling[2]. Here, we show that a direct current (dc) electromotive force emerges in heavy metal/ferromagnetic metal bilayers when surface acoustic waves are excited. DC voltage across a Hall bar placed in between interdigital transducers (IDT) is measured while surface acoustic waves propagates between the IDTs[3]. The electromotive force is dependent on the magnetization direction of the ferromagnetic layer. Interestingly, the magnitude of the electromotive force that depends on the field angle increases with increasing thickness of the heavy metal layer until it saturates. The thickness dependence of the field-dependent electromotive force resembles that of the spin Hall magnetoresistance, which indicates that dc spin current is generated via excitation of lattice rotation.

BE-07. Spin Transport at Heavy Metal/Ferromagnet Interfaces: Effective Spin-mixing Conductance and Spin Memory Loss. *L. Zhu*[1], D. Ralph[1] and R. Buhrman[1] *1. Cornell University, Ithaca, NY, United States*

Interfacial spin transport in heavy-metal /ferromagnet (HM/FM) systems is at the root of many spintronic phenomena. The spin current generated by the spin Hall effect of the HM [1-4] transports throught the HM/FM interface and exterts spin-orbit torques on the FM layer. In the reciprocal processes, the spin current due to spin pumping, spin seebeck effect and other effects transports through the HM/FM interface and can be detected by the inverse spin Hall effect of the HM. The effective spin-mixing conductance ($G_{eff}^{\uparrow\downarrow}$), the key

factor determining the spin transparency of a HM/FM interface, is typically ascertained from the inverse dependence of magnetic damping on the FM thickness under the assumption that spin pumping is the dominant mechanism affecting this dependence. This fails badly in many in-plane magnetized HM/FM systems in the nm-scale thickness regime [5], where instead the majority of the damping is from two-magnon scattering at the FM interface. If this is neglected, the result is an unphysical "giant" *apparent* $G_{eff}^{\uparrow\downarrow}$ and hence a considerable underestimation of both the spin Hall ratio and the spin Hall conductivity in inverse/direct spin Hall experiments. This talk will also report conclusive experiment evidence that interfacial spin orbit coupling linearly reduces the SOTs exerted on the FM layer by the spin currents generated in the HM [6] while interfacial intermixing at a Pt/Co interface can *increase* interfacial spin transparency [7], by approximately 30 %.

Conversion between spin and charge currents is essential in spintronics, since it enables a handful of potentially transformative phenomena such as modifying the magnetization of ultra-thin films by means of spin-orbit torque or generating energy by spin-current-driven rhermoelectric generation [1,2]. The inclusion of graphene in spintronics has allowed to unravel new arising spin-orbit effects unique of graphene/metal interfaces [3–5]. However, the thermal magnetotransport properties in Gr-based structures with perpendicular magnetic anisotropy have not been investigated at all. We have studied the thermal magnetotransport in Pt(Ta)/Gr/Co/Ir and Pt(Ta)/Co/Ir asymmetric epitaxial heterostructures on Al2O3(0001) single crystal substrates produced by means of a combination of DC sputtering, MBE and CVD techniques (see [3]). By applying a thermal gradient in the z direction (see figure 1) a transversal voltage can be observed in the y direction. This voltage is a combination of several effects arising from the magnetic (anomalous Nernst effect) and spin-orbit (Spin Seebeck effect) properties of the materials and interfaces involved. We have disentangled the origin of these components and observed that the inclusion of a graphene monolayer in the interface between cobalt and a metal can induce a significant interfacial contribution to the observed voltage.

Our devices are fabricated in the clean-room using a combination of electron beam evaporation through a shadow mask defined by electron beam lithography in a PMMA/MMA resist and conventional optical lithography and lift-off techniques. The use of a 3-axes sample rotation stage coupled with a base pressure 10^{-10} mbar permits a flexible device design whilst retaining very clean interfaces between the Silver (Ag) and Permalloy (Py) electrodes. Using the non-local geometry, one can separate heat, charge and spin currents and thereby study the effect of these independently[1]. Thermally generated spin currents are known as spin caloritronics[2] and are intrinsically interesting. In lateral spin valves (LSVs) it is important to understand the origin of the thermal signals generated as their magnitude dominates the detected voltage, illustrated in figure 1. We study the heat diffusion in lateral spin valves using a DC current bias technique and taking advantage of the linear and quadratic field independent parts of the non-local IVs that are related to the thermal effects in the system. We separate the Joule heating and Peltier effect contribution from 270 K down to 2 K and calculate their decay lengths in the same temperature range. Using Scanning thermal microscopy[3] we map their heat spatial distribution at room temperature for the first time in a lateral spin valve system to aid the understanding of the aforementioned effects and develop an analytical model based on that. Coupling the experimental data with the analytical model, we predict a temperature rise at the injector junction of more than 5 ^{o}C at 270 K, depicted in figure 2. Finally, we investigate the correlation of the thermal signals to that of the spin transport, thermal conductivity and Seebeck coefficients in order to fully analyse the device's behaviour from 270 K to 2 K.

BE-10. Magnetic Precession Induced by Surface Acoustic Waves in Magnetostrictive Nanostripes. *D. Castilla*[1], J.L. Prieto[1], M. Muñoz[1,2], G. Fuentes[1] and M. Sinusía[1] *1. Universidad Politécnica de Madrid, Madrid, Spain; 2. IMN-Instituto Micro y Nanotecnología, CSIC, Madrid, Spain*

We report a magnetic precession in a magnetostrictive nanostripe induced by a surface acoustic wave (SAW) resonator (see figure 1). This device was fabricated by EBL and sputtering deposition over a piezoelectric layer of ScAlN, 2 μm thick. The structure of the nanostripes is either Ni or FeCoB (35 nm) capped by a film of Pt (2 nm). By measuring Anisotropic Magnetoresistance loops for different amplitudes of the SAWs, we can measure a clear decrease of the coercivity in the samples. This is expected as the SAW is supplying an additional source of energy (stress) to the magnetization process. Interestingly, the SAW can also induce a non-resistive voltage (measured a zero current) in the nanostripe along the long axis. This is also a hysteretic voltage, dependent on the magnetization state. The comparison of the induced voltage V(H) with the AMR curve shows a clear relation. At high fields, the induced voltage is constant, which corresponds to a saturation state of the magnetization in the ferromagnet, when there is no precession of the magnetization (see figure 2). At low fields, ±100 Oe, a peak can be observed. This peak depends on the direction of the magnetization and occurs for the minimum in the AMR curve, i.e. when the magnetic moment of the sample has the largest component perpendicular to the long axis of the stripe. At this point, the torque induced by the SAW on the local magnetization is maximum and so it is the precession induced by the SAW. Within this work we present the results using different capping layers Pt, and Cr/Pt to determine if this SAW induced voltage has its origin in the Inverse Spin Hall Effect.

Institut für Theoretische Physik, Universität Frankfurt, Frankfurt, Germany*

Spin pumping by dipolar-exchange magnons parametrically excited in in-plane magnetized Yttrium Iron Garnet / Platinum (YIG/Pt) bilayers was investigated in the presence of the longitudinal spin Seebeck effect (LSSE) [1].

When the microwave parametric pumping is applied to the sample, the electric voltage generated in the platinum layer via the inverse spin Hall effect (ISHE) results from contributions of two opposite spin currents formed by the LSSE and by the spin pumping from parametric magnons. In our field-dependent measurements of the spin pumping induced component of the ISHE-voltage, a clearly visible sharp peak is detected at high pumping powers. It is found that the peak position and the corresponding magnetic field are determined by the process of confluence of two parametrically exited magnons into one magnon possessing twice the frequency and the sum of the wavevectors of the initial magnons. The experimentally measured ISHE peak fields for different parametric pumping frequencies perfectly correspond to the calculated dependence without additional fitting parameters. The three-magnon confluence process constitutes an additional damping mechanism for the group of parametrically pumped magnons. Thus, for low pumping powers the confluence will decrease the total number of magnons in the system that results in the decreasing of the ISHE-voltage. Nevertheless, we demonstrate by numerical calculations that under the action of a rather strong parametric pumping field this confluence process results in the increase of the total number of magnons in the magnetic sample. This leads to the enhancement of the spin pumping effect in the YIG/Pt bilayer in the presence of the three-magnon confluence process.

BE-12. Enhanced magnon spin transport, magnon polarons and vector spin Seebeck effect detection in $NiFe_2O_4$ thin films on lattice-matched substrates. *T. Kuschel*[1] *1. Bielefeld University, Bielefeld, Germany*

We report on enhanced magnon spin transport properties in epitaxial $NiFe_2O_4$ (NFO) films grown on $MgGa_2O_4$ substrates compared to NFO films deposited on standard $MgAl_2O_4$ [1,2]. The reduction of the lattice mismatch from 3.2% to 0.8% decreases the number of antiphase boundary defects in the NFO films and, thus, improves structural and magnetic properties. Further, spin transport is strongly improved as we have studied by nonlocal magnon spin transport experiments with Pt injector and detector strips [2]. While the magnon spin diffusion length in the NFO films of around 3 μm is not changed drastically, the nonlocal spin transport signal is enhanced by two orders of magnitude. This increase is detectable for both electrically and thermally excited magnons. In addition, we observe spin transport signals in NFO that point to magnetoelastic coupling identified as magnon polarons [2]. These findings make lattice-matched NFO being an important alternative to $Y_3Fe_5O_{12}$ (YIG) in terms of spin transport properties. Finally, we use these lattice-matched NFO films to demonstrate a new vectorial magnetometry technique based on the longitudinal spin Seebeck effect (SSE) [3]. Placing four electrical contacts on top of Pd/NFO, we trace both in-plane magnetization components of the NFO. We identify different anisotropy contributions in NFO on lattice-matched substrates with (001) and (011) orientation and reconstruct the in-plane magnetization reversal process via the vector SSE technique [3].

BE-13. Enhanced spin Seebeck effect in exchange-biased MgO/Fe_3O_4/Cu multilayers. *V. Kalappattil*[1], H. Nazari[1], S.G. Bhat[2], R. Das[1], A.P. Kumar[2], M. Phan[1] and H. Srikanth[1] *1. physics, University of South Florida, Tampa, FL, United States; 2. physics, Indian Institute of Science, Bangalore, India*

Spin Seebeck effect (SSE) along with spin pumping and spin Hall effect (SHE) is one of the most efficient ways to generate pure spin current [1]. Over the last decade, several approaches have been made to enhance the SSE voltage. One of the most effective methods established is through creating multilayers of Fe_3O_4 thin films [2]. In this study, we have fabricated high-quality multilayers of Fe_3O_4 (32 nm) thin films using pulsed laser deposition (PLD) on Magnesium Oxide (MgO) substrate separated by Cu (~10 nm) layers. As the number of layers increases, total magnetization drastically decreases due to the increased fraction of antiphase boundaries (APB), which leads to more antiferromagnetic interactions. Interestingly, we have achieved ~ 400% increase in the SSE voltage from one layer to three-layers, which can be attributed to the changes in interface magnetic anisotropy, spin mixing conductance (G) and characteristic length. Detailed magnetic characterization revealed a strong exchange bias of ~250 Oe present in the system mainly due to the presence of the AFM like antiphase boundaries. Building upon our previous studies on the SSE dependence on the magnetic anisotropy [3,4], we demonstrate, for the first time, the influence of exchange anisotropy on the SSE. Stronger exchange anisotropy in the sample subjected to a cooling field directly contributes to the generation and propagation of high-frequency magnons with short spin diffusion length. Although this leads to reduced thermal magnon numbers, spin wave pinning resulted in the coercivity enhancement and loop shift, similar to exchange bias in the field-cooled SSE. The ability to tune the spin current and propagation via exchanges anisotropy will give an extra degree of freedom in achieving new generation spintronics devices.

BF-01. Realisation of a 3D Frustrated Magnetic Nanowire Lattice.
S. Ladak[1], A. May[1], A. Van Den Berg[1], M. Hunt[1] and A. Hejazi[1] *1. School of Physics and Astronomy, Cardiff University, Cardiff, United Kingdom*

Patterning nanomagnets in three-dimensions [1] presents a new paradigm in condensed matter physics and allows access to a plethora of phenomena including spin textures that are topologically protected [2], ultrafast domain wall motion with an associated spin Cherenkov effect [3] and nanostructured frustrated systems with controlled degeneracy [4]. To date, the fabrication of single domain magnetic nanowires into complex 3D lattices has proven to be a formidable challenge. In this talk I will show that two-photon lithography (TPL), when combined with metallic deposition is a powerful methodology for realising 3D magnetic nanostructures. I will start by outlining why 3D nanostructuring is important, particularly within the context of frustrated magnetic materials, before detailing the physics of two-photon lithography and how this can be combined with other processes to transfer a polymer into a magnetic material. The challanges that one faces when trying to reach single domain wires with TPL will also be discussed. I will then show that using TPL and processing one can realise single domain $Ni_{81}Fe_{19}$ nanowires and arrange them into a 3D diamond-bond lattice geometry (Fig 1) [5]. The nanowires have a novel crescent-shaped cross-section with width of approximately 200nm, length of 1000nm and thickness 50nm. Finite element simulations suggest they switch via nucleation and propagation of vortex domain walls. The global switching of the lattice can be probed using optical magnetometry (Fig 2) and this shows a single sharp transition (H_c=8mT), suggesting that domain walls traverse the probed region with negligible pinning at upper vertices. Finite-element simulations upon building blocks of the diamond lattice (four-wire tetrapod structures) suggest a near degenerate set of ice-rules, indicating the system is a candidate 3D artificial spin-ice (3DASI). By carrying out magnetic force microscopy in a field and comparing obtained vertex contrast to simulations I will show that the spin texture upon the 3D lattice surface can be determined, paving the way to studies exploring ground state ordering within 3DASI systems that share lattice symmetry with their bulk counterparts.

BF-02. First Order Reversal Curves (FORCs) of Nano-engineered 3D Fe-Co Structures.
M. Al Mamoori[1,2], C. Schröder[3], J. Pieper[1], L. Keller[1], M. Huth[1] and J. Müller[1] *1. Institute of Physics, Goethe-University Frankfurt, Frankfurt am Main, Germany; 2. Institute of Materials Science, Technical University of Darmstadt, Darmstadt, Germany; 3. Institute for Applied Materials Research, Bielefeld University of Applied Science, Bielefeld, Germany*

A promising direction of developing complex new geometries of nanomagnets beyond planar arrays is the creation of three-dimensional structures, where unconventional spin textures emerge, paving the way towards novel nanomagnetic phenomena and applications. In a recent work [1,2], significant progress has become viable by an advanced platform of the direct-write process FEBID (focused electron beam induced deposition) combined with the possibility of high-resolution detection of small magnetic signals

using a home-built micro-Hall magnetometer. The latter device, based on a two-dimensional electron gas at the interface of a GaAs/AlGaAs heterostructure, allows to measure the local magnetic stray field of a single magnetic nanostructure. The major hysteresis loop measurements of a small (2 x 2) array of ferromagnetic Fe-Co nano-cubes and nano-tress, measured by the Hall sensor and supported by micromagnetic simulations, revealed complex vortex-like configurations developing through their magnetic elements [1,2]. In order to gain further insights into the hysteresis loops and mechanisms of magnetization reversal, (irreversible) magnetic interaction effects and coercivity distributions, we extend our studies by employing first-order reversal curves (FORCs) as a complementary tool for investigating the processes taking place during the complex magnetization reversal [3]. Here, we present FORC signatures of arrays of individual 3D CoFe nanomagnets as nano-cubes and nano-trees. Experimentally determined FORC diagrams seem to collectively reflect complex responses relevant to the vortex-like configurations through the magnetic elements. In comparison, a simple macro-spin model for both geometries appears to replicate the essential features observed in the experiment. Our objective is to develop a qualitative and, if possible, quantitative physical interpretation of these signatures.

BF-03. Determination of Demagnetizing Factors of Nanowire Arrays by Combining Experimental Data From First-Order Reversal Curves and Ferromagnetic Resonance. *K. Muster*[1] and R. Heindl[1] *1. Physics & Astronomy, San Jose State University, San Jose, CA, United States*

We developed a method for quantitative analysis of demagnetizing interactions between nanomagnets in an ordered 2D array by combining data from first-order reversal curves (FORC) with data obtained from ferromagnetic resonance (FMR). FORC measurement provides the Preisach distribution, a representation of magnetic reversal behavior in an external field. Preisach distributions of nanomagnet arrays have previously been quantitatively modeled with an additional uniform, internal field that is proportional to magnetization [1]. We developed a non-linear fit to the Preisach distribution to find: (1) the effective axial demagnetizing field strength, $H_{ds} = N_{ax}M_s$, where N_{ax} and N_{tr} are the demagnetizing factors in the axial and transverse directions with respect to the nanowires, and (2) a Gaussian Preisach distribution with respect to the internal field, $H_{int} = H - N_{ax}M$. Combining the FORC result, H_{ds}, with an FMR fit result, $(N_{ax} - N_{tr})M_s$, allowed us to algebraically solve for the array's effective demagnetizing factors. We tested this method on an ordered array of nickel nanowires with 4.6 ± 0.8 μm length and 80 nm diameter prepared by electrodeposition in a nanopore template. We determined the array's demagnetizing factor were $N_{ax} = 0.04 \pm 0.01$ and $N_{tr} = 0.476 \pm 0.006$. The axial demagnetizing factor was an order of magnitude larger than that of a theoretical isolated nanowire, and was comparable to the predicted value from the study of simulated nanowire arrays by Clime, et. al. [2]. Our experimental method provided quantitative evidence of the demagnetizing interaction between nanowires in an array.

BF-04. A New Approach of Constructing 3D Metallic Nanostructures on Arbitrarily-Shaped Substrate. *F. Chen*[1], R. Peng[1] and M. Wang[1] *1. Nanjing University, Nanjing, China*

Formation of three-dimensional (3D) nanostructures is an important step of advanced manufacture for new concept devices with novel functionality[1-4]. Despite of great achievements in fabricating nanostructures with state of the art lithography approaches, these nanostructures are normally made on flat substrates[5,6]. Up to now it remains challenging to build metallic nanostructures directly on a rough and bumpy surface. Here we demonstrate for the first time a unique way to fabricate metallic nanowire arrays on an arbitrarily-shaped surface by electrodeposition. Counter intuitively, here the growth direction of nanowire is perpendicular to its longitudinal axis, and the specific geometry of nanowires can be achieved by introducing specially designed shaped substrate. The spatial separation and the width of the nanowires can be tuned by voltage, electrolyte concentration and temperature in electrodeposition. By taking cobalt nanowire array as an example, we show that head-to-head and tail-to-tail magnetic domain walls can be easily introduced and modulated in the nanowire arrays, which is enlightening to construct new devices such as domain wall racetrack memory.

BF-05. Inter-particle magnetic correlations and fluctuations dynamics in assemblies of Fe3O4 nanoparticles. *K. Chesnel*[1], J. Rackham[1], B. Newbold[1], D. Griner[1], D. Smith[1], R. Harrison[2] and M. Transtrum[1]
1. Physics, BYU, Provo, UT, United States; 2. Chemistry, BYU, Provo, UT, United States

Magnetic nanoparticles (NPs) are increasingly used in biomedical applications such as drug and gene delivery, hyperthermia, or contrast agents for MRI. Magnetite (Fe3O4) NPs are good candidates for these applications due to their non-toxicity and long-life in the bloodstream. While the structural and magnetic properties of bulk Fe3O4 has been widely studied [1], knowledge is still lacking regarding the nanoscale magnetic behavior of collections of Fe3O4 NPs. In particular, when the NPs are small and superparamagnetic, it is useful to understand how the magnetic correlations evolve throughout cooling and heating. Here we use coherent x-ray resonant magnetic scattering (CXRMS) [2, 3] to probe nanoscale magnetic orderings in monolayers of Fe3O4 nanoparticles as illustrated in Figure 1. We show how magnetic orders depend on temperature throughout the blocking transition, as well as on particle size, varying from 5 to 11 nm [4] A model of the data using chains of NPs suggests the emergence of anti-ferromagnetic couplings for bigger particles when the field is reduced near zero. [5] Additionally, we exploit the coherence of the x-rays to investigate the dynamics of fluctuations via photo-correlation spectroscopy. We show a drastic change in the dynamics of fluctuation throughout the blocking transition between frozen state and superparamagnetic state.

BF-06. Modeling Magnetic Correlations in Magnetite Nanoparticle Assemblies Using X-ray Magnetic Scattering Data. *J. Rackham*[1], K. Chesnel[1], M. Transtrum[1], A. Reid[2], R. Harrison[3], B. Newbold[1], S. Kotter[1], D. Smith[1] and D. Griner[1] *1. Physics, Brigham Young University, Provo, UT, United States; 2. SLAC National Accelerator Laboratory, Menlo Park, CA, United States; 3. Chemistry, Brigham Young University, Provo, UT, United States*

Magnetic nanoparticles are increasingly used in nanotechnologies and biomedical applications, such as drug targeting, MRI, and bio-separation [1-4]. Magnetite (Fe3O4) nanoparticles stand to be effective in these roles due to the non-toxic nature of magnetite and its ease of manufacture [5]. To be more effective in these applications, a greater understanding of the magnetic behavior of the individual magnetite nanoparticles is needed when a collection of them is used. This research seeks to discover the local magnetic ordering of ensembles of magnetite nanoparticles occurring at various stages of the magnetization process. To complete this study, we use resonant x-ray magnetic scattering, which provides information about the magnetic orders in the material, see Fig 1. Here we discuss the modeling of the magnetic scattering data using a one-dimensional chain of nanoparticles with a mix of ferromagnetic, anti-ferromagnetic, and random order. The model utilizes twelve variable parameters and we used a Levenberg-Marquardt algorithm to find the best fit parameters [6,7]. By fitting the model to the experimental data, we extracted information about the magnetic correlations in the nanoparticle assembly, shown in Fig 2.

BF-07. Magnetic small-angle neutron scattering from self-assembled iron oxide nanoparticles influenced by field. N. Nandakumaran[1], T. Köhler[2], *L. Barnsley*[2], M. Feygenson[3], A. Feoktystov[2], O. Petracic[1] and T. Brückel[1] *1. Jülich Centre for Neutron Science (JCNS-2), Forschungszentrum Jülich GmbH, Jülich, Germany; 2. Jülich Centre for Neutron Science (JCNS) at Heinz Maier-Leibnitz Zentrum (MLZ), Forschungszentrum Jülich GmbH, Garching, Germany; 3. Jülich Centre for Neutron Science (JCNS-1), Forschungszentrum Jülich GmbH, Jülich, Germany*

Self-assembly of magnetic nanoparticles, in general, is of interest due to the broad range of applications in material science and biomedical engineering [1,2]. Parameters that affect self-assembly in nanoparticles include particle size, the applied magnetic field profile, concentration and synthesis routines [3]. A range of different sizes of iron oxide nanoparticles between 17 and 27 nm were investigated using polarized small-angle neutron scattering (SANS) at the KWS-1 instrument operated by the Jülich Centre for Neutron Science (JCNS) at Heinz Maier-Leibnitz Zentrum (MLZ) in Garching, Germany. Nanoparticles were dispersed in toluene and measured at room temperature in a range of applied fields between ±2.2 T. The observed self-assembly strongly depended on both nanoparticle size and applied field. For smaller particles (diameter ≤ 20 nm), there was no indication of self-assembly even at high concentration (1% v/v), while 27 nm nanoparticles assemble into linear chains even in low concentrations (0.42% v/v) and low field. The smallest nanoparticles (d = 17 nm) were studied by contrast variation; by altering the isotopic composition of the toluene solvent, the magnetization profile within the cores of the nanoparticles could be extracted with high-resolution when using a spin-polarized incident neutron beam [4]. For larger nanoparticle, the structural and form factors were obtained by sector analysis of the 2-D SANS patterns (Fig. 1(a) and (b)). The extracted structure factors suggest that the chains grow longer and straighter and align more closely with the field direction up until application of the maximum field (Fig. 1(c)). This is understood in terms of a minimization of the dipole energy of the nanoparticles in the presence of the applied field and neighbouring particles. The implications for the control of self-assembly of more complex nanoparticles will be discussed.

BF-08. Magnetic Field Study on Piezotronic and Piezo-Phototronic in ZnO and ZnO/Co_3O_4 Core/shell Nanowire Arrays. *W. Zhou*[1], S. Yan[1], Z. Zheng[1], S. Rai[1], M. Bhatt[1], L. Malkinski[1] and M. Retana[1] *1. Advanced Materials Research Institute, University of New Orleans, New Orleans, LA, United States*

Piezoelectric-related multi-property coupling effects have recently attracted much attention for developing next generation multi-functional devices. In this paper, the multi-property coupling effects among magnetic field, piezoelectricity and photoexcitation were investigated in ZnO nanowire arrays. The response of the current flowing through the array to the applied magnetic field was decreasing with increasing magnetic field strength. However, due to piezo-magnetotronic effect, the magnetically induced current was magnified by one order of magnitude by applying an external stress. In contrast, under UV light illumination, the magnetically induced current response increased with an increment of magnetic field strength, as the magnetic field is favorable to the separation of photo-induced electron-hole pairs. The magnetically-induced current response was enhanced by at least two orders of magnitude due to piezo-photo-magnetotronic effect. Furthermore, ZnO/Co_3O_4 core/shell heterojunction nanowire arrays was employed to improve the current responses up to 9 times and 3 times, under piezo-magnetotronic and piezo-photo-magnetotronic engagements, respectively, attributed to the improved charge carrier separation and transportation at the core/shell interface. This phenomenon projects a potential for multi-functional piezo-magnetotronic and piezo-photo-magnetotronic device development.

Department of Materials Science and Engineering, Friedrich-Alexander Universität Erlangen-Nürnberg, Erlangen, Germany*

Severe plastic deformation is a relatively new technique for the preparation of nanocrystalline magnetic alloys. The advantage of high-pressure torsion, a method of severe plastic deformation, is that the as-deformed sample is already available in bulk form and the continuous application of an arbitrary amount of shear strain is possible, which can induce alloy formation (supersaturated solid solutions)[1]. In this study, the Fe-Cu system is investigated in the low Fe-containing region (≤25wt%Fe). Fe is immiscible with Cu as the phase diagram exhibits a negligible solubility[2]. Deformation-induced intermixing is obtained by high-pressure torsion, which leads to a partial dissolution of Fe in Cu possibly yielding supersaturated states. SQUID magnetometric measurements of the as-deformed state show contributions of thermal relaxation and frustration, which are disentangled with AC-mode measurements (Fig.1). The limit of the frustrated regime is well described with the de Almeida-Thouless Line[3] (Fig.2). The results obtained from magnetic measurements are correlated to microstructural analysis including atom probe tomography, where the different magnetic effects can be allocated to the distribution of Fe-atoms in the nanocrystalline Cu matrix.

BF-10. In-situ Growth Trajectory of Ni Nano Dendrites by Liquid Cell Electron Transmission Microscopy. *L. Zheng*[1,2], S. Zhao[2], J. Jiao[2], D. Zhou[1], M. Zhu[1], W. Li[1] and H. Zheng[3] *1. Central Iron & Steel Research Institute, Beijing, China; 2. Hebei University of Engineering, Handan, China; 3. Lawrence Berkeley National Laboratory, Berkeley, CA, United States*

Nickel has attracted an increasing attentions as one of the important transition metals due to its interesting properties and applications in catalysis [1], supercapacitor [2], hydrogen storage [3], magnetic storage devices [4], magnetic fluids [5], magnetic resonance imaging [6], magnetic carriers for drug targeting [7], and electrochemical sensor [8]. Morphology controlling is a critical technique for fabrication of nickel nanostructures since the properties depend on its morphology. Real-time observations with high temporal and spatial resolution is conducive to our understanding of nanostructure growth mechanism. Here we use in situ liquid cell transmission electron microscopy (LCTEM) to elucidate the growth trajectories of Ni nano dendrites. We have observed that nickel nanodendrites formed initially and fractal grew swiftly (Shown in Figure 1). We have calculated the fractal growth dimension and simulated the growth process of nano dendrites using diffusion-limited aggregation (DLA) model. The dendrite growth mechanism and kinetics have been explored, which give a way to grow metallic porous materials for novel applications.

The length- and energy-scales within artificial arrays of nanostructures determines the magnetic order and emergent phenomena. The patterned element size and spacing defines the interaction energies, setting the global behavior and the dynamic window in which the mesospins of islands fluctuate. At low temperatures, there is insufficient energy to reverse islands resulting in a frozen mesospin manifold with only weak intra-island excitations. At higher temperatures, the flipping rate of individual islands rises, with a concomitant loss of long-range order. Thus, the dynamics are intrinsically related to the array configuration and evolve with temperature as island reversals act as grain boundaries between aligned regions. In this paper, we use resonant magnetic coherent x-ray scattering and correlation spectroscopies (via intensity-intensity temporal autocorrelation functions) to determine the dynamics of the mesospin manifold in simple Ising chains composed of FePd alloys [1 -4]. The use of a coherent beam introduces speckle into the diffraction pattern arising from the repeating in-plane structure (fig. 1). Each image reveals the magnetic disorder over the integration time (40-60 ms), with time correlations between images revealing the slow dynamics of the manifold (> seconds). We quantify the dynamics as a function of time, external field and temperature mapping out the dynamics across all relevant length scales in the array. By using samples with different element spacing, the effect of the coupling strength between the islands on the dynamics is elucidated. Our data is compared with photoemmision electron microscopy employing the x-ray magnetic circular dichroism (XPEEM) [5].

BG-01. MRI of Magnetic Thin Film Structures and Devices.
S.E. Russek[1] *1. NIST, Boulder, CO, United States*

Magnetic nanostructures have been extensively used to modify magnetic resonance imaging (MRI) contrast, either increasing (paramagnetic ions such as Gd^{+3}) or decreasing signal (ferrite nanoparticles). Here, we present a study of imaging around microfabricated thin film structures using a 3T MRI. The images are derived from contrast in the water proton magnetization near the thin film structures. Fig.1 shows an optical image and MRI of a magnetic tunnel junction wafer immersed in water, where magnetic structures are clearly seen. While the best MRI resolution is ~ 125μm, features smaller than 10μm can be individually detected. Since the thin film structures can be precisely fabricated, it is possible to numerically calculate the magnetic fields and predict proton relaxation times (T1, T2, T2*), thereby providing a method to validate contrast models. The magnetic fields generated by thin film structures depend on materials, device size and shape, and direction of the applied field. Fig. 2a shows an MRI of 10nm thick Co thin film dot and line arrays. A large number of exotic materials can be rapidly evaluated for MRI contrast. Fig. 2b shows MRI contrast above antiferromagnetic CoO films near their Neel temperature. Contrast differences are seen due to CoO layer thickness as well as structures formed in the CoO. The contrast arises from both nonlocal interactions with the CoO-generated magnetic fields as well as local interactions from water molecules adsorbing to the surface.

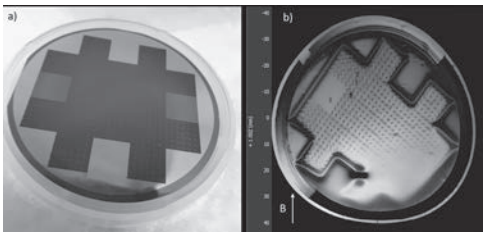

Fig. 1 a) Optical image of a 76mm-diameter magnetic tunnel junction (MTJ) wafer consisting of sensor arrays of elliptical junctions with size ~20μm. b) MRI of the wafer immersed in a water. The MTJ arrays can be seen as dark structures on a 2mm square grid. The black tri-lobed features seen in the upper left corner are small air bubbles.

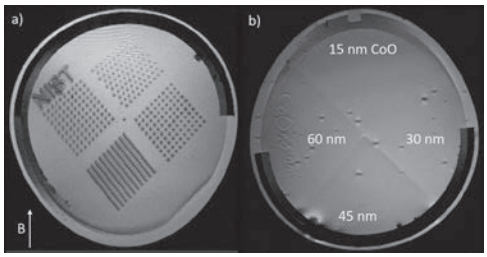

Fig.2 a) MRI of 10nm thick Co features including rectangular and hexagonal 1mm diameter dot arrays and 1mm wide lines. b) MRI of CoO films with wedges of different thickness. The water temperature was ~290K, which is close to the Neel temperature. The writing in the 60nm thick film is a region without CoO, clearly showing negative contrast provided by the CoO. The black tri-lobed features are small air bubbles.

BG-02. Electrodynamic theory of ferromagnetic resonance and its applications in precise measurements of ferromagnetic linewidth, permeability tensor and saturation magnetization. *J. Krupka*[1], A. Pacewicz[2], B. Salski[2] and P. Kopyt[2] *1. Institute of Microelectronics and Optoelectronics, Warsaw University of Technology, Warsaw, Poland; 2. Institute of Radioelectronics and Multimedia Technology, Warsaw University of Technology, Warsaw, Poland*

During the last few years the authors of this paper has developed rigorous electrodynamic theory of ferromagnetic resonance in spherical and rod shape, uniformly magnetized samples [1] – [3]. In this paper the state of the art in measurements of ferromagnetic linewidth, permeability tensor and saturation magnetization employing this theory is presented. It is shown that the electrodynamic theory allows significant improvements of measurement accuracy of these parameters with respect to the commonly used perturbation and magnetostatic theories. Contrary to the perturbation method the electrodynamic theory is not limited to small samples. It allows determination of the resonance frequencies and Q-factors for arbitrary size spherical and cylindrical gyromagnetic samples in suitably chosen metal enclosures. The influence of magnetic dielectric and conductor losses on the Q-factor is considered. Phenomena in lossy and dispersive gyromagnetic media related to the stored and dissipated electromagnetic energy in microwave resonators containing ferromagnetic samples are discussed in details. It is shown that the magnetic energy stored in dispersive gyromagnetic sample can be several orders of magnitude larger than for non-dispersive medium having identical but constant permeability. Results obtained with the electrodynamic theory for very small samples are identical to those obtained with perturbation and magnetostatic theories. Results of measurements of the ferromagnetic linewidth, permeability tensor and saturation magnetization on several single crystal and polycrystalline garnet samples are presented.

In recent decades, a large scientific effort has focused on harnessing spin transport for providing insights into novel materials and low-dissipation information processing. We introduce single spin magnetometry based on nitrogen-vacancy (NV) centers in diamond as a new and generic platform to locally probe spin chemical potentials which essentially determine the flow of spin currents. We use this platform to investigate magnons in a magnetic insulator yttrium iron garnet (YIG) on a 100 nanometer length scale. We demonstrate that the local magnon chemical potential can be systematically controlled through both ferromagnetic resonance and electrical spin excitation, which agrees well with the theoretical analysis of the underlying multi-magnon processes. Our results open up new possibilities for nanoscale imaging and manipulation of spin- related phenomena in condensed-matter systems.

BG-05. Emerging widefield magnetic imaging applications using NV-diamond magnetic microscopy. *P. Kehayias*[1], E. Bussmann[1], T. Lu[1] and A. Mounce[1] *1. Sandia National Labs, Albuquerque, NM, United States*

Magnetically-sensitive nitrogen-vacancy (NV) color centers in diamond are gaining momentum as a standard tool for magnetic imaging in a diverse range of applications. Using a shallow layer of NV centers at the surface of a diamond chip, we image the NV fluorescence intensity with an optical microscope, which yields information about the magnetic field of nearby external magnetic sources. The benefits for using NVs for magnetic imaging include the following: 1. Being able to image many pixels in parallel (rather than raster-scanning a single-pixel detector) 2. Being able to reduce the sample-sensor standoff distance (as small as a few nanometers) to measure a larger magnetic field with better spatial resolution 3. Having micron-scale spatial resolution over a few-mm field-of-view 4. Allowing a wide range of working conditions (magnetic field strength, temperature, pressure, and frequency) NV magnetic microscopy is being used to investigate fundamental questions in paleomagnetism, biomagnetism, and superconductivity [1-3]. With the goal of extending the NV imaging capabilities to a wider array of scientific problems, we will report on our recent progress using NV imaging for applications relating to hardware security, electronics, fabricated micromagnets, and magnetic materials.

BG-06. Interferometric Scanning Transmission Electron Microscopy of a Landau Domain. *A. Greenberg*[1], F. Yasin[1] and B.J. McMorran[1] *1. Physics, University of Oregon, Eugene, OR, United States*

Transmission electron microscopy is one of few methods capable of imaging magnetic features at the nanoscale. The sample's magnetic properties are inferred by measuring the phase shift imprinted on an electron's wavefront by a magnetic vector potential. Here we present the use of Interferometric Scanning Transmission Electron Microscopy (ISTEM) to measure magnetic phase.[1–4] In ISTEM, the electron beam is divided by a nanofabricated diffraction grating in an aperture above the sample (Fig. 1). The diffracted orders form spatially separated probes at the sample. We scan these probes across the specimen such that one of the probes interacts with the sample while others pass through vacuum. We image the interference pattern from which the phase shift induced by the sample on the interaction probe can be measured.[1–4] The best spatial resolution of a magnetic phase object attained, 1 nm, was achieved by Lorentz STEM with Differential Phase Contrast (DPC) analysis[5] although an atomic scale electron probe in a magnetic field free environment has been achieved.[6] There is an inherent tradeoff between DPC's spatial and phase resolution because the sensitivity of DPC depends on the ratio of the Lorentz deflection to the probe semi angle.[5] Because ISTEM measures the phase interferometrically, it does not suffer this trade off. As electron microscopes capable of forming a nanometer to subnanometer wide probe in a magnetic field-free environment become more common, ISTEM could be a powerful high-resolution magnetic phase measurement tool. We applied ISTEM to image a 1 um wide square composed of a layer of 25 nm thick permalloy and a layer of 100 nm thick silicon nitride. The square is supported by 200 nm wide tethers at each corner. A completely isolated thin film permalloy square has a vortex-like in-plane magnetic configuration known as a Landau domain. In the tethered square the Landau domain is altered because the domain walls fall to the side of each tether (Fig. 2). We confirm the measured magnetic induction by comparing it to standard Lorentz TEM measurements and micromagnetic simulation.

BG-07. Scanning Superconducting Quantum Interference Device (SQUID) setup for studies of magnetic materials under uniaxial stress or strain at millikelvin temperatures. *J. Franklin*[1], D. Davino[1] and I. Sochnikov[1] *1. Physics Department, University of Connecticut, Storrs, CT, United States*

Uniaxial strain is becoming an increasingly efficient tool for studying and controlling quantum materials. One of the challenges with the existing uniaxial stress or strain cells is combining the cells with microscopy techniques at ultra-low temperatures. Here, we demonstrate a unique copper bidirectional strain-stress cell. The cell is combined with an optical microscope and a scanning SQUID microscope. Benchmark measurements of magnetic signatures in strained quantum materials are demonstrated. This technique can lead to new discoveries such as enhanced superconductivity and new controlled magnetic states in various correlated material systems.

BG-08. Validated Nano Scanning Hall Microscopy. *M. Gerken*[1], D. Momeni Pakdehi[1], T. Weimann[1], A. Solignac[2], K. Pierz[1], S. Sievers[1] and H. Schumacher[1] *1. Physikalisch-Technische Bundesanstalt, Braunschweig, Germany; 2. SPEC, CEA, CNRS, Université Paris-Saclay, Paris, France*

Scanning Hall Microscopy (SHM) is a versatile tool for the quantitative characterization of magnetic microstructures. However, application relevant structures are increasingly being scaled-down to the nanometer range and thus become smaller than the active area of commercially available sliding Hall sensors. Furthermore, the stray fields of nanoscale magnetic structures are rapidly decreasing with increasing distance to the sample. We here adopt SHM to these challenges by combining a reduced sensor size with unconventional materials and by positioning the sensors on a cantilever that can be used in standard scanning probe microscopes (SPM). We discuss the fabrication and characterization of Hall sensors with active areas down to 50 x 50 nm^2 fabricated out of gold and epitaxially grown graphene on SiC(0001) [1]. Figure 1 shows typical calibration curves for graphene and gold Hall sensors. A high sensitivity of 1615 V/AT and a resolution of 1.5 mT is achieved with the graphene nano sensor. Gold sensors show a lower sensitivity of about 3 mV/AT but better stability. Here, a resolution of 2 mT can be achieved. Gold nano Hall sensors are prepared on silicon cantilevers that can be directly integrated into commercial SPMs. Thus, allowing a measurement height of

down to 400 nm. By employing a metrological SPM developed at PTB [2] a 3D mapping of the sample stray field can be performed with a positioning accuracy of 0.5 nm. Figure 2 shows quantitative SHM data of a magnetic scale including a comparison to magneto-optical (MO) and simulation data. Furthermore, we will present an analysis of the uncertainty budget. This work was supported by the EMPIR JRP 15SIB06 NanoMag through EU and EMPIR participating countries within EURAMET.

BG-09. Local Spin Exchange Microscopy by Chiral Molecules Adsorbed on an AFM Tip. *A. Ziv*[1], A. Saha[2], H. Alpern[1], N. Sukenik[1], L. Tomasz Baczewski[3], S. Yochelis[1], M. Reches[2] and Y. Paltiel[1]
1. Applied Physics, The Hebrew University, Jerusalem, Israel; 2. Institute of Chemistry, The Hebrew University, Jerusalem, Israel; 3. Institute of Physics, Polish Academy of Sciences, Warszawa, Poland

Local magnetic imaging at nanoscale resolution is highly desired for basic studies of magnetic materials, as well as for probing the reduction of magnetic memory size. However, such local imaging is hard to achieve by means of standard magnetic force microscopy (MFM) that exploits dipole-dipole interactions, where the resolution is fundamentally limited. While other magnetic imaging techniques such as spin polarized STM (SPSTM) and scanning squid microscopy (SSM) yielded highly resolved magnetic imaging, that lead to fundamental insights and research, they require low temperatures, high vacuum or strict limitations on the sample conditions. Other techniques such as MOKE and NV center are diffraction limited or able to probe weak magnetic stray fields only. In my talk, I will present a simple and robust method for locally resolved magnetic imaging based on the short-range spin exchange interactions that can be scaled down to atomic resolution. The presented method, realized at room temperature, requires a conventional AFM tip functionalized with a chiral molecule. In proximity to the measured magnetic sample, charge redistribution in the chiral molecule leads to a transient spin state, caused by the chiral induced spin selectivity (CISS) effect, followed by the exchange interaction with the imaged sample. This method acquires accurate results compared to methods based on measuring the magnetic stray field. Using the same tip with adsorbed chiral molecules, two oppositely magnetized samples were characterized, and magnetic imaging was performed. The method, we term CISS AFM, does not require high vacuum conditions, can be performed at room temperature and is simple to establish.

BG-10. Chirality probed in ferromagnetic and synthetic antiferromagnetic multilayers by quantitative MFM analysis at room temperature. *F. Ajejas*[1], W. Legrand[1], A. Haykal[2], Y. Sassi[1], A. Finco[2], S. Chouaieb[2], D. Maccariello[1], S. Collin[1], K. Bouzehouane[1], A. Vechiola[1], N. Reyren[1], V. Cros[1], V. Jacques[2] and A. Fert[1] *1. Unité Mixte de Physique, CNRS, Thales, Univ. Paris-Sud, Université Paris-Saclay, Palaiseau, France; 2. Laboratoire Charles Coulomb, Université de Montpellier and CNRS, Montpellier, France*

Dzyaloshinskii-Moriya interaction (DMI), a chiral exchange interaction, has attracted a great attention in the last years, because of its significant role in the stabilization of spin textures with a fixed chirality in thin films and magnetic multilayers (MML), such as chiral Néel domain walls (DW) [1] or skyrmions [2-3]. Depending on the direction of the DMI interaction vector, a counter clockwise (CCW) or clockwise (CW) chirality in the spin textures is stabilized. Extracting the sign of DMI and therefore the chirality sign has been experimentally assessed using different techniques e.g. Brillouin light scattering [4], asymmetric expansion of bubbles by Kerr microscopy [5], x-ray resonant magnetic scattering [6], or X- photoemission electron microscopy [7]. In this work, we present a novel method to determine the chirality of magnetization textures using magnetic force microscopy (MFM), an accessible tool in most laboratories. Two different systems have been characterized by AGFM and SQUID to extract magnetization and anisotropy values i.e. FM multilayers based on Pt(0.42)/Co(0.42)/Pd(0.42) and Pd(0.42)/Co(0.42)/Pt(0.42) and. SAF stacks which are composed of two (or more) FM thin layers (or blocks) separated by a thin spacer and coupled antiferromagnetically (AF) by RKKY interaction; with zero net magnetization. We acquire a series of MFM using variable scanning tip-surface distance to extract profiles of DWs. By comparing the MFM signal to micromagnetic simulations of the stray field emerging from the DW, the actual chirality can be assessed. Complementary characterizations of the DW stray field have been also performed using nitrogen vacancy (NV) microscopy relating quantitatively the stray fields in SAF. French ANR grant TOPSky TOPSKY (ANR-17-CE24-0025) and DARPA TEE program grant (MIPR#HR0011831554) and EU grant SKYTOP (H2020 FET Proactive 824123) are acknowledged for their financial support.

BG-11. Imaging Nanoscale Magnetization Using Scanning-Probe Magneto-Thermal Microscopy. *C. Zhang*[1], J. Bartell[1], J. Karsch[1], I. Gray[1] and G. Fuchs[1] *1. School of Applied and Engineering Physics, Cornell University, Ithaca, NY, United States*

Advanced magnetic microscopies are key to advancing our understanding and application of novel magnetic phenomenon such as skyrmions, spin-waves, and domain walls. However, due to the diffraction-limit of light, achieving the 10-100 nanometer spatial resolution and 10-100 picosecond temporal resolution required to image these phenomenon is beyond the reach of table-top techniques. To break free of the far-field diffraction limit, we have been developing a near-field magnetic microscope based on magne-to-thermo interactions: the time-resolved anomalous Nernst effect [1] and the time-resolved longitudinal spin Seebeck effect [2]. Our technique involves the excitation of plasmon-polaritons at the apex of a sharp gold tip. The resulting near-field tip-sample interaction creates a nanoscale thermal gradient for magneto-thermal microscopy [3]. Here, we study the near-field characteristics of our signal, demonstrate magnetic imaging of a multi-domain state, and present sub-optical diffraction spatial resolution. Our results suggest a new approach to nanoscale spatiotemporal magnetic microscopy in an accessible, table-top form to aid in the development of high-speed magnetic devices.

BG-12. *In situ* Compensation Method for High-Precision and High-Sensitivity Integral Magnetometry. *K. Gas*[1] and M. Sawicki[1] *1. Institute of Physics, Polish Academy of Sciences, Warsaw, Poland*

The most popular multipurpose commercial superconducting quantum interference device (SQUID) integral magnetometers are not object-selective probes, so the sought signal is very often buried in the magnetic response of the substrate or a carrier, which can be substantially contaminated by signals brought about by the chosen sample mount and magnetometer's instabilities. We report on a comprehensive method for mitigating these weak elements of integral magnetometry [1]. The method is based on the *in situ* magnetic compensation (on the sample holder level) of the vast majority

of the unwanted magnetic flux. This reduces the signal which is processed by the magnetometer up to two orders of magnitude, so the output is much less dependent on the inevitable fluctuations of some environmental variables which detrimentally reduce the real credibility of the outcome in the standard approach to precision magnetometry. Additionally, a two- to five-fold reduction in the absolute noise level has been observed. Practical solutions for the achievement of adequate compensation and proper expressions to evaluate the final results obtained in the compensational sample holder are given. Their universal form allows to practically employ one design of the compensational sample holder in investigations of a range of specimens characterized by different sizes, shapes and compositions. Importantly, the method does not require any modelling of the magnetometer output signal, nor any laborious fitting. All the necessary inputs to calculate the absolute magnitude of the net moment of the investigated object (e.g. magnetic layer) can be taken directly from the standard magnetometer output files. The method is tested to a very good result on some of the most demanding subjects as are single nm thin layers of dilute magnetic semiconductors. The solution given by us can be straightforwardly implemented in every field of activity where precise magnetic investigations are of a prime importance. This work has been supported by the National Science Centre, Poland through project DEC-2017/27/B/ST3/02470.

BH-01. Creating 3D-Magnetic Textures in Synthetic Antiferromagnets by Focused Ion Beam Irradiation. *F. Samad*[1,2], L. Koch[2], G. Hlawacek[1], S. Arekapudi[2], M. Lenz[1] and O. Hellwig[1,2] *1. Institute of Ion Beam Physics and Materials Research, Helmholtz Zentrum Dresden Rossendorf, Dresden, Germany; 2. Chemnitz University of Technology, Chemnitz, Germany*

The Dzyaloshinskii–Moriya interaction (DMI) assisted emergence of 3D-magnetic textures in general and magnetic skyrmions, in particular, were hitherto typically observed in bulk B20-materials at low temperatures or in ferromagnetic multilayers at room temperature [1]. In contrast, we used a synthetic antiferromagnet (AF) [2] as a platform, consisting of perpendicular anisotropy Co/Pt-multilayers, AF coupled via Ru interlayers. Such a system provides the striking benefits of the absence of stray fields as well as high domain wall velocities [3], making it interesting for possible future data storage applications. The ground state energy balance was previously shown to depend on the ratio of dipolar energy and AF exchange energy [2], which increases with the Co layer thickness or Co/Pt-repetition number, thus yielding a phase transition to a ferromagnetic stripe domain state. Here, differently, we use focused He^+ ion beam irradiation with different fluences and energies, to modify the local interplay between dipolar and AF interlayer exchange energy. Thus, we were able to create a variety of laterally coexisting magnetic phases (see Fig. 1) and 3D-magnetic textures in different confinements. Detailed investigation of their interactions as well as their magnetic field reversal behavior were performed with in-field high-resolution magnetic force microscopy (MFM).

Superspin glass (SSG) magnetic order is commonly observed in granular metallic alloys, where a high degree of disorder on the magnetic particles positions constitutes a key ingredient for the collective freezing behavior. Here we present a study of the nanostructure and magnetic properties of a Co/Ag multilayer, a system that due to the stacking periodicity incorporates a reduced disorder in comparison with the granular solids. The multilayer was grown by molecular beam epitaxy on a clean MgO (001) surface, alternating Ag and Co deposition up to complete 32 periods. It was covered by a 3nm Ag cap layer, and the nominal thickness of the Co and Ag layers per period is 1 and 16 monolayers (ML), respectively. The sample was studied by X-ray reflectivity and diffraction, TEM, magnetometry (VSM and SQUID), and ac susceptibility. Our results indicated that: 1) a well-defined superlattice periodicity was built in the sample, see Fig.1; 2) Co layers were discontinuous, with a close-to-monodisperse distribution of Co particles (TEM mean diameter 1.6 nm) embedded in a Ag(001) matrix; 3) the sample exhibited hysteresis (not saturable at fields of up to 6 T) below ca. 14 K, and sharp zero-field cooling ac susceptibility peaks at a temperature range in correspondence with that associated to the hysteresis onset; 4) the ac field frequency dependence of real part of the susceptibility peak temperatures can be described by the Vogel-Fulcher law (Fig. 2) with a frequency shift parameter $\Gamma = 0.049$. We can thus conclude that, below the critical temperatures identified from the ac susceptibility curves, our sample behave as a SSG originated by the interparticle dipolar interactions, and that the degree of disorder built within the Co layers is sufficient to originate the observed magnetic collective behavior.

Fluctuation and stochasticity are characteristics of material complexity that have been enduring themes in condensed matter and statistical physics research. Fluctuation provides basis for phase transitions and critical phenomena in statistical mechanics, order parameter field theories in quantum criticality etc. Systems that could be tailored so as to achieve phase transition is a candidate for studying effects of fluctuation. One such system is square Artificial Spin Ice (ASI), where magnetic nano-islands are arranged in a square lattice configuration. The shape anisotropy of the islands forces their magnetizations to align along their long axes, which gives them an Ising spin character. Geometrical constraints dictate the interactions between the Ising spins. In square ASI the arrangement of mutually perpendicular nanomagnets over a square lattice causes an asymmetry in the inter-island interactions that, in principle, favor an antiferromagnetic ground state. By choosing proper thickness of the nanomagnets it is possible to observe the paramagnet-to-antiferromagnet phase transition. In this work we have used resonant X-ray scattering to study the evolution of the antiferromagnetic Bragg peak in a square ASI that undergoes paramagnet-antiferromagnet phase transition around 380 K as a function of temperature. Further, we have used coherent soft X-ray Photon Correlation Spectroscopy (XPCS) to study thermally induced fluctuation of the domain wall as the phase transition temperature is approached. We observed an exponential slowing down of the fluctuation as the temperature is decreased. By analyzing the data within the framework of statistical mechanics we showed existence different type of fluctuations and relaxation. We observed two distinct regimes of domain wall motion; a low temperature ballistic and a high temperature diffusive type, as the sample goes through the antiferromagnetic phase transition. This work is supported by US DOE (Award# DE-SC0016519).

The influence of different energy scales and their interplay is essential to explain and predict the properties of many physical systems. We present results on the magnetic order in thermalized artificial spin-ice structures[1,2], in particular the so-called Shakti and the modified Shakti lattices[3,4,5]. Due to the element sizes in these lattices, there are different activation energies at play for the interacting Ising-like elements[6]. While the Shakti lattice consists of short and long Ising-like elements, the modified Shakti lattice has only short elements. The different thermally active temperature regions for these elements are schematically shown in figure 1, emphasizing the two different energy scales present in these lattices. We image the thermally equilibrated magnetic states of the nanostructures using synchrotron-based photoemmision electron microscopy employing the x-ray magnetic circular dichroism to extract the magnetic orientation of each element. We demonstrate a clear impact on the magnetic ordering, by comparing results obtained from structures with one or two different activation energies. The differences are manifested in the analysis of the magnetic spin structure factors, in which the role of the activation energies is shows a distinct short-range order. These results highlight the potential of artificial spin-ice structures to serve as model systems for designing various energy-scale hierarchies and investigating their impact on collective dynamics and magnetic order.

From the study of sand piles [1] to descriptions of the human mind [2], spin glass research influences many disciplines. Patterned thin-film nanomagnets [3] are Ising type magnets that may be printed into nearly any two-dimensional pattern imaginable. Their ability to have their dynamics directly visualized makes them perfect candidates for spin glass model systems. However, it is uncertain whether or not spin glass phases at finite temperature exist in two dimensional systems like these [1,4]. Here we take the first step towards realizing spin glasses in artificial spin systems [5]. From an ordered grid of Ising type nanomagnet thin films we randomly alter the angular orientations and deviations. After thermal-annealing, we study the if the characteristic features of the spin glass phase are achieved. We record relaxation timescales together with magnetic susceptibility variations over temperature, revealing trends towards short-range order as randomness is increased, but falling short of pure spin-glass behavior. We then explore possibilities to directly construct spin glasses from existing glassy systems such as neural networks [6] and the Bethe lattice [7].

Artificial spin ice systems [1] are arrays of interacting nanomagnetic islands originally designed to mimic the geometrical frustration of the complex pyrochlore spin ice materials. Each island has a single domain magnetization along its easy axis so the orientation can be treated as a single Ising spin. Recently, experimental realization of thermalized states [2] and slow thermal fluctuations, which drive lattices towards their ground state [3], have led to exciting new research in vertex-frustrated artificial spin ice. These are systems in which frustration is manifested in the allocation of ground state and excited state moment configurations at the lattice vertices. We have studied vertex-frustrated artificial spin ice using the tetris lattice (Fig. 1) [4] made with permalloy islands. We examined the temperature dependence of thermal fluctuations of moments along different island positions within the array using photoemission electron microscopy (PEEM) at various temperatures and lattice spacings using x-ray magnetic circular dichroism. We find that the moment fluctuations of the islands are highly dependent on nearest neighbor moment environments. Our results allow us to make a real space observation and characterization of the effects of neighboring moments on superparamagnetic behaviors of individual nanomagnet moments in this vertex-frustrated system and compare to results in square ice, where there is a well-defined and ordered ground state. Theoretical Division and Center for Nonlinear Studies, Los Alamos National Laboratory, Los Alamos, NM, United States*

Artificial spin ice systems (ASI) [1] are two-dimensional arrays of single-domain ferromagnetic nano-islands designed to study collective behavior of interacting magnetic systems. Vertex- frustrated ASI systems have highly degenerate ground states that are associated with the presence of excited vertices that are intrinsic to the lattice geometry, and these states can manifest a wealth of different emergent behavior [2]. One example of a vertex-frustrated ASI system is the Santa Fe lattice (Fig. 1a). Using a high temperature thermalization protocol [3], we have experimentally observed domains of the ground states of Santa Fe ASI (Fig. 1 b and C). We also performed Photoemission Electron Microscopy measurements as a function of lattice spacing and island moment to observe the kinetics behavior that driving Santa Fe ASI toward its ground state. Our results allow us to characterize ground state configurations and kinetics across different lattice parameters, demonstrating that Santa Fe lattice is an excellent candidate for studying novel order induced by vertex frustration. XZ, YZ, NB, JS, and PS are funded by the US Department of Energy, Office of Basic Energy Sciences, Materials Science and Engineering Division under grant number DE-SC0010778. BH-08. Controlled generation of emergent magnetic monopole like states in square artificial spin ice systems. *N. Keswani*[1], Y. Nakajima[2], N. Chauhan[2], R. Singh[3], T. Som[3], S. Kumar[2] and P. Das[1] *1. Department of Physics, Indian Institute of Technology, Delhi, New Delhi, India; 2. Bio Nano Electronics Research Centre, Toyo University, Kawagoe, Saitama, Japan; 3. Institute of Physics, Bhubaneswar, India*

Artificial spin ice structures (ASI) have attracted great attention, serving as potential analogues for frustrated magnetic systems, such as bulk spin ice materials [1]. In 2008, Castelnovo *et al.* realized that excitations above the degenerated ground state, governed by the ice rule violation, could be interpreted as emergent quasiparticles that behave like magnetic monopoles. Such monopoles have been discussed in literature as magnetically charged particles in a dumbbell model where a dipole is considered as consisting of equal and opposite magnetic charges [2]. While most efforts have focused on study of array of artificial spin ice structures [3-6], little work has been done on understanding the switching behavior of individual nanoislands coupled by dipolar interactions in ASI systems [7]. In this work, we have investigated in details the magnetic switching behavior in individual vertices of square-ASI system composed of lithographically patterned nanoislands of dimensions 300×100×30 nm^3 of $Ni_{80}Fe_{20}$, as shown in Fig.1 (a). From magnetic force microscopy (MFM) investigations in presence of external field, we observe that an emergent monopole-like state can be predictably stabilized at about 425 G as shown in Fig.1 (b). The MFM image shows the 1-in/3-out magnetic state with magnetic charge $\sum Q = -2$ at vertex. Thus, we demonstrate the possibility of controlled generation of an emergent magnetic monopole in an isolated artificial square spin ice vertex. We also investigated the switching behavior of the individual nanoislands involved in the ASI structure and observe that the switchings can be controlled by the interplay of imperfections and dipolar interactions in these systems.

BH-09. Magnetic Configurations in Artificial Spin Ice subject to an External Bias Field during Demagnetization. *V. Parakkat*[1] and K. Krishnan[1] *1. Material Science and Engineering, University of Washington, Seattle, WA, United States*

The low energy states of artificial spin ice (ASI) arrays, fabricated of nano-magnets with large blocking temperatures, are traditionally probed by field demagnetization processes where a time varying external magnetic field in the form of a square wave with decreasing amplitude is applied in the plane of the rotating ASI [1,2]. These studies probe only zero field effects since the time average of the external field is zero in both laboratory and device frames. In contrast, we present here low energy states of an athermal square ASI of epitaxial Fe nanomagnets [thickness = 10 nm, width = 95 nm and length = 240 nm; Fig. 1(a)], subjected to a global magnetic field (H_G) applied in the rotating frame of reference of the ASI during demagnetization. In a square ASI, 16 different vertices are grouped into 4 different energy levels [3] as shown in Fig. 1b,c with their energies determined only by mutual magnetostatic interactions (at H_G = 0 Oe). We show that a field acting in the frame of reference of the ASI during demagnetization does not average to zero ($H_G \neq 0$ Oe) and hence adds Zeeman energy resulting in rearrangement of vertex energies. This breaks the spin reversal symmetry causing the energies of the vertices with moments parallel (antiparallel) to H_G to decrease (increase). This in turn modifies their population compared to that of a standard ASI (H_G =0). An H_G of fixed magnitude but applied at various angles w.r.t ASI axis also alters the energies of vertices and influences the shape and size of the T1 domains and the type of T2 domain walls (Fig. 1d). Striped features are observed in T1 domains when H_G is applied along the diagonal direction. The current study is in agreement with our recent work where each element of the ASI is subject to exchange-bias [4]. The ability to apply local and global fields can selectively control vertex energies, domains and domain wall configurations, opening a new pathway to compare and understand behavior of athermal and thermally active ASI arrays.

BH-10. Interaction modifiers in artificial spin ices. E. Östman[1], *H. Stopfel*[2,1], I. Chioar[1], U.B. Arnalds[3], A. Stein[4], V. Kapaklis[1] and B. Hjörvarsson[1] *1. Physics and Astronomy, Uppsala University, Uppsala, Sweden; 2. Engineering Sciences, Uppsala University, Uppsala, Sweden; 3. Science Institute, University of Iceland, Reykjavik, Iceland; 4. Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, NY, United States*

We present here a generic solution to engineer the energy-landscape in fully planar magnetic nano-structures. This approach involves the mixing of nano-magnetic objects of distinctly different mesospin dimensionality[1]. In our example we use both elongated islands, spin dimensionality one, and discs, spin dimensionality two, to create a new type of square artificial spin ice (SASI) system dubbed modified SASI (mSASI) where a magnetic disc is placed in the center of each vertex. The disc mediate the interaction and therefore alters the effective coupling strengths between the elongated islands. In this way we can not only recover the degeneracy between Type-I and Type-II vertices, which is lost in SASI[2], but also promote an emergent magnetic order when the energy landscape is reversed, see Fig. 1. With the magnetic spin structure factor (SSF) we pinpoint the change of spatial correlations while altering the energy-landscape in mSASI. For a fixed lattice spacing, the decreasing of the gap size (G) and therefore an increase in the effective coupling leads to the magnetic SSF going from well defined bragg peaks (without interaction modifier), as expected when having large Type-I domains, to the characteristic intensity distribution which resamples the square-ice model for spin liquid (G=30), associated with an emergent Coulomb phase with slow decaying spin correlations[3,4,5]. Furthermore at the smallest gap size (G=15) the Type-I and Type-II population is reversed. Here the abundance of Type-II vertices give rise to an emergent flux lattice on the next length scale dictating the order of the spin system. The synergy

and cooperative behaviour between the two different mesospins provides a route for designing new types of magnetic metamaterials with rich magnetic phase diagrams and thermodynamics.

BH-11. Magnetization reversal mechanisms in Fe/NiO bilayers grown onto nanoporous alumina membranes and Si wafers. E. Navarro[1], M. Alonso[1], A. Ruiz[1], U. Urdiroz[1], M. Sánchez-Agudo[2], F. Cebollada[2], G. Domíguez-Cañizares[3], L. Soriano[3], A. Gutierrez[3], F. Palomares[1] and *J.M. González[1] 1. Nanostructures and Surfaces, Instituto de Ciencia de Materiales de Madrid, Madrid, Spain; 2. POEMMA-CEMDATIC, Universidad Politécnica de Madrid, Madrid, Spain; 3. Departamento de Física Aplicada, Universidad Autónoma de Madrid, Madrid, Spain*

We report on the Fe-thickness (5 nm – 20 nm) and temperature dependencies of the hysteretic parameters measured in two F/AF bilayer series: Fe/NiO/Al2O3 nanoporous membranes (series N) and Fe/NiO/Si wafers (series W). The Fe and NiO layers were deposited by pulsed laser ablation and magnetron sputtering, respectively. In both series different oxygen partial pressures (from 0% up to 70%) were implemented in the Ar plasma during NiO growth. The morphologies of both series (as imaged by atomic force microscopy) reflect those of their substrates and, particularly, the series N samples exhibit a six-fold columnar growth around each one of the nanopores (Fig. 1). The in-plane hysteresis loops measured (by means of a vibrating sample magnetometer) upon field cooling the samples down to different temperatures below 300 K evidenced (Fig. 2) the occurrence on the Fe 5 nm, series N samples of coercive forces larger than the Fe magneto-crystalline anisotropy field and decreasing with the increase of the NiO deposition oxygenpartial pressure. The series W samples including NiO layers deposited in the presence of oxygen, showed coercivities that were, for all the Fe thicknesses, below those measured on the corresponding series N samples. Our data are analysed, in close correlation to the deposits morphology, in terms of the occurrence of either propagation mediated reversal (collective mode linked to spatially averaged anisotropy) or localized switching (defect ruled mechanism taking place in a spatially confined environment). It is concluded that i) the magnetization reversal mechanism active in series N samples does not involve either propagation or domain wall pinning, and ii) the reversal events are spatially restricted to the Fe-covered, hexagonally closely packed dot-like tops of the NiO columns.

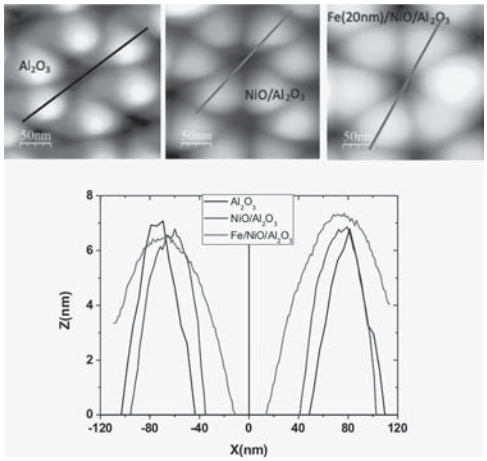

Fig. 1. Top: Atomic force microscope images of the region around a nanopore taken on, from left to right: the Al_2O_3 substrate, the NiO (30% oxygen) layer and Fe (20 nm) layer. Bottom: Profiles measured along the lines indicated in the images.

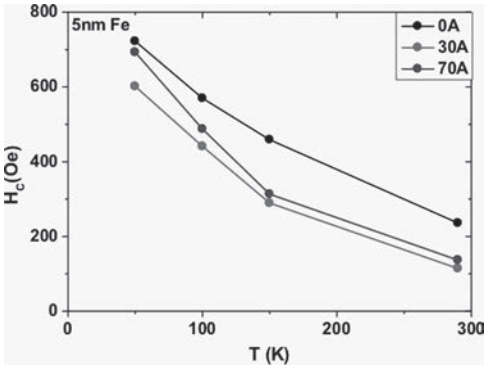

Fig. 2. Temperature dependencies of the coercivity in Fe (5 nm), series N samples deposited using 0% (0A), 30% (30A) and 70% (70A) oxygen-partial pressures.

BH-12. Field and size dependence of the thermal stability in CoFeB/MgO systems. *A. Meo*[1], R.W. Chantrell[2] and R.F. Evans[2] *1. Department of physics, Mahasarakham university, Mahasarakham, Thailand; 2. Department of physics, University of York, York, United Kingdom*

The high anisotropy of CoFeB/MgO-based magnetic tunnel junctions (MTJs) provides the thermal stability (energy barrier/ thermal energy) required to store the information at a specific temperature. To further improve the reliability of these systems it is necessary to fully understand the dependence of the energy barrier on parameters such as system size, temperature and external field. The latter can be due to the stray field acting on the free layer arising from the fixed layer in a MTJ. Here we use an atomistic spin model performing constrained Monte Carlo simulations [1] to investigate the effect of an applied field on the energy barrier as function of diameter of CoFeB/MgO nanodisk at finite temperature. In zero field for small dimensions the spins behave as a macrospin and the thermal stability has the expected quadratic behaviour as function of diameter. Deviations from this behaviour occur as the system size approaches the single domain size and for larger diameters the thermal stability depends linearly on the diameter of the disk, as shown in Fig 1(a). The application of an external field along the easy axis direction, perpendicular to the system, makes the energy barrier between the two stable configurations nonequivalent, as shown in Fig 1(b). As a consequence the minimum barrier that the system magnetisation needs

to overcome decreases and tends towards a constant value for increasing applied fields. Above diameters of 30 nm this behaviour is well described by the droplet theory including the contribution of an external field and agrees with zero-temperature micromagnetic calculations presented in [2]. Further studies for larger diameters and including magnetostatic interactions are required to confirm the observed trends.

BH-13. Tuning exchange bias and training effect in Co/CoO core/shell nanoparticle system by controlling surface defects. *M. Xing*[1], J. Mohapatra[1], J. Elkins[1], J. Beatty[1] and J. Liu[1] *1. Department of Physics, University of Texas at Arlington, Arlington, TX, United States*

A strategy is established to tune the exchange bias and training effect in Co/CoO nanoparticles of 14 nm size (Figure 1a) by controlling the surface defects. The surface defects in Co nanoparticles, and subsequently in the CoO shells, can be controlled by varying the Co-precursor to surfactant (hexadecylamine) mole ratio. The saturation magnetization of the freshly synthesized hcp-Co nanoparticles decreased from 144 emu/g to 126 emu/g with the increase of Co-precursor to surfactant mole content from 1:3 to 1:6, respectively. The low magnetization in the latter case is attributed to the higher surface spin disorder. Following surface oxidation, the sample with low surface spin disorder exhibited a giant exchange-bias field (H_{EB}) up to 2.7 kOe (Figure 1b), whereas the H_{EB} for the sample with high surface disorder is only 1.2 kOe. More importantly, the latter Co/CoO nanoparticles revealed prominent training effect (TE) of the H_{EB} with a large decrease of H_{EB} to 62 % from the first to the second cycles. The large training effects are attributed to spin-glass like behavior of the disorder spins at the interface of the Co/CoO core-shell. This conclusion is further supported by temperature dependent magnetization and thermal remanent magnetization measurements, which showed a spin-glass-like relaxation of CoO defect moments. These results provide a powerful approach towards manipulating and optimizing the exchange bias effects for applications.

BH-15. Temperature and Thickness Dependent Coupling in PyCu Spin Valves Whose Interlayer Undergoes a Magnetic Phase Transition. *K. Repa*[1], B.J. Kirby[2] and C.W. Miller[1] *1. School of Chemistry and Materials Science, Rochester Institute of Technology, Rochester, NY, United States; 2. National Institute of Standards and Technology, Gaithersburg, MD, United States*

We studied spin valves (SV) of the form $Py_{0.8}Cu_{0.2}/Py_{0.4}Cu_{0.6}/Py_1Cu_0/IrMn$ (free/interlayer/pinned). The different Cu content gives each layer a distinct Curie temperature (T_C), which allowed us to study the SV as the interlayer undergoes a magnetic phase transition (T_C = 160 K). We also studied the magnetic properties of the system as a function of interlayer thickness (t = 3.5 nm - 71 nm). We examined each film via DC magnetometry to probe exchange bias (H_{EB}) of the free and pinned layers, and polarized neutron reflectometry (PNR) depth profiles to understand the contributions of each layer as a function of temperature. *M(H)* curves from 50 K to 350 K yielded H_{EB} for the free (*Fig 1*) and pinned ferromagnetic layers. The former shows a blocking temperature-like feature that is correlated with when the interlayer becomes magnetically ordered, which allows direct exchange throughout the stack. This feature has an inverse relationship with spacer layer thickness. In line with exchange bias theory, the magnitude of H_{EB} at constant temperature decreases as 1/t. Magnetic depth profiles from PNR (*Fig 2*) were used to obtain *M(T)* for t = 13 nm and 71 nm interlayers; a 37 nm control film of $Py_{0.4}Cu_{0.6}$ ("x40") was also measured. We found that proximity effects play an important role in the ordering of the interlayer. While the *M(T)* for t = 71 nm resembles that of the control at 50 mT, T_C is enhanced by 70 K for t = 13 nm. However, the magnetic depth profiles do not reveal evidence for a proximity induced enhancement of the interlayer order parameter- i.e. data at all conditions for all samples are consistent with uniform magnetization within the interlayer. Given that the exchange length in Py is ~5 nm, it is curious that we see such a significant and uniform enhancement across a 13 nm interlayer. This result could have wide reaching implications in the field of tunable thermomagnetic devices.

***$H_{EB}(T)$* for each spin valve with inset *$H_{EB}(t)$* and *$T_B(t)$* with linear fit.**

Rare earth orthoferrites and ortochromites of an ABO_3 composition, where A is a lanthanide and B is Fe or Cr, have been under study for several decades. The strong interaction between these two sublattices of the total magnetic moment could produce the phenomena vastly studied: Magnetization Reversal (MR). The MR make this material suitable to spintronic, sensors, thermally assisted random access memory devices, etc. The MR is phenomena in which the spontaneous magnetization changes its sign at a compensation temperatura (T_{comp}) under low magnetic field. Recent in our investigation group it was designed, synthetized and characterized the compound $LuFe_{0.5}Cr_{0.5}O_3$ determining a T_{comp} of 255K [1]. The MR of this compound it's because the two metal transition cations showed antisymmetric exchange interactions or Dzyaloshinskii-Moriya interactions [2] leading to weak antiferromagnetic behavior (WF). Four members of the perovskite family $LuFe_{1-x}Cr_xO_3$ (x= 0.25; 0.45;0.55;0.75) have been synthesized with different thermal treatment and characterized. A systematic study of the crystal and magnetic structure was performed by neutron powder diffraction combined with magnetization measurements. All the compounds crystallize in a *Pbnm* orthorhombic. The study of the magnetic structure vs temperature showed the transition Γ_2/Γ_4^{TM} to Γ_4^{TM} in the compound Cr-rich. The rest of the compositions showed Γ_4^{TM} in all the temperatures in good agreement with the magnetic measurements [3]. The compounds with near to x=0.5 show MR but if change the synthesis temperature, this phenomenon disappears. $LuFe_{0.25}Cr_{0.75}O_3$ don't show MR but with two different synthesis temperature the phenomenon appears. This results is because the different thermal treatment allows or not the cluster (inhomogeneous distribution of cations) formation. We have performed MonteCarlo simulations using the the following Hamiltonian of classical Heisenberg spins [4] lying in the nodes of a cubic lattice with N= (L x L x L) sites to reproduced the MR observed experimentally in a field cooling (FC) process and the cluster formation according the different thermal treatment.

BI-02. The effect of phase separation on the structural and magnetic properties in $FeCoNi_{1+X}Cr_{1-X}Al$ high-entropy alloys. *S. Na*[1], P.K. Lambert[1], J. Park[2] and N.J. Jones[1] *1. Physical Metallurgy and Fire Performance Branch, Naval Surface Warfare Center, Carderock Division, West Bethesda, MD, United States; 2. Aerospace Engineering, University of Maryland, College Park, MD, United States*

High-entropy alloys (HEAs) generally contain five or more elements, often in equiatomic or near-equiatomic ratios. One of the most interesting HEAs from a magnetic perspective is the FeCoNiCrAl-based alloy system, which is highly attractive for investigating phase transformations and controlling small-scale microstructural features [1]. The phase transformation between BCC and FCC due to spinodal decomposition results in a significant change in magnetic properties, such as saturation magnetization [2]. In this work, we investigate the effects of annealing temperature on structural and magnetic properties in FeCoNiCrAl-based HEAs with varying Ni/Cr ratio. Ingots with nominal compositions of $FeCoNi_{1+X}Cr_{1-X}Al$ (X = 0 – 0.5) were prepared by arc melting and cut into discs for measurement. These discs were annealed at various temperatures from 300-1200 °C for 3 hours, then furnace cooled. The measured saturation magnetization (M_S) at room temperature strongly

depends on both the Ni/Cr ratio and annealing temperature, as shown in Fig. 1(a). These changing properties are associated with the change of FCC phase fraction, as determined by x-ray diffraction. Figure 1(b) shows hysteresis loops with different sample conditions in the equiatomic FeCoNiCrAl HEA. A wasp-waist hysteresis loop was found only after annealing at 600 °C, possibly due to negative (antiferromagnetic) exchange coupling between soft and hard magnetic phases in the BCC structure [3]. It was confirmed by MFM (see Fig. 1(c)-(d)) that the BCC phase is ferromagnetic, while the FCC phase is paramagnetic, as a ferromagnetic domain structure is clearly observed in the BCC structure.

BI-03. Inducing strong magnetism in non-magnetic $Cr_{20}Fe_{20}Mn_{20}Fe_{20}Co_{20}Ni_{20}$ by lattice-expansion. *M. Acet*[1] and A. Cakir[2] *1. Physics, Duisburg-Essen University, Duisburg, Germany; 2. Metallurgical and Materials Engineering, Mugla Sitki Kocman University, Mugla, Turkey*

Mixing numerous 3d-elements and subsequently melting them together or allowing them to undergo a solid-state reaction gives rise to random solid solutions with a high configurational entropy [1]. The classical example is the $Cr_{20}Fe_{20}Mn_{20}Fe_{20}Co_{20}Ni_{20}$ alloy with a 20% equiatomic composition forming a single FCC phase. It is paramagnetic at room temperature and has competing interactions at low temper- atures [2, 3]. This material has a valence electron concentration (*e/a*) = 8, which corresponds to that of elemental Fe, but instead of being BCC it is FCC. FCC-Fe has an enhanced enhanced anharmonicity known as anti-Invar. If FCC Fe could have been expanded, it would have been ferromagnetic with a high Curie temeprature T_C and a magnetic moment $\mu \approx 2.8\ \mu_B$. We show here first that $Cr_{20}Fe_{20}Mn_{20}Fe_{20}Co_{20}Ni_{20}$ can indeed be expanded by introducing carbon. We introduce carbon into the octahedral sites of this material and maintain (*e/a*) = 8 to obtain $Cr_{16}Fe_{16}Mn_{16}Fe_{16}Co_{16}Ni_{16}C_{20}$. This becomes FM with a Curie temperature $T_C = 400$ K with $\mu \approx 1.5\ \mu_B$ with room to increase.

Rare-earth (RE) compounds exhibit a variety of magnetic and electronic ground states through the hybridization between 4f and conduction electrons. In addition to the orbital and valence degrees of freedom generating a multitude of ground states, the discovery of new layered RE compounds that can act as precursors for the synthesis of two-dimensional (2D) magnetic materials is another fruitful avenue. The synthesis of three dimensional (3D) layered compounds such as RE in-plane ordered quaternary MAX phases (RE i-MAX) [1], which can be exfoliated to form magnetic 2D systems (e.g. MXene), in which the RE's magnetism is potentially transferred to the itinerant electrons and used for electron spin control and/or injection constitutes a real challenge. Here, we report on the electronic structure and magnetic properties of Mo4Ce4Al7C3, which belong to a recently discovered family of magnetically ordered nanolaminates with a Mo4RE4Al7C3 stoichiometry [2]. These phases, though of a different composition compared to the RE i-MAX phases, display the same characteristic in-plane chemical order of the Mo and RE elements. Powder sample was characterized with respect to structure and composition. Single crystals of Mo4Ce4Al7C3 were used for magnetization measurements. The crystal structure was investigated by means of x-ray diffraction and scanning transmission electron microscopy. Magnetization analysis reveals a ferromagnetic ground state with a Curie temperature of ~10.5 K. X-ray absorption near-edge structure at the Ce L3-edge provides experimental evidence that Ce is in a mixed-valence state. X-ray magnetic circular dichroism carried out at the Ce and Mo L3,2-edges shows that only the Ce atoms with 4*f*1 configuration occupying one of the two possible sites are ferromagnetically coupled, with a saturation moment of ~1.2μ*B* per atom.

BI-05. Preliminary resistivity results on U_2Ni_2Sn single crystals. *I. Halevy*[1,2], A. Kolomiets[3], S. Mašková[1], A. Andreev[4], J. Prchal[1] and L. Havela[1] *1. Condensed Matter Physics, Charles University, Prague, Czechia; 2. Physics, IAEC-NRCN, Beer-Sheva, Israel; 3. Physics, Polytechnic National University, Lviv, Ukraine; 4. Physics, Academy of Sciences, Prague, Czechia*

U_2Ni_2Sn is a member of intermetallic compounds with the tetragonal Mo_2FeB_2 crystal structure, which has been studied intensively [1-3]. It orders antiferromagnetically at 25K with a propagation vector q=(0,0,1/2). Magnetization, magneto-acoustic, and neutron-diffraction experiments on a single crystal provide evidence that the uranium moments align parallel to the *c*-axis with the anisotropy energy of ≈170K, indicating that U_2Ni_2Sn can be classified as an Ising system. This behavior is rather exceptional, majority

of the isostructural uranium ternaries have U moments confined into the basal plane. Last results [1] are actually at variance with previous studies on polycrystals, which indicated different magnetic structure, and which were incompatible with the 5*f*-5*f* two-ion anisotropy model dominant in most of U band systems. Few single crystals of U_2Ni_2Sn were grown by the Czochralski method. The four-point technique was used to measure the resistivity as function of pressure and magnetic fields. We expect fast suppression of magnetic order with pressure, already the ambient pressure data yield an interesting insight. The first finding is that single crystal resistivity has better RRR value, reaching 10 for *i*//[110] and 3 for the [001] direction. None of the two directions exhibits the negative resistivity slope found for the polycrystal, and $r(T)$ shows merely a saturation. The magnetic propagation vector implies an influence of magnetic superzone gapping for [001], which can explain much higher residual resistivity in this direction. There is AF coupling between the U moments within the same basal-plane sheet, but it all happens within one-unit cell, accommodating 4 U atoms. Further differences are revealed by a numerical analysis. Fitting for *i*//[110] indicates the quadratic dependence, compatible with the high uniaxial anisotropy, not permitting a population of magnons with energy lower than the anisotropy gap. On the other hand, *i*//[001] exhibits an additional gap excitation term, with $\Delta \approx 50$K, i.e. much smaller than the anisotropy gap 170K. Such exchange gap has to be identified as a spin gap, suggesting an easy spin flipping along *c*.

BI-06. Structure and physical properties of R_3TiSb_5 compounds (R = Ce, Pr, Nd). *A. Provino*[1,2], A.K. Pathak[3], C. Ritter[4], S.K. Dhar[5] and P. Manfrinetti[1] *1. Department of Chemistry, University of Genova, Genova, Italy; 2. Institute SPIN, Italian National Research Council, Genova, Italy; 3. Ames Laboratory, Ames, IA, United States; 4. Institut Laue-Langevin, Grenoble, France; 5. Condensed Matter Physics & Materials Science, Tata Institute of Fundamental Research, Mumbai, India*

Ternary rare-earth transition-metal antimonides R_3TiSb_5 (R = rare earth), anti-Hf_5CuSn_3-type (*h*P18, *P*6$_3$*/mcm*), are magnetically diverse. In the unit cell the R atoms occupy only the 6*g* site, Ti atoms the 2*b* site and Sb atoms the 4*d* and 6*g* sites. Depending upon R these compounds exhibit the most interesting physical properties, including antiferromagnetic Kondo lattices, heavy fermion, valence fluctuations, and possible superconductivity [1,2]. It was reported that the presence of a small amount of undetectable impurity phases makes it difficult to fully characterize without ambiguity the magnetic and transport properties of R_3TiSb_5 [1]; therefore, it is worth to further investigate the physical behaviors of these materials. Here, we present a study of the crystal structure from X-ray and neutron diffraction and magnetic, specific heat and transport properties of Ce_3TiSb_5, Pr_3TiSb_5 and Nd_3TiSb_5. The obtained results are unique among all the reported data so far. The ac-susceptibility and the specific heat of Nd_3TiSb_5 seem to indicate bulk superconductivity with $T_c = 4.5$ K, while neutron diffraction show the appearance of a commensurate magnetic order below $T_N = 5.5$ K. Ce_3TiSb_5, below about 7 K, sees two transitions corresponding to two different incommensurate magnetic structures, the appearance of which is strongly hysteretic. Pr_3TiSb_5, on the contrary, does not show any sign of long range magnetic order down to 1.5 K.

BI-07. Magnetic ordering of protons in NH_4I, NH_4Br and NH_4Cl. *F. Yen*[1], L. Meng[1], T. Gao[2] and S. Hu[3] *1. School of Science, Harbin Institute of Technology, Shenzhen, Shenzhen, China; 2. Shanghai University of Electric Power, Shanghai, China; 3. Southern University of Science and Technology, Shenzhen, China*

The methyl groups in hexamethylbenzene $C_6(CH_3)_6$ were recently found to become magnetically ordered below 118 K.[1-3] Naturally, we wondered whether similar behavior occurs in ammonium cations (NH_4^+) which are slightly more massive and possess a tetrahedron geometry. The ammonium halides were selected as there is ample literature concluding that their NH_4^+ exhibit hindered rotational motion even towards the lowest temperatures.[4-7] We present anomalies identified in the magnetic susceptibility of the ammonium halides NH_4I, NH_4Br and NH_4Cl at 232 K, 233 K and 243 K, respectively, which all coincide to the temperatures where geometric ordering of the NH_4^+ occur. To explain our results, we take into consideration that the orbital motion of the protons (H^+) also carries a magnetic moment and find that they are actually larger than that of the paired electrons. From such, the structural phase transitions are magnetically-driven as the system attempts to lift 8-fold energy degeneracies of the proton orbitals via Jahn-Teller distortions. Lastly, we discuss how magnetic ordering of NH_4^+ is rather ubiquitous in ammonia-based molecular solids.

BI-08. Ferromagnetism in 2D organic iron hemoglobin crystals based on nitrogenated conjugated micropore materials. *Y. Dahnovsky*[1], A. Pimachev[2], R.D. Nielsen[1] and A. Karonovich[3] *1. Physics and Astronomy, University of Wyoming, Laramie, WY, United States; 2. Aerospace Mechanics Research Center, University of Colorado Boulder, Boulder, CO, United States; 3. Physics, Virginia Polytechnic Institute and State University, Blacksburg, VA, United States*

In this work we study an environmentally stable, low-cost two-dimensional ferromagnetic semiconductor with possible applications in biomedicine, solar cells, spintronics, and energy and hydrogen storage. From first principle calculations we describe the unique electronic, transport, optical, and magnetic properties of a π-conjugated micropore polymer (CMP) with three iron atoms

placed in the middle of an isolated pore locally resembling heme complexes. We then study the stability of this material to an environment and how these properties change when bonded with CO, CO_2, and O_2. This material exhibits strong Fe-localized d_z^2 bands with a direct bandgap of 0.28 eV. The absorption coefficient and conductivity are roughly isotropic with conductivity in the energy range 0.3 - 8 eV. The material shows nonzero Faraday and Kerr rotation in the interval of 0.5-5.0 eV. This material is found to be a ferromagnet of an Ising type with long-range exchange interactions with a very high magnetic moment per unit cell, m = 6 μ_B. The estimated exchange integral is calculated to be about J_{nn} = 25 meV. The binding of CO, CO_2, and O_2 modifies the d_z^2 bands of the Fe ions with varying profiles and results in indirect bandgaps with values between 0.269 - 0.626 eV, 0.039 - 0.434 eV, and 0.291 - 0.347 eV for CO, CO_2, and O_2, respectively. The absorption coefficient becomes slightly anisotropic while conductivity remains isotropic with the same active energy regions. Both the absorption coefficient and conductivity have large modifications to the xy-components. The material remains ferromagnetic with the magnetic moment per unit cell decreasing to 4, 2, and 0 μ_B for gases attached to one, two, and three Fe ions per unit cell, respectively.

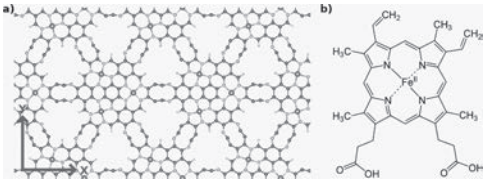

Fig. 1 Crystal structures of (a) the nitrogenated porous materials with three iron atoms inside the six-benzene-ring-CMP unit cell and (b) a heme group b molecule with an iron atom bound to the four nitrogen atoms.

BI-09. Ga- and Sc-substituted M-type ferrites for self-biasing circulators in LTCC microwave modules. M. Heidenreich[1], W. Gitzel[2], A. Jacob[2] and *J. Töpfer*[1] *1. Ernst-Abbe-Hochschule Jena, Jena, Germany; 2. Technical University Hamburg, Hamburg, Germany*

Future satellite communication technologies require microwave ferrites capable of being integrated in LTCC multilayer modules for applications in the K_a-band (26-40 GHz). Substituted hexagonal M-type Ba-ferrites $BaMe_xFe_{12-x}O_{19}$ exhibit significant potential as self-biasing microwave components such as for isolators and circulators and are well suited for the required frequency range. Ga- and Sc-substituted Ba ferrites with $0 \le x \le 2$ were prepared by the mixed oxide route. After calcination (1300 °C) and sintering (1400 °C) single-phase ferrites were obtained. For Ga-substitution, the lattice parameters a_0 decrease with x, while c_0 remains constant. In contrast, for Sc-substituted ferrites, both a_0 and c_0 increase with x, signaling a different substitution mechanism. Static magnetic measurements show that for both substitution series the saturation magnetization decreases with concentration of Ga or Sc. However, the coercivity slightly increases with Ga, whereas it decreases with Sc substitution, indicating respective changes of the anisotropy fields with substituent concentration. The ferromagnetic resonance frequency of the ferrites was determined by reflectance measurements in waveguides in U- and K-bands (30-60 GHz). The ferromagnetic resonance exhibits systematic shifts; for Ga FMR increases with y, whereas for Sc FMR is reduced. To implement ferrite layers into LTCC technology, the sintering behavior was modified by addition of BBSZ glass and sufficient densification at 900 °C was obtained. Ferrite tapes with x = 0.5 were co-fired with LTCC tapes. Alternatively, ferrite layers were screen-printed onto alumina substrates or LTCC tapes and fired at 850 – 900°C. Anisotropic ferrite layers were obtained by drying the films in a magnetic field. The texture of the films was characterized using XRD and EBSD. Ferrite layers were also applied by post-firing onto LTCC layers. Cofiring studies reveal the ferrite layers might be integrated into LTCC architectures. Circulators were fabricated and tested. The potential of such oriented hexagonal ferrite layers as integrated self-biased ferrite layers in microwave components is evaluated.

BI-10. Synthesis and Magnetic Characterization of Semi-Hard Magnetic Nanocrystalline Maraging Steel Powder. G. Thotakura[1], R. Goswami[2] and *T.V. Jayaraman*[1] *1. Mechanical Engineering, University of Michigan-Dearborn, DEARBORN, MI, United States; 2. Materials Science and Technology Division, Naval Research Laboratory, Washington, DC, United States*

Maraging steels are a particular class of high-strength steels that find themselves in a myriad aerospace and tooling applications [1]. A gap in the literature motivated to synthesize and investigate the magnetic properties of nanocrystalline maraging steel powders. Micron-sized nanocrystalline maraging steel powders were synthesized by mechanically milling the gas-atomized maraging steel powder. The structure of the as-milled steel powders was characterized by x-ray diffraction, scanning electron microscopy, and transmission electron microscopy; followed by the characterization of their magnetic properties from cryogenic temperatures to elevated temperatures (60 – 900 K). The phase constituents in mechanosynthesized alloy powder, at ambient temperature (300 K), was primarily martensite coupled with traces of retained austenite and intermetallics; atypical to traditional casting and forging techniques [2]. The magnetic saturation (σ_S) and coercivity (H_C) was estimated as ~165 Am^2/kg and ~5 kA/m, respectively. Both M_S and H_C decreased with the increase in temperature from cryogenic to elevated temperatures. Heat-treatment of the as-milled powder led to an increase in σ_S and a decrease in H_C, and the powders retained the nano-size grains. The change in magnetic properties from ambient temperature to cryogenic temperatures for the as-milled, as well as the heat-treated steel powders were less than 10%. The magnetic properties of the nanocrystalline steel were compared with their bulk counterparts as well as with similar nanocrystalline and commercially available semi-hard magnetic alloys [3]. The nanocrystalline maraging steel powder appears to have decent semi-hard magnetic properties.

The detailed structural, magnetic, transport and mechanical properties of Heusler like $Fe_{3-x}Y_xGe$ (Y = V & Cr) alloys with ($0 \le x \le 1$) have been investigated experimentally and theoretically. With high temperature annealing (950°C), V-substituted alloys for $0.375 \le x \le 0.75$ are found to

crystallize in the cubic $L2_1$ structure, while alloys with $0 < x \leq 0.25$ crystallize in the hexagonal DO_{19}, the high temperature structure of the parent Fe_3Ge compound. Higher V concentrations for $x > 0.75$ are multi-phased at all annealing conditions. At a lower annealing temperature (650°C), V-substituted alloys for $0.25 \leq x \leq 0.75$ are found to crystallize in the $L2_1$ structure, while all single phase Cr-substituted alloys ($0 \leq x \leq 0.75$) found to crystallize in the DO_{19} structure. Vanadium substitution is observed to induce a diffusionless martensitic phase transformation from $L2_1$ to DO_{19} structure, as corroborated by Differential Scanning Calorimetry. The addition of Y significantly decreases the grain size, inhibiting the grain growth by pinning the grain boundary migration. All the alloys in the series are found to be soft ferromagnets at 5K with saturation magnetic moments and Curie temperatures decreasing as Y concentration increases. The extracted low temperature saturation moments are in close agreement with the expected Slater-Pauling values for the $L2_1$ phases, while the hexagonal samples have markedly higher values of saturation moments. First-principles calculations verified the experimental findings and revealed that Y substitution energetically favors one of the Fe sites in Fe_3Ge. The electrical resistivity measured from 5K to 400K shows a negative temperature coefficient of resistivity at high temperatures with increasing V concentration, attributed to impurities at the grain boundaries, while Cr-substituted samples show purely metallic behavior. Relatively high mechanical hardness values are also observed with hardness increasing with increasing Y content. Vanadium is found to play a central role in changing the mechanical properties, stabilizing the $L2_1$ structure, and shifting the martensitic transformation temperature to higher values from that of parent Fe_3Ge.

BI-12. Self-Consistent Local Mean-Field Theory for Phase Transitions in FeRh. *B.R. McGrath*[1], K. Livesey[1] and R. Camley[1] *1. Physics, Center for Magnetism and Magnetic Nanostructures, University of Colorado, Colorado Springs, Colorado Springs, CO, United States*

FeRh has a phase transition from an antiferromagnetic state at low temperature to a ferromagnetic state near a temperature of 360 K. Various explanations for this behavior have been proposed over the past 20 years. However, many of the mechanisms are inconsistent with all the data. Early models were Ising like [1], but the large anisotropy fields necessary for this are not found in hysteresis curves. Using the four-spin Hamiltonian suggested by Barker and Chantrell [2], we obtain a complete theoretical description of the field/temperature phase diagram for this system. The theoretical results are in good agreement with experiments. For example, the transition temperature shifts downward as the external field is increased, with a reduction of about 25 K with the application of a 50 kOe field. Similarly, we find thermal hysteresis near the phase transition with a typical width of about 30-40 K. In-plane and out-of-plane magnetic field hysteresis loops also match well with experimental results. One of the advantages of the self-consistent local mean-field approach is that it can easily predict changes in behavior as a function of the thickness of the FeRh film. We find the four-spin Hamiltonian is particularly sensitive to the presence of a surface, with thinner films remaining ferromagnetic over a larger temperature range because the four-spin contribution to the energy (which favors the antiferromagnetic state) is smaller. This is clearly evident in Fig.1 which shows magnetization as a function of temperature for three different thicknesses of an FeRh film. We also note the presence of thermal hysteresis in each transition. We discuss our results in light of current experiments and device applications of FeRh, plus suggest future experiments to determine the interactions in FeRh.

[1] S. Maat, J.-U. Thiele, and E. E. Fullerton, Physical Review B, Vol 72, p 214432 (2005) [2] J. Barker and R. W. Chantrell, Physical Review B, Vol 92, p 094402 (2015)

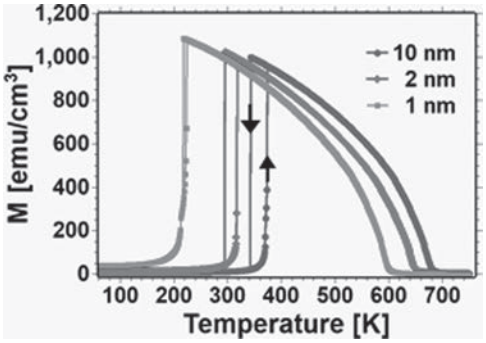

Fig. 1. Calculated magnetization as a function of temperature for FeRh films with different thicknesses. The low temperature phase is antiferromagnetic and has no net magnetic moment. The high temperature phase is ferromagnetic and has a typical decrease in magnetization as the temperature increases. As the film is made thinner, the transition temperature between the two phases is reduced.

BI-13. Magnetic and transport behavior in the non-centrosymmetric Nd_7Ni_2Pd compound. *A.K. Pathak*[2], Y. Mudryk[2], A. Provino[1], P. Manfrinetti[1] and V.K. Pecharsky[2,3] *1. Department of Chemistry, University of Genova, Genova, Italy; 2. Materials Science, Ames Laboratory, Ames, IA, United States; 3. Materials Science and Enginering, Iowa State University, Ames, IA, United States*

The studies of the R_7Pd_3 (R = rare-earth) compounds revealed interesting basic science and potential functional properties [1]. These compounds crystallize in the hexagonal Th_7Fe_3 structure type adopting non-centrosymmetric

space group symmetry $P6_3mc$, where the Pd atoms reside on a single 6*c* site, and R atoms occupy three different crystallographic sites (2×6*c* and 2*b*), resulting in three different magnetic sub-lattices formed by the lanthanide atoms. Crystallographic, magnetic, transport, and calorimetric investigations of Nd_7Ni_2Pd compound show that partial substitution of Pd with Ni changes the ground state from ferromagnetic in Nd_7Pd_3 to antiferromagnetic in Nd_7Ni_2Pd. The antiferromagnetic transition that occurs upon cooling at T_{N1} = 24.5 K is first order, and it is preceeded by a second order antiferromagnetic ordering at T_{N2} = 29 K. The electrical resistivity measurements show metallic behavior with magnetoresistance -12% at H = 30 kOe and T = 2 K. Temperature dependent x-ray powder diffraction clearly shows an anomaly in the lattice parameter *a* at ~30 K, however, there is no detectable structural distortion or volume discontinuity around 25 K, suggesting a significant weakening of the first-order transition compared to binary Nd_7Pd_3 [1]. Compared to the parent compound, Nd_7Ni_2Pd exhibits strong metamagnetic behavior with the application of an external magnetic field. Temperature dependence of lattice parameters as well as magnetic and electrical properties of Nd_7Ni_2Pd will be discussed. The Ames Laboratory is operated for the U. S. Department of Energy by Iowa State University of Science and Technology under contract No. DE-AC02-07CH11358. This work was supported by the Department of Energy, Office of Basic Energy Sciences, Materials Sciences Division.

BI-14. Next-Generation Magneto-Optic Surface Plasmon Resonance-Based Sensors. *C. Rizal*[2,1] *1. Electrical Engineering and Computer Science, York University, Toronto, ON, Canada; 2. R&D, SeedNanoTech & Consulting, Brampton, ON, Canada*

Magneto-optic surface plasmon resonance (MOSPR) is relatively a new physics that has significant potential in the industry [1-3]. In this work, I will provide a brief background of the surface plasmon resonance (SPR) principle, followed by several aspects of magneto-optic SPR (MOSPR) and sensing schemes from the viewpoint of fundamental studies and potential applications [4-7]. I will discuss new sensitivity metrics developed by our group that would allow researchers to compare the performance of SPR and MOSPR-based sensors side by side. I will also discuss the merits of new MOSPR sensors over conventional SPR-based sensors and challenges faced by the MOSPR sensors in terms of their practical use and portability. I will end the presentation with potential new configurations and prospects of various MOSPR configurations. This work is considered significant to engineers, graduate and undergraduate students, and researchers of all levels involved in developing new classes of devices for sensing, imaging, environmental monitoring, toxic gas detection, and surveying applications to name a few.

BI-15. Tailoring the structural and electrical properties of Ba-Zn-Co M-type hexaferrites by lanthanum substitution for high frequency applications. N. Amin[1], *M. Ajaz-un-Nabi*[1], S. Nadeem[1], M.I. Arshad[1], K. Mahmood[1], A. Ali[1] and M. Sharif[1] *1. Physics, Government College University, Faisalabad, Faisalabad, Pakistan*

In the past couple of decades, hexaferrites have gained considerable attention due to their potential applications in industrial and technological fields. Their high resistivity and low losses made them a strong candidate for use in next generation high frequency microwave devices. In this study, $Ba_{0.5}Zn_{0.2}Co_{0.3}Fe_{12-y}La_yO_{19}$ (y=0, 0.1, 0.2, 0.3, 0.4, 0.5) nano hexaferrites were synthesized by co–precipitation method. The prepared powder was sintered at 1100 ^oC for 6 hours to assist to crystallization process. The formation of single phase hexagonal structure was confirmed using XRD. The crystallite size of prepared nano ferrites was found in the range of 12.5 – 28.1 nm. The characteristic band of hexagonal structure observed around 560 cm^{-1} in the FTIR spectra also confirmed the formation of M-type hexagonal phase. The current voltage measurements were performed to study the electrical character of prepared samples in the temperature range of 300 – 900 K. The highest values "2 x 10^{11} Ω cm" and "0.5 eV" of electrical resistivity and activation energy respectively, are observed for the sample with La content y = 0.2 at room temperature. The enhanced dc electrical resistivity due to La substitution indicates that the prepared hexaferrites are beneficial to reduce the eddy current losses for device fabrication in the high frequency range.

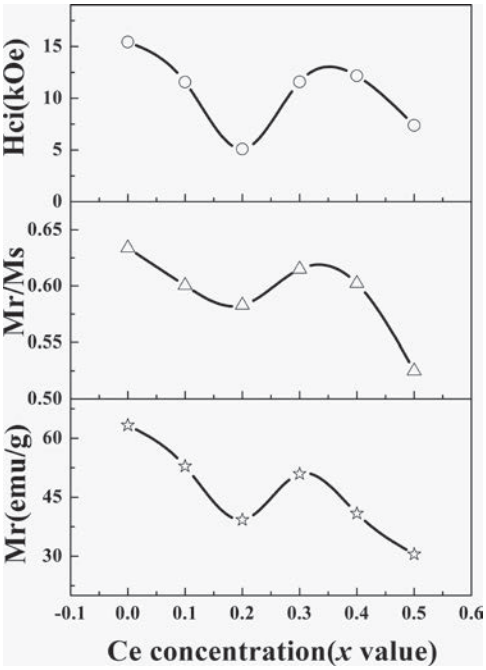
BP-02. Crystallographic alignment and magnetic anisotropy in melt-spun Nd-Ce-Fe-B ribbons. *J. Zuo*[1], M. Zhu[1], W. He[2], M. Zhang[1], Y. Li[1] and X. Zhang[1] *1. School of Science, Inner Mongolia University of Science and Technology, Baotou, China; 2. Department of Materials Engineering, Baotou Vocational & Technical Collage, Baotou, China*

In this paper, crystallographic alignment and magnetic anisotropy were studied for $(Nd_{1-x}Ce_x)_{30}Fe_{69}B$ ribbons prepared via melt-spinning. Effect of Ce concentration and wheel speed on the crystal structure and magnetic properties of the ribbons were investigated. Alloy ingots with nominal composition of $(Nd_{1-x}Ce_x)_{30}Fe_{69}B$ (wt %,x=0~0.5) was prepared by induction melting. The as-cast ingots were crushed into blocks that were subjected to melt-spun treatment under different wheel speeds of 10, 20 and 30m/s. The resultant ribbons were examined by XRD with Cu *K*α radiation on the free side surface. The magnetic hysteresis loops of the ribbons were measured with a VSM with a maximum magnetic field of 3T along the ribbons length. The XRD patterns showed that under the wheel speed of 10 and 20m/s, the reflections such as (004), (006) become dominant in the XRD patterns, indicating remarkable *c*-axis crystal texture in the ribbons. As the wheel speed increased, however, the *c*-axis crystal texture weakened gradually. The relative intensity ratio of $I_{(004)}/I_{(410)}$ and $I_{(006)}/I_{(410)}$ under different Ce concentration and different wheel speeds were calculated. Under the wheel speed of 10m/s, the value of $I_{(004)}/I_{(410)}$ was two times higher than of $I_{(006)}/I_{(410)}$. Under the same Ce concentration, while increasing wheel speed, the $I_{(004)}/I_{(410)}$ firstly decreased then increases monotonously, bottomed at x=0.2; the value of $I_{(006)}/I_{(410)}$ presented decreasing-increasing-decreasing. Similar results were found under the wheel speed of 20 and 30m/s. These results indicated that the Ce concentration could affect the magnetic anisotropy of Nd-Ce-Fe-B ribbon. Fig.1 showed the magnetic measurement results under the wheel speed of 10m/s, while increasing the Ce concentration the remanence and intrinsic coercivity firstly dropped and bottomed at x=0.2, which was the same bottom point the relative intensity ratio of $I_{(004)}/I_{(410)}$, then abnormally raised with a further Ce concentration. The remanence ratio presented the same variation.



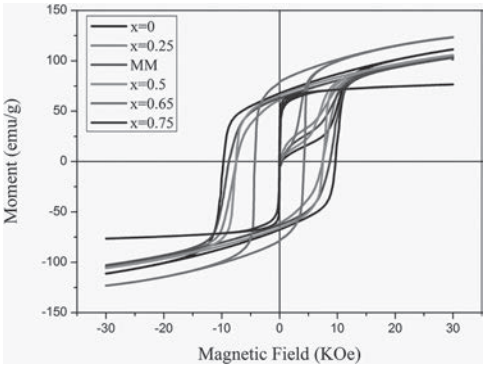


Fig.1 Magnetic properties of $(Nd_{1-x}Ce_x)_{30}Fe_{69}B$ melt-spun ribbons as a function of Ce concentration under 10m/s

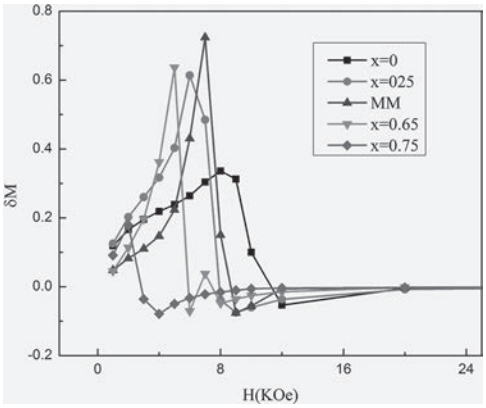

BP-03. Effect of Misch-Metal (MM) with the nature ratio on phase composition and magnetic properties in nanocrystalline $R_{30}Fe_{68.45}Al_{0.5}B_{1.05}$ ribbons. *F. Liu*[1,2], X. Wang[3,1], Y. Liu[1,2], X. Zhang[1,2] and Q. Ma[2,1] *1. School of Science, Inner Mongolia University of Science and Technology, Baotou, China; 2. Key Laboratory of Integrated Exploitation of Bayan Obo Multi-Metal Resources, Inner Mongolia University of Science and Technology, Baotou, China; 3. Division of Functional Materials, Central Iron & Steel Research Institute, Beijing, China*

The magnetic properties and microstructure of $R_2Fe_{14}B$ (R, rare earth) type magnets with nominal composition of $MM_{30}Fe_{68.45}Al_{0.5}B_{1.05}$ (MM, mischmetal) and $[Pr_{4.81}Nd_{16.38}(La_xCe_{1-x})_{78.76}]_{30}Fe_{68.45}Al_{0.5}B_{1.05}$ (x=0,0.25,0.5,0.65,0.75,1) prepared by melt spinning technique. Mischmetal (MM) is a typical mixed rare-earth in the mines with the nature ratio (28.63wt% La, 50.13wt% Ce, 4.81wt% Pr and 16.38wt% Nd), and the ratio of La to Ce is about 1:2. When the content of La is not 0, the intrinsic coercivity and the maximum energy product of $MM_{30}Fe_{68.45}Al_{0.5}B_{1.05}$ ribbon attains to the maximum of 9.8 kOe and 10 MGOe (Fig.1). With an increase of La content, both the saturation magnetization and remanence increase and then decrease with the maximum at x=0.65. When La content is more than 28.63wt%, the RFe_2 phase forms, which results in a decrease of the tetragonal phase content. The magnetization and Henkel plot (δM) measurements

indicate that the MM30Fe68.45Al0.5B1.05 ribbon has a relatively homogeneous microstructure and strong exchange-coupling interactions (Fig.2). The transmission electron microscope image verifies that the ribbons exhibit a homogeneous nanoscale microstructure. In addition, the Curie temperature Tc, the spin reorientation temperature TSR and thermal stability is investigated as a function of La content x, which demonstrates Tc, TSR and thermal stability of the ribbons are improved with proper amount of La. Furthermore, this work offers promise for developing MM-Fe-B based permanent magnets with high performance at low cost.

BP-04. Hydrogen Decrepitation Behaviors of Novel R-Fe-B Strip-Casting Alloys Based on Misch Metal. *Y. Liu*[1,2], X. Wang[1,2], F. Liu[1,2], Q. Ma[2,1], Y. Li[1,2] and X. Zhang[1,2] *1. School of Science, Inner Mongolia University of Science & Technology, Baotou, China; 2. Key Laboratory of Integrated Exploitation of Bayan Obo Multi-Metal Resources, Inner Mongolia University of Science& Technology, Baotou, China*

In order to reduce the Re-Fe-B material cost and balance the utilization of rare earth (Re) sources, misch metal(abbreviated as MM, is rich for La, Ce, Pr and Nd) substitution for Nd in the sintered magnet attract interest. Under the processing of fabricating Nd-Fe-B magnet, hydrogen decrepitation(HD) is widely use to obtain magnetic powder, however, the HD behaviors of Re-Fe-B strips base on MM may be complex. Therefore, HD behaviors of the $((PrNd)1\text{-}xMMx)_{30.8}Fe_{bal}Co_{1.4}B_{0.97}$ (x=0~1) (MM, Misch Metal)strips were study under 0.2 MPa pressure. We find that is similar to Nd-Fe-B, 2:14:1 tetragonal structure of Re-Fe-B strips base on MM is not broken during hydroden decrepitating. Whereas, when x<=0.50, the hydrogen absorption is more lagging as the ratio of MM/Re gets increasing. It should be ascribed to the grain cell volum changing. This finding suggests that La and Ce with stable 2:14:1 tetragonal structure upon HD process are promising alternatives for Nd However, to the $MM_{30.8}Fe_{bal}Co_{1.4}B_{0.97}$(x=1) strips, the hydrogen aborption behaviour is normal rapid, which may be attributed to the phase constitution of the strips(there exists $ReFe_2$ phase).

BP-05. Crystal structures and magnetic properties of synthesized Nd(Pr)FeCoB magnetic nanoparticles. A. Samardak[1], F. Nasirpouri[2], G. Ahmadpour[2], A. Portnyagin[1,3], E. Papynov[3,1], A.S. Samardak[1] and *A. Ognev[1] 1. School of Natural Sciences, Far Eastern Federal University, Vladivostok, Russian Federation; 2. Faculty of Materials Engineering, Sahand University of Technology, Tabriz, The Islamic Republic of Iran; 3. Institute of Chemistry Far Eastern Branch of Russian Academy of Sciences, Vladivostok, Russian Federation*

In this abstract, we report our experimental results for magnetic Nd-FeCo-B and Nd-Pr-Fe-Co-B nanoparticles synthesizing by a modified Pechini-type sol–gel method. Particle size, morphology, structures and elemental analysis of Nd(Pr)FeCoB oxide and reduced powders with cobalt additive varied from 0.05 up to 0.5 mole are investigated using XPS, SEM, TEM. The synthesized powders are composed from nearly spherical nanoparticles and irregular agglomerates with the presence of different phases in the microstructure of the Nd(Pr)FeCoB alloy. Magnetic hysteresis loop of NdFeB oxide and reduced powders with and without cobalt were measured. To better study of the magnetic behavior and its relationship to the microstructure and chemical composition, FORC results for NdFeCoB oxide powders are also obtained. Hysteresis loop of NdFeB oxide powders exhibits unusual magnetic behavior related with the presence and interaction between the paramagnetic and antiferromagnetic phases. But with the substitution of cobalt instead of iron in NdFeB oxide powders, hysteresis loop shows typical magnetic behavior. Also, the amount of M_r/M_s and H_c of NdFeB oxide powders are found to increase with cobalt content. Moreover, NdFeCoB oxide powders show lower and larger coercivity compared with reduced powders in H_2 atmosphere. The presence of soft CoFe magnetic phase in the microstructure of reduced powders in the H_2 atmosphere confirmed by the XRD pattern can be the main reason for this behavior. FeCo alloys have high saturation magnetization and low coercivity. The effects of the RE Pr on the magnetic behavior of the Nd(Pr)FeCoB powder will be show. This work has been supported by the Russian Science Foundation (project 19-72-20071).

BP-06. Chemical synthesis of $Nd_2Fe_{14}B$ particles with improved magnetic properties through wet ball milling process. *R. Kuchi*[1,2], S. Haider[1,2] and D. Kim[1,2] *1. Korea Institute of Geoscience and Mineral Resources, Korea Institute of Materials Science, Daejeon, The Republic of Korea; 2. Korea Institute of Materials Science, Changwon, The Republic of Korea*

$Nd_2Fe_{14}B$ based permanent magnets have attracted huge attention owing to its highest value of energy product (BH_{max}) and has been used enormously in electric motors for power generators, wind turbine generators, electric vehicles, energy conversion systems and many other novel applications. The simple chemical synthesis in this study including spray drying and reduction- diffusion process is very efficient startegy to obtain the $Nd_2Fe_{14}B$ particles. This technique offers a good plotform, and also inexpensive to produce permanent magnetic powders. The use of leached solution obtained from the monazite ore as a precursors could further decrease the production cost and is more economical way than utilisation of expensive inorganic salts (rare earths). In addition, the wet ball milling was introduced for particles after reduction-diffusion, on order to increase mangetic properties of $Nd_2Fe_{14}B$ particles. This can improve the dispersibilty of $Nd_2Fe_{14}B$ particles and separate out the by products which were formed during the reduction-diffusion process. The milled particles are subjected to washing process to get the final particles. However, milling is a key to enhance the magnetic properties of the final particles because the size, morphology and particle distribution strongly affect the coercivity, remenance and saturation magnetization. We investigated the magnetic properties of $Nd_2Fe_{14}B$ particles through wet ball milling in different solvents (Methanol, ethanol, and iso propanol) at different rotation speeds and time. At 200 rpm for 1 h, milling in ethanol resulted spherical particles with average size of 1.58 μm. This particles showed the corcivity of 2185 Oe, and remanence of 98 emu/g. This remanence is attributed to the pure $Nd_2Fe_{14}B$ phase and minimal defects and fractures of crystallites for the $Nd_2Fe_{14}B$ particles.

BP-07. Synthesis and characterzation of 1 dimensional NdFeB nano fiber using reduction-diffusion process. *N. Eom*[1], S. Noh[1] and B. Kim[1] *1. Korea Institute for Rare Metal, Korea Institute of Industrial Technology, Incheon, The Republic of Korea*

Neodymium-Iron-Boron (Nd-Fe-B) magnets are well known as the strongest magnets due to their high energy density than other magnetic materials such as ferrite and Sm-Co. These magnets have been widely used for motors, hard disc drive, and MRI. NdFeB based magnetic materials were generally synthesized using the classical powder metallurgy process and chemical synthesis methods for nanofibers. Among these processes, nanofibers fabricated by electrospinning are excellent for reproducibility and have a large aspect ratio. The electrospinning method is a simple and scalable nanostructure/microstructure fabricating process to produce 1-D-structured materials. By adjusting the amounts of each ingredient, typically the polymer, it is easy to control the dimensions and morphology of produced fiber. However, there has been little significant research reports on Nd-Fe-B fibers because the reduction of rare-earth elements oxide for Nd-Fe-B fibers is difficult without high temperatures with hydrogen. In this study, a novel method for the synthesis of neodymium-iron-boron (Nd-Fe-B) fibers was demonstrated by adopting three continuous processes: electrospinning, step heat treatment, and a facile reduction-diffusion which is new process. The structural and crystalline studies revealed that as-spun precursor fibers were transformed into $FeNdO_3$, Fe_2O_3, and $NdBO_3$ phases by non-isothermal heat treatment, and the oxide mixture fibers were reduced to the single Nd-Fe-B phase by the facile reduction-diffusion process. The morphology of the synthesized Nd-Fe-B material were analyzed by field emission scanning electron microscope (FE-SEM) and X-ray diffraction (XRD). The magnetic property as function of Nd-Fe-B wire diameter was conducted using vibrating sample magnetometer (VSM).

BP-08. Temperature dependent magnetization reversal process of a Ga-doped Nd-Fe-B sintered magnet based on first-order reversal curve analysis. *S. Okamoto*[1,2], K. Miyazawa[1], T. Yomogita[1], N. Kikuchi[1], O. Kitakami[1], K. Toyoki[3,2], D. Billington[3,2], Y. Kotani[3], T. Nakamura[3,2], T. Sasaki[2], T. Ohkubo[2], K. Hono[2], Y. Takada[4], T. Sato[4], Y. Kaneko[4] and A. Kato[5] *1. Tohoku University, Sendai, Japan; 2. ESICMM, NIMS, Tsukuba, Japan; 3. JASRI, Sayo, Japan; 4. Toyota Central R&D Labs., Nagakute, Japan; 5. Toyota Motor Corp, Susono, Japan*

Recently, a Ga-doped Nd-Fe-B sintered magnet has attracted much attention as a high-performance permanent magnet [1]. This magnet exhibits a unique behavior against annealing treatment. The coercivity of the as-sintered state is not large as about 1 T, however, it largely increases to be about 1.8 T after an optimum annealing treatment [2]. In this study, the magnetization reversal process of the Ga-doped Nd-Fe-B sintered magnet has been investigated using the first-order reversal curve (FORC) analysis. Fig. 1(a) shows the FORC diagram of the optimally annealed Ga-doped Nd-Fe-B sintered magnet measured at RT. The typical FORC diagram pattern of conventional Nd-Fe-B sintered magnets exhibit two spots at low and high field regions, respectively. According to our previous study, these two FORC spots correspond to multi- and single-domain magnetization reversals [3]. Contrary to these previous results, only one FORC spot is observed in Fig. 1 (a), indicating that the single-domain magnetization reversal is dominant in the Ga-doped Nd-Fe-B sintered magnet. To confirm the actual magnetization reversal process, we employed the soft X-ray magnetic circular dichroism (XMCD) microscopy observation performed at SPring-8. Fig. 2 shows the XMCD microscopy images taken along the reversal magnetization curve of the Ga-doped Nd-Fe-B sintered magnet. These XMCD microscopy images clearly evidence the single-domain magnetization reversal. At 200 °C, however, two FORC spots appear as shown in Fig. 1(b), that is similar to that of conventional Nd-Fe-B sintered magnets. This fact indicates that the magnetization reversal process of the Ga-doped Nd-Fe-B sintered magnet varies from the single-domain magnetization reversal at RT to the multi-domain magnetization reversal at high temperature, and this change in the magnetization reversal process crucially affects the temperature dependent coercivity of this magnet.

BP-09. Coercivity Mechanism of Ga-doped Nd-Fe-B Sintered Magnets. *Y. Matsuura*[1], T. Nakamura[2], K. Ishigami[2], K. Sumitani[2], K. Kajiwara[2], R. Tamura[3], M. Nagae[1] and K. Osamura[1] *1. Research Institute for Applied Sciences, Kyoto, Japan; 2. Japan Synchrotron Radiation Research Institute (JASRI), Sayo, Japan; 3. Tokyo University of Science, Tokyo, Japan*

The alignment dependence and angular dependence of coercivity (ALDC and ANDC, respectively) of aligned and isotropically aligned Ga-doped $Nd_{14.79}Ga_{0.57}B_{5.24}Co_{1.11}Fe_{bal.}$ were investigated and compared with those of the Nd–(Dy)–Fe–B sintered magnets and ferrite magnets [1], [2], [3]. The ALDC was similar to those of Nd–(Dy)–Fe–B magnet and the ferrite magnet. The coercivity of Ga-doped Nd–Fe–B magnets decreased as the alignment improved. It is postulated that every grain reversed independently by the magnetic domain walls. The angle of magnetization reverse area (θ_1) (AMRA) for the coercivity [2] as a reversed magnetization area at coercivity was calculated and compared with the θ_1 that was obtained from the experimental ALDC. The AMRA that was calculated from the ALDC increased, and was similar to the Nd–(Dy)–Fe–B sintered magnets and ferrite magnets [2], [3]. The AMRA of the aligned Ga-doped magnets was 41.4° at coercivity, which is wider than the 40.7° of the ferrite magnets [3]. Figure 1 shows the ANDC of the Ga-doped Nd–Fe–B sintered magnets and ferrite magnets. The ANDC of the Ga-doped Nd–Fe–B sintered magnets is expected to be similar to the ferrite magnet but slightly lower than the ferrite magnets as established from the AMRA. The ANDC of these magnets decreases from 0° to 40° and increases after 40°. The ANDC behavior might be explained by the coherent rotation model. However, the relationship between the ALDC and ANDC suggests that these phenomena originate from the magnetic domain wall motion. Figure 2 shows the ANDC of isotropically aligned Ga-doped Nd–Fe–B sintered magnets and ferrite magnets. These results support our proposed coercivity mechanism; for aligned magnets, the magnetic domain walls are pinned at grains that are tilted in easy magnetization directions or the c-axis is tilted from the easy magnetization of the magnet. When the magnetic domain walls are de-pinned from the pinning sites, they jump through several grains, which determines the coercivity.

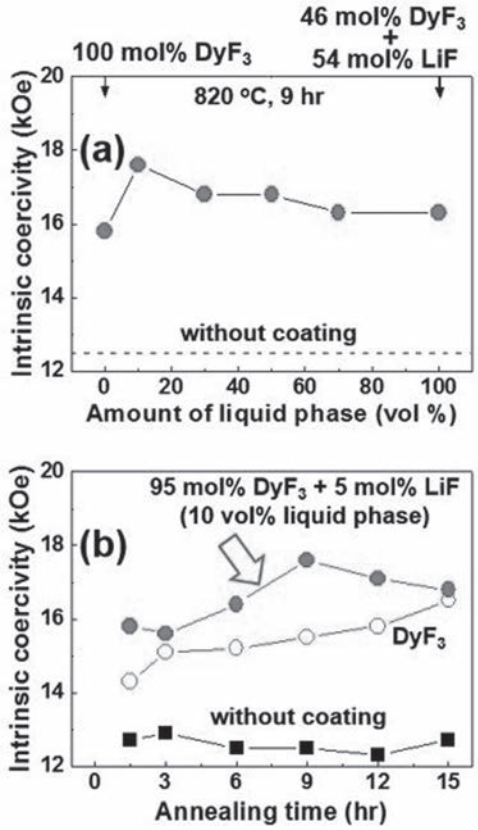
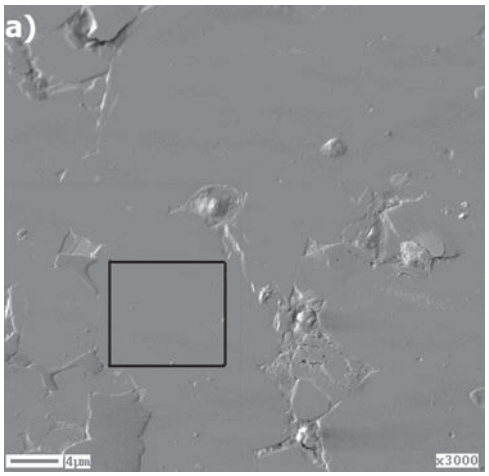
BP-10. Liquid phase diffusion source of heavy rare-earth for enhancing coercivity of grain-boundary-diffusion-processed Nd-Fe-B-type magnet. J. Choi[1], *H. Kwon*[1], B. Kim[1] and J. Lee[2] *1. Pukyong National University, Busan, The Republic of Korea; 2. Korea Institute of Materials Science, Changwon, The Republic of Korea*

Nd-Fe-B-type magnet has been exclusively used for rotor magnet in traction motor of HEV and EV, but it still has one big drawback: poor thermal stability (high temperature coefficient of coercivity (b)) due to low Curie temperature (T_c). Standard approach for solving this problem is sufficiently enhancing room temperature coercivity by means of grain boundary diffusion (GBD) of heavy rare-earth (HRE), such as Tb or Dy. Commonly used diffusion sources of the HRE for GBD are HRE fluoride or oxide salts. As these salts exist as solid during GBD process, diffusion of HRE towards interior is inherently sluggish. It is expected that using HRE diffusion sources in liquid form would lead to speedier diffusion of HRE, thus leading to more rapid and efficient coercivity enhancement. By a lucky chance, we could find a good candidate of diffusion source of Dy in DyF_3 – LiF binary system, which becomes liquid during GBD annealing. Promising liquid diffusion source containing Dy is available in two-phase region (solid DyF_3 + liquid (DyF_3 – LiF)) above peritectic line (~ 815 °C) in DyF_3 – LiF binary system, and the peritectic temperature is desirably lower than typical GBD annealing temperature for Nd-Fe-B-type magnet. In this study, efficacy of using liquid phase Dy diffusion source for enhancing coercivity in GBD-processed Nd-Fe-B-type magnet was investigated. Commercial (Nd,Pr)-Fe-Co-Cu-B-type sintered magnet was coated with (DyF_3 – LiF) mixture having desired composition. The coated Nd-Fe-B magnet was annealed at 820 °C and then quenched, and followed by ageing at 550 °C. It was found that the (DyF_3 – LiF) mixture having 10 vol% liquid (DyF_3 – LiF) + 90 vol% solid DyF_3 at annealing temperature was the best for enhancing coercivity of the Nd-Fe-B-type magnet (Fig. 1(a)). More importantly, it was also revealed that more rapid and consistently higher coercivity enhancement was achieved by using liquid phase diffusion source containing Dy with respect to solid

DyF_3 diffusion source (Fig. 1(b)). Overall, the magnet GBD-processed with Dy-containing liquid phase diffusion source outperformed the one processed with solid DyF_3.





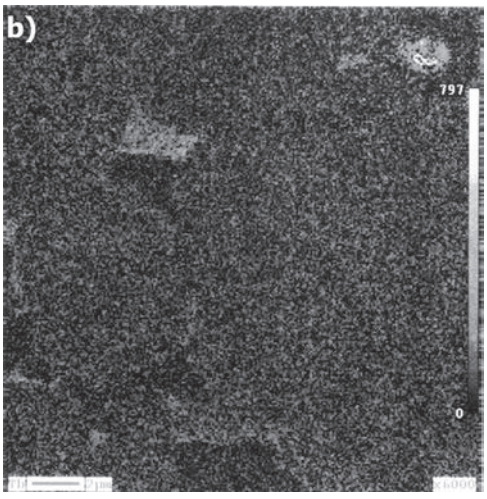


Fig. 1. Coercivity variation in Nd-Fe-B-type magnet GBD-processed using liquid phase Dy diffusion source.

BP-11. Application of Hydrogen-Containing REM-Based Additions in Designing Nd-Fe-B Magnetic Materials. *K. Skotnicova*[1], N.B. Kolchugina[2], G.S. Burkhanov[2], M. Kursa[1], T. Cegan[1], A. Lukin[3], O. Zivotsky[1], P. Prokofev[2], N. Dormidontov[2], J. Jurica[1] and B. Smetana[1] *1. Regional materials science and technology centre, VSB-Technical University of Ostrava, Ostrava, Czechia; 2. Baikov Institute of Metallurgy and Materials Science, Russian Academy of Sciences, Moscow, Russian Federation; 3. JSC SPETSMAGNIT, Moscow, Russian Federation*

The focusing of new technologies on the formation of inhomogeneous distribution of heavy rare-earth metals (REMs) in the hard magnetic Nd-Fe-B materials is the scientific importance of the problem of increase in their functional properties [1-3]. Our novel manufacturing process of these materials includes strip casting, hydrogen decrepitation and treatments in a hydrogen atmosphere, high-energy milling plus mechanical alloying of multicomponent mixtures [4]. We studied the role of alloying REMs and their alloys with transition metals, which were added in the form of hydride or hydrided compounds (TbH_x, DyH_x, ScH_x, Tb_3CoCu, Dy_3CoCu) to initial Nd-Fe-B-based powder mixtures in the course of their mechanical activation, in the formation of phase composition, microstructure, fine structure of grains and given hysteretic properties of hard magnetic materials based on $(RR')_2Fe_{14}B$ compositions. New knowledge on the formation of structured state of $(RR')_2Fe_{14}B$-phase grains, namely, the formation in them of compositional inhomogeneities of heavy REMs, and on the creation of optimum grain surface, Nd-rich grain boundary phase, was acquired. The found Tb distribution inhomogeneities (see Fig.1) are typical of different compositions containing Tb, in the total case, for compositions with a heavy REM. The magnets prepared with 2 and 4 wt.% TbH_2 demonstrates 52 and 90% increase in $_jH_c$ and only 4 and 10% decrease in B_r as compared to those of magnets prepared without the hydride additions, respectively. This effect manifests itself more substantially in using some manufacturing processes, such as strip casting, hydrogen decrepitation, mechanical alloying of binary powder mixtures, etc. Along with the formed core-shell grain structure, the nonuniformity of principal hard-magnetic phase leads to the increase in structure-sensitive magnetic parameters. Magnets prepared with DyH_2 addition demonstrate the higher thermal stability of hysteretic properties at the expense of higher lattice rigidity in the presence of heavy REM. The modified manufacturing process allows us to prepare magnets with the wide range of hysteretic characteristics in using unified initial Nd-Fe-B strip-casting alloy. (Projects LTARF18031 and 14.616.21.0093).

BP-12. Comparison on the coercivity enhancement of sintered NdFeB magnets by grain boundary diffusion with low-melting (Tb, R)$_{75}$Cu$_{25}$ alloys (R = Y, La, and Ce). *Y. Wong*[1], H.W. Chang[1], Y. Lee[1], W. Chang[1], C. Chiu[2] and C. Mo[3] *1. Department of Physics, National Chung Cheng University, Chia-yi, Taiwan; 2. New Materials Research & Development Dept., China Steel Corp., Kaohsiung, Taiwan; 3. R&D Department, Himag Magnetic Corporation, Pingtung, Taiwan*

NdFeB sintered magnets exhibit the highest energy product ($(BH)_{max}$) among all developed permanent magnets due to the outstanding magnetically intrinsic properties of $Nd_2Fe_{14}B$. Traditionally, Dy or Tb is generally added to the Nd-Fe-B magnets to enhance the coercivity ($_iH_c$) for the applications at higher temperature. Since the price surge of critical RE elements in 2011 and also the trade war arises this year, how to reduce the usage of Dy or Tb in the magnets while keeping high coercivity for practical applications becomes the crude issue again. Nevertheless, the grain boundary diffusion (GBD) technique has been developed to conquer this challenge. In this work, significant coercivity enhancement of the commercial NdFeB magnets, 5 mm in thickness, with the magnetic properties of $(BH)_{max}$ = 48.4 MGOe and $_iH_c$ = 17.5 kOe is demonstrated through GBD with low-melting $Tb_{55}R_{25}Cu_{25}$ alloys (R = None, Y, La, Ce). The experimental results show that the adoption of $Tb_{55}R_{25}Cu_{25}$ alloys as GBD sources is effective in increasing coercivity to 29.0 kOe for R = None, 23.8 kOe for R = Y, 25.6 kOe for R = La, 28.0 kOe for R = Ce, respectively. $(BH)_{max}$ is slightly reduced to 46.2-48.2 MGOe. The preferential appearance of Cu at grain boundary and triple junction of the grains and the core-shell structure occurred due to Tb at grain surface remarkably enhances the coercivty. Interestingly, higher coercivity enhancement per wt% Tb usage (Δ_iH_c/wt%Tb) of 7.2 kOe/wt% for the magnet with $Tb_{55}Ce_{25}Cu_{25}$ than 5.9 kOe/wt% for that with $Tb_{75}Cu_{25}$ has been found due to the magnetic isolation effect caused by the preferential appearance of Ce at GB, though slightly lower coercivity enhancement for the samples with R = Y, La, and Ce. Lower melting point of 637 ^oC for $Tb_{55}Ce_{25}Cu_{25}$ than $Tb_{75}Cu_{25}$ (743 ^oC) leads to larger diffusion depth of Tb into the magnet and therefore contributes to higher Δ_iH_c/wt%Tb for the magnet with R=Ce. The coercivity mechanism through micromagnetic model and thermal stability with temperature coefficients of the above samples will be discussed in this presentation. The results of this study suggest the low-melting $Tb_{55}R_{25}Cu_{25}$ alloys for GBD process is cost effective in enhancing the coercivity of sintered NdFeB magnets.

None

BP-13. PLD-fabricated Pr-Fe-B thick film magnets applied to small motors. *S. Takeichi*[1], K. Inoue[1], K. Takashima[1], A. Yamashita[1], T. Yanai[1], M. Nakano[1] and H. Fukunaga[1] *1. Nagasaki University, Nagasaki, Japan*

Although a cylinder-type small motor comprising a rare earth bonded magnet on a stainless shaft has been conventionally used, it is difficult to achieve the high values of residual magnetization and $(BH)_{max}$ of the magnets because each motor contains a nonmagnetic phase such as a thermosetting resin. In the study, preparation of miniaturized magnets without non-magnetic materials was carried out using PLD (Pulsed Laser Deposition) method [1]. In order to deposit a Pr-Fe-B thick film magnet on a stainless shaft, we optimized Pr contents of Pr-Fe-B films on stainless substrates through the evaluation of magnetic together with mechanical properties. Then, an approximately 250 μm-thick Pr-Fe-B film magnet which has superior magnetic properties compared with those of a conventional bonded magnet could be obtained on a stainless shaft applicable to a small motor. A rotated $Pr_XFe_{14}B$ (X=1.8~2.4) target was ablated using a Nd-YAG pulse laser in the vacuum atmosphere to deposit Pr-Fe-B film magnets on stainless substrates and shafts, respectively. In order to crystallize an as-deposited Pr-Fe-B film with amorphous structure, a pulse annealing (PA) method was utilized. Figure 1 shows the relationship between the peeling phenomenon and Pr contents in as-deposited Pr-Fe-B films on stainless substrates. In the thickness range from 10 to 100 μm, Pr-Fe-B films with the Pr content above 15 at. % tended to peel from the substrates. This result is considered to be attributed to the different linear expansion coefficient between a stainless (10.3×10^{-6} K^{-1}) and Pr element (6.7×10^{-6} K^{-1}). On the other hand, an increase in Pr contents of the samples enabled us to enhance the magnetic properties compared with those of a conventional bonded magnet. We, therefore, deposited a Pr-Fe-B film with the Pr contents of slightly less than 15 at. % on a stainless shaft. Resultantly, a PLD-made 250 μm-thick film on a stainless shaft with the diameter of around 0.5 mm could be prepared. We also found that the coercivity of the film was about 1250 kA/m which was applicable to a small motor.

BP-14. Synthesis of Nd-Fe-B/Fe hybrid micro-magnets. *N. Gunduz Akdogan*[1], O. Akdogan[2] and B. Misisrlioglu[3] *1. Piri Reis University, Istanbul, Turkey; 2. Bahcesehir University, Istanbul, Turkey; 3. Sabanci University, Istanbul, Turkey*

There is an overgrowing interest in the synthesis of high-performance micro magnets due to their wide application areas in MEMS, microfluidics, and micro-robotics. In addition, they possess great potential to become a model system for the development of next-generation hard magnets. In this study, NdFeB/Fe hybrid micro-magnets have been synthesized by a photolithography technique. NdFeB and Fe micro powders in the form of nano-thin flakes have been synthesized by one step surfactant assisted planetary ball milling. The fabricated nano-thin flakes with different lateral sizes have been obtained by varying the milling time. Room temperature coercivities of up to 3.1 kOe for NdFeB has been achieved after milling for 8 hr (Fig. 1a). Photoresist and powders of NdFeB and Fe have been mixed at various powder-to-resist ratios. SU-8 has been chosen as the photoresist due to its resistance to chemicals and its suitability to be utilized in MEMS technology. Micro islands of SU-8/NdFeB/Fe have been prepared according to the manufacturer's recommendations for pure SU-8. The hybrid micromagnets in disk form (height: 50 μm and diameter: 100 μm) have been successfully produced. (Fig. 1b.) The evolution of magnetic, structural and microstructural properties of these micro magnets will be reported. Successful fabrication of hybrid micro-magnets using the methodology prescribed in this work can pave the way for the development of next-generation MEMS. This work was supported by TUBITAK project: 116C080. Photolithography has been conducted in Sabanci University Nanotechnology Application Center.

Currently, processes named as grain boundary diffusion and grain boundary restructuring are widely used as approaches, which allow one to improve hysteretic properties of Nd-Fe-B-based magnets, namely, to enhance the coercivity and reduce the heavy rare-earth consumption of Nd–Fe–B sintered magnets simultaneously. Some progresses have been made in efforts to introduce heavy rare-earth metals (REMs) in the form of hydrides. In recent years, permanent magnets based on $(Nd,Pr)_2Fe_{14}B$ compound are of interest for investigators owing to the possibility to use these magnets at low and cryogenic temperatures. In contrast to $Nd_2Fe_{14}B$ compound (at 135 K, its easy-magnetization axis anisotropy changes to easy-axis cone anisotropy), the $Pr_2Fe_{14}B$ compound does not undergo the spin-reorientation transition, and the natural increase in the hysteretic parameters with decreasing temperature can be adequately used. In the present study, we investigate the effect of HoH_2 hydride addition on the hysteresis loop parameters of sintered Pr-Fe-Ti-Al-Cu-B magnets. The magnets were prepared by traditional powder metallurgy technology, and 3 wt. % HoH_2 was added to the powder at the fine-milling stage. The magnets demonstrate the monotonic increase in all hysteretic parameters with decreasing temperature up to 4.2 K. The structure of the magnets was studied in detail by scanning electron microscopy (SEM/EDX - Fig. 1), and the formation of so-called "core-shell" structure was demonstrated (Fig. 2), which is assumed to favor the marked improvement of hysteretic properties of Pr-Fe-B-based magnets. The coercive force and maximum energy product at 4.2 K are H_c = 5420 kA/m and $(BH)_{max}$ = 352 kJ/m^3, respectively. Domain structure of the magnets was studied perpendicular and parallel to the magnet texture using magnetic force microscopy. The data obtained indicate the well-formed magnetic texture. The average domain width is 1.2-1.8 μm.

The distribution of Ho in the matrix grains of Pr-Fe-B sintered magnet prepared from the powder mixture with 3 wt.% HoH_2.

SEM image of $Pr(Ho)_2Fe_{14}B$ phase grain showing so-called "core-shell" structure, i.e. cores of grains are Ho-depleted, whereas the edges of grains are Ho-enriched.

BQ-01. Influence of HfO_2 Interlayers on Magnetocrystalline Anisotropy in Fe|MgO|Fe Magnetic Tunnel Junction: First-Principles Investigation.
W. Chen[1], J. Zhang[2], B. Yang[1], T. Yu[3] and *X. Han*[1] *1. Institute of Physics, Beijing, China; 2. Huazhong University of Science and Technology, Wuhan, China; 3. Sichuan University, Sichuan, China*

Perpendicular magnetic anisotropy (PMA) is important for MgO based magnetic tunnel junction and magnetic random access memory (MRAM) to be large-scale integrated due to high thermal stability and low critical switching current. Here, we applied density function theory to study the effect of HfO_2 inserting layers on PMA of Fe|MgO|Fe tunnel junction. It was found that the magnetocrystalline anisotropy (MCA) of the junction for 5 layers Fe electrode was up to 1.95 mJ/m^2 with one unit cell HfO_2 interlayer, while 1.72 mJ/m^2 without the interlayer. More importantly, analyzed by the layer and orbital-resolved MCA based on second-order perturbation theory, MCA characters and the underlying mechanism of PMA become very different after inserting HfO2. The remarkable difference is the MCA contribution of the second interfacial Fe layers, which is about 0.4 mJ/m^2 for Fe|MgO|Fe junctions, while larger than 0.7 mJ/m^2 for Fe|HfO_2|MgO|HfO_2|Fe junctions. Furthermore, Fe-dz^2 and O-pz hybridization plays a crucial role on MCA contribution from the first interfacial Fe layers since the interfacial Fe-O bond length reduces from 2.20 Å to 1.77 Å with inserting the HfO_2 layers. Besides, the reduction in Fe-O bond length can redistribute the orbital-resolved electrons of the second and third closest Fe layer to the interface to enhance their absolute values of MCA contributions, which results in the strong dependence of MCA on Fe thickness.

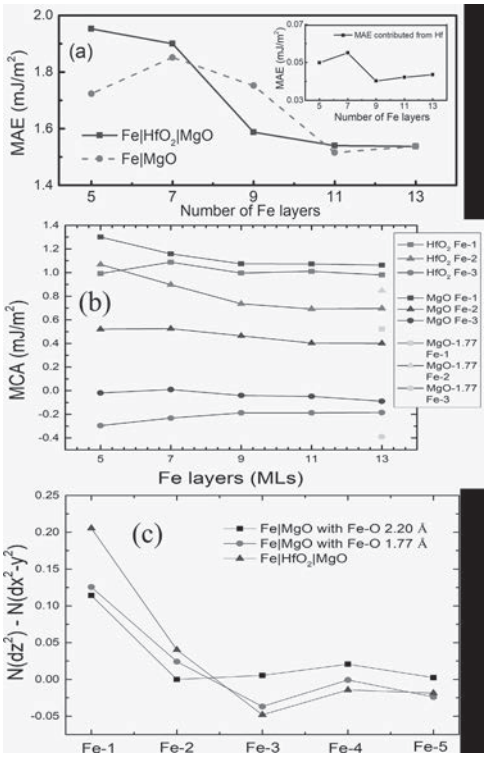

FIG. 1. (a) MCA for different number of Fe layers in supercell, where dashed lines and solid lines represent Fe|MgO|Fe and Fe|HfO_2|MgO|HfO_2|Fe junctions, respectively. (insert) Interface MCA contributed by Hf atoms in Fe|HfO_2|MgO|HfO_2|Fe junction. (b) MCA contribution of the closest (Fe-1), the second closest (Fe-2) and the third closest (Fe-3) Fe layer to the interface for three supercells with different Fe layers, where red, blue and green represent Fe|HfO_2|MgO, Fe|MgO and artificial Fe|MgO with Fe-O bond length of 1.77 Å, respectively. (c) Difference of orbital-resolved electrons N(dz^2) and N(dx^2-y^2) for three supercells with 13 ML Fe layers.

BQ-02. Strong bias effect on voltage-driven torque at epitaxial Fe-MgO interface.
S. Miwa[1,2], Y. Jibiki[1], J. Fujimoto[3], M. Goto[1] and Y. Suzuki[1] *1. Graduate School of Engineering Science, Osaka University, Toyonaka, Japan; 2. The Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan; 3. Institute for Chemical Research, Kyoto University, Uji, Japan*

Torque can be provided to induce magnetization in nanomagnets directly by electric current and/or voltage. This technique enables electric current (voltage)-to-spin conversion without electromagnetic induction, and has been intensively studied for memory device applications. Among the various kinds of torque, torque induced by spin-orbit splitting has recently been found [1,2]. However, quantitative understanding of bulk-related torque and

interface-related torque is still lacking [3] due to their identical symmetry for current-in-plane devices. In this presentation, we propose that a pure interface-related torque can be characterized by spin-torque ferromagnetic resonance with a current-perpendicular-to-plane tunnel junction utilizing tunnel anisotropic magnetoresistance [4]. We prepared epitaxial Fe-MgO-V tunnel junctions with various MgO thicknesses giving a wide range of current density. As a result, we found that the interface-related current-driven torque was negligible but the voltage-driven torque increased as the MgO thickness decreased. The maximum voltage-driven torque was as large as 2.8×10^{-5} J/(Vm^2). This is comparable to the VCMA at an Fe-MgO interface of 180 fJ/Vm, which is larger than any reported VCMA-induced voltage-driven torque. The voltage-driven torque shows nonlinear DC bias voltage dependence, with a maximum around zero DC bias as shown in Fig. 1(a); thus, an electronic state in the vicinity of the Fermi level at Fe-MgO interface is likely to be of importance to generate the large voltage-driven torque. An interface resonant state at Fe-MgO was also found in the vicinity of the Fermi level from the conventional tunnel spectroscopy (Fig. 1(b)) as well as tunnel anisotropic magnetoresistance spectroscopy. This surface-state-sensitive electric modulation of magnetic properties provides new insight in the field of interface magnetism. A part of this work was supported by JSPS KAKENHI (Nos. JP26103002), TEPCO Memorial Foundation, and The Asahi Glass Foundation.

BQ-03. Strain Mediated Current-induced Magnetization Switching in PMN-PT/Ta/Pt/Co/Pt Heterostructures. M. Wang[1], *X. Xu*[1], J. Miao[1] and Y. Jiang[1] *1. school of materials science and engineering, University science and technology of Beijing, Beijing, China*

Current-induced spin-orbit torques (SOT) induced magnetization switching and electric filed controlled magnetism in ferroelectric materials are two interesting topics with potential application in spintronic devices [1-7]. However, the research of the strain mediated SOT switching on ferroelectric substrates is still limited. Therefore, it is important to clarify the mechanism of the strain mediated electric field induced SOT switching. In this work, we study strain mediated SOT induced magnetization switching in $PbMg_{1/3}Nb_{2/3}O_3$-$PbTiO_3$ (PMN-PT)/Ta (1)/Pt (3)/Co (1.3)/Pt (1) (thickness in nanometer) multilayers. The film was patterned into a Hall bar using EBL and an Ar ion milling technique. The multilayer takes on a perpendicular magnetic anisotropic state on the basis of the figure of the Hall resistance (R_H) as a function of the out-of-plane magnetic field. R_H-I curves under external in-plane magnetic field H_x=100 Oe is shown in Figure 1, the magnetic field is applied along the positive current direction. The changes of resistance ΔR of the clockwise switching loops can respond to the extent of the magnetization switching. Along the magnetic field direction, applying an electric field of E=10 kV/cm, the magnetization switching becomes close to full switching compared with E=0 kV/cm under H_x=100 Oe. Therefore, the effective magnetic anisotropy field can promote the magnetization switching under the external magnetic field. We can also observe the easy axis rotated in hysteresis loops before and after applying E=10 kV/cm in Figure. 2. According to our experiments, strain modulation of interface magnetic anisotropy plays an essential role in manipulating the SOT induced magnetization switching. By applying the electric-filed E=10 kV/cm, the magnetization switching can be increased about 40%, which suggests that magnetization witching can be realized with lower external in-plane magnetic field or even zero field.

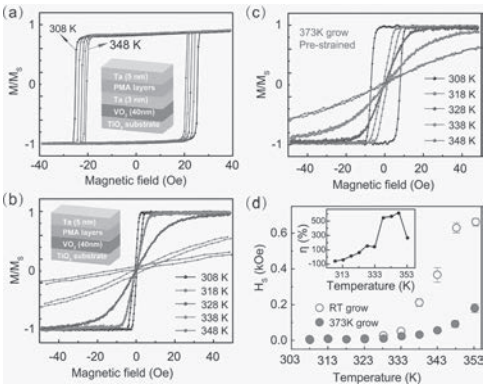
BQ-04. Phase-transition-induced magnetic anisotropy change in VO_2/(Co/Pt)$_2$ heterostructure. *W. Guodong*[1], X. Lin[1], Z. Si[1] and W. Zhao[1] *1. Beihang University, Beijing, China*



Perpendicular magnetic anisotropy (PMA) is one of the most significant technologies to be used in next generation spintronics devices as its potential in promoting thermal stability and device miniaturization. It is an important

issue to find an efficient way to modulate its property in the process of PMA application. In this work, we report the phase-transition controlled magnetic anisotropy modulation in the VO_2/(Co/Pt)$_2$ heterostructure, where VO_2 is introduced into the system to applied an interfacial strain by its metal-insulator transition. Fig.1 (a) shows the schematic drawing of the phase-transition controlled modulation of magnetic anisotropy (PCMA) heterostructure used in this work. The Hall resistance (R_{Hall}) was measured to investigate the magneto-transport properties of the PCMA film. Fig.1(b) shows the R_{Hall}-H curves of the sample at 300 K and 360 K. The difference of the curves between 300 K and 360 K shows that the phase change of VO_2 can indeed regulate PMA properties of the sample. To further investigate the magnetic modulation effect in this heterostructure, magnetization measurements were performed by MOKE. As shown in Fig. 4, only faint shrinking of coercive field can be detected in a sample with 3 nm Ta inserted between VO_2 and PMA layers. However, for the ordinary sample a significant variation of H_S is observed (Fig.4 (b)). This sharp contrast confirms that the modulation effect relies on the interface coupling between VO_2 and PMA layers. The modulation effect is further studied by a comparison between the ordinary sample and a pre-strained one which is prepared with the PMA layers deposited at 373 K. The variation of *Hs* for these two samples has been summarized in Fig.5 (d). The inset gives the difference ratio which value reaches 620%. It reflects that if the interfacial strain effect is pre-released, the modulation effect would be highly weakened. The present result is expected to provide guidelines for the improvement of the efficiency of PMA modulation and benefits the development of spintronic research.

BQ-05. Mechanism of Voltage-Induced Change in Magnetism of Pt/Co with HfO_2 Dielectric Layer. *T. Hirai*[1,2], T. Koyama[2,3] and D. Chiba[2,3]
1. Department of Applied Physics, The University of Tokyo, Bunkyo-ku, Japan; 2. The Institute of Scientific and Industrial Research, Osaka University, Ibaraki-shi, Japan; 3. Center for Spintronics Research Network, Ibaraki-shi, Japan

Voltage control of magnetism (VCM) in transition metal (TM) has a potential to realize ultra-low-power spin manipulation in future spintronic devices. Two mechanisms have been proposed as the origin of VCM; the modification of the electronic state by electrostatic charge doping at the TM/dielectric oxide (DO) interface[*1] and thermally-activated chemical effect in the TM layer.[*2] In this talk, we show that the quality of the DO layer determines which mechanism dominates the VCM.[*3] The DO layer quality strongly depends on its deposition temperature. This result is expected to be the key for both pursuing the underlying physics of VCM effect and expanding the possibility of the application of the field-effect spin devices. We fabricated two Pt/Co capacitor structures with the HfO_2 DO layer deposited at 150°C (sample A) and 60°C (sample B) using atomic layer deposition. The frequency-dependent phase angle (θ-*f*) measured using LCR meter for both samples are shown in Fig. 1. In sample A, θ shows -90° for a wide range of *f* as a conventional capacitor whereas the peculiar θ-*f* relation is observed in sample B, indicating that the high quality DO layer is formed in sample A. As for the VCM effect, the anomalous Hall (AH) measurement is performed under gate voltage V_G. In sample A, the change in coercivity H_c and the 2-wire resistance R (~0.02%) following to V_G change without delay can be seen (Fig. 2 (a)). This means the effect of electrostatic charge accumulation is dominant in VCM using high quality DO. On the other hand, in sample B, the modulation of R is much larger (~10%) and H_c greatly changes in the range of ~20 to 0 mT (Fig. 2 (b)). The gradual changes in R and H_c are observed even though V_G is fixed. Moreover, the values do not go back to the initial state when setting V_G = 0 V. These results indicate that the voltage-driven redox reaction is dominant in the sample with the low-quality DO. This work was partly supported by JSPS KAKENHI and Spintronics Research Network of Japan.

The electric-field-induced manipulation of magnetic systems has gained much attention in recent years. Typical examples include voltage-controlled magnetic anisotropy [1,2] and the voltage induced manipulation of exchange. In the second case, the effect of voltages applied to magnetic multilayers in insulator stacks has been studied [3-5]. However, the consequences of applying electric fields on the exchange interaction of single particles are not fully explored. The indirect exchange interaction between magnetic moments in metals is named Ruderman-Kittel-Kasuya-Yosida (RKKY). The coupling constant, known as the RKKY function, depends on the separation distance. In this work [6], we study a non-magnetic metal sandwiched by two insulators and subject to a voltage bias (see Fig. 1). One impurity is at the top interface, and we study the interaction with another impurity at a different position. We show the voltage-induced modification of both the strength and the wavenumber of the RKKY function. Figure 2(a) shows the RKKY function for two magnetic particles at opposing interfaces and Fig. 2(b) illustrates the type of coupling (Ferro- and Antiferromagnetic) for several applied fields and separation distances. As this figure illustrates, the type of coupling can be switched from Ferro- to Antiferromagnetic orders, and vice-versa, by voltages. The interaction can also be switched off. Finally, possible applications to switching dynamics are also discussed. BQ-07. Electric control of exchange bias in Co/FeO$_x$ bilayer by resistive switching. L. Wei[1], R. Liu[1], Y. Yuan[1], J. Wang[1], L. Sun[1], B. You[1], W. Zhang[1], Q. Xu[2] and *J. Du*[1] *1. Department of Physics, Nanjing University, Nanjing, China; 2. School of Physics, Southeast University, Nanjing, China*

Electric control of exchange bias (EB) in ferromagnet/antiferromagnet (FM/AFM) bilayer provides a pathway for full electric control of magenetism, which is of great importance in developing energy-efficient spintronic devices. Among various mothods people used before, very recently we proposed a new way to realize non-volatile, repeatable electric control of EB at room temperature by resistive switching (RS) with an antiferromagnetic resistive layer [1]. However, this can only be operated when high-density magnetic filaments are formed/ruptured at the FM-AFM interface during the RS process. In this work, the electrol of EB has been accomplished by interface-barrier-type RS, which is much easier to be realized in comparison with the filament mechanism described in Ref. [1]. The Ti(2 nm)/Pt(50 nm)/FeO$_x$(65 nm)/Co(2.6 nm)/ITO(50 nm) multilayer device was made by magnetron sputtering on Si(100) substrate with the diameter of the top electrode of about 160 μm, as sketched in the inset of Fig. 1(a). The FeO$_x$ ($x \approx 3$) layer was made by reactive rf sputtering with $P_{Ar} : P_{O2} = 2:1$. The *I-V* curve shown in Fig. 1(a) indicate typical bipolar RS effect in the device and the on/off ratio is larger than 10^3. The in-plane magnetic hysteresis (*M-H*) loops were measured by a commercial focused MOKE with the spot size of about 100 μm. Figure 1(b) shows that the EB field (H_E) is 116 Oe and 122.5 Oe and the coercivity (H_C) is 66 Oe and 112.5 Oe at the low- and high resistance states (LRS and HRS), respectively. Therefore, compared with LRS, H_E increases a little but H_C increases significantly at HRS. All the measurements were performed at room temperature and the results repeat well. The migration of the oxygen vacancies under different voltages is considered to mediate the interfacial barrier height, leading to the bipolar RS effect and distinctly different exchange coupling as well at LRS and HRS for the FeO$_x$/Co bilayer.

Voltage-induced motion of a magnetic domain wall (DW) has potential in developing novel devices with ultralow dissipation [1, 2]. However, the speed for the voltage-induced DW motion (VIDWM) in a single ferromagnetic layer is usually very low. In this work, we proposed VIDWM with high speed in a synthetic antiferromaget (SAF) [3]. The velocity for the coupled DWs in the SAF is significantly higher than its counterpart in a single ferromagnetic layer. Strong interlayer antiferromagnetic exchange coupling plays a critical role for the high DW velocity since it inhibits the tilting of DW plane with strong Dzyaloshinskii-Moriya interaction [4]. On the other hand, the Walker breakdown of DW motion is also inhibited due to the stabilization of moment orientation under a strong interlayer antiferromagnetic coupling. In theory, the voltage-induced gradient of magnetic anisotropy is proved to be equal to an effective magnetic field that drives DW [1, 5].

BQ-09. Steplike anomalous Hall effect switching in mixed BFO-based heterostructure. P. Liu[1], *Y. Jiang*[1], J. Miao[1], K. Meng[1], J. Chen[1] and Z. Li[1]
1. School of Materials Science and Engineering, University of Science and Technology Beijing, Beijin, China

$BiFeO_3$ (BFO)-based heterostructure has a big potential in magnetoelectric coupling and spintronic applications. And different phases in BFO films also brings on various functionalities. [1] Therefore, the research on the combination with BFO-based heterostructure and different phases of BFO has received much attention. [2,3] In this study, the perpendicular magnetic anisotropy (PMA) is realized in BFO-based heterostructures with different phases. Figure (a) shows the schematic diagram of the Hall bar structure. The anomalous Hall effect (AHE) of R-, T- and mixed phase BFO hetero were measured in Figure (b-d). The anomalous Hall resistance of every samples exhibit good perpendicular magnetic anisotropy (PMA) in room temperature (RT). Interestingly, a steplike switching is found in the AHE of mixed-phase hetero. Referring to fig. (b) and (c), the H_c' s results of steplike signals do not correspond with the results in pure R phase and T phase. As the mixed-phase BFO is not the single superposition about pure T phase regions and R phase regions, the steplike signals in mixed-phase hetero are also not the sum of pure R phase signals and T phase signals. Some contrastive measurements are also shown in fig. (e) and (f). Considering the mixed-phase BFO can be reversibly controlled via polarization field, our results have a prospect on spintronic and memory devices.

BQ-10. Theoretical Study on Voltage-Controlled Exchange Coupling via Nonmagnetic Metal Layers. *K. Ohgane*[1], Y. Yahagi[1], D. Miura[1] and A. Sakuma[1] *1. Applied Physics, Tohoku University, Sendai, Japan*

Control of the spin Seebeck diode effect (SSDE) [1] has been desired to realize magnonic logic circuits. The SSDE is the phenomenon that the amplitude of a magnon current induced by the spin Seebeck effect depends on the direction of the tempareture gradient applied on magnonic spin tunneling junctions (MSTJs), which have the structure of FI/NM/FI (FI: ferromagnetic insulator, NM: nonmagnetic layer). Recently, we showed that the SSDE strongly depends on the magnetization direction in FIs [2]. As a next step, we consider a possibility to control the SSDE electrically. In the SSDE, the presence of an exchange coupling, Jeff, between the FIs is essential because it is just the tunneling amplitude of magnons between the FIs. In this study, we aim to electrically control Jeff and to reveal its dominant factors from microscopic viewpoints. The inset in Fig. 1 is a schematic view of the MSTJ that a bias voltage, V, is applied, and the main figure shows our result for Jeff vs. V calculated on the basis of a tight-binding model for conductive electrons in NM (now we consider 2 mono-layers case, for simplicity), and we found features as follows: (1) at zero bias, the sign of Jeff depends on model parameters, (2) however, in a strong voltage range, Jeff has the positive sign in the 2 mono-layers case, that is, the magnetic coupling between FIs is ferromagnetic, (3) therefore, as shown in the case 1 of Jeff<0 at zero bias, the Jeff monotonically decreases with increasing V, (4) on the other hand, as shown in the case 2 of Jeff<0 at zero bias, the sign of the Jeff changes at a threshold voltage V0. From the above, the case 2 is very important in applications of the SSDE in the sense that the effect may be efficiently controllable by the voltage; for example, in integrated magnon circuits with many MSTJs, one can locally break a circuit by applying V0 on the MSTJ. In the conference, we will further discuss the voltage-controlled SSDE, focusing on its dependences on NM thickness and electron density.

BQ-11. Improving Perpendicular Magnetic Anisotropy in $SrTiO_3$/Co/Pt Films by Inserting $CaTiO_x$ Layer. *Z. Zhang*[1], Z. Li[1], Y. Jiang[1], X. Xu[1], K. Meng[1], Y. Wu[1], J. Chen[1] and J. Miao[1] *1. university of science and technology beijing, Beijing, China*

The integration of metallic spintronic devices and multifunctional oxides with perovskite structure can induce coupling between functionalities such as ferroelectricity and the spin transport properties. However, the perpendicular magnetic anisotropy (PMA) of the magnetic films is difficult to be achieved when they are directly deposited on perovskite oxide substrates according to literature research,[1] therefore, related devices for example spin orbital torques (SOT) induced magnetization switching device cannot be realized.[2] The control of interfacial structure and oxidation state of magnetic elements by oxygen migration is effective in tailoring the magnetic properties.[3] Here, we study the effect of $CaTiO_x$ spacer on $SrTiO_3$(STO)/$CaTiO_x$/Co/Pt films and Both magnetization vs. magnetic field (M-H) and Hall resistivity vs. magnetic field (R-H), as shown in Figure 1, at different temperature are measured. It can be found that the spacer can improve the PMA of magnetic films. By varying the spacer thickness, the PMA to planar magnetic anisotropy transition temperature can also be tailored. The high resolution transmission electron microscopy (HR-TEM) image of the film suggests the $CaTiO_x$ layer is amorphous while Co/Pt layer is polycrystalline, as shown in Figure 2. The energy dispersive X-ray spectroscopy (EDS) and electron energy loss spectroscopy (EELS) in TEM are also used to study the chemical stoichiometry of the films. The X-ray photoelectron spectroscopy (XPS) indicates the Co valence state is reduced by insertion of $CaTiO_x$ between Co and $SrTiO_3$. Our results suggest the $CaTiO_x$ spacer can stabilize the metallic state of ultrathin Co and strengthen the PMA. More importantly, the $CaTiO_x$ compound is more compatible with functional perovskite oxides than other oxides such as MgO which is normally used to achieve PMA of magnetic layer, therefore, amorphous or epitaxial $CaTiO_x$ layer could serve as a good spacer layer to achieve the integration of the single crystalline perovskite functional films and metallic magnetic devices, and further tuning of spin transport properties by functionalities from perovskites, such as nonvolatile electric field modulation of SOT.

BQ-12. Magnetic bipolar transistor based on ZnO/NiO/Si Heterostructure using Pulsed Laser Deposition. H. Kaur[1], M. Sharma[2], R.K. Ghosh[2], S. Mohapatra[1] and *B.K. Kuanr*[2] *1. Indrapratha University, New Delhi, India; 2. Special Centre for Nanoscience, Jawaharlal Nehru University, Delhi, India*

With the advent of technology, a magnetic transistor could be the potential candidate for non-volatile data storage and improved device performance as compared to traditional transistors [1]. Transition metal oxides (TMOs) have attracted much attention due to their unique properties for new generation electronics [2]. In this work, a magnetic bipolar transistor was fabricated by growing p-NiO and n-ZnO thin films on n-type silicon wafer by pulsed laser deposition technique with in-situ annealing at 670° C in the presence of oxygen. The structural characterization of these films was done by X-ray diffraction (XRD), and Raman spectroscopy, optical properties of the deposited films were done by UV-visible spectroscopy, and magnetic properties were studied by vibrating sample magnetometer (VSM). The I-V characteristics of the fabricated transistor were tested in common emitter (CE[L1]) configuration with DC biasing. Junction parameters such as ideality factor, barrier height, series resistance, q-point, and amplification gain were determined by using conventional output characteristics. The ideality factor and barrier height for NiO/Si is calculated to be 0.056 and 0.09 eV and for ZnO/NiO is 0.202 and 0.32 eV respectively. Interestingly, the anti-ferromagnetic semiconducting nature of NiO in the presence of oxygen vacancies basically helped in spin-polarized bipolar transport in these devices [3, 4]. The diode and transistor showed a linear increase in current with the applied magnetic field and therefore the current amplification in these devices can be controlled by spin; making attractive for spintronic applications.

BQ-13. Ferroelectric polarization control of the Hall resistance in $BiFeO_3/SrRuO_3$. *Z. Ren*[1], J. Miao[1], P. Liu[1], K. Meng[1], J. Chen[1], X. Xu[1] and Y. Jiang[1] *1. School of Materials Science and Engineering, University of Science & Technology Beijing, Beijing, China*

$SrRuO_3$ (SRO) is a complex oxide perovskite with itinerant ferromagnetism, which has fascinating properties originating from the strong spin-orbit coupling.[1] Most interestingly, the temperature dependence of Hall resistance (R_{xy}) is not only nonmonotonic, but also the sign will change at a critical temperature. It can be attributed to the change of electron distributions around Fermi energy.[2] The electron distributions around Fermi energy or the Fermi level position can also be affected by ferroelectric polarization, this raises the possibility of electrically modulating the R_{xy} in SRO. The sample of $(La_{0.3}Sr_{0.7})MnO_3$ (LSMO) (10 nm)/$BiFeO_3$ (BFO) (100 nm)/SRO (20 nm) was epitaxially grown on atomically-flat $SrTiO_3$(001) substrate by pulsed laser deposition (PLD), the bottom layer of LSMO (10 nm) is as the bottom electrode. We measured the R_{xy} by sweeping the magnetic field Hex perpendicular to the sample surface from 50 K to 120 K. Fig. 1 shows temperature dependence of R_{xy}-H in SRO/BFO, it is obvious that R_{xy} is nonmonotonic. To investigate the polarization-field-induced effects on the Rxy of heterostructure BFO/SRO, the gate voltage with +/- 9V (upward/downward polarization of BFO) in the Hall bar was applied. Fig.2 shows the Rxy of initial state, oppositely switched state and reversibly switched state for heterostructures, when ferroelectric polarization is from upward to downward, decrease of R_{xy} are clearly observed. When ferroelectric polarization is switched back to the original state, R_{xy} are indeed switched back to the initial state. These results confirm that the R_{xy} are mainly modulated by the ferroelectric polarization along the out-of-plane direction. In summary, the polarization-field-induced effects on the Rxy of heterostructure BFO/SRO were investigated. We found that both the magnitude and sign of R_{xy} can be modulated by manipulating the polarization of BFO.

Magneto-electric coupling enables us to control the magnetic properties of magnetic materials by voltage *i.e.* electric field which is one of the key requirements for realizing ultralow power spintronics devices. One of the most promising phenomena is the recently discovered electric field controlled magnetic anisotropy (ECMA), generally observed at the interface between 3*d*-ferromagnet (FM) and oxide [1]. Among them, the CoFeB/MgO interface has gained great attention. Generally, SW properties are modulated by charge current induced method which produces unavoidable Joule heating. However, ECMA can be used to modulate SW properties at ultralow power consumption. Here, we report an experimental study on the modulation of propagating SW frequency in ultrathin $Co_{20}Fe_{60}B_{20}$ (CoFeB) films by tuning interfacial perpendicular magnetic anisotropy (iPMA) by an electric field applied through a top metal gate electrode. The devices were fabricated by a combination of UV-maskless photolithography and electron beam lithography from heterostructures: Ta(10nm)|CoFeB(t = 1.6, 1.8, 2.0 nm)|MgO(2nm)|Al_2O_3(10nm), deposited on Si/SiO_2 substrate by rf magnetron sputtering [2]. The SW signals are detected by measuring inverse spin Hall effect voltage (V_{ISHE}) across the Ta layer underneath CoFeB films (Fig. 1(a)). Figure 1(b) shows a typical SW signal measured as a function of frequency for 2 nm-thick CoFeB film at $\mu_0 H_{ext}$ = 160 mT. To modulate SW frequency, a dc gate voltage is applied from a voltage source. Figure 1(b) shows that the resonance frequency either decreases or increases under the application of negative or positive gate voltages due to the increment or decrement of iPMA with negative or positive gate voltages. We have also measured SW signals from other lower thicknesses of CoFeB films and observed significant modulation of SW frequency with gate voltage (V_{DC}) due to the higher magneto-electric coefficient.

BQ-15. High-speed write error rate evaluation of a voltage-torque magnetic random access memory cell. *S. Tamaru*[1], T. Yamamoto[1], T. Nozaki[1] and S. Yuasa[1] *1. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan*

Voltage-torque magnetic random access memory (VT-MRAM) based on a magnetic tunnel junction (MTJ) is a promising candidate for the next generation solid state memory. In VT-MRAM, the free layer magnetization is toggled by applying a short voltage pulse to the MTJ cell to excite coherent precession over half cycle[1]. The resistance of a VT-MRAM cell is very high, typically of the order of 100 kΩ. These properties result in very fast and low power write operations. However, they adversely affect the read speed. Therefore, the maximum write error rate (WER) evaluation speed in the conventional system is about 4 kbps, which is too slow because the WER has to be lower than 10^{-10} for practical applications[2]. To overcome this problem, we developed a high-speed WER evaluation system, whose block diagram is shown in Figure 1[3]. In the new system, a high-speed semiconductor analog switch (SW) switches the connection to the MTJ cell between the read and write channels, and a custom amplifier/comparator circuit is directly connected to the SW to detect the magnetization state of the MTJ cell with a minimum time constant. Figure 2 shows the waveform of the amplifier output observed when the WER is evaluated at 500 kbps. During the write cycle, the waveform stays 0 V. When the system transitions from the write to the read cycle, the waveform first discontinuously jumps due to charge injection of the SW, then converges to either high or low level depending on the magnetization state of the MTJ cell. The figure shows that the waveform has a large enough read window at the end of the read cycle.

This result confirms that it can actually evaluate the WER at 500 kbps, which is 2 orders of magnitude faster than the conventional system. In the presentation, the detail of the WER evaluation system, including the design guideline, the factors limiting the WER evaluation speed and some strategies for further enhancing the speed.

BQ-16. Voltage-induced switching with long tolerance of voltage-pulse duration in a perpendicular MRAM. *R. Matsumoto*[1], T. Sato[1,2] and H. Imamura[1] *1. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; 2. Department of Electrical and Electronic Engineering, Faculty of Engineering, Chiba Institute of Technology, Narashino, Japan*

Voltage-induced magnetization switching [1-5] has been attracting a great deal of attention because it enables low-power-consumption writing in magnetoresistive random access memory (MRAM), but this writing method requires the adjustment of the voltage-pulse duration (t_p) to obtain low write error rate (WER). The range of t_p where WER is below 1×10^{-3} has been only several hundred picoseconds [4, 5]. We call this range of t_p as the tolerance of t_p just for convenience. The long tolerance of t_p is desirable because of the distribution of t_p from pulsed power supply in MRAMs and the distribution of precession periods among the MRAM cells. In this study [6], we theoretically investigate the voltage-induced magnetization switching with the long tolerance of t_p [1] in a perpendicular MRAM cell shown in Fig. 1(a). Before and after the voltage pulse, the free layer is relaxed at $K_{eff}^{(pre)}$ = 70 kJ/m^3 and $K_{eff}^{(post)}$ = 40 kJ/m^3. Here K_{eff} is the effective perpendicular anisotropy constant including the demagnetization energy and $K_{eff}^{(+V)}$ in Fig. 1 represents K_{eff} during t_p. In Fig. 1(b), types of the magnetization dynamics at 0 K are classified in $K_{eff}^{(+V)}$ – the Gilbert damping (α) space. Between the two solid curves, the switching with the long tolerance of t_p is available by utilizing the damping torque. Even under thermal agitation at 300 K, WER lower than 10^{-3} is obtained in 0.5 ns ≤ t_p ≤ 10 ns (see Fig. 1(c)). The tolerance of t_p is much longer than 1 ns. We will also show that WER can be reduced by increasing the external magnetic field (H_{ext}) and/or decreasing θ (see Fig. 1(a)) with increasing $K_{eff}^{(pre)}$. This work was partly supported by the ImPACT Program of the Council for Science, Technology and Innovation, and JSPS KAKENHI Grant No. JP16K17509.

Switching of magnetization direction between two stable states separated by an energy barrier is one of the most important processes for magnetic recording and information storage [1]. This is conventionally done by applying an external magnetic field or spin polarized currents. One way to reduce the energy required for magnetization switching while maintaining sufficiently high magnetic anisotropy energy is to control the magnetization direction by other means than the external magnetic field or charge current. An electric field-control of magnetic anisotropy is a promising candidate. We anticipate that this can be accomplished in (Ga,Mn)N-based structures, in which the magnitude and the sign of magnetic anisotropy can be changed by appropriate material engineering and by an electric field. Recently, we have shown that a strong coupling between piezoelectricity and magnetism exists in paramagnetic $Ga_{1-x}Mn_xN$ with x = 0.025 [2]. In these piezoelectric systems a voltage V applied across the crystal strains it linearly. This in turn deforms the crystal field which surrounds the magnetic ions and so modifies their magnetic anisotropy. Now, by using molecular beam epitaxy grown structures we investigate the magnetoelectric effect at $T \geq 2$ K in the ferromagnetic state. We observe an electric field-induced decrease of coercivity, shown in the Fig. 1, and a non-reversible magnetization switching for magnetic fields close to the coercive field (not shown). The work is supported by the National Science Centre, Poland, through projects DEC-2018/31/B/ST3/03438, DEC-2011/02/A/ST3/00125, DEC-2016/23/B/ST3/03575

and DEC-2014/12/S/ST3/00549. We also acknowledge the access to the computing facilities of the Interdisciplinary Centre for Mathematical and Computational Modelling at the University of Warsaw.

BR-01. Fabrication and characterization of YIG nanotubes. X. Zhang[1], S. Parajuli[1], J. Feng[1], G. Yu[1] and *X. Han[1] 1. Chinese Academy of Science, Instite of Physics, Beijing, China*

We have successfully synthesized Y3Fe5O12 (yttrium iron garnet, YIG) nanotubes (NTs) of different diameters using a conventional sol-gel method in anodized aluminum oxide (AAO) templates. An annealing process at 800 °C is performed to get a pure phase of YIG. The room-temperature magnetization measurements show that the coercivity decreases significantly as the diameter of nanotubes increases. The temperature dependence of magnetic moments in field-cooled (FC) and zero-field-cooled (ZFC) modes indicates that YIG NTs transform from ferromagnetic-like (FM-like) state to superparamagnetic (SPM) state when temperature decreases (in the region of 310 K–400 K). The Blocking temperature dramatically decreases as the size of YIG NTs reduces. In the FM-like state, the temperature-dependent coercivity in three different samples yields a 1/2 power law of the temperature. The temperature dependence of saturation magnetization in three different samples can be well fitted to Bloch's T3/2 law. Characterization of ferromagnetic resonance (FMR) is conducted, which indicates the Gilbert damping parameter of YIG NTs is around $7\sim9 \times 10^{-3}$.

BR-02. The effect of gadolinium substitution in inverse spinel Nickel Ferrite: structural, magnetic, and mossbauer study. *T.P. Poudel*[1], B.K. Rai[2], S. Yoon[3], D. Neupane[1], D. Guragain[1] and S.R. Mishra[1]
1. Department of Physics and Material Science, University of Memphis, Memphis, TN, United States; 2. Oak Ridge National Laboratory, Oak Ridge, TN, United States; 3. Gunsan National University, Gunsan, The Republic of Korea

Nickel ferrite is an inverse spinel ferrite with nickel ions located at the B site the iron ions at both A and B sites. $NiFe_2O_4$ is regarded as a superior candidate for microwave devices and sensor application because of high resistivity and intermediate magnetization. Any change in cationic distribution can alter their cationic distribution, and hence, one can achieve the required change in magnetic and dielectric properties. Doping the parent spinel ferrite with rare-earth ions leads to structural disorder and lattice strain, thereby enhancing the electrical and magnetic parameters. The rare-earth element, Gadolinium, doped $NiGd_xFe_{2-x}O_4$ ($0<x<0.1$) materials were synthesized using the sol-gel route. X-ray diffraction analysis (XRD) showed that the specimens exhibited a single-phase spinel structure up to $x = 0.1$. The lattice parameter and induced strain increased with an increase in the Gd^{3+} content. The magnetic parameters derived from hysteresis loops show a decrease in saturation magnetization (Ms) and coercivity (Hc) value with Gd^{3+} substitution and reaching a minimum value of Ms ~ 39 emu/g and Hc ~ 110 kOe at $x = 0.1$. The magnetocrystalline anisotropy, as determined from the Law of Approach to saturation magnetization, is observed to be highest for $x = 0.1$ at 5K with the value $K1 \sim 1.53 \times 10^6$ J/m^3. The Curie temperature decreased to 898 K at $x = 0.1$ from 918 for $x = 0.0$. Hyperfine parameters were derived from fitting Mössbauer spectra. The Mossbauer spectral analysis indicated that iron was in the Fe^{3+} state, the magnetic hyperfine field at both the sites tended to decrease, and isomer shift of B site increased while that of A site remained invariant with an increase in the Gd^{3+} content. Furthermore, migration of Ni^{2+} from B site to A site was observed with the increase in the Gd^{3+} occupancy at the B site in the sample. The structural, magnetic, and Mossbauer results are elucidated by the occupancy of Gd^{3+} at the octahedral (B) site in the inverse spinel $NiFe_2O_4$ ferrite. Our study suggests that with the judicious Gd^{3+} doping in Ni-ferrite, soft ferrite properties can be enhanced for potential application in radio and microwave range application.

BR-03. Enhanced magnetic and magnetodielectric properties of Al-doped gallium ferrite nanoparticles. *T. Han*[1], Z. Tu[1] and Y. Huang[1]
1. Department of Applied Physics, National University of Kaohsiung, Kaohsiung, Taiwan

Gallium ferrite, $GaFeO_3$ (GFO), has ferrimagnetic (FM) and piezoelectric orderings and has been intensively studied recently for its potential application as a magnetoelectric ferrimagnet [1]. Site-disorder in bulk GFO is reported to be induced by adopting different preparation methods, which are shown to affect the magnetic properties significantly [1-3]. Moreover, the physical properties of GFO at reduced grain sizes remain underexplored due to the challenges associated with their synthesis with a proper control over the crystalline phase. In addition, the origin of the doping effects on the correlation between the site-disorder and magnetism in the nanosized GFO system has not yet been completely established. Therefore, it is worthy to explore the possibility of tuning the magnetic properties of doped GFO nanoparticles. In this work, we prepare a series of $Ga_{1-x}Al_xFeO_3$ (GAFx) ($0 \le x \le 0.5$) nanoparticles by the sol-gel method to systematically study the effect of Al-doping on their structural, magnetic, and magnetodielectric (MD) properties. The X-ray diffraction pattern analysis indicated that all samples have an orthorhombic structure with $Pc2_1n$ space group. Al substitutions slightly modify lattice parameters and induce lattice distortion within the same crystalline structure. The average grain sizes of the GAFx nanoparticles are around 28 nm. Interestingly, the magnetic characterization indicates that with increasing Al-content, up to 0.5, the FM transition temperature (T_C) increases from 310 to 350 K. The magnetization has been enhanced due to doping of Al^{3+} in GFO compared to that of the pristine sample. The cause of magnetic enhancement could be explained from the modification exchange interaction due to the substitution of smaller size cations of Al^{3+} in place of relatively larger size cations of Ga^{3+}. The dielectric constant of each GAFx sample is strongly perturbed by the external magnetic field. It is to be noted that the value of MD increases in the Al-doped samples for different applied magnetic fields. Furthermore, the simultaneous improvement of magnetic behavior and MD coupling effect in Al-doped GFO are prominent candidates for the applications of room temperature multiferroic devices.

BR-04. Tailoring of Magnetic Spectra of Magneto-Dielectric Composites by Grain and Particle-Size Distributions of Ferrite Inclusions. *Q. Li*[1], Y. Chen[2] and V. Harris[1] *1. Department of Electrical and Computer Engineering, Northeastern University, Boston, MA, United States; 2. Innovation Center, Rogers Corporation, Burlington, MA, United States*

Magneto-dielectric composites, in the form of magnetic particles dispersed in an electrically insulating matrix, are promising candidate materials for high frequency applications, such as VHF up to 5G wireless communications.[1] Such magneto-dielectric materials require particularly high permeability and low magnetic loss, which are closely related to both the grain size and the particle size of the magnetic fillers.[2,3] This work reports an extended effective medium theory (EMT) including the grain-size distribution and the particle-size distribution to predict the magnetic spectra of magneto-dielectric composites. Starting with solving the frequency response of domain wall motion, the grain-size dependent dynamic susceptibility of a ferrite grain is derived.[4,5] Figure 1 shows the theoretical permeability spectra of Co-Ti substituted M-type barium ferrites with grain sizes of 5, 10 and 15 μm, respectively. Then, the permeability spectrum of the polycrystalline ferrite is calculated from a model of crystalline ferrite grains with a certain size distribution surrounded by thin, non-magnetic grain boundaries. The effective permeability of the magneto-dielectric composite is finally obtained from the extended EMT formula considering the particle-size distribution of ferrite inclusions. The proposed EMT formula is experimentally verified by the measured permeability spectra of Co-Ti substituted M-type barium ferrite ($BaCo_{1.15}Ti_{1.15}Fe_{9.7}O_{19}$)/paraffin composites prepared by the conventional ceramic process with specifically designed grain-size and particle-size distributions. Taking the grain-size dependent intrinsic permeability into consideration, the modified EMT formula describes a more accurate model to predict the effective permeability of magneto-dielectric composites filled with polycrystalline ferrite particles over a wide frequency range. It also provides an effective tool to optimize the magnetic properties of magneto-dielectric composites by tailoring both the grain-size and the particle-size distributions of the ferrite inclusions in various polymer matrices.

BR-05. Impedance Engineered Ultra-High Frequeny Low-Loss Co_2Z Ferrite Composites for Broadband RF Applications. *P. Kulik*[1], G. Winter[1], K. Murphy[1], J. Adams[1], O. Obi[2] and V. Harris[1] *1. ECE, Northeastern University, Boston, MA, United States; 2. Kostas Research Institute at Northeastern University, Burlington, MA, United States*

The demand for miniaturized and high performing broadband communication systems in the GHz frequency range is steadily growing due to severely crowded and rapidly changing modern commercial and military spectral environments. Hexaferrite composites have proven to be one of the few key enablers in providing miniaturized form factors due to their high permeability and permittivity as well as their capability to reach high resonance frequencies up to 100 GHz [1]. In this work, we demonstrate a broadband and low loss ferrite composite engineered for equivalent permittivity and permeability at 0.2-1.2 GHz. For the first time in $\mu = \varepsilon$ engineered Co_2Z hexaferrites, single domain grains are controlled to less than 1 μm allowing reduction in losses. Additionally, co-polymers of isobutylene and maleic anhydride (ISOBAM) were employed to achieve theoretical densities (~5.37 g/cm^3, Co_2Z ferrite [2]). Polycrystalline Co_2Z ferrites, having a nominal composition of $Ba_3Co_{2+X}Ir_XFe_{24-2X}O_{41}$, where x=0 to x=.1, were prepared by a solid-state process. $BaCo_3$, IrO_2, Co_3O_4, and Fe_2O_3 of high purity were mixed and calcined in oxygen for 5-8 hours at 900-1000 °C, which then were ball milled for 18-24 hours to reduce the grain size to under 1 μm. The grain size was measured by scanning electron microscope as shown in Fig. 1. After ball-milling, ISOBAM was added as a binder and mixed for several minutes. Samples were then pressed to form toroids with an inner diameter of 3 mm and an outer diameter of 7 mm. The toroids were pressed by a cold isostatic press in order to maximize compaction before sintering in oxygen for 4-6 hours at 1000-1250 °C. Finally, samples were measured using the Agilent E864A PNA and a 7 mm precision airline. Samples showed a density of 5.36 g cm^{-3} which is 99% of the theoretical density. Low magnetic loss tangents were achieved as shown in Fig. 2. These results show that a nine-time reduction in size can be achieved while maintaining an impedance of 360 Ω close to that of free space over a broadband.

BR-06. Epitaxial magnesium aluminum ferrite films grown by magnetron sputtering. *M. Mishner*[1], A. Jara[1] and I. Krivorotov[1] *1. Physics and Astronomy, University of California, Irvine, Irvine, CA, United States*

Thin films of magnetic insulators are extensively used in nano-magnonics and spin caloritronics. Up to date, most research efforts in these fields employ films of yttrium iron garnet (YIG). While much progress has been made using YIG-based devices, YIG is not ideally suited for patterned magnonic crystals due to its low saturation magnetization, which results in weak dipolar interactions among individual nanomagnets of the crystal. Therefore, epitaxial films of magnetic insulators with high saturation magnetization and low damping are highly desirable. Recently, growth of thin films of magnesium aluminum spinel ferrite $MgAl_{0.5}Fe_{1.5}O_4$ (MAF) with high saturation magnetization and low damping by pulsed laser deposition was reported [1]. Here we have developed a method for growth of epitaxial thin films of MAF by radio-frequency magnetron sputtering. MAF films were deposited onto lattice-matched (001)-oriented $MgAl_2O_4$ substrates from a stoichiometric target in a mixture of Ar and O_2 gases. We varied the partial pressures of O_2 and the substrate temperature to optimize epitaxial growth of the MAF films. At the substrate temperature of 550°C, high quality epitaxial growth is achieved as evidenced by the appearance of strong Laue oscillations in θ-2θ X-ray diffraction scans and rocking curve full-width-at-half-maximums of 0.04° for an 18 nm thick MAF film as shown in Fig. 1. Ferromagnetic resonance measurements made as a function of magnetic field angle in the film plane reveal high effective saturation magnetization $4\pi M_{eff}$ = 15.2 kOe, g = 2.01 ± 0.04 and an in-plane cubic anisotropy field of H_a = 933 Oe. A g-factor near 2.0 verifies that the films show minimal spin-orbit coupling needed to achieve low magnetic damping. We will discuss the dependence of Gilbert damping parameter on the film growth conditions and post-annealing treatment.

BR-07. Di-valent doping effect on structural and magnetic properties of nanocrystalline $Pr_{0.7}Ba_{0.2}Sr_{0.1}MnO_3$. *M. .*[1], A. Gaur[1] and R.N. Mahato[1] *1. School of Physical Sciences, Jawaharlal Nehru University, New Delhi, India*

Nowadays, magnetic refrigeration (MR) technology is considered as an alternative to the conventional vapor pressure cycle, due to its environmental-friendly nature and higher cooling efficiency [1]. The basic principle of the magnetic refrigeration technology is the magnetocaloric effect which can be defined as the change in entropy of a magnetic material on applying the magnetic field. The magnetocaloric effect (MCE) is characterized mainly by the isothermal magnetic entropy change (ΔS_M) and the relative cooling power (RCP). Thus, it is of great importance to search the magnetic materials which can possibly exhibit large values of magnetic entropy changes close to the room temperature at lower applied fields. In the present work, we have synthesized the nanocrystalline $Pr_{0.7}Ba_{0.2}Ca_{0.1}MnO_3$ sample using the sol-gel method. The Rietveld refinement of the X-ray diffraction (XRD) pattern (recorded at room temperature) confirmed the formation of the rhombohedral crystal structure with space group. The temperature dependent magnetization M(T) measurements suggested that the sample undergo paramagnetic to ferromagnetic phase transition and the Curie temperature was found to be ~ 128 K and M(T) plot is shown in Fig. 1. The field dependence of magnetization M(H) data at 2 K showed the formation of hysteresis loop which

indicates the presence of ferromagnetism in the sample at lower temperatures and the linear behavior of M(H) at 300 K confirms the paramagnetic nature of the sample at room temperature. The slopes of the Arrott plots for the present sample are positive indicating the second order of magnetic phase transition, as per the Banerjee criterion [2]. The maximum value of magnetic entropy change and relative cooling power (RCP) were found to be ~2.3 J $kg^{-1}K^{-1}$ and 230 Jkg^{-1} for a field change of 5 T. The relatively large values of $|\Delta S_M|$ and RCP make the present compound promising for magnetic refrigeration technology.

BR-08. Tunable high-frequency magnetic and dielectric properties of NiZnCo ferrite/resin magneto-dielectric composites. *Z. Zheng*[1], Z. Xiong[1], X. Wu[1] and Q. Feng[1] *1. School of Information Science and Technology, Southwest Jiaotong University, Chengdu, China*

Nowadays, as the rapid development of electronic and communication technology, the various devices are developing towards miniaturization and lightweight, especially the devices with small size and high performance are ever increasingly demanded. A challenge in this process is that the reduced size of device often produces performance degradation due to the fact that the performance of many devices is dependent on their size. In recent years, magneto-dielectric ferrite materials have received considerable attention and show unique advantage for miniaturized and high-performance radio frequency (RF) and microwave devices, such as in the applications of antennas, EBG structures, LC filters, oscillators, magnetic sensors, etc. In this work, a series of magneto-dielectric composite materials that consist of NiZnCo ($Ni_{0.5}Zn_{0.3}Co_{0.2}Fe_2O_4$) spinel ferrites and low-loss resin (weight ratio x = 0, 2, 4 and 6 wt% respectively) are synthesized for their potential applications as novel high-frequency magneto-dielectric materials. The magnetic and dielectric properties of the samples are investigated over a wide frequency range of 0.1–5 GHz. It is revealed that the permeability and permittivity are significantly tunable through the variation of composite ratio. With increasing x from 0 to 6 wt%, μ′ and permittivity ε′ are varied in the range of about 2.0~6.5 and 5.0~8.5 respectively. These variations are carefully analyzed based on the magnetic circuit model and effective medium theory. Correspondingly, the magnetic losses and impedance performances are effectively modulated. The microstructure and densification of the composite samples are also analyzed in detail to correlate with the variations of the magnetic and dielectric properties.

Spinel ferrite thin films have been widely studied from the past few decades because of their potential applications in the microwave and high-frequency device fabrications. These materials possess low coercivity, high saturation magnetization, and high remnant magnetization. Here, we report the epitaxial growth of $NiFe_2O_4$ thin films on two different isostructural substrates i.e. $MgGa_2O_4$ (MGO) and $ZnGa_2O_4$ (ZGO) using pulsed laser deposition technique. These substrates have lattice mismatch of 0.62% and 0.04%, respectively with bulk $NiFe_2O_4$. Our result shows that the films on $MgGa_2O_4$ substrate have considerable strain because of the tetragonal distortion in the crystal structure, whereas the films on lattice matched $ZnGa_2O_4$ substrate are free of strain and cubic in structure. The magnetometry data suggests that the film strain is the principal factor for magnetic anisotropy contribution in $NiFe_2O_4$ film. Moreover, we show that the reduction in magnetic strain anisotropy greatly impacts the effective Gilbert damping constant obtained from ferromagnetic resonance (FMR) measurement. We further show that there is an enhancement in spin voltage generation in spin Seebeck effect (SSE) experiment as a combined effect of lower damping and lower film strain.

BR-10. Magnetic Properties of Polycrystalline Y-type Hexaferrite $Ba_{2-x}Sr_xNi_2(Fe_{1-y}Al_y)_{12}O_{22}$ using Mössbauer Spectroscopy. *J. Kim*[1], H. Choi[1] and C. Kim[1] *1. Kookmin University, Seoul, The Republic of Korea*

Synthesis of the polycrystalline $Ba_{2-x}Sr_xNi_2(Fe_{1-y}Al_y)_{12}O_{22}$ (x = 0.0, 1.5, y = 0.00, 0.01, 0.03) was accomplished by the polymerizable complex method. The samples were investigated for the crystallographic and the magnetic properties by x-ray diffraction (XRD), vibrating sample magnetometer (VSM), and Mössbauer spectrometer. The Mössbauer spectra were obtained by a conventional spectrometer with a ^{57}Co source in a Rh matrix in the temperature range from 4.2 to 295 K. From refined XRD patterns, all samples were confirmed of the rhombohedral structure with space group *R*-3*m*. Also, we were able to identify six distinguish sublattices, which are four octahedral sites ($18h_{VI}$, $3b_{VI}$, $6c_{VI}$, and $3a_{VI}$) and two tetrahedral sites ($6c_{IV}$*, $6c_{IV}$). The lattice constant of a_0 and c_0 decrease by Sr, Al substitution because the ionic radius of Sr^{2+} (1.12 Å) is smaller than that of Ba^{2+} (1.34 Å) and the ionic radius of Al^{3+} (0.535 Å) is smaller than that of Fe^{3+} (0.645 Å). The zero-field-cooled (ZFC) measurement between 4.2 and 295 K applied 100 Oe shows that spin transition temperature (T_S). Substitution of Sr ions increased T_S. Al ions were further substituted after Sr ions were substituted, and T_S increased to around room temperature. The Mössbauer spectra were fitting six distinguish sublattices: $18h_{VI}$, $3b_{VI}$, $6c_{VI}$, $6c_{IV}$*, $6c_{IV}$, and $3a_{VI}$. The measured isomer shift of all samples indicated that the charge state of Fe ions is Fe^{3+}. The Mössbauer spectra according to temperature change confirmed the changes in the magnetic hyperfine field curves at T_S.

BR-11. Static and dynamics magneto-viscoelasticity in $Co_{1-x}Zn_xFe_2O_4$ ($0 \le x \le 1$) based magnetic nanofluid. *A. Singh*[1], A. Rathi[1], P. Kumar[1], R. Pant[1], G. Basheed[1] and K.K. Maurya[1] *1. Indian reference Material (BND), AcSIR-National Physical laboratory, New Delhi, India*

The study of rheological characteristics of magnetic nano-fluid plays an important role in device development, as magnetic control on fluid behavior is a promising field in numerous applications. The present work investigates the magneto viscoelastic behavior of Zn substituted cobalt ferrite based magnetic fluid synthesized by surface modified chemical Co-precipitation route. The crystalline spinel phase and purity of all the samples have been confirmed by X-ray diffraction (XRD) and High-resolution transmission electron microscopy (HRTEM). The crystallite size calculated by W-H methods which are corroborated with HRTEM. The room temperature magnetic measurements confirm systematic decrease in saturation magnetization. Although for x = 0.4 the decrease is slightly low as compared to other composition. This has been confirmed from viscoelastic measurements performed in dynamics and oscillatory mode using magentorheometer. The steady-state rheograms (viscosity vs shear rate curve) shows a decrease in dynamics viscosity behavior with the increase of Zn substitution. The rheograms for all compositions are well fitted with power-law confirming the shear thinning behavior with n ≤1. Also from magneto-sweep rheograms (viscosity vs magnetic field), we have found that the steady increase in viscosity with increase in magnetic field is due to the formation of a chain like structure which causes an interruption in smooth streamline flow of the MNFs. With a small addition of Zn, we have observed a drastic decrease in the viscosity of fluid behavior. Field-induced viscoelastic behavior of Co-Zn MFs in static and dynamic mode provides significant information for optimization of MNFs for various applications

BR-12. Study of complex permeability spectra of Co-substituted Ni-Zn ferrite composites and processing of ferrite thin sheets for RF applications. *P. Lathiya*[1] and J. Wang[1] *1. Electrical Engineering, University of South Florida, Tampa, FL, United States*

Introduction: With the recent advancements related to imminent rollout of 5G and IoT technologies, there is a growing demand for soft magnetic materials for different applications such as radio frequency circuits, antennas, isolators, circulators, and interference suppressors etc. Ni-Zn ferrites exhibit excellent soft magnetic properties such as high resistivity, high permeability and low magnetic loss for both low and high frequency applications. To meet the performance specifications for aforementioned applications, thin Ni-Zn sheets with a high permeability and low magnetic loss is desired. In this work, we present a new method to prepare thin Ni-Zn ferrite sheets with high permeability and low magnetic loss. More specifically, Co-substitution was used to achieve desired properties of Ni-Zn powders and thin sheets were prepared subsequently using a doctor blade coater. Experimental Section: Co-substituted (Co: x-0.2, 0.18, 0.15) $Ni_{0.65-x}Co_xZn_{0.35}Fe_2O_4$ ferrite was synthesized by a conventional solid-state method. The calcined granular powders were mixed with 5 wt% PVA binder to make cylindrical test samples and sintered in air at 1100 °C. For the preparation of thin Ni-Zn ferrite sheet, PVA was used as the binder and the thin sheets were obtained using a doctor blade coater. Results: Substitution of Cobalt in Ni-Zn ferrite increases the real part of permeability from 6.5 (x=0.20) to 8.5 (x=0.15) at 250 MHz. Similarly, the imaginary part of permeability increases from 0.12 to 0.24. An increase in magnetic loss from 0.18 to 0. 28 is observed as the amount of cobalt is decreased from 0.2 to 0.15. Further increase of Cobalt to substitute Nickel decreases the real part of permeability. Conclusion: The variation in composition for Ni-Zn and doping strongly influence the dynamic magnetic properties of the soft magnetic ferrites. The cobalt substitution has exhibited a direct effect on combined high permeability and low magnetic loss of ferrites at RF and microwave frequencies. Future work: Further experiments will be conducted on thin sheets to measure FMR frequency and loss measurements using strip-line cavity method. Also, we are exploring the process methodology of 3D printing Ni-Zn ferrites using PVA binder.

BR-13. Precursor effects and field-induced short-range order above the Verwey transition in single Fe_3O_4 crystals. C. Boekema[1] and *C. Morante*[1] *1. Physics & Astronomy, San Jose State University, San Jose, CA, United States*

The internal fields in single crystals of magnetite (Fe_3O_4) have been previously studied through muon-spin rotation (μSR). [1] By Maximum-Entropy (MaxEnt, ME) μSR [2] we analyze Fe_3O_4 μSR data with external fields parallel to the <111>, <110> or <100> axis. We optimize the ME peak-to-noise ratio by varying the filter time and time interval. [2] Several μSR time series indicate a beat pattern. Using MEμSR, a second frequency signal is seen at *non-zero* fields in the temperature range above the Verwey transition (T_V= ~123 K). At zero field, MEμSR confirms with much improved precision the existence of one frequency signal found earlier [1] by curve fitting (CF) and Fourier transformation (FT). We compare our room temperature (RT) field-dependent MEμSR results for <110> Fe_3O_4 with those found at 205 K to study a second order phase transition at the Wigner temperature (T_W= ~247 K). At RT and 205 K for fields below the demagnetization field and parallel to <110> Fe_3O_4, a second MEμSR frequency is observed, *missed* by CF and FT. These secondary magnetic fields fall on the extended magnetization curves below and above T_W. At RT a small field induces a short-range order similar to the precursor effects in the T_V– T_W interval. At 205 K within that precursor T-interval, we observe a comparable RT-disordered state. The existence of these additional internal fields are likely related to phonon-assisted 3d-electron(-spin) hopping and short-range order behaviors. [3] Our MEμSR studies lead to a better understanding of the local magnetism in this Mott-Wigner glass. [1, 3] Research is supported by DOE-LANL, AFC & SJSU.

BR-14. Wideband Square Spiral Metamatereial Absorbers Based on Flaky Carbony Iron/Epoxy Composites. *R. Yang*[1], J. Yang[1] and S. Lo[1] *1. Aerospace and Systems Engineering, Feng Chia University, Taichung, Taiwan*

Radar absorbing materials (RAMs) also known as microwave absorbers, which can absorb and dissipate incident electromagnetic waves by converting them to thermal energy, are widely used in the fields of radar-cross section reduction (stealth technology), electromagnetic interference reduction (EMI) and human health protection. Metamaterials (MMs) are artificial subwavelength periodic structures engineered to have properties that may not be found in nature. In this paper, a broadband and thin microwave absorber composed of metal-base planar metamaterials sandwiched between two layers of flaked-shaped carbonyl iron (FCI) composites is presented. FCI powder was prepared by ball milling spherical carbonyl iron powder and then added to epoxy resin to prepare FCI composite (FCIC) samples with different weight fractions. A coaxial transmission/reflection method is used to obtain the complex permittivity (ε′-jε″) and permeability (μ′-jμ″) of FCIC samples at 2-18 GHz. Figure 1 shows the complex permittivity and permeability of the FCIC with weight ratios of 30, 40, 50, 60 and 70 wt.% of magnetic fillers, respectively. With these electromagnetic characteristics, a broadband, polarization-insensitive and thin metamaterial absorber comprising of arrays of square spirals imbedded between two different layers of FCIC is optimally designed through a genetic algorithm. Figure 2 shows a schematic of bandwidth-enhanced metamaterial absorbers and the reflection loss of the optimally designed metamaterial absorbers with or without the embedded MM layer. The planar metamaterial is etched on a 0.1 mm-thick FR4 with each unit consisting of four identical spiral structures with different rotational angles to enhance the polarization insensitivity. The thickness of the upper layer (50 wt.% of FCI) is 1.93 mm and the bottom layer (70 wt.% of FCI) is 0.76 mm. The absorbing bandwidth below -10 dB is extended to from 4.8 GHz to 9.1 GHz with the embedded MM layer.

BR-15. Study of structural, electrical, and magnetic properties of rare-earth Tb^{3+} doped $NiFe_2O_4$ ferrite. *D. Guragain*[1], T.P. Poudel[1], B.K. Rai[2], S. Yoon[3] and S.R. Mishra[1] *1. University of Memphis, Memphis, TN, United States; 2. Oak Ridge National Lab, Oak Ridge, TN, United States; 3. Gunsan National University, Gunsan, The Republic of Korea*

$NiFe_2O_4$, a ferrimagnetic inverse spinel, has a high specific resistance, low losses in high-frequency applications, low coercivity, a moderate saturation magnetization with positive magneto-crystalline anisotropy. Doping the parent spinel ferrite with rare-earth ions leads to structural disorder and lattice strain, thereby enhancing the electrical and magnetic parameters. The present work delineates study on terbium doped $NiTb_xFe_{2-x}O_4$ ($0<x<0.1$) ferrite to understand the influence of a rare-earth ion (Tb^{3+}) on structural, electrical and magnetic properties of Ni-ferrites. We have successfully synthesized spinel type ferrites $NiTb_xFe_{2-x}O_4$ (x=0.0 to 0.1) by sol-gel auto combustion followed by heat treatment, and characterization is done by XRD, FTIR, SEM, SQUID, LCR meter and Mossbauer spectroscopy. The Rietveld analysis shows that the lattice parameter and induced strain increased with an increase in the Tb^{3+} content in the ferrite. The crystallite size decreased with increasing Tb^{3+} content due to grain refinement. The octahedral band in FTIR show a progressive variation with Tb^{3+} doping in Ni-ferrite. The magnetic parameters derived from the room temperature RT hysteresis loops show a decrease in saturation magnetization, from 54.9 emu/g (x=0) to 26.06 emu/g (x=0.1) and coercivity value from 164 Oe to 94 Oe at x = 0.1. A significance reduction in magnetization results from lattice distortion and magnetic dilution upon replacing Fe^{3+} with Tb^{3+}. The Curie temperature decreased from 921 at x=0 to 904 K at x = 0.1 due to weakening of Fe^{3+}-O^{2-}—Fe^{3+} super-exchange interaction, while the electrical resistivity peaked at $3x10^8$ for x=0.1. Hyperfine parameters were derived from fitting Mossbauer spectra at RT. The Mossbauer spectral analysis indicated that iron was in the Fe^{3+} state, the magnetic hyperfine field at both the sites tended to decrease, and isomer shift at B site increased while that of A site remained invariant with an increase in the Tb^{3+} content. Furthermore, migration of Ni^{2+} from B site to A site was observed with the increase in the Tb^{3+} occupancy at the B site in the sample. The structural, magnetic, and Mossbauer results are elucidated by the occupancy of Tb^{3+} at the octahedral (B) site in $NiFe_2O_4$.

BR-16. Withdrawn

BR-17. Temperature Dependence of Antiferromagnetic Coupling at the YIG-GGG Interface. *M. Roos*[1], B.J. Kirby[2], P. Quarterman[2], J. Ding[3], M. Wu[3] and B.L. Zink[1] *1. Physics and Astronomy, University of Denver, Denver, CO, United States; 2. Center for Neutron Research, NIST, Gaithersburg, MD, United States; 3. Department of Physics, Colorado State University, Fort Collins, CO, United States*

Yttrium iron garnet (YIG) is a ferrimagnetic insulator that has been extensively studied for spintronic applications due to its low Gilbert damping.[1] High quality ultra thin YIG with remarkably low damping is often grown and annealed on gadolinium gallium garnet (GGG) due to exceptional lattice matching. During the high temperature anneal gadolinium atoms embed into the YIG crystal, creating a thin Gd-infused layer ($(Gd_{1-x}Y_x)Fe_5O_{12}$). Recent evidence shows antiferromagnetic coupling between this interfacial layer and the crystalline YIG film.[2,3] In this work we use SQUID magnetometry and spin-polarized neutron reflectometry (PNR) to confirm antiparallel alignment of the interface layer and reveal complex temperature-dependent interactions between the GGG substrate, $(Gd_{1-x}Y_x)Fe_5O_{12}$ layer and YIG thin film. Neutron nuclear scattering of 20 nm crystalline YIG film grown on GGG[1] shows a roughly 3nm $(Gd_{1-x}Y_x)Fe_5O_{12}$ layer. PNR magnetization profiling describes antiparallel alignment of the $(Gd_{1-x}Y_x)Fe_5O_{12}$ up to room temperature for low fields, and enhancement of the interfacial antiferromagnetism with decreasing temperature. While magnetometry shows the magnetization closely agrees with literature for room temperature[2], we find a different temperature dependent evolution down to 2 K. Magnetometry reveals the GGG has field-dependent negative thermoremanent magnetization, and overall shows more complicated magnetism than a simple paramagnet at all temperatures studied. This is possibly related to defects in the substrate. The role of the $(Gd_{1-x}Y_x)Fe_5O_{12}$ interface layer's magnetic properties in ultra thin film spintronic devices is still an open question, as the impact of the GGG substrate to the interface dynamics is non-negligible. A more thorough characterization process of GGG might be important when selecting device substrates.

BS-01. Exploring magnetic resonance with a compass. *D. Nelson*[1], E. Cookson[1], M. Anderson[1], D. McKinney[2] and I. Barsukov[1] *1. Physics and Astronomy, UC Riverside, Riverside, CA, United States; 2. Santa Rosa Academy, Menifee, CA, United States*

Magnetic resonance plays an important role in today's science, engineering, and medical diagnostics. Learning and teaching magnetic resonance is challenging since it requires advanced knowledge of condensed matter physics and quantum mechanics. Driven by the need to popularize this technologically impactful phenomenon, we develop an inexpensive table-top demonstration experiment. It unveils the magnetic resonance of a hand-held compass in the magnetic fields of a permanent magnet. The setup provides an immediate visualization of the underlying physical concepts and allows for their translation to broad student audiences. This work was supported by the National Science Foundation under Grant No. ECCS-1810541.

BS-02. Magnetic Fields Web Series: Engaging Middle School Students in STEM. *P. Pena Martin*[1], J. Isberg[1], E. Ertekin[1,3], V. Lorenz[1,2] and N. Mason[1,2] *1. Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 2. Department of Physics, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 3. Department of Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, United States*

Web based media can make scientific content accessible to audiences far beyond the scientific community. We created a web series called "Magnetic Fields" that aims to introduce materials science, particularly concepts related to magnetism, and promote themes more general to STEM fields, such as persistence and the scientific process, through use of characters and a story geared towards a middle school audience. The goal is to build and maintain interest in science at an age where this tends to drop off. The four-episode arc follows a group of high school characters as they encounter a strange new material during a class field trip to a laboratory. The series is directed by John Isberg, with professional actors making up most of the cast. The series was initiated by scientists in the Illinois MRSEC, and the storyline was developed in collaboration with MRSEC students and faculty. The episodes were released in May 2019 through Youtube. We report on the process of creating this series, response to it upon release, and discussion of its use as an educational tool. The authors acknowledge primary support of the NSF through the University of Illinois at Urbana-Champaign Materials Research Science and Engineering Center DMR-1720633.

Fig.1 Scene from an episode of "Magnetic Fields." Photo by John Isberg.

BS-03. In-class experiments with smart phones for teaching upper-level electricity and magnetism. A. Davidson[1], A. Ranjan[2] and *X. Fan*[1] *1. Physics and Astronomy, University of Denver, Denver, CO, United States; 2. Cherry Creek High School, Greenwood Village, CO, United States*

Interactive-engagement method such as studio physics [1, 2], has demonstrated higher learning gains than traditional lecturing in intro-level physics classes. However, there have been limited applications in upper-level classes, such as Electricity and Magnetism (E&M), possibly because experiments on E&M topics can be too costly and sophisticated to be carried out in the classroom. Smart phone, which is equipped with magnetic field sensors, radio signal detectors and light sensors, provides a convenient platform for carrying out E&M-related experiments. In this poster, we will present three examples of the implementation of smart-phone-based studio physics in an E&M class for Physics majors: (1) Detection of earth magnetic field inclination; (2) quantifying skin depth of aluminum foil with cellphone tower signals; and (3) Measurement of Brewster's angle. Besides sensitive sensors, smart phone also has computational power, which can be explored to further expand the breadth and depth of the smart-phone-based studio physics. Due to the wide accessibility of smart phones and the simplicity of experimental setup, we expect this teaching technique can be easily transferred to other institutes in the world.

BS-04. The Use of Virtue Modules in Physics Lab Teaching. *W. Zhang*[1], R. Bidthanapally[1], T. Sebastian[2], Y. Xiong[1,3], H. Qu[3] and J. Sklenar[4] *1. Physics Department, Oakland University, Rochester, MI, United States; 2. THATec Innovation GmbH, Mannheim, Germany; 3. Electronic and Computer Engineering, Oakland University, Rochester, MI, United States; 4. Physics Department, Wayne State University, Detroit, MI, United States*

Lab sessions in physics education connect the fundamental concepts to practical examples and are effective measures of the students' understanding and reasoning through ultimate real-world tests. Many topics in condensed

matter physics are known to be challenging to convey in both lectures and labs. In addition, these topics are usually resource demanding, which has been one of the challenging issues. Here, we introduce and demonstrate the use of virtue lab modules for teaching physics labs and for effectively integrating research and education. Experiments that are relevant to magnetism and spintronics include, but not limited to, spin current detecting, microwave energy harvesting, and spin-based thermoelectric effects. An important highlight of these modules is the highly-interactive laboratory learning platform. In the class, each piece of experimental hardware (e.g. electrometers, oscilloscopes, etc) will be paired with a computer-based virtual module. The individual modules mimic the hardware, which the students can use to become familiar with the hardware, acquire real-time feedback, and visualize the data acquisition dynamics, on-demand and risk-free. The virtual component is also helpful for demonstrating delicate, shared hardware in class, without risk of damaging the actual instrumentation. These individual components are connected to a central operating system and the experiment can be re-programmed by simple coding and user-interfaced commands [1]. Work at Oakland University is supported by NSF DMR-1808892.

BT-01. Magnetotransport of $SrIrO_3$ Films on (110) $DyScO_3$. A. Jaiswal[1,2], A. Zaitsev[1], R. Singh[2], R. Schneider[1] and *D. Fuchs*[1] *1. Institute for Solid-State Physics, Karlsruhe Institute of Technology, Karlsruhe, Germany; 2. Department of Physics, Indian Institute of Technology Delhi, Delhi, India*

Epitaxial perovskite (110) oriented $SrIrO_3$ (SIO) thin films were grown by pulsed laser deposition on (110) oriented $DyScO_3$ (DSO) substrates with various film thickness t (2nm < t < 60 nm). All the films could be produced with stoichiometric composition, in single orthorhombic phase and with high crystallinity. The films display untwinned and nearly strain free growth over the complete thickness range. The nearly perfect in-plane lattice matching of DSO with respect to SIO and similar orthorhombic symmetry of DSO and SIO result in a full epitaxial in-plane alignment, i.e., the *c*-axis of DSO and SIO are parallel to each other with only slightly enlarged d_{110} out-of plane lattice spacing (+0.38%) due to the rather small in-plane compressive strain by the DSO substrate. Measurements of the magnetoresistance (MR) were carried out for current flow along the [001] and [1-10] direction of DSO and magnetic field perpendicular to the film plane. MR appears to be distinct different for both directions. The anisotropy $MR_{001}/MR_{1\text{-}10} > 1$ increases with decreasing T and is especially pronounced for the thinnest films where, in addition, hysteretic field dependence appears. The results strongly indicate magnetic ordering in the SIO films. The ordering temperature T^* is between 2K and 5 K, and the coercive field H_c amounts to 2-5 T. Both, T^* and H_c are very similar to the field-induced magnetic order of Dy moments in DSO which strongly suggests substrate induced magnetism in the SIO films.

BT-02. Spintronic Terahertz Emission by Ultrafast Spin-Charge Current Conversion in Organic-Inorganic Hybrid Perovskites. *W. Zhang*[1,2], K. Cong[3], E. Vetter[4], Y. Liang[5], Y. Li[1,2], Q. Zhang[3], Y. Xiong[1,6], R. Schaller[3], A. Hoffmann[2], W. You[5], H. Qu[6], H. Wen[3] and D. Sun[4] *1. Physics Department, Oakland University, Rochester, MI, United States; 2. Hybrid Metal Halides (HMHs) is a new class of synthetic semiconductors prepared by low-temperature solution processing with a large chemical and structure 'universe' given the synthetic versatility of their molecular cations. While the family of HMHs has shown remarkable performance in photovoltaic and optoelectronic applications, their rich spintronic functionalities have yet to be fully utilized. We report the successful observation of the inverse Rashba-Edelstein Effect (IREE) in a prototypical 3D-HMH material, $CH_3NH_3PbBr_3$ polycrystalline thin films and single crystals, driven by spin-pumping from a $Ni_{80}Fe_{20}$ (NiFe) ferromagnetic metal. We found a large surface-dominated IREE spin-to-charge conversion efficiency, which is comparable to that observed in more traditional Rashba-type systems (e.g., Bi/Ag, etc.). The THz emission can be controlled by the magnetic field, and furthermore, exhibits a unidirectional behavior and peculiar laser linear polarization dependence. Considering that HMH materials are grown from solution, our findings demonstrate a substantial advance towards low-cost, low-temperature processable HMH-based spintronics applications. This work was supported by AFOSR FA9550-19-1-0254. E.V. and D.S. were thankful for NCSU start-up and NCSU-Nagoya Collaboration Grants. BT-03. Hysteretic temperature dependent spin-wave response associated with phase transitions in V_2O_3/Ni/NiFe thin films. *Y. Chen*[2], N. Vargas[1], P. Salev[1], P.N. Lapa[1], I. Schuller[1] and A.D. Kent[2] *1. Department of Physics and Center for Advanced Nanoscience, University of California San Diego, La Jolla, CA, United States; 2. Center for Quantum Phenomena, Department of Physics, New York University, New York City, NY, United States*

Spin-torque nano-oscillators (STNOs) are a new class of microwave oscillators with operating frequencies that can be precisely tuned by external magnetic fields, injected spin currents, or prior states. We report a study of the hysteretic magnetization dynamics of a V_2O_3/Ni/NiFe heterostructure associated with the structural phase transition (SPT) and metal-insulator transition (MIT) of V_2O_3 near 150 K [1]. Ferromagnetic resonance (FMR) was measured with a dc magnetic field applied perpendicular to the sample plane for different thicknesses of Ni/NiFe bilayers between 50 and 300 K. The phase transitions in V_2O_3 induces a clear increase of the FMR resonant fields, indicating the strong coupling between V_2O_3 structural/electronic state and the spin-wave modes in the adjacent ferromagnetic bilayers. In addition, the resonance fields are hysteretic, showing clear shifts between sample cooling and heating (Figure 1). The FMR linewidths are also enhanced at temperatures lower than 150 K. The FMR results show that the spin-wave modes of the V_2O_3/Ni/NiFe thin films can be tuned by external parameters (such as applied magnetic fields) as well as state of V_2O_3. This makes the heterostructure studied a good candidate for realizing non-volatile STNOs and potential devices for neuromorphic computing [2]. Vibrating sample magnetometer (VSM) and magneto-optic Kerr effect (MOKE) characterization of the V_2O_3/Ni/NiFe samples will be presented along with the temperature-dependent FMR results. This work is supported by the Quantum Materials for Energy Efficient Neuromorphic Computing Energy Frontier Research Center funded by the U.S. Department of Energy (DOE), Office of Science, Basic Energy Sciences (BES), under Award DE-SC0019273.

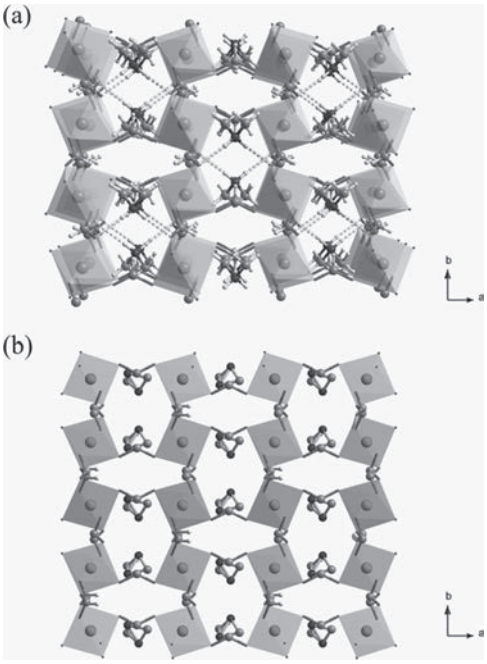
BT-04. Investigating the Magnetic Ground state of the Skyrmion Host Material Cu_2OSeO_3 using Long-Wavelength Neutron Diffraction.
K.J. Franke[1,2], P.R. Dean[1], M. Ciomaga Hatnean[3], M.T. Birch[1], D. Khalyavin[4], P. Manuel[4], G. Balakrishnan[3] and P.D. Hatton[1] *1. Centre for Materials Physics, Durham University, Durham, United Kingdom; 2. School of Physics and Astronomy, University of Leeds, Leeds, United Kingdom; 3. Department of Physics, University of Warwick, Coventry, United Kingdom; 4. ISIS Facility, STFC Rutherford Appleton Laboratory, Chilton, Didcot, United Kingdom*



Skyrmions are topologically protected, nano-sized swirls of spins found in a range of magnetic materials. In recent years a number of advances have demonstrated the existence, not only of magnetic skyrmions, but also their ordering into a skyrmion lattice (SL) in several magnetic materials with a chiral structure. This symmetry can lead to the formation of an antisymmetric Dzyaloshinskii-Moriya interaction (DMI). Competition between the symmetric exchange interaction and the DMI leads to a magnetic ground state that generally consists of helices, long period magnetic structures where the magnetisation rotates in a plane perpendicular to the propagation direction. The magnetic phase diagram of multiferroic Cu_2OSeO_3 resembles that of other skyrmion hosting systems, consisting of a helical (H) ground state, a conical (C) phase in applied fields, a field polarised (FP) phase in large applied fields, and a SL phase in a pocket in applied field and temperature just below T_c [1]. Previous investigations have either shown that Cu_2OSeO_3 is a ferrimagnet [2] without addressing the chiral nature of the magnetic ground state, or investigated the chirality without taking into account ferrimagnetism [1,3-5]. Here we investigate the microstructure of the magnetic phases of Cu_2OSeO_3 and address the question of whether the ground state H structure is also ferrimagnetic. Using time-of-flight long-wavelength neutron diffraction on a single crystal sample, we observe magnetic satellites around the (0-11) diffraction peak not accessible to other techniques. Furthermore, our measurements uniquely allow us to distinguish helical from conical spin textures in reciprocal space. We show successive transitions from H to C to FP as the external magnetic field is increased in the magnetically ordered phases, and the formation of a skyrmion lattice with propagation vectors perpendicular to the field direction in a region of the field-temperature phase diagram that is consistent with previous reports [1,3]. We use powder diffraction measurements to determine the magnetic microstructure of the FP and H phases, and show that not only the FP phase but also the H ground state are made up of ferrimagnetic clusters instead of individual spins [6].

BT-05. Magnetic-Field Tuning of Hydrogen Bond Order-Disorder Transition in Metal-Organic Frameworks.
Y. Sun[1], Y. Ma[1], J. Cong[1] and Y. Wang[2] *1. Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2. Department of Chemistry, Nankai University, Tianjing, China*

The ordering of polar hydrogen bonds can induce ferroelectricity or antiferroelectricity. This process is usually immune to external magnetic fields so that magnetic control of hydrogen bonds is very challenging. We find that the ordering of hydrogen bonds in the perovskite metal-organic frameworks $[(CH_3)_2NH_2]M(HCOO)_3$ (M=Fe, Co) can be manipulated by applying magnetic fields [1]. After cooling in a high magnetic field, the order-disorder transition of hydrogen bonds shifts to a lower or higher temperature, depending on antiferroelectricity or ferroelectricity induced by hydrogen bond ordering. Besides, the order-disorder transition leads to a giant thermal expansion, exceeding ~35000 and ~20000 ppm for M = Fe and Co, respectively, which is much higher than that of inorganic ferroelectrics. The influence of magnetic field on hydrogen bond ordering is discussed in terms of the magnetoelastic coupling.

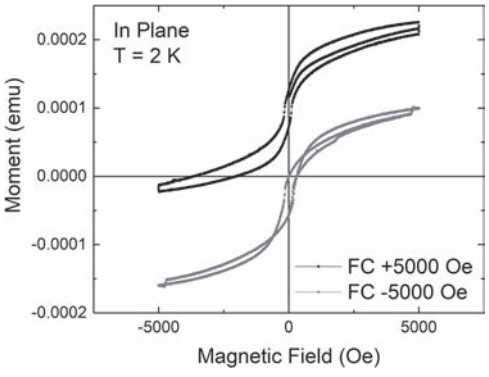
The structure of the metal-organic framework $[(CH_3)_2NH_2]M(HCOO)_3$ with M=Fe and Co, respectively.

(a) Schematic of a capacitance dilatometer. The linear expansion/ striction of the sample is transformed into the change in the capacitance which is precisely measured by a capacitance bridge. Temperature dependence of the linear thermal expansion along the [012] direction in several magnetic fields for (b) the ferroelectric Co-MOF and (c) the antiferroelectric Fe-MOF. The order-disorder transition of hydrogen bonds induces a large change in length. After cooling in a high magnetic field, the transition temperature shifts to a higher temperatur for the Co-MOF but to a lower temperature for the Fe-MOF.



BT-06. Solution-Processed Yttrium Iron Garnet Thin Films as Novel Magnetostrictive Materials. *S.K. Patel*[1], C.T. Karaba[1] and S. Tolbert[1]
1. Chemistry and Biochemistry, University of California - Los Angeles, Los Angeles, CA, United States

Multiferroic antennas have the potential to revolutionize modern technology since they can be made orders of magnitude smaller than conventional antennas.[1] Successful multiferroic antennas have previously employed metallic magnetostrictive materials due to their optimal magnetic properties, including having low coercivity, high saturation magnetization, and high magnetostriction.[2] However, the radiation efficiency of such antenna devices is limited by the high conductivity of metallic magnetostrictive materials, causing significant electrical losses in RF systems.[3] Yttrium iron garnet ($Y_3Fe_5O_{12}$, or YIG) is a promising alternative to metallic magnetostrictive materials due to its extremely low Gilbert damping.[4] Additionally, YIG exhibits acceptable magnetic properties for a RF applications including a relatively low anisotropy field and low coercivity.[5] Despite these advantages, YIG intrinsically exhibits near-zero magnetostriction. Theoretical and experimental data has shown that doping YIG with ruthenium (substituting for iron) and with cerium (substituting for yttrium) can significantly increase magnetostriction due to increased spin-orbit coupling in bulk, single crystal materials.[6,7] In this work, we synthesize doped YIG thin films to use as new magnetostrictive materials, which would improve radiation efficiency upon integration into multiferroic antennas. We utilize solution-processing for facile stoichiometry control as well as integratability into future devices. The synthesis and characterization of these magnetostrictive YIG materials will be presented.

BT-07. Exchange Bias in $La_{0.7}Sr_{0.3}CrO_3/La_{0.7}Sr_{0.3}MnO_3/ La_{0.7}Sr_{0.3}CrO_3$ Heterostructures. *R. Olmos*[1], H. Iturriaga[1], D.S. Blazer[1], K. Gandha[2], C.I. Nlebedim[2], D.P. Kumah[3] and S. Singamaneni[1] *1. Physics, University of Texas at El Paso, El Paso, TX, United States; 2. Critical Materials Institute, Ames Laboratory, Ames, IA, United States; 3. Physics, North Carolina State University, Raleigh, NC, United States*

In the recent past, heterostructures of magnetic oxide thin films have attracted a great deal of research excitement due to very interesting physical properties such as antiferromagnetic interlayer coupling, tunable exchange-bias, interfacial driven magnetic properties and high mobility electron gas across the interfaces. In this work, we report on the comprehensive magnetic properties observed from the heterostructures of (2 unit cells)$La_{0.7}Sr_{0.3}CrO_3$/ (8 unit cells)$La_{0.7}Sr_{0.3}MnO_3$/ (2 unit cells)$La_{0.7}Sr_{0.3}CrO_3$, which are epitaxially deposited on $SrTiO_3$ substrate by plasma-assisted oxide molecular beam epitaxy at a growth temperature of 800° C. The thickness of each layer and valence states of elements were inferred from the aberration-corrected high-angle annular dark field-scanning transmission electron microscopy, electron energy loss spectroscopy, and energy dispersive x-ray spectroscopy chemical maps. Using Quantum Design SQUID magnetometer, the magnetic properties were studied when the magnetic field was applied both in-plane and out of plane of this sample. The Curie temperature of this structure is found to be at 290 K. Most significantly, at 2 K, we observed a complete up/down shift (along the magnetization axis) of hysteresis loop when the sample was cooled under the magnetic field of ±5000 Oe in the in-plane configuration. We believe that the strong antiferromagnetic (super) exchange coupling of Mn-Cr across the two interfaces is responsible for the observed exchange bias. We will present and discuss our in-detailed experimental findings collected on this heterostructure as a function of temperature and magnetic field.

BT-08. Strain-affected Modulation of Oxygen Ions Transfer in Topotactic Phase Transition. *J. Li*[1,2], J. Wang[1,2], C. Zhang[1,2], K. Qiao[1,2], F. Hu[1,2], J. Sun[1,2] and B. Shen[1,2] *1. Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2. School of Physical Sciences, University of Chinese Academy of Sciences, Beijing, China*

Recent studies have shown that the topotactic phase transition is of great significance to the application of complex oxides in the fields of energy technology, ferroelectrics and catalyst.[1-3] Therefore, not only the degrees of freedom such as lattice, charge, orbit, and spin, but also the transfer of ions need to be considered in the design and regulation of functional materials. We grew 40 nm perovskite $La_{0.7}Sr_{0.3}CoO_{3-\delta}$ (LSCO) films on $(LaAlO_3)_{0.3}$-$(SrAl_{0.5}Ta_{0.5}O_3)_{0.7}$ (LSAT) and $LaAlO_3$ (LAO) substrates by pulsed laser deposition. The pristine perovskite films with different strains were vacuum annealed under different temperature (300-500 degrees Celsius). The X-ray diffraction (XRD) results identify a series of samples with structures from perovskite to brownmillerite (Fig. 1a and 1b). The lattice volume calculated from the (008) peak position shows a continuous expansion with the annealing temperature (Fig.1c), indicating an enhancement of the strain with the escape of oxygen ions in both films. Meanwhile, for both films, the normalized integral intensity of the brownmillerite characteristic (00$\underline{1}$0) peak shows a gradual saturation with the increase of the annealing temperature (Fig. 1d). However, an unexpected decrease appears in the film on LAO when the temperature further increases up to 500 degrees Celsius, indicating a reduction in the order degree of oxygen vacancies. Our results manifest that the strain in the film prefers suppressing the formation of long-range order of oxygen vacancies although the escape of oxygen ions is insusceptible to the strain type. In addition, large changes in magnetic and electrical properties were found in both films during the topotactic phase transition. Our work reveals the influence of strain on the evolution of oxygen ions transfer in topotactic phase transition, which provides new possibilities for the development of functional materials and devices in the future.

BT-09. Analysis of thermal effects in current driven magnetic wires. *T. Sawa*[1], S. Sumi[1], P. Van Thach[1], K. Tanabe[1] and H. Awano[1] *1. Toyota Technological Institute, Nagoya, Japan*

Current-driven domain walls in magnetic nanowires will be one of the attractive candidates for the next generation of low energy consumption memory devices. When domain walls on magnetic nanowires are driven by injected electric current, it is necessary to consider also Joule heating effect for the DW motion. So far, have been few reports on it. Therefore, heat generation and absorption are evaluated in detail. For the measurement, we use a nanoMDS which can observe the magnetic domain image and heat distribution on the magnetic wire with TMR head and Ni sensor [1]. Samples of TbFe alloy magnetic wire with a platinum cover was prepared by sputtering on a thermally oxidized silicon substrate. The wire is 6 um width, 20 um length, and 10 nm thickness. A DC current of 17 mA (current density of 5.7 $\times$ 10^{10} A/m^2) is applied into the nanowire. The measured image of the heat distribution is shown in Fig.1. A temperature gradient from the center of the sample to the electrode was observed. Next, To see the asymmetry component, temperature distribution was measured when the direct current direction was reversed, and a difference image with the above result was taken. The results are shown in Figure 2. In the figure, the red area indicates heat generation, and the blue area indicates heat absorption. It can be confirmed that the left end of the sample generates heat and the right end absorbs heat. From this, we succeeded in seeing the asymmetric heat generation and heat absorption generated by the thin wire. This work was partly supported by JSPS Grant-in-Aids for Scientific Research (17H03240), the MEXT-Supported Program Research Foundation at Private University (2014-2019)

BT-10. Tuning Magnetic Anisotropy and Exchange Bias by Interfacial Engineering in Pervoskite Oxide Suplerlattice. *H. Huang*[1], J. Zhang[1], B. Shen[1] and J. Sun[1] *1. Beijing National Laboratory for Condensed Matter & Institute of Physics, Chinese Academy of Sciences, Beijing, China*

The interfacial in oxide heterostructures providing a rich playground to explore emergent interfacial phenomena that arise due to electronic, spin, or orbital reconstruction. One good example is tunning the magnetic anisotropy (MA) of materials by interfacial engineer. Herein we report huge perpendicular magnetic anisotropy of $La_{2/3}Sr_{1/3}MnO_3$ (LSMO) when it sandwiches between $La_{0.8}Sr_{0.2}CoO_{3-\delta}$ (LSCO) on $SrTiO_3$ (STO) substrate, different from the bare LSMO with in-plane magnetic anisotropy. The sketch of LSCO/LSMO/LSCO is shown in Fig 1(a), and the high-angle annular dark-field (HAADF) image of the cross-section is shown in Fig 1(b). Noting that MnO_6 octahedron is connected to CoO_4 tetrahedron at interface of trilayer, enhanced lattice distortion of MnO_6 octahedron near interface, inducing orbital reconstruction and PMA properties[1,2]. The thermomagnetic (MT) curves of the trilayer with in-plane (IP) and out-of-plane (OP) mode are shown in Fig 1(c), and the red triangles mark stands for spin reorientation. The anisotropy constant of the trilayer is calculated as shown in Fig 1(d), the maximal anisotropy constant is as large as ~1.88×10^6 erg/cm^3 at 10K. More interesting, the coercivity enhancement and exchange bias (EB) phenomenons by interfacial effect are also discovered in LSCO/LSMO/LSCO trilayer[3]. The hysteresis loops of trilayer are shown in Fig 2(a). The maximal coercivity field of trilayer is ~6000 Oe at 10K, more than two order than bare LSMO, as shown in Fig 2(b). The minor hysteresis loops after 5T and -5T bias fields at 10K are shown in Fig 2(c). EB of the trilayer is clearly seen and the EB shift as a function of temperature is shown in Fig 2(d).

BT-11. Inteplay Between Doping and Size Effects of Multiferroic $Y_{1-x}Eu_xMn_2O_5$ Nanorods. T. Hsu[1], *C. Yang*[1], Y. Tung[1], C. Kao[1], W. Wu[1] and K. Lin[2] *1. Chung Yuan Christian University, Taoyuan, Taiwan; 2. Yuan Ze University, Taoyuan, Taiwan*

$Y_{1-x}Eu_xMn_2O_5$ nanorod samples (x = 0, 0.5, and 1) were prepared by hydrothermal method. Each x composition contains two sizes. X-ray diffraction analysis shows that the lattice constants increased with increasing Eu doping and the nanorod size. Magnetic susceptibility experiments revealed that all six samples exhibited antiferromagnetic peaks at around 43 K under zero magnetic field cooling, and all converted to ferromagnetic ones as cooling with a magnetic field. The x = 0.5 sample displayed a relative larger magnetic susceptibility before and after phase transition in both zero field cooling (ZFC) and field cooling (FC), which implied that the doping effect increased the magnetic response near the magnetic phase transition. In the all three difference x of samples, the small-sized nanorods exhibited a weaker change in magnetic susceptibility experiments near the magnetic phase transition temperature. This observation shows that the size effect weakens the strength of the magnetic order. Room temperature Raman spectra of x = 0.5 samples show no shift of all peaks in both <*Lc*> = 81 nm and 201 nm sizes under the zero and 0.2 T magnetic fields. Only the small size of 65 nm YMn_2O_5 sample exhibited peak shift at 0.2 T. In the contrast, all sizes of $EuMn_2O_5$ samples show the peaks shift by the magnetic field. These observations imply that the size effect weakens the force constant between th e magnetic ions in the crystal, so that resulted in the external magnetic field can shift the Raman peaks. However, the doping effect enhanced the force constant and overcome the size effect, thus reducing the influence of the Raman peak on the external field.

Faculty of Materials Science and Engineering, Phenikaa University, Hanoi, Vietnam; 8. Phenikaa Research and Technology Institute, A&A Green Phoenix Group, Hanoi, Vietnam*

The inverse magnetocaloric effect in materials with noncollinear spin textures reveals essential details about their complex ordering and magnetization processes, including spin fluctuations and thermally-activated metamagnetism. [1,2] Near the paramagnetic (PM) to helicoid and skyrmion lattice (SkL) transitions in B20 FeGe, positive isothermal entropy change to an applied magnetic field (ΔS_M) was associated with the first-order nature of the chiral fluctuation-enhanced transition. [3] Multiferroic GaV_4S_8 (GVS) displays a cycloidally-modulated Néel skyrmion lattice under the influence of easy axis anisotropy. Among several unique phase transitions, the strong anisotropy drives an expansion of the cycloid pitch as temperature is lowered and leads to a ferromagnetic (FM) ground state. [4] GVS also displays magnetoelectric coupling, evident from the excess spin-driven polarization of the magnetic textures. [5] Thus, GVS is an ideal system to examine the effects of anisotropy, coexisting order parameters, and modulated spin ordering on magnetic field-induced caloric effects. We exploit the magnetocaloric effect to analyze ΔS_M as a function of temperature (T) and field (H) across the magnetic phase diagram of GVS (T_C = 13 K). Detailed magnetization versus T data was collected with H applied along each of the three principle cubic axes: [111], [110], [100]. Below 11 K, ΔS_M decreases in a step-like fashion across sequential Cyc to SkL and SkL to FM metamagnetic transitions due to field-induced spin ordering. However, for a narrow temperature regime below T_C, a ridge of positive ΔS_M separates the modulated states from the PM phase. The nature of phase evolution from high T in GVS has not been investigated, and the results open important questions about the mechanisms driving the formation of a noncollinear texture from a disordered phase. By analyzing incremental changes in entropy, dS/dH, we verify the extent of the increasing entropy regime at lower temperatures. Below ~ 5 K, a broad dome of $\Delta S_M > 0$ exists within the expected FM phase. Our results reveal an extended incommensurate-commensurate transition that agrees with the scenario of an anisotropy-driven conversion of the spin cycloid into the FM ground state.

BT-13. Magnetization studies of Magnetoelectric Coupling in $0.8BaTiO_3$-$0.20Mn_{0.1}Zn_{0.9}Fe_2O_4$ Ceramic Composite. *A. Farheen*[1] and R. Singh[1] *1. School of Physics, University of Hyderabad, Hyderabad, India*

Multiferroics are the materials that contain at least two ferroic orders in them such as electric, magnetic and elastic behaviour simultaneously [1]. The coupling interaction present in the multiferroic materials between various order parameters can develop new effects, such as magnetoelectric effect. [2]. The multiferroic properties of ferromagnetic- ferroelectric composites are due to induced electric polarization in the magnetic order and vice versa. Therefore, the composite multiferroics offer a way to attain magnetic and ferroelectric ordering simultaneously. Composite of $0.8BaTiO_3$+$0.20Zn_{0.9}Mn_{0.1}Fe_2O_4$ was synthesized via solid-state route. X-ray diffraction pattern and microstructure of the sample confirm the coexistence of $BaTiO_3$ (BTO) and $Zn_{0.9}Mn_{0.1}Fe_2O_4$ phases without any detectable third phase. Clear hump in magnetization vs. temperature ($M(T)$) plots (Fig.1(i)) around BTO structural phase transition temperature is an evidence of the origin of strain mediated magnetoelectric coupling. Derivative of zero field-cooled curve (dM/dT vs. temperature plot, Fig.1(ii)) shows clear hump around 190 and 280K which coincide with BTO transition temperatures and not observed in pure ferrite sample. It is well known that BTO has different crystal structure depending upon temperature due to different lattice strains, which represent different ferroelectric phases respectively. The lattice strain generated in BTO phase could be a possible reason for the occurrence of peaks in M (T) plot around transition temperatures. Due to well interface matching this strain will be transferred to the ferrite phase which alters the magnetization of ferrite phase in the composite. Further, sample exhibit magnetic hysteresis (Fig.1(iii)) behaviour which indicates the soft ferromagnetic behaviour of composites with much lower value than pure ferrite. This indicates the existence of non-magnetic ferroelectric phase with ferrite phase [3]. The presence of magnetic and electric hysteresis loop confirms ferromagnetic ordering as well as ferroelectric ordering in the composite sample.

BT-14. Metastable Multi-Domain Effects in FeGa Magnetoelectric Heterostructures for Cell Sorting. *M. Guevara*[1], R. Khojah[2], K. Fitzell[3], G. Carman[1] and C.S. Lynch[1] *1. Mechanical and Aerospace Engineering, University of California, Los Angeles, Los Angeles, CA, United States; 2. Bioengineering, University of California, Los Angeles, Los Angeles, CA, United States; 3. Chemical and Biomolecular Engineering, University of California, Los Angeles, Los Angeles, CA, United States*

Cell Sorting (CS) has been implemented in the field of biomedical devices with potential applications in cell therapy. Current methods of CS lack the ability to control individual cells and optimum imaging feedback. A new method of CS has been proposed that has the potential to overcome these challenges. It consists of using magnetoelectric heterostructure in a microfluidic channel to capture cells containing magnetic particles. An array of FeGa elliptical microstructures on top of PMN-PT is used to capture and release super paramagnetic (SPM) beads. Using the shape anisotropy of the microstructure, a metastable multi-domain (MD) state can be achieve and used to capture SPM beads. Due to the instability of these MD state, the magnetic state can be switching from MD to vortex state through a strain mediated method. Preliminary modeling work has shown the dependency of the MD state on the shape and size (aspect ratio and major axis diameter, respectively). The MD state can be optimized to enhance magnetic flux (e.g. bead capture) and the energy barrier required to switch it into vortex. The MD state observed in the modeling work matches observations using magnetic force microscopy (MFM) imaging, showing that the MD state has an effective magnetization along the easy axis, therefore allowing magnetic flux to leave the structure generating a magnetic field gradient that produces a force on SP particles. The effects of this force are observed in the microfluidic imaging, where the SPM beads are attracted to the poles of the nanoscale magnets.

BT-15. Magnetodielectric and electric transport properties of ITO/$CoFe_2O_4$/$BaTiO_3$/$CoFe_2O_4$ multilayer composite. *E. Lopez Moreno*[1], H. Montiel[1] and G. Alvarez Lucio[2] *1. Micro and Nanotecnology, National Autonomous University of Mexico, Mexico City, Mexico; 2. Science and Tecnology, Autonomous University of Mexico City, Mexico City, Mexico*

The magnetodielectric characterization of ITO/$CoFe_2O_4$/$BaTiO_3$/$CoFe_2O_4$ multilayer by Impedance Spectroscopy (IS) is presented for the FM/insulator/FM system deposited by Pulsed Laser Deposition (PLD) on the semiconductor Indium-Tin Oxide (ITO) coated substrate with Ag top electrodes. GIXRD studies confirm spinel-type and hexagonal crystal structure of cobalt ferrite ($CoFe_2O_4$) and barium titanate ($BaTiO_3$) layers, respectively. Raman spectroscopy studies confirm spinel-type structure of $CoFe_2O_4$, while $BaTiO_3$ has a mixture of phases (hexagonal, tetragonal, and amorphous phases). Vibrating Sample Magnetometry (VSM) at room temperature reveals ferromagnetic behavior with high coercivity of 2.9 KOe of multilayer composite, while for individual layers of $CoFe_2O_4$ and $BaTiO_3$ have diamagnetic and ferromagnetic properties, respectively. The chemical characterization was carried out X-ray Photoelectron Spectroscopy (XPS) confirming the correct elemental composition. Real and Imaginary part of impedance data have remarkable changes at different DC magnetic field intensities with an analogous behavior to the magnetoimpedance phenomenon. Furthermore, impedance Z*, electric permittivity ε* and AC conductivity show frequency dependence with changes under magnetic field providing magnetodielectric properties at room temperature. The electric transport of the composite is discussed in terms of the electric response of individual layers where hopping conduction mechanism is attributed to $CoFe_2O_4$, while in $BaTiO_3$ structural disorder or defects can modify the electronic band structure. The obtained multilayer composite we obtained can be proposed as a magnetocapacitive system as it is supported by impedance measurements.

BT-16. Resistive Switching behavior on semimetallic $SrIrO_3$ thin films. V. Fuentes[1], B. Vasic[2], Z. Konstantinovic[2], L. Balcells[1], A. Pomar[1] and *B. Martinez[1] 1. Magnetic Materials and Complex Oxides, ICMAB-CSIC, Bellaterra, Spain; 2. Institute of Physics Belgrade, University of Belgrade, Belgrade, Serbia*

The relation between Metal Insulator Transitions (MIT) and Resistive Switching (RS) is important from the fundamental point of view, but also highly relevant because of the possible applications of RS based devices in non-volatile memories [1]. We studied RS of 5d $SrIrO_3$thin films in the vicinity of a MIT triggered by the reduction of thickness [2]. RS was studied for two characteristic cases: 1. in a thick film which behaves like a semimetal, and 2. in a very thin film which has undergone the MIT and is in an insulating state (see Figure 1). Local electrical properties were measured by means of Conductive Atomic Force Microscopy (C-AFM). In the case of very thin and initially insulating films, I/V curves presented an abrupt increase of the current intensity only for high enough sample voltage indicating a sharp transition into low resistance state (LRS). On the other hand, in the case of initially semimetallic films, this transition was less pronounced without clear threshold voltage for the switching into LRS (see Figure 2). As a result, such different behavior indicates that the MIT has indeed a high impact on the RS. Possible mechanisms of RS in both samples involving oxygen vacancies will be discussed.

BT-17. Design of efficient p-type spin caloritronic devices using flexible macroscopic interconnected nanowire networks. *T. da Câmara Santa Clara Gomes*[1], F. Abreu Araujo[1], N. Marchal[1] and L. Piraux[1] *1. Institute of Condensed Matter and Nanosciences, Université catholique de Louvain, Louvain-La-Neuve, Belgium*

Spin-dependent thermoelectric mechanisms are at the heart of the rapidly emerging field of spin caloritronics and are crucial steps in designing next generation heat management devices [1,2,3]. Highly efficient flexible spin caloritronic devices using macroscopic network films made of interconnected FM/Cu multilayered nanowires (FM = Co, NiCo, NiFe) were recently fabricated by direct electrodeposition into 3D nanoporous polymer host with no sample size limitation (see Fig. 1) [4,5]. Large magneto-thermoelectric effects have been observed and the spin-dependent Seebeck coefficients were directly obtained, being both negative (n-type) in all those systems. However, significant boost in magneto-thermoelectric performance can be expected in FM/Cu systems where the Seebeck coefficients for the spin-up and spin-down electrons have opposite signs. Such sign asymmetry is possible because the sign and magnitude of the diffusion thermopower depend strongly on the energy derivative of the density of states at the Fermi level, and has already been demonstrated in some FM dilute alloys [6,7]. Moreover, practical thermometric device required both p- and n-type elements. Here, interconnected nanowire networks made of diluted CoCr and NiCr alloys (<5% of Cr) are studied, revealing large modifications in the magneto-transport and thermoelectric properties, as shown in Fig. 2. Negative anisotropic magnetoresistance have been observed, highlighting the large effect of Cr on the density of state (reversal of the resistivity spin asymmetry coefficient) [8]. Moreover, large positive Seebeck coefficients have been obtained in interconnected nanowire networks made of diluted NiCr alloys, opening the door to magnetically tunable p-type thermoelectric devices and, thus, p-n spin caloritronic junctions.

BT-18. Interplay between magneto-elasticity and magneto-electricity in FePt/$BaTiO_3$. *Q. Ain*[1], D. Odkhuu[2], S.H. Rhim[1] and S.C. Hong[1] *1. University of Ulsan, Ulsan, The Republic of Korea; 2. Incheon National University, Incheon, The Republic of Korea*

Using first-principles calculations, the interplay between magneto-electricity (ME) and magneto-elasticity (MEL) is investigated. As a prototype, magnetization of epitaxial FePt heterostructure on $BaTiO_3$ is explored, where TiO_2-terminated interface is taken into account. In particular, the interfacial ME coefficient,a_l= $3.56x10^{-9}$ $G.cm^2/V$, one order larger than Fe/$BaTiO_3$ interface [1], as a consequence of considerable difference in magnetization under the polarization (P) reversal at the interface. Furthermore, strain (η) significantly modifies the interfacial electronic structure when P>0 as compared to P<0. At zero-strain, out-of-plane magnetization is preferred regardless of polarization directions. However, at η =1.75%, magnetization switches from out-of-plane (P<0) to in-plane (P>0). The interplay is analyzed by the different responses of out-of-plane (*xz*and *yz*) and in-plane (*xy* andx^2-y^2) orbitals with respect to strain and polarization, where the magnetization direction is governed by and matrices.

BT-19. Effect of the magnetic impurity on the charge diffusion in highly dilute Ce doped $LaMnO_3$. G. Cabrera-Pasca[1], B. Bosch-Santos[2], A. Burimova[2], E. Correa[3] and *A.W. Carbonari*[2] *1. Faculdade de Ciências Exatas e Tecnologia, Universidade Federal do Pará - UFPA, Abaetetuba, Brazil; 2. CERPQ, Instituto de Pesquisas Energéticas e Nucleares - IPEN, São Paulo, Brazil; 3. Materials Science Laboratory, National Laboratory of Standards and Technology - NIST, Gaithersburg, MD, United States*

$LaMnO_{3+\delta}$ is a complex oxide, which, depending on the oxygen excess concentration δ, presents different crystalline structure and interesting magnetic and electric properties such as colossal magnetoresistance, polaron dynamics, multiferroic behavior, and charge-orbital ordering. This complexity requires different characterization techniques to draw a picture as complete as possible allowing a good understanding of these phenomena. Here, we have used the perturbed angular correlation (PAC) technique to measure hyperfine interactions at La and Mn sites of $LaMnO_{3+\delta}$ (δ ~0.15) using ^{140}Ce (at La sites) and ^{111}Cd (at both La and Mn sites) as probe nuclei in order to investigate within an atomic scale the magnetic and electric interactions in this compound. Results show that ^{111}Cd nuclei occupy quite high symmetric local sites in agreement with a rhombohedral structure. The magnetic hyperfine field (B_{hf}) measured with ^{111}Cd at La sites is very small (B_{hf} = 0.40 T) due to the supertransferred magnetic field from Mn neighbors through oxygen orbitals. On the other hand, ^{140}Ce nuclei at La sites present a saturation field of around 3.7 T much higher than that expected for La sites (due to the weak transfer field by superexchange mechanism). In addition, for temperature range above the magnetic ordering (200-300 K) a dynamic hyperfine interaction was observed characterized by the attenuation parameter λ(T) whose temperature dependence allowed to determine the activation energy (E_a) associated to the polaron diffusion, as displayed in Fig. 1.

BT-20. Magnetization dynamics of epitaxially grown manganite thin films on (001) oriented ferroelectric PMN-PT substrates. *S. Pati*[1], T. Usami[1] and T. Taniyama[1] *1. Department of Physics, Nagoya University, Nagoya, Japan*

Interfacial multiferroic materials comprising of a ferromagnetic (FM) and a ferroelectric (FE) layer have attracted great attention due to their interesting voltage controlled magnetic phenomena and its applicability in energy efficient spintronic devices [1,2]. Among FM oxides, perovskite manganites particularly $La_{1-x}Sr_xMnO_3$ (LSMO) have potential for a vast range of applications due to the unique properties such as half metallicity, i.e., high spin polarization, and high Curie temperature. In this work, we report on the static and dynamic magnetic properties of LSMO thin films epitaxially grown on (001) oriented ferroelectric (1-x)$Pb(Mg_{1/3}Nb_{2/3})O_3$-x$PbTiO_3$ (PMN-PT, with x=0.3). 100-nm-thick LSMO films were grown using a pulsed laser deposition technique equipped with a Nd:YAG laser of wavelength 266 nm at 650°C. XRD measurement confirms epitaxial growth of samples having out-of-plane lattice parameter c=3.843 Å. Temperature dependent magnetization shows that the Curie temperature, T_C, is around 355 K. In-plane magnetic anisotropy is confirmed from the M-H curve measurements, while the in-plane angular dependence of the remanence ratio reveals isotropic nature of the sample in the plane at room temperature. Room temperature

ferromagnetic resonance (FMR) was measured in in-plane magnetic fields using a vector network analyzer with a coplaner waveguide. A clear single dispersion of the FMR is seen, in contrast to the double dispersion structure on a $SrTiO_3$ substrate. Fitting of the Kittel's equation estimates the effective saturation magnetization of 280 G, the inhomogeneous broadening ($\Delta H(0)$) of 72.6 Oe, and the effective Gilbert damping (α_{eff}) of 0.036. This ensures the high quality of the LSMO based interfacial multiferroic structure, given the immediate relaxation of the lattice mismatch at the LSMO/PMN-PT interface, in agreement with the x-ray diffraction data. From the combined results, the lattice mismatch induced strain in LSMO plays an important role for controlling the static and dynamic magnetic properties. This work was supported in part by JST CREST Grant Number JPMJCR18J1, JSPS KAKENHI Grant Numbers JP17H03377, JP18F18353, the Asahi Glass Foundation, and the Kato foundation for Promotion of Science.

BU-01. The Formation Mechanism of the Insulating Amorphous BN Barrier in Magnetic Tunnel Junctions Prepared by Sputtering. *T. Ichinose*[1], K. Elphick[2], A. Hirohata[2] and S. Mizukami[1,3] *1. WPI-Advanced Institute for Materials Research, Tohoku University, Sendai, Japan; 2. Department of Electronic Engineering, University of York, York, United Kingdom; 3. Center for Science and Innovation in Spintronics (Core Research Cluster) and Center for Spintronics Research Network, Tohoku University, Sendai, Japan*

The development of barrier materials for magnetic tunnel junctions (MTJs) have attracted immense attention recently. The one of the candidates is BN. The hexagonal BN barrier has been prepared by using chemical vapor deposition (CVD) or exfoliation. [1, 2] However, in these techniques, the crystal size is limited in micrometer scales, and the transfer of small flakes requires the exposure to atmosphere. Thus, the large-scale deposition and conventional microfabrication techniques should be developed to grow a BN barrier layer. Although the amorphous BN (a-BN) could be formed on various substrates with large-scale, [3] the MTJs with a-BN have not been reported. The one of the issues is preparation of insulating BN due to the difficulty of nitridation. In this work, a-BN thin films were prepared by using sputtering which is suitable for large-scale deposition, and the formation mechanism of insulating BN was investigated, resulting in the observation of the tunnel magnetoresistance (TMR) ratio comparable to that in MTJs with h-BN prepared via CVD or exfoliation. [4] MTJ stacking structures composed of Ta(5)/ Ru(10)/ $Ir_{22}Mn_{78}$(10)/ Co(4)/ BN(t_{BN})/ Co(3)/ Ta(3)/ Ru(7) (thickness in nanometers) were deposited on Si/ SiO_2 substrates via sputtering. All the films were deposited at room temperature (~290 K), and the post-annealing at 523–673 K under a magnetic field of 2 kOe was performed. The magnetization of the bottom Co in the as-deposited sample was ~ 850 emu/cm^3 which was smaller than that of bulk Co, indicating nitridation due to the deposition of a BN overlayer. After post-annealing, the magnetization of the bottom Co layer increased to ~ 1400 emu/cm^3. In addition to the recovery of magnetization of bottom Co, the resistance of MTJs increased 2–3 orders of magnitude. These indicated that the N diffused from a bottom Co into a BN barrier layer via annealing because the Co-N is thermodynamically unstable, which reduced the N deficiency in the BN. The insulating a-BN formed via N diffusion could be used as the tunneling barrier of the MTJs, which showed the TMR ratios of -0.2% (-0.7%) at 300 K (10 K). This work was supported in part by JST CREST (No. JPMJCR17J5), JSPS Core-to-Core Program, and EPSRC (EP/M02458X/1).

BU-02. Effect of Fe and FeCo insertion on MgO-interface of TbFe-Co-based perpendicular magnetic tunnel junction. R.C. Bhatt[1,2], L. Ye[1,2], M. Guo[1,2] and *T. Wu*[1,2] *1. Graduate School of Materials Science, National Yunlin University of Science and Technology, Taiwan, Yunlin, Taiwan; 2. Taiwan SPIN Research Center, National Yunlin University of Science and Technology, Taiwan, Yunlin, Taiwan*

The MgO barrier layer interface is crucial not only for perpendicular magnetic anisotropy of the magnetic layer but also for the preservation of spin alignment for the large tunnel magneto-resistance[1,2]. Here, we study the effect of inserting Fe and FeCo thin layers between the MgO and the magnetic layer in the TbFeCo-based perpendicular magnetic tunnel junction. First, we deposited TbFeCo-MgO half structures as a reference and free layers separately and then the magnetic tunnel junction full structure. Further, in these half and full structures, we inserted Fe and FeCo thin layers to change the MgO interface. The minor and major hysteresis loops of different full structures are compared with the hysteresis curves of free and reference layer half structures, respectively. It is observed that in both the reference and free layer half structures the coercivity decreases on inserting Fe or FeCo thin layer, however, the magnetization remains nearly the same except FeCo for which it is increased. In MTJ full structure, the magnetization decreases to the nearly same value for Fe and FeCo insertion whereas the free layer coercivity increases with Fe and FeCo insertion. The transmission electron microscope images of without and with FeCo insertion MTJ show the MgO interface smoothness for the latter case. We found that the MgO interface roughness could be improved by the insertion of Fe and FeCo thin layer (1-2 nm), however, the effect of MgO interface reconstruction has a different impact on magnetic properties of the TbFeCo-based MTJ.

BU-03. Role of Boron in Sustaining Magnetic Thermal Tolerance in MgO/CoFeB/Mo Magnetic Tunnel Junction. *C. Yang*[1], C. Yang[1] and C. Lai[1] *1. Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan*

CoFeB/MgO-based magnetic tunnel junction (MTJ) has been considered an outstanding candidate to be applied to the embedded spin-transfer-torque magnetic random access memory (STT-MRAM). This work systematically studies the issues arising from the interdiffusion in an MgO/CoFeB/Mo MTJ system in terms of varying CoFeB's stoichiometries and the temperature of thermal annealing. Employing an Mo cap on CoFeB [1,2] enables the thermal endurance above 400 °C with a sustainable perpendicular anisotropy, which features less diffusion than Ta on the presence of reduced deadlayer (DL). By varying the stoichiometry of CoFeB, $Co_XFe_YB_{20}$ & $Co_XFe_YB_{30}$ [3,4], the magnetic properties of CoFeB were found in a wide tailorable window as a result of the competing diffusion mechanism between CoFeB and adjacent Mo. A clear suppression on DL was achieved upon increasing B composition to 30 at% (Fig. 1) at all the investigated annealing temperatures, which further boosted the H_k in nature. In addition, B also played a significant role of preventing the perpendicular anisotropy from thermal issue above 400 °C. A monotonic increasing on K_{eff} can be observed on the samples with high B composition (Fig. 2), which was absent in the previous reports and suggested the significant improvement of the thermal tolerance in this CoFeB/Mo combination. An optimized MTJ based on this MgO/CoFeB/Mo heterostructure has been proposed to be applied to the high temperature of BEOL process.

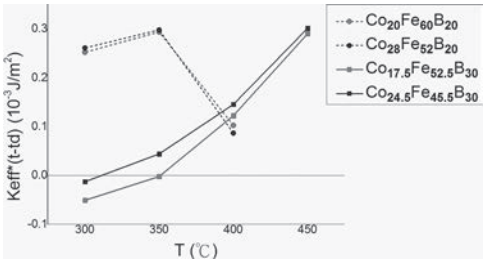

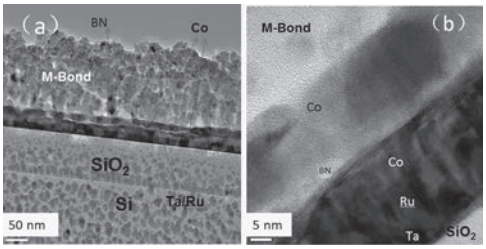

Fig. 2 K_{eff} x ($t-t_d$) versus annealing temperature for all the investigated CoFeB samples. Here K_{eff} is defined by M_s x H_k/2, t=1.5 nm and t_d is the DL thickness corresponding to which obtained at the specific annealing temperature.

BU-04. Investigation on the structural property of the sputtered hcp-phase Boron Nitride tunnel barrier for spintronic applications. *C. Peng*[1] and D. Zhang[1] *1. Electrical and Computer Engineering, University of Minnesota, twin cities, Minneapolis, MN, United States*

As a key building block of the next-generation high density non-volatile memory devices, magnetic tunnel junctions (MTJs) based on MgO tunnel barrier have attracted a significant attention in past decades due to the good performances (1). However, when the MgO tunnel barrier keeps thinning down to realize ultra-low RA with optimal spin transfer torque switching, there are challenges including the non-uniformity, defects and pinholes of MgO tunnel barrier. In addition, to apply the hcp phase perpendicular magnetic anisotropy materials for MTJ stacks, there is a limit for the cubic MgO tunnel barrier. Recently, it was found that the hexagonal boron nitride (hcp-BN) is a promising candidate as a tunnel barrier (2,3). The inert nature of hcp-BN provides a potential good control on the morphology and interface at the atomic scale and could minimize the defects. In this study, MTJ stacks with the hcp-BN tunnel barrier were prepared with a structure of Ta(4 nm)/Ru(20 nm)/Co(7 nm)/BN(8.4 nm)/Co(7 nm)/Ta(5 nm). All the samples were developed on Si/SiO_2 substrates by a magnetron sputtering system with the base pressure better than 5.0×10^{-8} Torr. The Ta (4 nm)/Ru (20 nm) seed layer was deposited at room temperature, and all other layers were deposited at 340°C. Nitrogen/Argon gas was used to deposit the hcp-BN tunnel barrier. The structural property of the MTJ stack is characterized through the cross-sectional TEM. As shown in Fig.1, the Ta/Ru/Co forms a high quality hcp texture, then induces the hcp texture BN layer as well as the top Co layer. This clearly shows that we successfully developed the hcp-BN tunnel barrier for fabricating the hcp textured perpendicular MTJ devices. Magnetic and transport measurements for the prepared MTJ stacks will be reported in the full paper

A bulk Co-rich CoMn binary disordered alloy has an antiferromagnetic fcc phase as thermodynamically stable phase [1]. On the other hand, metastable ferromagnetic bcc Co-Mn films have been prepared by molecular beam epitaxy (MBE) technique on optimum substrates such as GaAs [2] and MgO [3]. Here, we report, for the first time, relatively large tunnel magnetoresisitance (TMR) effect in magnetic tunnel junctions (MTJs) comprising of bcc Co-Mn electrode. The stacking structures of the Co-Mn films and the MTJs were MgO(001) sub./ Cr (40)/ Co-Mn(10)/MgO(2)/ Ta(3) and MgO(001) sub./ Cr (40)/ Co-Mn (10)/ Mg (0.4)/ MgO (2)/ CoFeB (4.5)/ Ta (3)/ Ru (5) (thickness is in nm), respectively. The samples were prepared by a magnetron sputtering system. The film composition was $Co_{74}Mn_{26}$ (at.%). The crystalline structures were characterized by x-ray diffraction (XRD) and transmission electron microscopy (TEM). The magnetic properties were measured by a vibrating sample magnetometer (VSM). The microfabrication of the MTJs were performed using a standard photolithography technique. The TMR effect was measured by a four-probe method at room temperature. The out-of-plane XRD measurements showed the 002 peaks from bcc Co_3Mn, however, those from fcc Co-Mn were not detected. The saturation magnetization M_s was approximately 1640 emu/cm^3. This value is similar to the magnetic moment value evaluated by x-ray magnetic circular dichroism for bcc $Co_{76}Mn_{24}$ alloy films [3], rather than that of fcc CoMn alloys with the similar Mn concentration. The MR curves measured at RT for the 40×2 μm^2 MTJ annealed at 350°C is shown in Figure 1. The resistance changes depending on the magnetization configuration are observed, however, the antiparallel state would not be well defined because the MTJ is a pseudo-spin valve type. The maximum TMR ratio was observed as 158% at the annealing temperature of 350°C for 1 hour. The TEM images showed the coherent epitaxial growth of the MgO barrier on the (001) Co_3Mn electrode, indicating possible coherent tunneling [4]. This work was partially supported by CREST (No. JPMJCR17J5), and JSPS Core-to-Core Program.

BU-06. Interface Characterisation Using Non-Destructive Method in MTJ. *K. Elphick*[1], T. Ichinose[2], S. Mizukami[2] and A. Hirohata[1] *1. University of York, York, United Kingdom; 2. Tohoku University, Sendai, Japan*

In the past decade Magnetic random access memory (MRAM) has overcome serval obstacles which increased the performance. [1] Magnetic tunnel junction (MTJ) is the predominant storage unit in MRAM. The performance of MTJ is highly dependent on the barrier interface in MTJ. The most common methods to characterise atomic interfacial structure is high-resolution transmission electron microscopy (HRTEM). [2, 3] However, this is known as a destructive imaging method where the device will be destroyed permanently. We are here to introduce a non-destructive method relying on back-scattered electrons which carries abundant information from the barrier interface. [4] MTJs consisting of Si(substrate)/Ta(5)/Ru(10)/Ta(5)/ CoFeB(10)/ MgO(2)/ CoFeB(2)/ Ta(3)/ Ru(5) (thickness in nm) were prepared by using magnetron sputtering at room temperature. Non-destructive characterisation method was undertaken on two distinctive MTJs, where the corresponding TMR ratios were almost 30 times different. The used acceleration voltages were estimated by the CASINO simulation. [5] SEM images were acquired using 16.4keV and 16.2keV to characterise the top MgO/CoFeB interface, whilst 16.6keV and 16.4keV were used to characterise the bottom CoFeB/ MgO interface. Figure 1a shows the images after image subtraction between the two images collected at two voltages above. Black and white dots in the middle of MTJ were observed representing pinholes in high TMR MTJ. On the other hand, the low TMR MTJ shown in Figure 1b contains fewer black dots. These results may suggest that the high TMR junction may create some pinholes due to the CoFeB/MgO crystallization process. Our results confirm that the capability of the non-destructive method in charaterising MTJ samples. It delivers supportive information for understanding the selective sample interface quality, which can be fed back to the fabrication process. This work is partially supported by JSPS-EPSRC Core-to-core programme (EP/M02458X/1) and JST CREST (JPMJCR17J5). The authors thank financial and technical support by JEOL UK to develop the non-destructive imaging.

BU-07. Effect of capping material on the reduction of write current in perpendicular magnetic-tunnel-junctions for STT-MRAM application.
H. Tomita[1,2], K. Nakamura[1], S. Bosu[1,2], K. Nagasaka[1,2], A. Gomi[1], A. Fukushima[2], H. Kubota[2], K. Yakushiji[2], S. Yuasa[2], H. Maehara[3,2] and N. Watanabe[1] *1. Tokyo Electron Technology Solutions, Nirasaki, Japan; 2. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; 3. Tokyo Electron Limited, Tokyo, Japan*

Perpendicular magnetic-tunnel-junctions (p-MTJs) with large MR ratio and lower resistance-area (*RA*) products [1] are required for spin-transfer-torque (STT) magnetic random access memory (STT-MRAM) applications. Recently, STT-MRAM has attracted much attention for its potential to replace SRAM, in particular for Last Level Cache (LLC) applications by taking advantage of its non-volatility and scalability. However, LLC applications require high-speed operation, low write current, and as well as low power consumption. One of the major challenges is to develop efficient pMTJ devices with low current operation in order to overcome the bottleneck for substitution of SRAM. In this study, we systematically investigated the effect of capping layer material on magnetic, and electric transport properties to reduce write current in pMTJ devices. In comparison with conventional MgO capping layer [2-4], we used Mg, Ru, and Ta as cap materials to control damping factor, and effective magnetic moment, M_s of the free layer, thereby to reduce the write current. The pMTJ films were prepared by DC magnetron sputtering using Tokyo Electron EXIM™ sputtering system. And the MgO tunnel barrier layer formed by natural oxidation process after metallic Mg layer deposition. Fig. 1(a) shows a schematic image of MTJ films. After deposition, MTJ films were followed by 400 degC post annealing for 1 hour. MR and *RA* properties (Fig. 1(b) and (c)) are almost independent of capping layer material. However, Ms considerably reduces for all other capping layers than conventional MgO cap. From the STT-switching properties of cylindrical nano-pillar pMTJ devices in Fig2, write current (I_{c0}) reduces about 30% than MgO capping layer for using Mg, Ru, or Ta capping layers with maintaining a high thermal stability factor, Δ over 70. In the presentation, we will also discuss the detailed STT-switching properties such as pulse width dependence with different cap materials.

BU-08. Development of thermally robust perpendicular MTJ for embedded MRAM application.
S. Bosu[1,2], H. Tomita[1,2], K. Nakamura[1], Y. Tanaka[1], K. Nagasaka[1,2], A. Gomi[1], A. Fukushima[2], H. Kubota[2], K. Yakushiji[2], S. Yuasa[2], H. Maehara[3,2] and N. Watanabe[1] *1. Tokyo Electron Technology Solutions Limited, Nirasakai, Japan; 2. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; 3. Tokyo Electron Limited, Tokyo, Japan*

Despite recent advances in STT-MRAM technology [1,2], improvement of thermal stability and energy efficiency still remains challenges because of the practical requirement of wide operating temperature range. Furthermore, a perpendicular magnetic tunnel junction (pMTJ) must possess a high thermal budget to withstand semiconductor back-end-of-line (BEOL) [3] process for embedded MRAM application. We report, development of the thermally robust (up to 250 °C) pMTJ by optimizing magnetization, M_s and anisotropy field H_k of CoFeB(CFB) free layer(FL). Low RA(~ 5 Ωμm^2) pMTJ films with high TMR ratio (~165%) were prepared by DC magnetron sputtering with the MgO barrier fabricated by natural oxidation process after metallic Mg layer deposition using Tokyo Electron EXIM™ sputtering system. Fig.1 shows a schematic structure of MTJ film based on two FLs separated by a Mo spacer. In this study we have investigated the effect of CFB FL2 thickness(t_{FL2}) on magnetic and transport properties to improve the thermal stability factor Δ. M_s increases linearly with increasing t_{FL2}(Fig.2(a), whereas, H_k is constant at t_{FL2}= 0.6, 0.8 nm and suddenly drops over 30% at t_{FL2}=1nm(Fig.2(b). Temperature (T) dependence of delta of pMTJ devices with electrical critical diameter, eCD = 80 nm in Fig.2(c) reveals that the Δ increases with increasing t_{FL2}, and decreases monotonically with increasing T. A considerably high Δ = 60 maintained even at T= 200 °C for t_{FL2} = 1 nm. Detail characterization and evaluation results will be reported in the presentation.

BU-09. Second order interfacial magnetic anisotropy for MgO/CoFeB/Ta films. *T. Ogasawara*[1], M. Oogane[1,2], M. Tsunoda[3] and Y. Ando[1,2]
1. Applied physics, Tohoku University, Sendai, Japan; 2. CSIS, Tohoku University, Sendai, Japan; 3. Electronic engineering, Tohoku University, Sendai, Japan

Magnetic tunnel junctions (MTJs) with MgO can exhibit a high tunnel magnetoresistance (TMR) ratio [1], which leads to the development of highly sensitive magnetic sensor devices [2]. For their electric vehicle applications, a linear output, i.e. low nonlinearity should be achieved for the safe operations, where nonlinearity has been recently reported to depend on the second order magnetic anisotropy, K_2 [3]. Hence, controlling K_2 is significantly important for the reduction of nonlinearity in MTJ sensor devices. Therefore, we have systematically investigated the CoFeB thickness dependence of K_2 and discuss its interfacial contribution in MgO/CoFeB/Ta films. The samples with the stacking of Ta(3)/MgO(2)/$(Co_{1-x}Fe_x)_{80}B_{20}$ (1.2-2.0)/Ta(5) (thickness in nm) were deposited on SiO_2 substrates using dc/rf sputtering at room temperature. All samples were post annealed at 300ºC for the CoFeB crystallization. The magnetic properties were characterized using a SQUID and an angular dependent FMR with microwave frequency of 9.4 GHz. Figure 1 shows an angular dependent resonance field, H_{res} for 1.4-nm-thick CoFeB with x=75. The small dip shown at around θ_H = 33 deg. is due to the easy cone state, which is realized under the condition of K_2/K_1^{eff}<-0.5, where K_1^{eff} is effective perpendicular magnetic anisotropy. Hence, we confirmed the presence of K_2 in CoFeB film. For the investigation of an interfacial effect, as shown in Figure 2, we plotted the areal K_2 against effective thickness, extracting dead layer, t_d of 0.2-0.5 nm for each x. The apparent linear relationships indicate the existence of interfacial K_2, $K_i^{(2)}$ similarly to well defined interfacial K_1^{eff}, $K_i^{(1)}$ [4]. Also, all compositions show negative $K_i^{(2)}$, implying that thinner film prefers smaller K_2 in contrast of well know positive $K_i^{(1)}$. We also found that the $K_i^{(2)}$ increases as increasing x, and shows the maxima of -0.024 erg/cm^2 at x = 100. The control of $K_i^{(2)}$ by CoFeB composition is significantly important to realize a reduction of K_2 leading to small nonlinearity in MTJ sensor devices.

BU-10. Detecting interfacial quadrupoles at Fe/MgO interfaces by X-ray magnetic linear dichroism. *J. Okabayashi*[1], Y. Iida[2], Q. Xiang[2], H. Sukegawa[2] and S. Mitani[2] *1. The University of Tokyo, Tokyo, Japan; 2. NIMS, Tsukuba, Japan*

Magnetic tunnel junctions using MgO barrier have been developed by exploiting the strong perpendicular magnetic anisotropy (PMA) of 1.4 MJ/m^3 at the interfaces between MgO and Fe [1]. As a fundamental understanding of PMA induced at the interface between ferromagnetic layer and MgO barrier layer, the interfacial electronic and magnetic states have to be clarified explicitly. There are numerous studies for the interfacial PMA between MgO and Fe including x-ray magnetic circular dichroism (XMCD) and the first-principles calculations [2,3]. For investigating the PMA energy, it is necessary to evaluate the anisotropy of not only orbital magnetic moments but also quadrupole moments through the interfacial strain [2]. In order to investigate the detailed site- and element-specific magnetic properties, we focus on the novel technique using x-ray magnetic linear dichroism

(XMLD) for PMA interfaces which enables to detect the quadrupole and magnetic anisotropy. In this presentation, we report the XMLD technique adopting for PMA at Fe/MgO interfaces and discuss the origin of PMA beyond the anisotropic orbital moments. Samples grown by electron-beam evaporation methods on MgO substrates are stacked as Cr buffer layer and the 0.7-nm-thick Fe layer with MgO capping layer. Post annealing was performed to enhance PMA. XMLD measurements were performed at room temperature using linear polarized beams. Fe $L_{2,3}$-edge X-ray absorption spectra exhibit clear metallic line shapes. XMLD intensities of 2.7 % are detected by the linearly polarized beam. XMLD sum rule suggests that the integrals of XMLD line shapes are proportional to quadrupole moment Q_{zz} and PMA energy [4]. We confirmed that the sign of Q_{zz} is positive; that is, $3dz^2$ orbitals are slightly elongated to out-of-plane direction. Therefore, the results of XMLD are consistent with those analyzed by XMCD line shapes. As for the origin of PMA in Fe/MgO interfaces, we found that orbital moment anisotropy can be a main factor for PMA with the small contribution of Q_{zz}. These results are comparable with the theoretical calculations [2]. In the presentation, we discuss the site-specific magnetic and quadratic properties of Fe/MgO interfaces using XMLD technique.

BU-11. Polycrystalline $Co_2Fe_{0.4}Mn_{0.6}Si$ Heusler alloy thin films with high *B*2 ordering and small magnetic anisotropy for magnetic tunnel junction based sensors. *N. Kudo*[1], M. Oogane[1], M. Tsunoda[2] and Y. Ando[1] *1. Applied Physics, Tohoku University, Sendai, Japan; 2. Department of Electronic Engineering, Tohoku University, Sendai, Japan*

The measurement of the magnetic field from the heart was successfully demonstrated at room temperature using magnetic tunnel junctions (MTJs) based sensor [1]. However, the sensitivity of MTJs-based sensor is still short for detection of the brain field. Since the sensitivity is defined as TMR ratio / $2H_k$ (H_k: magnetic anisotropy field of the free layer), high TMR ratio and small H_k are required. The $Co_2Fe_{0.4}Mn_{0.6}Si$ (CFMS) Heusler alloy is a candidate to realize the high sensitivity because of the high spin polarization and small H_k [2]. In particular, the polycrystalline CFMS films are useful for reduction of H_k by averaging of the crystalline magnetic anisotropy in the film plane. However, fabrication of the polycrystalline films with high *B*2-phase ordering parameter (S_{B2}), which is required for high spin polarization, is quite difficult. In this study, polycrystalline CFMS thin films were prepared on SiO_2 substrates to realize both high *B*2 ordering and small H_k. To optimize S_{B2} and soft magnetic property of CFMS films, Si/ SiO_2 sub./ Ta(5)/ CoFeB(5)/ Mg(0.4)/ MgO(10)/ CFMS(d_{CFMS})/ Ta(5) (thickness in nm) structure was fabricated by sputtering method and were annealed at various temperature (T_a) in a magnetic field of 1 T. MTJ devices with structure of Si/ SiO_2 sub./ Ta(5)/ CoFeB(5)/ Mg(0.4)/ MgO(10)/ CFMS(75)/ Mg(0.3)/ MgO(2)/ CoFeB(3)/ CoFe(2)/ IrMn(10)/ Ta(5) were also fabricated and characterized by DC 4-probe method. Fig. 1 shows the T_a dependence of S_{B2} for 25-100 nm thick CFMS films. We observed the highest S_{B2} of 83% for 75-nm-thick CFMS films with T_a = 500°C. The obtained S_{B2} was extremely high for polycrystalline Heusler thin films. Fig. 2 shows the T_a dependence of H_k for CFMS films with various d_{CFMS}. The lowest H_k of 4.0 Oe was achieved under the condition of d_{CFMS} = 75 nm and T_a = 500°C. We have also confirmed a small H_k in TMR curves for MTJ devices. The optimized polycrystalline CFMS thin films with high *B*2 ordering and small H_k can realize a very high sensitivity in MTJs-based sensors.

BU-12. Generating temperature gradients in three-dimensions, the Anomalous Nernst effect in magnetic tunnel junctions. U. Martens[1], T. Huebner[2], H. Ulrichs[3], O. Raimer[2], T. Kuschel[2], R. Tamming[4], C. Chang[4], R. Tobey[4], A. Thomas[5], M. Münzenberg[1] and *J. Walowski*[1] *1. Greifswald University, Greifswald, Germany; 2. Bielefeld University, Bielefeld, Germany; 3. Göttingen University, Göttingen, Germany; 4. Zernike Institute for Advanced Materials, Groningen, Netherlands; 5. IFW, Dresden, Germany*

Thermomagnetic effects are the key elements for energy efficient spintronic and sensing applications. Their application field is the usage of the otherwise wasted heat generated in ever-smaller electronic circuits. In a systematic investigation of three-dimensional temperature gradients created by localized laser heating in magnetic devices, we study the generated thermomagnetic voltages in magnetic devices [1]. We measure the tunnel magneto-Seebeck effect (TMS) and extract the anomalous Nernst effect (ANE) generated on a nanometer length scale by micrometer sized temperature gradients in magnetic tunnel junctions (MTJs). The best conditions to generate the TMS in MTJs is to create the highest possible, homogeneous temperature difference through the layer stack i.e. having the same temperature at each layer thickness. Therefore, the ANE can be extracted by analyzing the influence of in-plane temperature gradients on the TMS in in-plane magnetized pseudo spin valve MTJs based on CoFeB electrodes with uniaxial magnetic anisotropy (UMA) and an MgO tunnel barrier. The direction-controlled

temperature gradients are created by a focused cw diode laser spot. The spatial extent of the measured effects is defined by the elliptically shaped MTJ sized 6 μm×4 μm, while the spatial resolution is given by the laser spot size and the step size of its lateral translation. We investigate the influence of the CoFeB electrodes UMA on the generated ANE voltage in by systematically rotating the temperature gradient in the MTJs plane. Our measurement method is highly sensitive to low voltages and yields an ANE coefficient of $K_N \approx 1.6\times10^{-8}$V/TK for the used CoFeB composition. This is slightly lower than was found for other CoFeB compositions. At such a high sensitivity, the generated ANE effect allows to expand the MTJs' functionality from simple memory storage to nonvolatile logic devices and in combination with the UMA opens new application fields, for example, direction-dependent temperature sensing.

BU-13. Applying Oblique-Incidence Deposition to Tailor Magnetic Properties of CoFeB in Single Thin Films and TMR Stacks. *K. Schlage*[1], S. Willing[1,2], T. Gurieva[1], M. Ramin Moayed[1] and R. Röhlsberger[1,3] *1. DESY, Hamburg, Germany; 2. PIER Helmholtz Graduate School, Hamburg, Germany; 3. The Hamburg Centre for Ultrafast Imaging, Hamburg, Germany*

CoFeB has developed into one of the most used magnetic materials for tunneling magnetoresistance (TMR) applications. To exploit the TMR effect in a CoFeB-MgO-CoFeB stack, an annealing step is required for templated crystallization and the relative orientation of magnetization in the two CoFeB electrodes needs to change in external magnetic fields. In practice, the latter is often achieved by pinning one of the magnetic layers in an exchange bias structure. Recently, we showed that oblique-incidence deposition (OID) is an easy and flexible technique to tailor the magnetic properties of ultrathin films by inducing additional shape anisotropy [1]. The two angular degrees of freedom during sputter deposition freely tune the orientation of magnetization as well as the coercive field in every single magnetic layer of a multilayer stack. In this contribution, we present the interdependencies of film thickness, deposition angles, thermal annealing and resulting magnetic properties in single CoFeB layers and TMR stacks. From a scientific point of view, OID-CoFeB is very interesting due to a sensitive balance of different anisotropy terms that leads to an anomalous in-plane rotation of magnetization that relaxes upon annealing. From the application point of view, it is possible to tailor switching fields and functionalities of TMR-stacks for the first time in a simple and convenient fashion by choosing appropriate deposition angles and layer thicknesses. A thorough understanding of the OID parameters' influence on magnetic and magneto-resistive properties of CoFeB itself and embedded in a TMR stack could pave the way to custom-designed TMR sensors in the future.

[1] K. Schlage, L. Bocklage and R. Röhlsberger, Adv. Funct. Mater. 26, 7423 (2016)

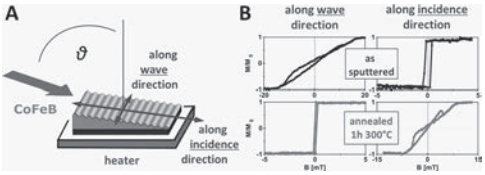

Fig. 1) (A) The wavy surface profile obtained through OID adds a shape anisotropy that supports a magnetic easy axis perpendicular to the particle incidence. (B) However, in thin CoFeB layers, the magnetization is oriented along the incidence direction (sharp switching) in the as-sputtered state and only rotates into the OID-induced direction upon annealing.

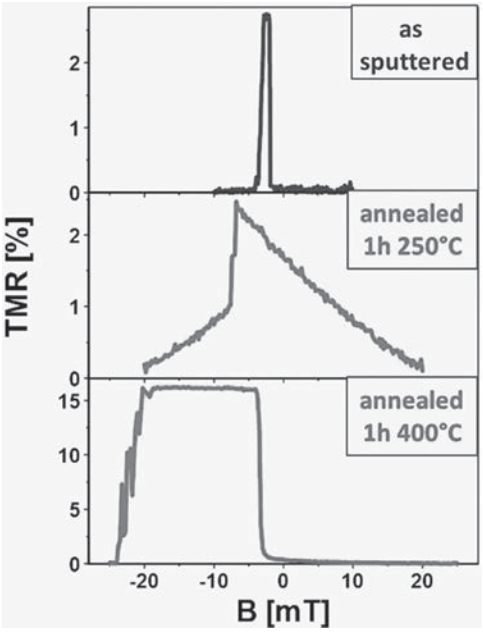

Fig. 2) A TMR stack with OID-induced parallel easy axes shows the 90°-rotation in one of its layers upon partial annealing at low temperature, but assumes the expected plateau shape after about 350°C.

BU-14. Large tunnel magnetoresistance effects in Fe_3O_4(001)/MgO(001)/Fe(001) epitaxial magnetic tunnel junctions. S. Yasui[1], J. Okabayashi[2], T. Yanase[3], T. Shimada[3] and *T. Nagahama*[3] *1. CSE, Hokkaido University, Sapporo, Japan; 2. Research Center for Spectrochemistry, University of Tokyo, Tokyo, Japan; 3. Graduate School of Engineering, Hokkaido University, Sapporo, Japan*

The Fe_3O_4, which is a typical iron oxide with spinel structure, has attracted much attention because of the potential as a spintronic material. It is predicted to be a half-metal with -100% spin polarization theoretically[1], so that large tunnel magnetoresistance (TMR) ratio is expected in the magnetic tunnel junctions (MTJ) with Fe_3O_4 electrodes. However, the TMR ratio remains small value, though many research groups have been worked on the Fe_3O_4-MTJs[2]. Moreover, the sign of the TMR effect varies according to the papers. This is a crucial issue to develop the spintronics with magnetic oxides matters. In this study, we fabricated fully epitaxial Fe_3O_4(001)/MgO(001)/Fe(001) junctions and observed the TMR ratio of -55%. Samples were fabricated by an MBE system with the base pressure of 5×10^{-8}Pa. The sample structures were MgO(001) substrate / MgO(20 nm) / NiO(5nm) / Fe_3O_4(60 nm)/MgO(2.5nm)/Fe(10nm)/Au(30nm). Fe_3O_4 thin film was formed by reactive deposition at a substrate temperature (Tsub) of 573K in an O_2 gas atmosphere of 4×10^{-4} Pa. Then the films were annealed at T_{sub} of 873K for 30 minutes in an O_2 gas atmosphere. MgO tunnel barrier and Fe/Au top electrodes were deposited at room temperature. The junctions of 10x10 μm^2 were fabricated by photolithography, Ar ion milling, and sputtering.

To examine the magnetic states at Fe_3O_4/MgO interface, The XMCD measurements were performed at BL-7A in the Photon Factory (KEK). Figure 1 showed the TMR curve of the Fe_3O_4-MTJ at 80K. We observed TMR of -55% which is the largest TMR ratio in Fe_3O_4-MTJ as far as we know. The negative TMR corresponded with negative spin polarization predicted theoretically. The shape of the TMR curve had small squareness indicating incomplete antiparallel magnetic configuration. The TMR ratio increased with decreasing temperature monotonically, which is similar behavior to previous reports[3]. The bias dependence of TMR and XMCD spectra will be also discussed.

Institute of Ion Beam Physics and Materials Research, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany*

The resistive switching (RS) in various materials has attracted much attention due to its interesting physics and potential applications.[1] Conductive filaments have been widely reported as an important mechanism of unipolar resistive switching (URS), which can be manifested by the observation of magnetoresistance (MR) effect if ferromagnetic metallic filaments are formed.[2] In this work, Pt film as bottom electrode, then Ni and Al_2O_3 layers were deposited in turn on SiO_2/Si substrates at room temperature. An array of Ni top electrodes were deposited to obtain the Ni/Al_2O_3/Ni/Pt capacitors. Typical URS can be clearly observed in Figure 1. The device initially is in high resistance state (HRS). After the forming process with current compliance of 1 mA, the device changes to low resistance state (LRS). The LRS changes to HRS at voltage of 0.68 V with increasing voltage from 0 V, which is called the set process. And HRS changes to LRS again at the voltage of 3.84 V during the subsequent voltage sweeping from 0 V. It is understood that Ni^+ ions migrate into Al_2O_3 layer to form the metallic Ni conductive filaments under the external electric field.[2] To further confirm this, we perform the MR measurements. Clear MR effect can be observed when the device is in LRS. We further change the field direction from in-plane to perpendicular, similar positive MR curve can be observed, in contrast the conventional anisotropic MR in Ni film, suggesting the possible giant MR (GMR) effect.[3] No MR is detected in HRS due to the broken of filaments. We further add resistors of various resistance values in serial connect to the device to modify the resistance of the device in LRS (63 Ω, 97 Ω, 114 Ω, 126 Ω). Similar GMR effect is observed, however, the MR value continuously decreases with increasing the resistance in LRS. With increasing the resistance in LRS, the diameter of Ni conductive filaments becomes smaller. Thus, the nonmagnetic scattering at the surfaces of filaments increases, leading to the decrease of MR value.

The tuning of magnetization, coercivity, and spin-orbit torque (SOT) through composition, film thickness and temperature in the rare earth-transition metal ferrimagnets have revealed enormous possibilities for spintronics applications[1-5]. The control of electrical current in nanoscale devices is important for advanced applications of spintronics. In this work, the influence of a wide range of dc sense currents on the anomalous Hall voltage and switching field in Tb-rich TbFeCo thin film structure have been studied. we deposited Tb-rich TbFeCo thin film structure with a Ta/MgO capping layer. The blanket film showed perpendicular magnetic anisotropy (PMA). The anomalous Hall measurements on two Hall bar widths of 5 and 10 μm were carried out with a series of dc sense currents. The coercivity (H_C) and the switched state anomalous Hall resistivity (ρ_{AHE}) are found to be decreasing with increasing the dc sense current. A sharp drop in ρ_{AHE} and H_C is observed after 1 mA sense current. The investigation on V_{AHE} variation with sense current revealed linear behavior except at large current, where V_{AHE} either drops or saturates. The V_{AHE} behavior is explained by considering the current induced SOT and the Joule heating knowing that the V_{AHE} is proportional to the perpendicular component of magnetization M_Z. At large currents, the SOT field pushes the magnetization away from the Z-direction which drops the M_Z. Further, Joule heating at large currents also drops down the M_Z. The switching speed is estimated by reciprocal of the difference in the saturation and the nucleation field. It is argued that at large dc currents, the switching speed is higher for 10 μm in comparison to the 5 μm Hall bar width. The Joule heating is larger for 10 μm width in comparison to the 5 μm width, which supports the fast switching behavior. This study initiates the sense current effect on device performance in various spintronic applications.

BV-02. Spin-Orbit Torques in In-plane Magnetized Systems Driven by Breaking of Inversion Symmetry. *D. Gupta*[1], A. Kumar[1], P. Gupta[1], N. Chowdhury[1] and P.K. Muduli[1] *1. Physics, Indian Institute of Technology Delhi, New Delhi, India*

The injection of charge current into a system comprising of a heavy metal (HM) and a ferromagnet (FM) can produce a spin-orbit torque (SOT)[1], which can be used to manipulate the magnetization of the FM layer. SOT can have two origins, namely, spin Hall effect[2] (in bulk HM layer), and Rashba effect[3] (at FM/HM interfaces). Harmonic Hall measurements have been widely used to study SOT in systems with perpendicular magnetization anisotropy[4,5]. In this work, we have studied two different sputter deposited in-plane magnetized anisotropic systems; NiFe(10 nm)/Ta(2 nm) (S1) and Ta(5 nm)/CoFeB(10 nm)/MgO(4 nm) (S2) to investigate the role of breaking of the inversion symmetry in SOT generation. We have fabricated Hall bar structures (500×50 μm^2) using lift-off technique. We used a recently proposed harmonic Hall measurement[6] method to simultaneously measure the damping like (H_{DL}) and field-like (H_{FL}) effective fields. In this measurement, we use a vector magnet assembly, which consists of two electromagnets. The field along the x-axis was used to saturate the sample while the field along the y-axis was varied and the first (R_w) and second (R_{2w}) harmonic resistances were measured. Figure 1 (a, b) shows the variation of R_{2w} with the applied field in the perpendicular direction of current (H_y) in the presence of the fixed field H_x = ±100 Oe and ±200 Oe for S1 and S2 respectively. According to Ref. 5, the sign of R_{2w} should change on reversing the direction of magnetization or the magnetic field. In the case of S1, R_{2w} does not show any sign change on reversing the sign of H_x, while, R_{2w} does changes its sign with the H_x for S2. This result shows the absence of SOT in S1. The presence of oxide layer, which breaks the inversion symmetry along the growth direction, is found essential to observe SOT. We have quantified the H_{DL} and H_{FL}. A linear variation is obtained for their current dependence and is shown in Fig. 1 (c, d).

An important goal of current spintronics research is the development of efficient and reliable ways to produce spin-polarized electrical currents. In classical spintronics, such spin-polarized currents are obtained when a charge current passes through a magnetic material. A new approach for the generation of spin-polarized electrical currents takes advantage of the spin-dependent scattering notably observed in heavy metals. This phenomenon is related to the spin Hall effect (SHE) and could be extended to Edelstein effect in 2D materials [1]. Spin-orbit torques (SOT) produced by such spin currents have the advantage to eliminate the need for a magnetic layer and to dissociate the spin current from the charge current. It is established that using small in-plane fields, it is possible to reverse thin magnetic layers with perpendicular anisotropy [2]. Nevertheless, the origin and the microscopic understanding of the spin current absorption mechanisms at the interface are still debated. Here, we present a recent work on the perpendicular magnetization reversal induced by SOT of micronic and submicronic patterns of [Co(0.2nm)/Ni(0.6nm)]x5 multilayer films on top of 6-nm-thick Pt electrodes. The electrically induced switching process details is probed by anomalous Hall effect measurements and Kerr microscopy. It leads, as recently reported [3], to a deterministic nucleation of magnetic domain involving the field- and damping-like torques and the Dzyaloshinskii-Moriya interaction (DMI). We measured switching diagrams for disks (Figure 1) for in-plane field directions and current. In light of these experiments and micromagnetic simulations, we will discuss the key parameters needed to understand the magnetization reversal.

BV-04. Spin-orbit torque acting on a perpendicularly-magnetized Py. *T. Chen*[1], Y. Ou[2], R. Buhrman[2] and C. Pai[1] *1. National Taiwan University, Taipei, Taiwan; 2. Cornell University, Ithaca, NY, United States*

Current-induced spin-orbit torque is an efficient mechanism to drive magnetization switching [1]. When a charge current flowsin heavy metal (HM) layer with large spin-orbit interaction, the spin Hall effect (SHE) therein generates a transverse spin current that will flow into the ferromagnetic layer (FM). However, the transmission of this spin current or spin transparency at the HM/FM interface will also strongly affect the resulting SOT efficiency acting on the FM layer. The effective dampinglike SOT (DL-SOT) efficiency of a particular heterostructure therefore should be expressed as, where and represent the internal spin Hall ratio of HM and the HM/FM interfacial spin transparency factor, respectively. In this work, we show that Py, a commonly used soft ferromagnetic material with weak anisotropy, which iswidely used as in-plane magnetized FM layer in the ST-FMR measurement [2], can become perpendicularly magnetized while depositing Ta buffer layer with Hf or Zr insertion layers (ILs) and an MgO capping layer. By using harmonic voltage measurement [3] and hysteresis loop shift measurement [4], the damping like spin-orbit torque efficiency are systematically characterized and the current-induced switching are also demonstrated in both heterostructures. We find that though Ta has a significant spin Hall effect, the DL-SOT efficiencies are small in systems with the Ta/Py interface compared to that obtained from the control sample with the traditional Ta/CoFeB interface. Our results indicate that the spin transparency for the Ta/Py interface is much less than that for the Ta/CoFeB interface, which might be related to the variation of spin mixing conductance for different interfaces.

BV-05. Material and Thickness investigation in Ferromagnet/Ta/CoFeB Trilayers for Enhancement of Spin-orbit torque and Field-free Switching. Y. Oh[1], *J. Ryu*[1] and B. Park[1] *1. Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Daejeon, The Republic of Korea*

The generation of spin current in a magnetic nanostructure has drawn a great deal of attention because it can be used to efficiently manipulate the magnetization via in-plane current induced spin-orbit torque (SOT)[1, 2]. In a conventional SOT structure of a heavy metal (HM)/ferromagnet (FM) bilayer, the direction of spin polarization is aligned in the film plane, thus an external magnetic field is required for the SOT-induced switching of perpendicular magnetization. On the other hand, our previous study demonstrated that a spin current generated at FM/Ti interface in FM/Ti/CoFeB magnetic trilayers[3,4] has spin polarization along out of plane direction, enabling field-free switching. Here, we report SOTs in FM (CoFeB, NiFe)/Ta/CoFeB trilayers, in which the spin current generated by spin Hall effect (SHE) in Ta can be combined with the interface-generated spin current at the FM/Ta interface. Figure 1 shows the first (V_{1w}) and second (V_{2w}) harmonic Hall voltages as a function of in-plane magnetic fields (B_x or B_y) for the samples with various Ta thicknesses t_{Ta}. This shows that the sign of the SOTs depends on the FM when t_{Ta} is thinner than 1.5 nm, demonstrating that the SOTs are dominated by the spin current in bottom FM/Ta interface. However, as t_{Ta} increases, the sign of the SOTs follows spin Hall angle of Ta, indicating the SOTs mainly rely on the SHE in Ta. Furthermore, we observe field-free magnetization switching in the Ta thickness ranges, where a sizable amount of the interface-generated spin current in the CoFeB/Ta bilayers is present (Fig. 2). Our study demonstrates that SOTs in trilayers are determined by the contributions of interface-generated spin current in bottom FM/Ta and SHE in Ta, suggesting that a proper material combination in the trilayer provides a way for optimistic material engineering of SOT-based applications.

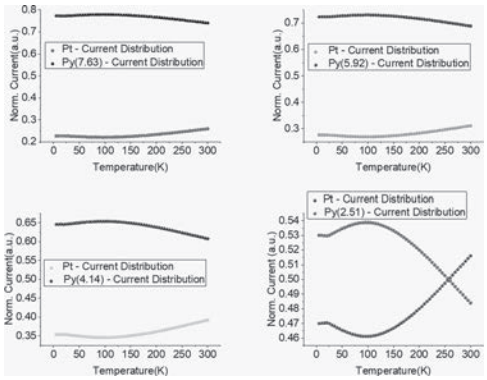
One can use spin-polarized currents or spin currents to drive domain wall motion in magnetic thin film strips or wires. This phenomenon has potential applications in energy-efficient memory and logic devices, such as race-track memory. To realize high-dense memory, thin films with perpendicular magnetic anisotropy (PMA) are needed; to achieve fast domain wall motion, films with low damping are desired since in general the speed of domain walls is inversely proportional to the damping constant. To date, the research on this subject has been based mainly on metallic PMA thin films that usually show relatively large damping due to magnon-electron scattering. It is well known that damping in magnetic insulator $Y_3Fe_5O_{12}$ (YIG) is lower than in any other magnetic materials, but the anisotropy in YIG films is usually very weak and the magnetization is usually confined in-plane due to the demagnetization field. Here we report the realization of low-damping YIG thin films with PMA. The films are epitaxially grown on single-crystal, (111)-oriented, substituted gadolinium gallium garnet (SGGG) substrates by sputtering. Due to the lattice mismatch between the films and the substrates, in-plane tensile strain presents in the YIG films and induces strong PMA in the films. The films show smooth surfaces, (111) orientation, square magnetic hysteresis loops, and low damping. For example, a 6-nm-thick YIG film showed a rms surface roughness of 0.3 nm, an effective PMA field of 2200 Oe, a coercive field of 60 Oe, a hysteresis loop squareness of almost 100%, and a Gilbert damping constant of about 4.8×10^{-4}. Note that the damping constant was determined using perpendicular fields; it is about one or two orders of magnitude lower than the values reported previously for PMA thin films. Anomalous Hall effect (AHE) was detected in YIG(6 nm)/Pt(5 nm) bi-layers. Via AHE measurements, current-induced magnetization switching was demonstrated on the YIG/Pt

bi-layers at room temperature. The switching current density is 0.8 MA/cm^2, which is significantly lower than in most of the previous spin-orbit torque-induced magnetization switching experiments.



BV-07. Spin-Orbit Torque in Heavy Metal/ Ferromagnetic Bilayers.
H. Kannan[1], Y. Ou[2], R. Barri[3], H. Chen[3], K. Haughey[3], M. Doty[2] and J. Xiao[3] *1. BE Metals, Intel Corporation, Hillsboro, OR, United States; 2. Materials Science and Engineering, University of Delaware, Newark, DE, United States; 3. Physics and Astronomy, University of Delaware, Newark, DE, United States*

In the past, the current-driven spin-orbit torques (SOT) in metallic ferromagnetic/heavy metal (FM/HM) bilayers were analyzed by neglecting the current in FM layer. However, it has been revealed recently that an electric current through a FM layer can introduce SOT not only in a neighboring FM layers [1,2], but also in itself [3]. Therefore, the contribution to SOT from the current in FM layer in FM/HM bilayers cannot be ignored. While developing analytical expressions for interface contribution to current-induced SOT, Kim, et al [4] have concluded, that the currents in both FM and non-magnetic (NM) layers contribute to the SOTs with additive field-like torque and canceling damping-like torque. In this work, we aim to verify the contribution to SOT from the FM layer in FM/HM bilayers. We design the bilayers with the same HM (Pt) but FMs of markedly distinct resistivities, such as NiFe and CoFeB. Therefore the current distribution is very different in HM and FM layers in two systems. In addition, the temperature coefficients of resistivity (α) for the chosen materials are also very different with $\alpha_{CoFeB} << \alpha_{NiFe} \sim \alpha_{Pt}$. Consequently, the current distribution in HM and FM remains similar in Pt/NiFe but changes in Pt/CoFeB as a function of temperature. The temperature dependent resistance of the bilayer structures are shown in Fig. 1, and derived temperature dependent current distributions in FM and HM layers are depicted in Fig 2. The temperature dependence of field-like and damping-like torques have been measured using magneto-optical Kerr (MOKE)-based spin-orbit torque magnetometer [5]. Experimental results will be compare to theoretical predictions.

BV-08. High Power Spin Torque Nano-Oscillators Integrated Directly on a MOSFET. *D. Kang*[1], W. Jeong[1], J. Lee[1] and M. Shin[1] *1. KAIST, Daejeon, The Republic of Korea*

Spin torque nano-oscillators (STNOs) have been significantly studied over the past few decades due to their potentials for practical application as devices in the gigahertz band [1-4]. It is necessary to increase the output power and reduce the linewidth for practical application of STNOs [5]. Here, employing a macrospin simulation and the Technology-Computer-Aided-Design (TCAD) device simulator, we investigated the output power of synchronized STNOs integrated directly on a metal-oxide-semiconductor field-effect-transistor (MOSFET), where both electrical and magneto-dipolar coupling between the STNOs induce the synchronization of STNOs [Fig. 1]. Our proposed model not only overcomes the issue of the noise generated from a metal wire between STNOs and an amplifier but also maintains the degree of integration by minimizing the area of devices. The operating principle of this model is simple. The DC voltage induces the magnetization precession of the free layer, and the combination of the GMR (TMR) effect and magnetization precession induces the voltage oscillation across the load resistance acting as the gate voltage of the MOSFET. The voltage across the load resistance can be amplified in a normally-on MOSFET in this model. We found that the output power is greatly enhanced by amplifying the AC voltage generated by synchronized STNOs. For example, in case of the serially connected STNOs, the output power obtained upon the amplication of four synchronized STNOs is approximately 118.8 times larger than the output power of the single STNO [Fig. 2]. Futhermore, we reveal that the number of serially connected STNOs is theoretically unlimited within the cutoff frequency of the MOSFET.

BV-09. Angular Characterization of the Spin-Orbit Effective Fields.

H. Yang[1] and X. Qiu[1] *1. School of Physics Science and Engineering, Tongji University, Shanghai, China*

Spin-orbit torque (SOT) in heavy metal (HM)/ferromagnet (FM) heterostructures opens a new avenue to switch magnetization and move magnetic textures in an efficient and fast manner [1-4]. In studies of SOT, the existing techniques to evaluate SOT effective fields, such as the DC, AC and FMR measurement, have been still restricted by many factors such as the anisotropy, the artifacts from the thermal gradient and planar effect *etc*. [5]. Therefore, it is necessary to develop a versatile and general technique to accurately characterize SOT effective fields to advance the development of spin-orbitronic. In this work, we showed the characterization of the sign and amplitude of SOTs by angular measurements. Compared to most of the previous measurements, this angular characterization does not require perquisites of the strong perpendicular anisotropy thus it is capable for more general schemes. The large second harmonic Hall signal contribution of the thermal gradient caused by Joule heating can be readily removed by the external field (H_{ext}) dependence. Fig. 1 shows the finite element analysis of the current induced thermal gradient and the characterization of anti-damping effective field (H_L). As shown Figs. 2(a) and (b), the SOTs cause the oscillation of magnetization in two geometries and the oscillation amplitude decreases with the H_{ext} increases while the thermal gradient contribution did not affect. By analyzing the H_{ext} dependence of the second harmonic voltage, the SOTs effective field and thermal effect can be determined as shown in Figs.2c. Our work provides a comprehensive and versatile method to characterize SOTs and paves the necessary foundation for the spin-orbitronic studies.

BV-10. Spin-orbit torques in low-resistive mixed phase Ta Thin Films.

A. Kumar[1], R. Sharma[1], S. Chaudhary[1] and P.K. Muduli[1] *1. Department of Physics, Indian Institute of Tachnology Delhi, New Delhi, India*

Current-induced spin-orbit torques (SOTs) in ferromagnet/heavy metal (FM/HM) heterostructures provide the opportunity for magnetization switching[1] and auto-oscillations[2]. SOTs can enhance or compensate the Gilbert damping (α_{eff}) depending upon the direction of current flow. Initially, spin Hall effect is considered as essential for SOTs, however, recent studies have suggested breaking of inversion symmetry at the FM/HM interface due to Rashba effect also contributes to a large extent[3]. In this work, we have studied the current induced modulation of α_{eff} using spin-torque ferromagnetic resonance (ST-FMR) technique in NiFe (10 nm)/Ta (10 nm) bilayers. Here, we have optimized the growth of Ta thin films for low resistive mixed phase (α+β)-Ta having a high spin Hall angle (θ_{SH} = -0.17)[4]. The electrical resistivity for Py and Ta thin films are ρ_{Py} = 33 μΩ-cm and ρ_{Ta} = 68 μΩ-cm, which results in 32% total current passing through Ta. The rectangular mesa of size 16×40 μm^2 of NiFe/Ta bilayer deposited using DC magnetron sputtering and fabricated using optical lithography for STFMR measurements. Figure 1(a) shows observed STFMR spectra for 5 GHz RF frequency (*f*), observed spectra can be fitted with Lorentzian equation (Red line)[5] to determine symmetric (V_S), asymmetric (V_A) voltage signal, linewidth (ΔH) and resonance field (H_R). Inset of Fig. 2 shows *f* vs. ΔH, where the red line shows

a linear fit to the observed data to calculate α_{eff}. Current-induced modulation of α_{eff} for +6 mA to -6 mA is shown in Fig. 2. We have found 34.6% current modulation in α_{eff} for current density ($J_{C,Ta}$) = 2.8×10^{10} A/m^2. The high current modulation and θ_{SH} in mixed phase Ta compared to their β-phase counterpart can be understood by the interplay of bulk spin Hall effect and interfacial Rashba type effects. These results are very promising for the rapid developments in the fabrication of efficient spin Hall effect based devices.

BV-11. Switching Perpendicular Ferromagnetic Layer by Spin Orbital Torque from Cu_xNi_{1-x} Non-heavy Metal. *Y. Yen*[1], P. Lin[1] and C. Lai[1]
1. Material Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan

Spin orbital torque (SOT) has become a promising candidate for MRAM switching method due to it's fast switching speed and low switching power consumption. Contribution of spin current by SOT is believe to correlate with Z number of element due to spin orbital interaction such as Pt, Pd, Ta elements. Recent research also shows spin hall effect from non-heavy metal such as Cr, Ni, CuO. A research published recently shows nearly unity spin hall angle in $Cu_{40}Ni_{60}$ system measured by ferromagnetic resonance technique[1]. In this work we use Cu_xNi_{1-x} (x=0.34, 0.39, 0.44, 0.48) as spin current source to switch perpendicular magnetized Co/Ni multilayer. The critical switching current density is at the level of 3 – 6 x 10^7 A/cm^2, comparable to Pt case. The high switching efficiency of perpendicular ferromagnetic layer by non-heavy metal provides a much cost-effective spin current source compare to noble metals. The film stack is Si/SiO2/Ti (5)/Cu_xNi_{1-x} (6)/[Co (0.3)/Ni (0.6)]x2/Ti (2) fabricated by magnetron sputtering. Composition of the sample is determined by ICP-MS result. Numbers in parentheses are thickness in nm. Films were pattern into devices with lithography system with lift-off technique with a linewidth of 10 um. The switching test is conduct under various Hx and magnetization is measured by micro magneto-optic Kerr effect (MOKE) system. The shunting current into CuNi layers is calculated by resistivity measured from 4-point probe experiment on sheet film. Figure 1a shows typical switching behavior from $Cu_{0.39}Ni_{0.61}$ sample. Figure 1b shows critical switching current density versus applied Hx. We successfully demonstrate perpendicular ferromagnetic layer switching by non-heavy metal with low critiical swtching current densty, which can be used as both cost effectve and energy effcient spin current source.

BV-12. Spin torques on the surface of magnetic topological insulators with hexagonal warping. *Y. Imai*[2], T. Yamaguchi[1], A. Yamakage[2] and H. Kohno[2] *1. National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan; 2. Department of Physics, Nagoya University, Nagoya, Japan*

Recently, two-dimensional Dirac electrons on the surface of magnetic topological insulator (MTI) have been attracting attention in spintronics. Usually, the Dirac electrons are modeled by a linear-dispersion model, but it was found experimentally [1] and pointed out theoretically [2] that the dispersion of Dirac electrons on some topological insulators, such as Bi_2Te_3 [3], is deformed hexagonally, and such "hexagonal warping" can be important in certain phenomena. For example, it was shown that the quantum anomalous Hall effect is induced by in-plane magnetization [4,5]. On the other hand, spin torques on the surface of MTI were studied without hexagonal warping and it was demonstrated that the ordinary spin-transfer torque and the dissipative correction (beta torque) do not exist on the surface of MTI [6]. In this work, we investigate spin torques due to Dirac electrons with hexagonal warping, including the spin-transfer torque and the beta torque. First, we list all possible form of spin torques allowed by symmetry. We introduce three viewpoints to classify the torques, which are viewpoints of spin-transfer torque, spin-orbit torque, and the one which does not allow a simple interpretation. Then, we show the result of microscopic calculation for each spin torque. We found that the spin-transfer torque and the beta torque arise due to the hexagonal warping. We also found that a nonequilibrium Dzyaloshinskii-Moriya interaction is induced by in-plane electric field owing to the hexagonal warping.

BV-13. Enhanced Spin-Orbit Torques and Multi-Level Current-Induced Switching in W/CoTb/Pt Heterostructure. *Z. Zheng*[1,2], Y. Zhang[1], X. Feng[1], K. Zhang[1], J. Nan[1], Z. Zhang[1,2], G. Wang[1], J. Wang[1], N. Lei[1], Y. Zhang[2] and W. Zhao[1] *1. School of Microelectronics, Beihang University, Beijing, China; 2. School of Electronics and Information Engineering, Beihang University, Beijing, China*

Spin-orbit torque (SOT) driven magnetization switching in Ferrimagnets (FIMs) can inspire variety of low-power, high-speed and multifunctional spintronic devices [1-4]. Recently, SOT efficiency in FIM/heavy metal systems has been found to be increased when FIM is approaching its magnetic compensation point [3-5]. However, the effective spin Hall angle cannot be obviously augmented owing to the net magnetization reduction [1,2,6], which degrades FIM's future application potential. Here, we investigate enhanced SOT effect in a heterostructure composed of a near-compensated CoTb layer sandwiched by W and Pt layers (see Fig. 1a), where CoTb is a typical rare-earth-transition-metal (RE-TM) ferrimagnetic alloy with bulk perpendicular magnetic anisotropy (PMA) and W has the opposite spin Hall angle against Pt [7-8]. As shown in Fig. 1b, beyond a large SOT efficiency (58.6×10^{-10} Oe m^2/A), 1.84 times damping-like effective spin Hall angle and 20% switching power consumption can also be achieved simultaneously by optimizing the thickness of Pt layer, compared with SOT performance in conventional W/CoTb structure. We further carry out current-induced multi-level magnetization switching in Pt(3nm)/CoTb(2nm)/W(5nm)/CoTb(4nm)/Pt(3nm) stack (see Fig. 2a). Anomalous Hall effect (AHE) curve in Fig. 2b confirms that zero coupling effect exists between two CoTb layers. By sweeping current pulse under a certain in-plane magnetic field along the current direction, four magnetization states ($CoTb_{thin,\uparrow}$, $CoTb_{thick,\downarrow}$), ($CoTb_{thin,\downarrow}$, $CoTb_{thick,\downarrow}$), ($CoTb_{thin,\downarrow}$, $CoTb_{thick,\uparrow}$) and ($CoTb_{thin,\uparrow}$, $CoTb_{thick,\uparrow}$) can be achieved in sequence (see Fig. 2c), which doubles the capacity of normal SOT devices. Our work combining efficient and multi-bit magnetization switching provides an alternative route to leverage ferrimagnetic material in future spintronic devices.

BV-14. Detecting spin hall signals of permalloy and heavy metal using inverse spin Hall effect. *K. Lai*[1], D. Shiu[1], C. Chang[1] and L. Horng[1] *1. National Changhua University of Education, Changhua, Taiwan*

In the spin Hall effect, a current passed through sample. The spin–orbit coupling induced spin polarized electrons accumulation of inverse signal on either side of the sample. Conversions between charge current into spin current which are called the inverse spin Hall effect. We made a multi-terminal device with a Ta Hall bar and a permalloy nanowire spin injector to detect inverse spin Hall effect. In this device, we read out different signal from magnetic state of permalloy. We using magneton sputtering and e-beam lithography to made devices and measured by four point probes at room temperature. We find asymmetry shift of inverse shin Hall voltage at different magnetic states and find difference signal in opposite current.

BV-15. Spin-orbit torque switching in a T-type magnetic configuration. W. Kong[1], *C. Wan*[1], C. Fang[1] and X. Han[1] *1. Chinese Academy of Sciences, Institute of Physics, Beijing, China*

Different symmetry breaking ways determine various magnetization switching modes driven by spin-orbit torque (SOT) and breed diverse spin dynamics. For instance, an applied or effective symmetry breaking field parallel to applied current is indispensable to switch magnetization with perpendicular anisotropy by SOT [1-3]. Besides of this switching mode, here we demonstrate a distinct field-free switching mode in a T-type magnetic system with the structure of MgO/CoFeB/Ta/CoFeB/MgO where a perpendicular layer was coupled to an in-plane layer with a uniaxial easy axis. Switching current was applied orthogonal to the easy axis and thus also normal to an in-plane effective field experienced by the perpendicular layer. By symmetry analysis, we found that the perpendicular layer could become switchable if the in-plane layer was first switched by the current. These switching modes realized in the T-type magnetic system might expedite the birth of novel multi-state spin memory or spin logic devices which are fully operational by pure electric manners [4].

BW-01. Thermal Performance Evaluation of a Ferrofluid Filled Power Transformer by 3-D Magnetic-Thermal-Fluidic Coupled Analysis.
Y. Zhang[1], S. Ho[1], W. Fu[1], X. Yang[2] and H. Wu[1] *1. The Hong Kong Polytechnic University, Hong Kong, Hong Kong; 2. Hebei University of Technology, Tianjin, China*

I. Introduction Power Transformer is one of the key equipment in power grid, and its thermal performance is critical for the safe operation. In order to improve the inherently low thermal conductivity of transformer oil, oil-based nanofluids, which are manufactured by dispersing nanoparticles of large thermal conductivity into transformer oil, are widely studied [1]. Compared with the ordinary nanofluids, the ferrofluids (magnetic nanofluids) prepared with colloidal magnetic nanoparticles have another advantage, which is to utilize external magnetic field to force the circulation [2]. In order to evaluate the cooling capacity of ferrofluid in power transformers, a magnetic-thermal-fluidic coupled analysis [3], in which two separated solvers are indirectly coupled, is conducted in this paper. II. Numerical model The thermal analysis of ferrofluid filled power transformers is a typical multi-physics problem, which couples the magnetic, fluid and thermal field. A coupled numerical model is built for the analysis, and the interaction between fields is taken into consideration by modifying the governing equations. The temperature dependent material properties, such as saturation magnetization, viscosity, and thermal conductivity, are considered to model the practical two-way coupling. The magnetic field is discretized and solved with finite element method, while the finite volume method is used to solve the fluidic-thermal field. To save the computational resources, two sets of meshes are employed, and data transfer between fields are realized by the mapping between meshes. Based on the estimate of the flow pattern, adjustment of the governing equations of the fluid field may be required. As shown in Fig. 1, a three-phase oil natural cooling transformer (10-0.4kV, 50Hz and 50kVA), in which the regular transformer oil is replaced by the Fe_3O_4/oil ferrofluid (0.1% volume fraction of nanoparticles), is modelled to evaluate the performance of ferrofluid. The derived results will be compared with the oil cooled transformer to showcase the improvement in cooling ability.

BW-02. Practical Application of ELF Stimulation to Early Diagnosis System for Detecting Mild Cognitive Impairment.
H. Nakagawa[1], M. Sugai[1] and S. Ueno[2] *1. Department of Electrical and Electronic Engineering, Tokyo Denki University, Tokyo, Japan; 2. Department of Applied Quantum Physics, Kyushu University, Fukuoka, Japan*

Up to the present, numerous techniques have been developed to investigate human brain functions for application in both therapeutic and preventive medicine. Our previous trial using ELF stimulations provided a new finding concerning the fail in the phosphene sensitivity caused by aging of more certain age [1]. As our new attempt, for the rapid progress to the development of early diagnosis system for detecting a mild cognitive impairment (MCI), we examined the prefrontal hemodynamics corresponding to retinal responsibilities with ELF-inducing phosphene, employing functional near-infrared spectroscopy (fNIRS) analysis. In this research, four iron-core coil systems were used for ELF magnetic stimulations. Their capabilities of performing the task are very high and controllable, as shown in Fig. 1. The ELF stimulations to subjects' eyes were carried out in the same way as in a previous report [2]. Hemodynamic changes at the prefrontal regions were measured using an fNIRS instrument (Hitach HOT121B). The relative concentration of total hemoglobin, and the pulse as well as the heart beat fluctuation index (LF/HF: LF, low frequency; HF, high frequency) were measured with a prefrontal probe every 0.1 s during each measurement session (rest–task–rest). Additionally, subjects' localizations in their retinal regions for the phosphenes were recorded by filling in an original form. For detecting the connection between retinal activities and prefrontal hemodynamics during the measurement session, we attempted to evaluate the changes of our subjects' autonomic nervous system. The LF/HF index is considered to reflect the activity condition of the autonomic nervous system of the human body. As it turned out, the connection between retinal activities and prefrontal hemodynamics during ELF stimulations may be able to provide preventive solutions for some conditions of an MCI. Besides, judging from the essential low energies of ELF fields, the stimulations may also provide clinical safety for the development of early diagnosis system for detecting an MCI.

BW-03. Control of Magnetic Particle Size in Magnetic Fluid and Its Effect on Rheological Properties. *S. Chen*[1] and D. Li[1] *1. Country State Key Laboratory of Tribology, Tsinghua University, Beijing, China*

Magnetic fluid exhibits liquid behavior coupled with the ability to response to external magnetic field, thus has been widely used in many devices, such as seals, sensors and dampers[1-3]. Rheological properties are theoretical base and key to common problems in applications. And size of magnetic particles has a significant influence on rheological properties[4]. In this work, we prepared 4 samples with different magnetic particle size by controlling precursor solution concentration during chemical coprecipitation process (concentration decreased with sample number) and investigated rheology properties of these samples. The flow curves were fitted according to Herschel-Bulkley model. With the increase of magnetic field, consistency increased, demonstrating magnetoviscous effect, flow index decreased, gradually deviating from 1, showing stronger non-Newtonian behaviors, and yield stress increased, indicating formation of more complex microstructures. As we can see from Fig. 1, magnetoviscous effect got weaker from No.1 to No.3 sample, but increased at No. 4 sample. Fig. 2 showed the viscoelastic properties. Storage modulus experienced a plateau and then decayed by power law, while loss modulus increased to a peak after a plateau and then decayed by power law with a different decay index. The intersection of the two moduli could be treated as a transition from solid-like to liquid-like behavior. With the increase of applied field, the moduli increased, and the transition shear stain decreased. According to experimental results, magnetic fluid exhibited field-controlled rheology properties, which could be explained by formation and destruction of microstructures. There were two opposing mechanisms. With the reduction of precursor solution concentration, the size of particle produced by chemical reaction got smaller. Meanwhile, surfactants became insufficient to completely coat magnetic particles due to an increased specific surface area, causing the particles to aggregate and form clusters which strongly enhanced magnetoviscous effect and viscoelastic effect.

BW-04. Structure and Magneto-viscosity of Ba-Sr Ferrite Ferrofluid. *N. Gautam*[1] and R. Singh[1] *1. School of Physics, University of Hyderabad, Hyderabad, India*

M type-ferrite family is well known because of their unique magnetic properties. The optimized Ba-Sr ferrite (BSF) nanoparticles of $Ba_{0.8}Sr_{0.2}Fe_2O_4$ composition were synthesized using hydrothermal process at 200 ^{0}C in autoclave for 24 hours. The nanoparticles were coated with DBSA and Oleic acid to prevent cluster formation and dispersed in water and silicone oil for preparing the water based and silicon oil based ferrofluids (FF). The transmission electron micrographs (TEM) show the hexagonal structure of nanoparticles. The magnetization (M(H)) plots at 300 K, 5 K and M (T) plots in ZFC and FC modes in100 Oe applied field of the nanoparticles show ferromagnetic behaviour. The magneto-viscosity results recorded using rheometer are shown in Fig. 2. Different hysteresis behavior in the magneto-viscosity plots (fig 2) at 1 s^{-1} shear rate for the DBSA based and silicone oil based ferrofluids respectively. This is due to the different relaxation rates of formed chains in the ferrofluids when the magnetic field is removed [1]. The silicone oil based FF showed slower relaxation with higher viscosity compared to DBSA based FFdue to the stronger formed magnetic chains [1]. The magnetic hysteresis of DBSA based FF found to be more compared to the silicone oil based FF due to its response in different colloids and applied magnetic field. The silicone oil based FF is found to be more stable FF compared to DBSA water based FF. The flow curves at different magnetic fields show power law behavior. The viscosity showed higher variation at low shear rates due to strong chain formation which is controlled by the magnetic field over flow field [1]. These magneto-viscosity properties are useful in heat absorber application.

BW-05. Reaction field-dependent spin-correlated radical pair model: A new insight into liposomal DDS. *H. Nakagawa*[1] *1. Department of Electrical and Electronic Engineering, Tokyo Denki University, Tokyo, Japan*

The therapeutic use of magnetic field effects on spin-correlated radical pair mechanisms is a new approach for applications to liposomal drug-delivery systems (DDSs). The pair mechanisms are known as the one and only phenomenon by which magnetic fields can switch over chemical reaction paths. It goes without saying that the use of magnetic fields has a certainly long-range potential when aided with high substance permeability. As a matter of course, their essential forces must be of low energies. As previously reported [1], the liposomal DDS methodology is regulated mainly via *S-T* intersystem crossing and magnetic relaxation (Fig. 1). A further detailed evaluation of the drug-release potential and invasivity was carried out for the rapid progress of the methodology. The instrument mainly consists of: a computer-controlled monochromator (Nikon, G250), two of regulated DC power supplies (Kikusui, PAK6 and PMC18) and an original detector enabled to monitor the degree of the photoreactivity of anti-cancer flutamide (FM) in liposomal membranes. Small unilamellar vesicles containing FM were prepared by the membrane filtration method [2], [3]. Under exposure to static/pulsating magnetic fields, FM in the liposomal membrane was excited by an emission wavelength of 325 nm. To compare magnetic field effects on the behaviour of the model membranes, the delayed fluorescence was measured as well as the spectral changes with absorbance at 380 and 260 nm after the emission. According to the measurement results, it was obvious that a pulsating field influences the pair mechanism in the process of membrane peroxidations induced by reactive oxygen species—mainly, excited singlet oxygen ($^1O_2$). This finding might be expected to reveal new knowledge for resolving important clinical problems. And the liposomal drug-release technology with magnetic controls must be one of the most adaptable DDS.

BW-06. Magnetic Field Effects on Reaction Field-Dependent Radical Pair System. *H. Nakagawa*[1] *1. Department of Electrical and Electronic Engineering, Tokyo Denki University, Tokyo, Japan*

It goes without saying that magnetic field effects on radical pair mechanisms are known as the one and only phenomenon by which magnetic fields can switch over chemical reaction paths despite of their low energies. We previously demonstrated the design of liposomal nanoparticles modified with 2,2'-azobis(2,4-dimethylvaleronitrile) to show the broad potential opportunities in drug delivery systems [1]. In our present research, we considered examining magnetic field effects of combined AC/DC fields to measure the physicochemical changes of liposomal membranes peroxidized by reactive oxygen species. Each dry film composed of various molar ratios of phospholipids, photosensitizers and antenna pigments was hydrated by vortexing them with some appropriate buffer solutions. Each of the dispersions was transferred to a Mini-Extrudor (Avanti Polar Lipids, Inc.) to produce small unilamellar liposomal nanoparticles. Irradiation of the nanoparticles and exposure to magnetic fields were carried out in the same way as in our previous report [2]. ^{1}H- and ^{13}C-NMR spectra of reaction products in methanol-d_4 were obtained with a JEOL JNM A-600 (600.05 MHz) spectrometer at 27°C. Chemical shifts (δ) were referred to internal CD_2HOD at 3.35 ppm for ^{1}H-NMR and $^{13}CD_3OD$ at 49.0 ppm for ^{13}C-NMR. FAB mass spectrum was recorded by a JEOL JMS SX-102 mass spectrometer. HPLC was performed using a Shimadzu SCL-10A system controller equipped with a LC-10AS pump and a SPD-10AV detector. As it turned out, we found the possibility that a pulsating field influences the pair mechanism in the process of membrane peroxidations induced by excited singlet oxygen ($^1O_2$). Comparison of our experimental results showed no relationship between lipophilic and hydrophilic radical scavenging activity, suggesting the possibility of the existence of some types of magnetic field effects on radical pair mechanisms. Accordingly, further studies on the reaction field-dependent radical pair system are now under investigation.

BW-07. Methyl Orange Adsorption onto magnetic removable Fe_3O_4 / Carbon (AC, GO, PGO) nanocomposites. *G.C. Hermosa*[1], C. Liao[1], S. Wang[2] and A. Sun[1] *1. Chemical Engineering and Materials Science, Yuan Ze University, Zhongli District, Taiwan; 2. Department of Materials and Mineral Resources Engineering, National Taipei University of Technology, Taipei, Taiwan*

Dyes are widely used to color products in textile, leather tanning, cosmetics, pigment and many other industries. Effluents discharged from these industries cause potential hazards to environment and human health. Hence, the removal of dyes from water/wastewater has gained a huge attention in recent years. Adsorption as one of the most effective methods for wastewater treatment has been successfully applied to reduce hazardous inorganic/organic pollutants present in the effluents. Adsorbents such Activated Carbon (AC), Graphene Oxide (GO) and Porous Graphene Oxide (PGO) exhibit good adsorption capacity owing to their high specific area, adequate pore size distribution and relatively high mechanical strength. In spite of the

advantages of these adsorbents, the separation and recovery from water is still hard as it causes secondary pollution. Combined magnetic nanoparticles with sorbents as to recover particles from the water that provides a simple and economically friendly for various applications. In this study, carbonaceous nanomaterials (AC, GO and PGO) were synthesized and attached to Fe_3O_4 magnetic powder for the effective removal of synthetic Methyl Orange (MO). AC and GO were successfully conjugated with Fe_3O_4 whilst PGO was not due to its surface functional groups. Batch adsorption experiments were performed and showed significant removal efficiency of 90% at the first ten minutes for Fe_3O_4/AC nanocomposite. Analysis of adsorption equilibrium revealed that AC/Fe_3O_4 is well fitted with Langmuir model, a homogeneous adsorption having an adsorption capacity of 270 mg/g. The GO/Fe_3O_4 can fit with both Langmuir and Freundlich models indicating multilayer adsorption on the surface of the adsorbent with an adsorption capacity of 81.9 mg/g. Both adsorbents follow the pseudo second order kinetics model showing high R^2 values. The adsorbents demonstrated advantageous superparamagnetic properties for their easy recovery from aqueous solutions and prospective applications to toxic removal in water and wastewater.

BW-08. ELF Magnetic Effects on Forced Metamorphosis of Mexican Axolotls (*Ambystoma mexicanum*). *H. Nakagawa*[1] and T. Tadokoro[1]
1. Department of Electrical and Electronic Engineering, Tokyo Denki University, Tokyo, Japan

Objective: Up to the present, a wide variety of intestinal microflorae (e.g., Proteobacteria, Firmicutes, Bacteroidetes, Actinobacteria, and Verrucomicrobia) have been isolated from the gut microbial community of salamander larvae [1]. Nevertheless, judging from the best of our knowledge, there are almost no reported studies of the observation of their behaviors under exposure to magnetic fields. Our previous report already provided a novel finding about the influences of a gradient or an extremely low frequency (ELF) magnetic field on amphibian metamorphosis induced forcibly with a thyroid hormone [2]. In this study, as our new attempt, we investigated the gradient/ELF magnetic effects on serious anorexia with respect to the forced metamorphosis of Mexican axolotls (*Ambystoma mexicanum*). Methodology: Before performing this experiment, axolotls were individually kept in 0.85-L square boxes containing a de-chlorinated water (0.7 L) without aeration at a temperature of 24°C under illumination of 250 $\mu Em^{-2}s^{-1}$ on a 12 : 12 h L : D photocycle. They had become accustomed to being given food rotating of a solid / a tubifex worm; and additionally, they were acclimatized to our experimental environment at least a week. Exposures of thyroxine (T_4)-administrated axolotls to magnetic fields were performed using a strong permanent magnet (17 T/m), as well as an air-cored coil system (5.0 mT at 10–100 Hz). The survival rates of the axolotls influenced by the presence of T_4 were monitored every day, and the digestive capacities were evaluated minutely. Discussion: From our experimental results, we found that the initiation timings of the field exposures affect the survival rates of the following salamanded axolotls. Particularly, there were a few distinct patterns that revealed a serious anorexia in each of the salamanded bodies. We postulated that some changes in the behaviors of their intestinal microflorae might be induced, because of a kind of stress under the exposures. Therefore, further detailed evaluations of the methodology are now under investigation. Our data could prove to be helpful for future reference with respect to a magnetic control study of gut microbial community.

BW-09. Magnetic field control of moiré fringes on guanine crystal plate surface utilizing its optical interference pattern. *H. Asada*[1], E. Muneyama[1], R. Nagai[1], T. Kimura[1] and M. Iwasaka[2] *1. Yamaguchi University, Ube, Japan; 2. Hiroshima University, Higashi-Hiroshima, Japan*

Periodically aligned guanine crystals (GCs) exhibit a structural color caused by the light interference effect. So far, we have reported that the optical interference stripe pattern is observed at a smooth broadest surface of biogenic GC (102) plane combining with mirror surface substrates [1]. Moiré fringes are created by superimposing periodic or quasi-periodic network of lines. This technique is now established as an important metrological tool such as super-resolution microscope. In this study, we observed the GC plate of goldfish floating in water over the herringbone patterns (HBPs) and found that the moiré fringes were appears on GC surface utilizing its optical interference pattern. This measurement technique has the advantage of being magnetically controllable, which was demonstrated experimentally, because the orientation of GC can be controlled magnetically due to the diamagnetic anisotropy [2]. HBPs of Cr film were fabricated by using microfabrication techniques. Figure 1 shows microscope images of GC floating in water over 1/1 μm line and space (L/S) HBP on (a) Si and (b) glass substrates. As clearly seen in both the images, different moiré fringes appear on the GC surface. Figure 1(c) shows a schematic view of overlapping HBP and interference strips. The moiré fringes in Figs. 1(a) and (b) are reproduced. These results indicate that the various moiré fringes can be obtained by rotating the GC according to the rotation of the in-plane magnetic field. Applying the vertical magnetic field of several hundred mT, the GC is oriented so that the short-axis of the (102) plane is parallel to the field [2]. This property enables to continuously change the inclination angle between the substrate and the (102) plane according to the rotation of GC caused by the magnetic field change. As shown in Figs.2 (a)-(c), the interference pattern period becomes wider due to the decrease of the inclination angle of GC. This means that the magnification ratio of moiré fringes can be changed magnetically (see Figs. 2(d)-(e)). We also successfully observed the moiré fringes in the case of 0.5/0.5 μm L/S HBP. This work was supported by JST-CREST Grant number JPMJCR16N1, Japan.

BW-10. High-efficient catalytic reduction of 4-nitrophenol with magnetically recoverable Cu-Fe_3O_4 nanocrystals. *Y. Yang*[1], J. Guo[1], P. Si[1] and H. Ge[1] *1. Zhejiang Province Key Laboratory of Magnetism, China Jiliang University, Hangzhou, China*

Nowadays, the serious water pollution and water resources crisis cause damaging consequences and a threat to human life [1,2]. Among the harmful toxins and compounds, 4-nitrophenol (4-NP) is widely present in waste water from printing, textile, petrochemical and pharmaceutical industries. It becomes one of the most difficult water pollutants to tackle since it has high solubility and stability in water. 4-NP not only cause serious ecological problems, but also cause carcinogenic or devastating effects on humans and wildlife [3-5]. Meanwhile, magnetically recoverable noble metal nanoparticles are promising catalysts for chemical reactions[6]. In this paper, a highly efficient Cu-Fe_3O_4 nanocatalyst was fabricated through hydrothermal method. When loaded with Cu nanoparticles, the Cu-Fe_3O_4 nanocatalyst exhibits high efficiency in catalytically reduce 4-NP to 4-aminophenol (4-AP), the 4-NP is able to be fully degraded in a period shorted than a minute [Figure 1]. With the increase of Cu dosage, the time for complete degradation of the 4-NP is gradually decreases. For the $Cu_{1.0}$-Fe_3O_4 nanocatalyst, the complete degradation of the 4-NP sharply reduced to 5s and the conversion rate reaches at least 98%. As shown in Figure 2, the Cu-Fe_3O_4 nanocatalyst demonstrated good magnetic recoverability and high conversion in 1 min (>98%) after 8 successive cycles. The results here provide a simple and environmentally friendly choice for preparing magnetic noble nano-catalyst and stimulate the study of highly efficient catalysts for 4-NP reduction.

BW-11. Magnetic orientation of biogenic guanine crystal plate combined with magnetic nanoparticles. *R. Nagai*[1], M. Kurahashi[1], K. Kishimoto[1], T. Koyanagi[1], M. Iwasaka[2] and H. Asada[1] *1. Yamaguchi University, Ube, Japan; 2. Hiroshima University, Higashi-Hiroshima, Japan*

A biogenic guanine crystal (GC) is receiving much attention due to its unique optical properties such as high reflectivity. Diamagnetic anisotropy of GC enables to magnetically align the orientation of GC in water, though the field of hundred mT is needed[1]. So far, we reported that the orientation of GC with the ferromagnetic film can be controlled by a low magnetic field[2,3]. In this study, we examined the combination of magnetic nanoparticles (NPs) and GCs for magnetic orientation in order to maintain the optical transparency of GC and successfully confirmed that GC can be oriented by a low magnetic field. Goldfish GCs were dropped in water dispersed with Fe_2O_3 NPs having the size ≥50 nm. After shaking, the liquid was sealed in a micro-chamber. The magnetic fields were applied by a three-axis Helmholtz coil. The magnetization curve of NP in the low field range was almost saturated at 1 Oe with the value of 13 emu/cc. Microscope images of GC without magnetic field are shown is Figs.(a) and (b). A few NPs (probable three) are attached to the side of GC. It is found that Fe_2O_3 NP is attached preferentially to the side of GC. Moreover, the clear undisturbed light interference pattern is observed, meaning that NPs do not cause crystal distortion and do not affect the optical properties. Next, the magnetic orientation experiments were done. As shown in Figs.(c) and (d), increasing vertical field ((c) 0.1 and (d) 1.0 mT), GC stands on so that the long-axis of (102) plane is parallel to the vertical field like GC with the ferromagnetic film as reported before[2,3]. This motion seems to occur so that the magnetization of NP becomes parallel to the GC (102) plane to decrease the magnetic field component orthogonal to the (102) plane generated by NP, that is, to decrease the diamagnetic energy of GC. The magnetization of NP is oriented parallel to the external field direction, resulting in the orientation of GC. The magnetic orientation field is comparable to that of ferromagnetic film/GC hybrid plate, meaning that NP is quite effective to reduce the orientation field. The NP number and size dependence of magnetic orientation are also presented. This work was supported by JST-CREST Grant number JPMJCR16N1, Japan.

TMS is a non-invasive technique used to regulate the synaptic activity of neurons in the human brain improving the functionality of several regions and bringing effective treatment to different neurological and psychiatric disorders. Many of these conditions can be treated by applying external magnetic fields to superficial regions of the brain, but most of them originate in deeper areas difficult to stimulate without overstimulation of the cortex. The study of the complete mechanism that intervenes in the progression of these diseases and their relation with the networks between brain regions in animals is needed to stimulate the deeper regions by employing the cortical areas of these networks. However, the stimulation of small areas in animals like rodents is not easy, since most of the studies in TMS use commercial equipment for human, with power and coil geometries not designed for small animals. In mice and rats, e.g., the use of standard human TMS coils does stimuli the whole body of the animal, instead of a targeted area. This work presents the design and evaluation of a focused conical coil with a MnZn ferrite core to increase the magnetic flux in areas as small as 1mm^2 using finite element analysis software, ANSYS Maxwell. The coil has an angle of opening of 5.71 degrees that shifts the point of maximum flux density towards the tip - closer to the objective - rising the flux while reducing the area. The results show B-flux magnitudes at the air-core interface without and with tip-sharpening (Fig.1) of up to 0.57T and 0.56T, respectively, while flux densities of up to 0.30T and 0.15T (Fig.2) at 4.25mm from the tip to the brain surface (average lambda-bregma distance in adult mice) were observed. The values demonstrate the usefulness of the coil to perform *in vivo* experimentation on rodents for the identification of fiber tracts and brain networks. Further work on the coil and rat stimulator construction are in progress, expected to complete before the MMM 2019 conference. This study was funded in part by the Dpt. of VA Biomedical Lab Research and Development 2I01BX001147-05A2 merit review award (M. Baron, PI).

BW-13. Study of magnetic micelles as a drug carrier for anti-inflammation treatment. *C. Tsou*[1], F. Dong[1], W. Wang[2], Y. Huang[1], C. Su[3], T. Chen[1] and T. Ger[1] *1. Biomedical Engineering, Chung Yuan Christian University, Taoyuan City, Taiwan; 2. Nephrology, Tao-Yuan General Hospital, Ministry of Health and Welfare, Taoyuan City, Taiwan; 3. Institute of Biomedical Engineering and Nanomedicine, National Health Research Institutes, Miaoli County, Taiwan*

The chemical synthesis, biocompatibility and drug delivery study of pH-dependent temperature response magnetic micelles were investigated. The micelles of grafted modified magnetic nanoparticles which called magnetic micelles, were used as they have magnetic manipulation characteristics for accumulating the micelles in the lesion area through external magnetic field. Drug carrier micelle was characterized by Fourier transform infrared spectroscopy (FT-IR), Transmission electron microscope (FEG-TEM), critical micelles concentration (CMC), low critical solution temperature (LCST) superconducting quantum interference device (SQUID) and the thermogravimetric analysis (TGA). Micelles were divided into cell viability testing and inflammation assessment. We used lipopolysaccharide (LPS) to induce the inflammatory response in RAW264.7 mouse macrophages/monocyte and co-culture with multi-functional drug carrier micelles for inflammatory evaluation. This study provided multi-functional micelles as the anti-inflammation drug carrier with good biocompatibility, while maintaining the

characteristics of pH-dependent temperature response and magnetic properties. It is suggesting that these magnetic micelles can be a good candidate for anti-inflammatory therapy in the further clinical trial.

BW-14. Noncontact Manipulation of Magnetic Particles Using Arrays of Permanent Magnets. *N. Riahi*[1] and A. Komaee[1] *1. ECE, Southern Illinois University, Carbondale, IL, United States*

Magnetic manipulators provide a unique ability for noncontact control of magnetic or magnetically tagged objects, which is of particular interest for medical and biochemical applications, including drug targeting, cell sorting, and magnetic tweezers. The current technology focuses on electromagnets to produce magnetic fields, while permanent magnets are well known to make stronger force compared to the electromagnets of the same size. This feature can lead to more compact, more efficient, and yet less expensive magnetic manipulators. The main drawback of the permanent magnet manipulators is the need to control the magnetic field by mechanically changing the position of magnets, and the highly nonlinear nature of this class of manipulators. We investigated the effectiveness of feedback control to overcome this nonlinearity. Our study is focused on the magnetic manipulator of Fig.1, which is comprised of six identical radially magnetized cylindrical magnets, spaced equally around a circular petri dish in which a magnetic object can move freely inside a viscous fluid. Each magnet in this setup is equipped with a servomotor, so that they can rotate individually to adjust the total magnetic field in the petri dish. By computer simulations, we implemented state feedback control to steer the magnetic particle along a desired reference trajectory. We then improved the results by adding integral action to the controller. The controllers were designed for a state-space model describing the dynamics of system with the position and velocity of the particle as the state vector and the angular positions of the magnets as its control vector. This nonlinear dynamics was first approximated by a linear model to facilitate the control design procedure. Since integral action constantly compensates for linear approximation error of the state space model, it can enlarge the region of attraction, i.e., the set of points over which the closed-loop system remains stable. As Fig.2 shows, this improvement results in the enlargement of tracking area by more than twice.

BW-15. Safety issues of electric field induced in human body by a high field Magnetic Resonance Imaging system. *M. Trapanese*[1], G. Ala[1], P. Romano[1], F. Viola[1], G. Rizzo[1], M. Midiri[2], S. Salerno[2] and M. Galia[2] *1. Dipartimento Ingegneria, Palermo University, Palermo, Italy; 2. Biomedicina, Neuroscienze e Diagnostica avanzata, Palermo University, Palermo, Italy*

Safety issues and discussions associated with magnetic resonance imaging (MRI) systems and procedures have been intense over last years: the main topic has been the disputed assertions about the role of electromagnetic fields

in carcinogenesis or the promotion of abnormalities in growth and development On the contrary, since the introduction of MRI in the early 1980s, more than 100,000,000 diagnostic procedures (estimated) have been completed worldwide, with relatively few major incidents. However, recently the level of magnetic field used in commercial MR has been increased (up to 3T) and the safety issues have increased accordingly. As a result, in order to enhance the level of safety for the workers, European and Italian standards have recently fixed several value limit of the induced electric field that must not be exceeded. This limit is 1.1V/m. In this work, we evaluate analytically, numerically and experimentally the level of the induced electric field in proximity of MRI machine in a moving human body. The calculation has been performed by assuming several movement schemes. The analytical approach allows us to adapt the results to several cases and several level of magnetic field. The numerical approach has been based of a finite element method software where suitable models of moving human body and MR device have been implemented. The MR has been modelled as a coil of radius equal to the main commercial models and human body has been modelled as a water volume with some dielectric inserts. Finally, an experimental approach has been performed. All the approaches indicate that the limit imposed by the regulation is always respected for MRI device which a magnetic field up to 1.5T, for higher level of field the level of induced electric field can be exceeded in case of rapid movement of the arms.

CA-01. Machine learning and high-throughput methods for the accelerated discovery of new magnets. *S. Sanvito[1] 1. School of Physics and CRANN, Trinity College Dublin, Dublin, Ireland*

The development of novel materials is a strong enabler for any technology, and often technology and materials innovation cannot be separated. Unfortunately the process of finding new materials, optimal for a given application, is lengthy, often unpredictable and has a low throughput. Here I will describe a systematic pathway to the discovery of novel materials, which demonstrates an unprecedented throughput and discovery speed. The method can be applied to any materials class and any potential application. I will use the example of magnetism to introduce the main features of the method, and I will demonstrate the discovery of several new high-performance magnets. Furthermore, I will highlight how such high-throughout schemes can be combined with machine-learning methods for data-mining to extract novel materials designing rules and for identifying new prototypes for further investigation. Based on an extensive electronic structures library of Heusler alloys containing 236,115 prototypical compounds, we have filtered those alloys displaying magnetic order and established whether they can be fabricated at thermodynamical equilibrium [1]. Specifically, we have carried out a full stability analysis for intermetallic Heuslers made only of transition metals. Among the possible 36,540 prototypes, 248 are found thermodynamically stable but only 20 are magnetic. The magnetic ordering temperature, T_C, has then been estimated by a regression calibrated on the experimental T_C of about 60 known compounds. As a final validation we have attempted the synthesis of a few of the predicted compounds and produced two new magnets. One, Co_2MnTi, displays a remarkably high T_C in perfect agreement with the predictions, while the other, Mn_2PtPd, is a complex antiferromagnet. In the second part of my talk I will discuss the use of machine-learning methods for predicting the Curie temperature of ferromagnets, based solely on their chemical composition, and for sorting magnets into hard and soft [2]. In particular I will discuss how to develop meaningful feature attributes for magnetism and how these can be informed by experimental and theoretical results. I will also show a potential promising scheme for extracting information from published literature. All these together can pave the way for the large-scale design of novel magnetic materials at unprecedented speed.

CA-02. Machine learning enhanced characterization of magnetic materials. *K. Ono[1] 1. High Energy Accelerator Research Organization (KEK), Tsukuba, Japan*

The recent development of materials informatics (MI) accelerates the efficiency of material fabrication and enables the automated and high precision characterization and analysis of materials. In the characterization and analysis of magnetic materials, machine learning techniques make it possible to measure a desired physical quantity optimally and shortly, and high-throughput experiment has been developed along with the automation of measurements. However, while measurement throughput has been increased, analysis of measurement data, that is, extraction of desired physical quantities and material characteristics from measurement data, is almost always performed by skilled experts. It is often to be a bottleneck for research and development of materials. We have studied optimization, automation, and acceleration of measurement and data analysis for magnetic materials. These studies not only significantly reduce human intervention in measurement and analysis but also commoditize characterization of material that only experts could ever perform. Furthermore, the measurement and analysis results become reproducible. It is considered to be an essential technology for future materials developments.

CA-03. Classification and optimization of a magnet's microstructure. *A. Kovacs[1], T. Schrefl[1], J. Fischbacher[1], L. Exl[2], N. Sakuma[3], M. Ito[3], A. Kinoshita[3], T. Shoji[3] and A. Kato[3] 1. Department for Integrated Sensor Systems, Danube University Krems, Wiener Neustadt, Austria; 2. WPI c/o Faculty of Mathematics, University of Vienna, Vienna, Austria; 3. Advanced Material Engineering Div., Toyota Motor Corporation, Higashifuji, Japan*

Growing demands for permanent magnets are predicted for green technology applications such as sustainable energy production and eco-friendly transport. With the quest for rare-earth reduced or rare-earth free permanent magnets, an optimal control of the magnet's microstructure becomes increasingly important. For example, grain boundary engineering and the use of core-shell grain structures have high potential to improve coercivity while reducing the material costs. In other fields of materials research, data driven machine learning approaches have been applied recently, in order to obtain a deeper understanding of the material's microstructure on its properties [1]. In the talk we present an automated search and optimization tool for the granular microstructure of permanent magnets. Machine learning is a method to relate microstructure and hysteresis properties of

a permanent magnet. Once built, the model can be used to replace time consuming micromagnetic simulations as design tool that predicts coercivity or energy density quickly. The machine learning tool chain needs (i) key features that characterizes a magnet's microstructure, (ii) fast methods for data generation, (iii) a machine learning predictor that is trained to predict hysteresis properties for a given microstructure, and (iv) model validation and interpretation. Similar to conventional materials modeling machine learning can be applied at different length scales. Key features of a grain are the crystallographic orientation, the position within the magnet, the sphericity, the maximum dihedral angle, and the number of neighbors. On a sub-grain scale, important features are the intrinsic magnetic properties of core, shell and grain boundary phase together with its spatial dimensions. For feature selection we apply cross-correlation and drop redundant features (see Figure 1). To generate hysteresis data quickly, we use a reduced order micromagnetic model for multigrain systems or fast parallel micromagnetic solvers for single grains. We train a random forest classifier with switching field maps computed with reduced order micromagnetics. This classifier is used to predict the weak grains where nucleation of a reversed domain will occur first. By identifying the features that cause low coercive grains, we have a handle to improve coercivity efficiently [2]. We developed an automated tool for the optimization and design of the core-shell structure in a permanent magnet. A universal deep Bayesian optimizer [3] is used to randomly sample a high dimensional feature space for the grain. A finite element model reflecting a specific feature set is generated and coercive field and energy density product are computed. Evaluating different machine learning models for predicting coercivity, we achieved the best regression scores with a gradient boost model. An uncertainty measure tells us whether the predicted coercive field for a given input can be trusted or should be recalculated with the micromagnetic solver. The machine learning models help to enhance the understanding and can be used for optimization: (i) The computed feature importance tells us which parameters have to be improved first before others become more relevant. For example, a feature identified as highly important is the magnetization of the grain boundary phase. The partial dependence plot (see Fig. 2) shows how the coercive field changes with the grain boundary magnetization while averaging over all other features of the model. (ii) Using classification, we can identify the grains that cause a low or a high coercive field. (iii) The use of local linear surrogate models tells us how feature changes near a specific design point affect coercivity or energy density product.

CA-04. Neural network based magnetic hysteresis modeling.
C. Serpico[1] *1. University of Napoli "Federico II", Napoli, Italy*

Magnetic Hysteresis in a moderately large ferromagnet arises as a consequence of the presence of a multiplicity of metastable equilibrium states. The magnetization of the ferromagnet, for a given external magnetic field, can assume many different values depending on the past history of the magnetic system [1]. This behavior depends both on intrinsic properties of the media (anisotropy, exchange interactions) and on extrinsic characteristics such the shape, the density of impurities and defects. This leads to a considerably complex phenomenon which is very difficult to be described using first principles physical modeling. The complexity of hysteresis, on the other hand, can be effectively handled by using machine learning techniques based on neural network [2]. The fact that hysteresis is a memory effect seems to require the use of dynamic neural networks [3]. However, by using a suitable framework to describe the mechanism of memory update in hysteretic systems, based on Preisach Model [4], this problem can be circumvented and it is possible to use only memoryless neural networks such feed-forward neural networks [3]. These aspects will be illustrated in the talk in detail. The last part of the talk will be devoted to an overview of the developments made in the last decades in the application of machine learning technique to hysteresis modeling [5].

CA-05. Estimation of the Magnetic Field Distribution through Deep Learning.
D. Lowther[1] and A. Khan[1] *1. Elec and Comp Eng, McGill University, Montreal, QC, Canada*

In the analysis and design of electromagnetic devices, the distribution of the magnetic field is crucial to determining the performance of the device. The air gap field is needed for the force generated in a motor or actuator; the eddy currents and hysteresis losses in the components of the device give rise to local losses and thus lead to local heating and potential failure of a device; etc. Computing the field through the solution of the partial differential equations that result, in non-radiating systems, from Ampere's and Faraday's laws can be slow and thus limit the interactivity of any design space exploration. Solving the field equation is equivalent to replacing the construction of physical prototypes a with virtual prototyping process which can reduce overall costs and time but is rarely capable of providing a designer with

performance feedback which would allow an interactive exploration of a design space. The physics equations which are solved are, themselves, a set of rules which have been developed based on logical deductions drawn from the outputs of a series of experiments. In a sense, they are surrogates which represent real world performance. The question can be asked as to whether other surrogates can be created. For example, is it possible to estimate the field distribution with suitable fidelity from just the input data, i.e. the geometry, material properties, the excitations and a series of examples connecting these inputs to the observed field distributions, without using the physics equations directly. If so, there are two potential benefits that could be derived from this approach. The first is that the field estimates could be used to accelerate existing numerical solution systems. Many solvers are, in fact, optimizers and work on minimizing the error in the solution. If a good estimate of the solution can be provided, the solver can reach a solution very much faster. The second benefit comes with the speed at which an estimate can be obtained, potentially allowing the effect of design modifications to be evaluated interactively. Additionally, the estimation system should be able to provide a level of certainty with its estimate, i.e. to suggest where its prediction might be in error. The goal here is to try to simulate the performance of a design engineer who is capable of estimating the impact of changes on device performance largely through experience. Over the last few decades the idea of estimating the field distribution has been explored using machine learning based on neural networks. There has been some success in achieving the first benefit using relatively simple systems [1]-[3] when the estimates are used along with an adaptive solver. However, obtaining an estimate of sufficient accuracy to be useful for design exploration has proven more difficult [3]. Basically, the computational power and network architectures that were considered were insufficient to achieve a result which met the goal. More recently, the development of deep learning systems based around convolutional neural networks and treating the field solution as an "image" or "pattern" related to the input data has shown some promise. The paper will discuss some of the history behind the use of machine learning and artificial intelligence in the area of magnetic field estimation and describe a recent system based on a convolutional neural network which has had reasonable success both in estimating a field solution and in determining the errors and their locations in the prediction [5].

Materials with strong spin-orbit coupling can convert a charge current to a spin current, and vice versa. Heavy metals are one class of such materials in which the spin-orbit coupling is associated with the spin Hall effect in the bulk or the interfacial Rashba effect. When a heavy metal film is interfaced with a ferromagnetic (FM) film, the spin-orbit coupling-produced spin current in the heavy metal can exert a torque on the magnetization in the FM film, which is the so-called spin-orbit torque (SOT). This SOT can be used to switch magnetization, drive domain-wall motion, or excite magnetization precession. Due to the spin-momentum locking of the topological surface states (TSS), topological insulators (TIs) are expected to host spin-orbit coupling that is considerably stronger than in heavy metals and can thereby produce substantially larger SOT. In fact, very recently there have been several experimental demonstrations of SOT-induced magnetization switching in TI/FM bi-layers.[1-7] The demonstrated switching efficiencies were all higher than in the heavy metal/FM counterparts. The FM films in those studies, however, were all conductive, with conductivities either about one order of magnitude higher than or comparable to the conductivities of the TI films. A straightforward consequence of this is the severe shunting current in the FM film, which not only limits the switching efficiency but may also cause certain thermal issues. In addition, the conductive nature of the FM components has a much more serious consequence – the TSS may have been largely spoiled by the FM films and may not account for the observed strong SOT effects. Previous works have shown that interfacing a TI with a conductive FM film can result in a significant modification or even complete suppression of the TSS in the TI.[8-12] One can eliminate the above issues simply by replacing the conductive FM components with insulating FM materials. A recent theoretical work compared the effects of conductive and insulating FM films on the TSS in TI/FM heterostructures. It showed that, in stark contrast with the conductive FM case, the TSS in a TI/magnetic insulator (MI) structure can be largely preserved, except for opening of a small gap at the Dirac point when strong coupling exists at the interface.[10] This presentation reports the demonstration of TSS-induced switching in a TI/MI bi-layered structure where the TI layer is a Bi_2Se_3 film consisting of 6 quintuple layers, and the MI layer is a 5-nm-thick $BaFe_{12}O_{19}$ film that has large magneto-crystalline anisotropy and shows an effective perpendicular anisotropy field of about 22 kOe. The switching response in the $BaFe_{12}O_{19}$ film strongly depends on the charge current applied to the Bi_2Se_3 film. When a constant magnetic field is applied in the film plane, the charge current in the Bi_2Se_3 film can switch the magnetization in the $BaFe_{12}O_{19}$ film between the up and down states. When the magnetization is switched by sweeping an obliquely applied magnetic field with a constant charge current in the Bi_2Se_3 film, the current can cause the switching field to decrease or increase, depending on the current polarity, by as much as 4000 Oe. A decrease in temperature (T) results in a monotonic reduction in the switching current in the field-fixed measurements and a monotonic increase in the change of switching field in the current-fixed measurements. This result evidently indicates the presence of strong SOT responses at low T, while the latter can be attributed to the presence of strong TSS due to enhanced surface state conductivity and decreased bulk state conductivity. When compared with $Pt/BaFe_{12}O_{19}$, the SOT efficiency is comparable at room temperature but is about 30 times higher at T=3 K. These results demonstrate the merits of TSS in manipulating magnetization and thereby shed light on the applications of topological insulators in spintronic devices.

The spin Seebeck effect (SSE), where a thermal gradient in a ferromagnet generates spin current, is a widely used method to generate and study spin waves. Further, there has been increasing interest in characterizing spin transport, specifically, in thin insulating antiferromagnets (AFM). This is not only because they can transmit spin waves efficiently while providing electrical isolation, but also because they can provide insight about the nature of the transport and how it relates to the magnetic order in the AFM. We have studied heterostructures of the form ferromagnet-antiferromagnet-heavy metal ($Y_3Fe_5O_{12}$(YIG)-NiO-Pt) to detect spin transport flow through NiO. A temperature gradient is created by applying high current densities to the heavy metal (Pt) while the spin current is detected by the inverse spin Hall effect in the heavy metal. A lock-in technique is used to measure the 2nd harmonic response as a function of temperature and in-plane magnetic field, which sets the magnetization of YIG layer (inset Fig. 1). We have found a sharp increase in the SSE amplitude around 110 K (Fig. 1). The fact that the peak is not present in our control samples (YIG/Pt) suggests that the origin is either the NiO layer or the YIG/NiO interface. In addition, we have conducted X-ray Magnetic Circular Dichroism Absorption Spectroscopy (XMCD) to gain insight into the magnetic order (Fig. 2). For 5 nm thickness of NiO, we observe a change in the circular dichroism of nickel and iron near 100 K which is associated with a change in the coupling of Fe and Ni moments. Results on samples with varied NiO thickness and external magnetic field are used to identify the origin of this large enhancement and sharp peak in the spin-transport efficiency.

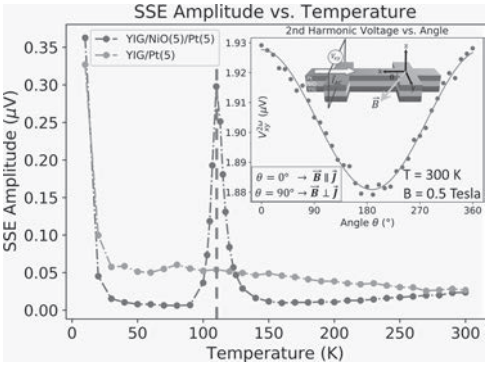

Fig. 1: Temperature dependence of the Spin Seebeck Effect in YIG/NiO/Pt and YIG/Pt samples. The sharp increase of the SSE amplitude around 110 K is only present in samples with NiO layers. The inset shows the measurement geometry and a sine fit to the field angular dependence.

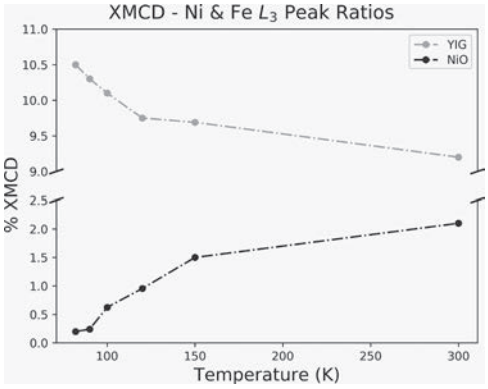

Fig. 2: XMCD of nickel and iron inside the heterostructure. The change around 100 K suggest the coupling between iron and nickel magnetic moments change near the SSE peak temperature.

CB-03. Roles of Magnon Angular Momentum in Non-collinear Magnetic System. *Y. Cheng*[1] and S. Zhang[1] *1. University of Arizona, Tucson, AZ, United States*

Magnons and electrons are essential angular momentum carriers in spintronics. For the collinear ferromagnets and antiferromagnets, the angular momentum of each magnon is quantized in the direction of the order parameter with the magnitude \hbar. The interaction between magnons and electrons yield a number of spin transport phenomena such as spin transport torques, spin-magnon current conversion at interfaces, and magnon drag effects. We study the magnon spectrum and its associated spin transport in non-collinear antiferromagnets. We consider a standard antiferromagnetic Heisenberg Hamiltonian with a Dzyaloshinskii-Moriya interaction and an easy-axis anisotropy in a two-dimensional triangular and Kagome lattice. We first determine the energy-momentum dispersion of the magnons and the corresponding average angular momentum of each magnon. Note that the angular momentum is no longer an eigenvalue of the magnon. The directions of the angular momentum and the linear momentum, known as spin-momentum locking, become nontrivial. We then investigate the magnon spin accumulation in the presence of an external spin current injection, spin-magnon drag, and the electron conductivity due to the scattering of these magnons. The results will be compared with those of magnon transport for collinear magnetic systems.

Center for Quantum Spintronics, Norwegian University of Science and Technology, Trondheim, Norway; 3. Utrecht University, Utrecht, Netherlands; 4. Johannes Gutenberg University, Mainz, Germany; 5. Helmholtz-Zentrum Berlin für Materialen und Energie, Berlin, Germany*

In contrast to ferromagnets, antiferromagnets benefit from enhanced stability with respect to applied external fields, magnetization dynamics at THz frequencies and a lack of stray fields [1,2]. Many theoretical studies have been undertaken describing the mechanisms through which antiferromagnets could allow for the propagation of spin current across the long distances in antiferromagnets, which would be required for integration into information transfer and logic devices [3,4]. Here we demonstrate that in the most common insulating antiferromagnet, hematite (α-Fe2O3) [5], a

diffusive magnonic spin current is able to propagate over micrometers in both single crystals [5] and thin films [6]. With a low damping and characteristic frequencies of hundreds of GHz, this compound allows antiferromagnetic spin-waves to propagate as far as in YIG, a ferromagnetic material with the lowest known damping, which is the material of choice for magnonic devices. We detect a first harmonic signal, related to the spin conductance, that exhibits a maximum at the spin-flop reorientation, while the second harmonic signal, related to the Spin Seebeck conductance, is linear in the amplitude of the applied magnetic field. The first signal is dependent on the direction of the Neel vector of the antiferromagnet and the second one depends on the induced magnetic moment due to the field. From the power and distance dependence, we unambiguously distinguish long-distance transport based on diffusion [5] from predicted spin superfluidity [4]. To understand the mechanisms behind magnon propagation, we extract the critical fields using the spin-Hall magneto-resistance technique [7], allowing for a precise determination of the magnetic anisotropies without the need for synchrotron-based facilities. We finally discuss establish the interactions between antiferromagnetic spin-waves and domain walls, and demonstrate that one can even achieve zero-field, room temperature magnon transport in insulating antiferromagnets[6].

CB-05. Realization of spin current across the interface of Pt and thin films of antiferromagnetic manganites. *A. Das*[1], A. Watson[1], A. Burema[1], P. Zhang[1] and T. Banerjee[1] *1. Zernike Institute for Advanced Materials, University of Groningen, Groningen, Netherlands*

Antiferromagnets are incipient material choice to study long distance magnon transport across an insulating channel, given their fast magnetization dynamics and robustness against stray fields[1,2]. The detection of spin currents and spin wave excitations in antiferromagnets, exploiting the (inverse-)spin hall effect on heavy metal electrodes, have attracted lot of attention in recent years. However, complex oxides, with their rich magnetic phase diagram, are relatively unexplored. In particular, manganite thin films, due to the strong coupling between the orbital degrees of freedom and magnetic exchange interactions are worth exploring. In this work, we demonstrate a scalable spin current in antiferromagnetic thin films of (SMO), detected using a Hall bar made of Pt. By growing SMO films epitaxially on two different substrates ($SrTiO_3$ and $LaAlO_3$), we tailor the strain, from compressive in the former to tensile in the latter. This gives rise to different orbital occupancies, thus different magnetic orderings. We further investigate the influence of partial pressure of oxygen, during the growth of thin SMO films, on the spin current at different temperatures. We find that the resultant mixed structural phases of perovskite and brownmillerite exhibit an exchange bias in SMO on both substrates. Spin Hall magnetoresistance (SMR) studies on differently strained SMO thin films [3], show a phase shift in the angular dependence of the SMR signal, allowing a differentiation between ferromagnetic and antiferromagnetic moments. This work highlights the strong correlation of magnetic ordering with structural properties, such as epitaxial strain and oxygen vacancy-induced orbital occupancies, inherent in transition metal oxides, and demonstrate the suitability of SMO for magnon transport. Fig. 1: (right panel) Hall bar geometry of Pt patterned on SMO with charge current making an angle θ with the applied magnetic field in-plane to the charge transport. (Left panel) Transverse SMR response at Pt/SMO interface grown on $SrTiO_3$ (top) and $LaAlO_3$ (bottom). The phase shift of 90 degrees indicate an anti-ferromagnetic (top) to ferromagnetic (bottom) ordering in SMO.

CB-06. Spin currents in antiferromagnetic insulators: optical excitation, zitterbewegung, and magnon conductivity. *I. Proskurin*[1,2] and R.L. Stamps[1] *1. Department of Physics and Astronomy, University of Manitoba, Winnipeg, MB, Canada; 2. Institute of Natural Sciences and Mathematics, Ural Federal University, Ekaterinburg, Russian Federation*

Antiferromagnetic insulators are of interest for creating and transmitting spin currents, which is a key issue in spintronics. Spin currents in antiferromagnets can be excited by various methods [1] including spin-Seebeck and spin-Nernst effects, spin pumping from a ferromagnet, spin injection, and photo-excitation [2]. It has been suggested that a magnon spin current in antiferromagnetic materials is affected by interband tunneling [2]. Based on the special features of magnon dynamics in antiferromagnets [3], we demonstrate that the interband terms in the magnonic spin current correspond to the zitterbewegung (trembling motion) effect expected for magnon wave packet dynamics [4]. We show how these terms contribute to the mechanism of optical excitation of spin currents proposed in Ref. [2]. This mechanism involves polarized light and is motivated by the photogalvanic effect in metals, where circularly polarized light can produce a direct electron photocurrent, which direction depends on the polarization. In electron Dirac materials, interband effects are significant near the band crossing.

In particular, they are responsible for the minimal conductivity of graphene [5]. By analogy, we discuss similar effects in the spin conductivity of magnons, which is determined as a linear response coefficient to the eclectic field via the Aharonov-Casher phase. The effect can be interpreted as a magnon contribution to the electric dipole moment created by the magnon spin current.

CB-07. Effect of Dzyaloshinskii–Moriya and Dipolar Interactions in the Propagation Length of Thermally Excited Magnons in Low Anisotropy Antiferromagnets. R. Yanes[1] and *L. Lopez-Diaz*[1] *1. Applied Physics, University of Salamanca, Salamanca, Spain*

Long-range spin transport in low anisotropy antiferromagnets has been recently proved [1,2]. The increase of the spin conductance around the spin-flop transition (B_{sf}) is interpreted in terms of the field dependent gap between the two magnon modes carrying opposite angular momentum [1,3]. However, the mechanisms that couple spin accumulation to antiferromagnetic order enabling transport over long distances are not well understood yet. In particular, the role played by Dzyaloshinskii–Moriya interaction (DMI), essential to explain the equilibrium states under field in some cases [1], and dipolar interactions, usually neglected in antiferromagnets, is to be elucidated. We use an atomistic spin localized model to investigate the propagation of thermally excited spin currents (SCs) in a bi-partite antiferromagnet under the effect of an external field along the easy axis, analyzing the role of DMI and dipolar interaction. The parameters are chosen so that the spin-flop transition occurs around B_{sf} =6 T, close to the value obtained for α-Fe2O3 in [1]. As observed in Fig.1, the influence of dipolar interaction is negligible in equilibrium, whereas DMI smooths out the spin-flop transition favouring the gradual orientation of the Neel vector, n. Starting from equilibrium, thermal fluctuations are introduced in a region on the left side corresponding to T=50K, whereas the rest of the system is at T=0. Thermal magnons are excited and they propagate along the x-axis. The propagation length of this SC, L_{SC}, is computed and the results are presented in Fig.2. A sharp increase of the propagation length around B_{sf} is obtained, in good agreement with experimental results [1]. Interestingly, this increase is more pronounced when dipolar interactions are included, yielding propagation lengths in the order of 400 nm. This result suggests that dipolar interactions might be partially responsible for the long distance propagation of SC in low anisotropy antiferromagnets close to B_{sf}. The detailed mechanism behind this result is a consequence of the appearance of significant net angular momentum and the spatial rotation of n around B_{sf}.

CB-08. Spin Seebeck effect from antiferromagnetic magnons in epitxial Cr_2O_3 films. *W. Yuan*[1], J. Li[1], V.H. Ortiz[1] and J. Shi[1] *1. UC Riverside, Riverside, CA, United States*

A temperature gradident can generate pure spin currents in ferro- and ferri-magnetic materials that can be detected by the inverse spin Hall effeect (ISHE), which is called spin Seebeck effect (SSE). Recently, SSE has been reported in antiferromagnetic (AFM) insulators, such as Cr_2O_3 single crystal [1] and MnF_2 thin films [2]. As the easy-axis field increases, the SSE signal shows a step-like jump at the spin-flop (SF) transition. However, it is still unclear whether AFM SSE requires a field-induced static magnetic moment. Here we report a study of the SSE in Cr_2O_3 thin films, which are epitaxially grown on pre-annealed Al_2O_3(11-20) substrates using a high vacuum pulsed laser deposition system. The lattice structure of Cr_2O_3 films is characterized by reflection high energy electron diffraction and X-ray diffraction. After deposition of a 5 nm Pt (or Ta) layer on Cr_2O_3, we fabricate the SSE devices by covering with a 80 nm Al_2O_3 insulating layer and then Cr(45 nm)/Au(5 nm) layers as a heater. Systematic measurements of SSE in Cr_2O_3/Pt and Cr_2O_3/Ta heterostructures are performed as a function of magnetic field and temperature. The SSE signal clearly shows a sign reversal across the SF transition while sweeping the magnetic field along the c-axis of Cr_2O_3, which is consistent with the SSE result observed in our Cr_2O_3 single crystal samples. The sign revcersal at the SF transition suggests that AFM magnons carry opposite angular momenta below and above SF transition. The magnitude of the SSE signal increases with decreasing temperature, reaches a maximum at T = 8 K, and then starts to decrease towards zero. Our observations can be explained by a model based on AFM magnons and is consistent with our presious report on SSE in FeF_2 epitaxial thin films [3]. This work is partly supported by SHINES, an Energy Frontier Research Center funded by the US Department of Energy, Office of Science, Basic Energy Sciences under Award No. SC0012670.

CB-09. Spin Current Suppression by Antiferromagnetic Ordering in Spin Pumping in $Y_3Fe_5O_{12}/Cr_2O_3$/Pt Heterostructure. *V.H. Ortiz*[1], J. Li[1], B. Arkook[1], W. Yuan[1], I. Barsukov[1] and J. Shi[1] *1. Physics and Astronomy, University of California Riverside, Riverside, CA, United States*

Antiferromagnetic insulators (AFMI) have recently attracted a great deal of attention due to many unique interesting properties [1]. For example, thin AFMI layers are found to enhance spin current transmission around the antiferromagnetic phase transition temperature when they are inserted between a ferrimagnetic insulator (FMI) and a heavy metal (HM), such as the NiO and CoO layers in $Y_3Fe_5O_{12}$(YIG)/NiO/Pt [2] and YIG/CoO/Pt [3]. In a recent work [4], a sharp decrease of spin Seebeck effect (SSE) signal below Néel temperature of Cr_2O_3 was reported in a YIG/Cr_2O_3/Pt heterostructure. It was suggested that the blockage of spin current was caused by the spin-orbit torque absorption exerted by the relative spin orientation of the FMI/AFMI layers. However, this proposed picture has not been validated. In this work, we report a greatly suppressed spin current transmission due to the presence of AFM ordering in spin pumping (SP) experiments in YIG/Cr_2O_3/Pt heterostructures. We grew a 10 nm Cr_2O_3 film on epitaxial YIG (111) film using a high-vacuum pulsed laser deposition (PLD) system and then post-annealed it in oxygen prior to the deposition of Pt layer. Coplanar waveguide SP devices were fabricated on top of the film, and systematic measurements of SP and SSE signals were carried out as a function of microwave frequency, magnetic field, and temperature. We observed a significant suppression of both SP and SSE signals below the AFM phase transition of Cr_2O_3 films (T_N~295 K), which is very similar to what was reported by Z. Qiu *et al* [4]. However, our high-resolution transmission electron microscopy study revealed that the Cr_2O_3 is a randomly oriented polycrystalline thin film, contradicting the previously proposed model [4]. Our experimental results suggest that the spin current blockage may be caused by the large magnon gap of AFM material that prevents the magnon diffusion from the ferrimagnet. This work was supported as part of the SHINES, an Energy Frontier Research Center funded by the US Department of Energy, Office of Science, Basic Energy Sciences under Award No. SC0012670.

The use of insulating antiferromagnets (AFM) as a medium to transport spin angular momentum has generated great excitement. Thin NiO films not only transmit but can also enhance a spin current [1, 2]. So far experiments have been limited to the detection of dc spin current and mainly performed on polycrystalline NiO layers. By employing element specific x-ray ferromagnetic resonance (XFMR) [3] we demonstrate transport of ac spin current, generated via spin pumping within a NiFe layer, through adjacent epitaxial NiO(001) layers. For a FeCo/NiO/NiFe multilayer, magnetization precession at the resonant frequency of the NiFe is also observed in the FeCo, with the phase of precession being very similar in both layers. The amplitude of precession of the sink FeCo layer (a measure of the amplitude of the spin current propagating through NiO) depends on the NiO thickness. The amplitude reaches a maximum at 6 nm of NiO and decays exponentially above this thickness (see Fig.1), in a similar manner to that in both previous experimental reports concerning the dc spin current [1, 2] and theoretical studies [4, 5]. For comparison, we present results for FeCo/NM(5nm)/NiO/NiFe, where the NiO is decoupled from the sink layer by insertion of a 5 nm thick non-magnetic (NM) layer of Ag or Pd. The magnetization precession of the FeCo sink layer at the NiFe resonance has amplitude nearly one order of magnitude smaller than for the case of directly coupled layers. Furthermore, the precession of the sink layer exhibits a bipolar variation of phase that is a signature of spin transfer torque associated with ac spin current transmitted through the NiO layer [3]. Our results suggest that the observed propagation of ac spin current within NiO layers is mediated by coherent magnons, rather than by diffusion of thermal magnons.

Materials and Nanophysics, KTH Royal Institute of Technology, Kista, Sweden*

Antiferromagnets (AFMs) have great benefits for the future spintronic applications [1] involving high frequencies (up to THz) and high speeds (up to dozens of km/s) of magnetic excitations. Also, the AFM spin-torque nano-oscillators (STNOs), in which the applied spin current rotates the Neel vector [2-4], do not require an external magnetic field for their operation. Advanced devices will require high-speed propagating spin waves (SWs) as signal carriers, i.e. SWs with the high k-vectors, the excitations of which remains challenging. We demonstrate theoretically and by micro-magnetic simulations that the simple spin texture, such as an AFM domain wall (DW), driven by spin current, can be a source of the propagating SWs with substantially high frequencies and short wavelengths, comparable to the exchange length of the AFM. We consider AFM with the anisotropy and/or Dzyaloshinskii-Moriya interaction (DMI) with n-fold rotational symmetry in the hard plane. In the proposed generator the spin current, which polarization is directed along the principal axis, excites the precession of the Neel vector within the DW. The threshold current is defined by the value of the in-plane anisotropy, and frequency of the DW precession ω_{DW} is tuneable by the strength of the spin current. We show that the above precession of the DW leads to the excitation of two modes of magnons with the frequencies with $(n\pm1)\omega_{DW}$, where n is the order of the anisotropy and/or DMI symmetry [5]. A robust emission of the propagating SWs into the AFM strip takes place in the case, when $(n\pm1)\omega_{DW} > \omega_{AFMR,}$ where ω_{AFMR} defines the frequency of antiferromagnetic resonance. Consequently, the maximum achievable frequency of SWs is $(n+1)\omega_{AFMR}$, which corresponds to a very short wavelengths of the SW, comparable with the exchange length, especially for the hexagonal AFMs. The excitation of the high wavevectors is possible due to the substantially small width of the DW in AFM and is hard to achieve by any other method.

CB-12. Magnon spin-Edelstein effect in an antiferromagnetic insulator. *R. Cheng*[1,2] *1. Electrical and Computer Engineering, University of California, Riverside, CA, United States; 2. Physics, University of California, Riverside, CA, United States*

In an antiferromagnetic insulator with biaxial anisotropy and the Dzyaloshinskii-Moriya interaction (DMI), symmetry ensures a spin-momentum locking similar to the gapped Rashba electrons. A temperature gradient can generate an interfacial magnon accumulation with a preferred spin polarization, realizing the magnonic counterpart of the spin Edelstein effect. This thermally-driven magnonic spin accumulation can be injected into an adjacent heavy metal and converted into a measurable voltage. It is found that the magnon spin-Edelstein coefficient increases monotonically with an increasing temperature and an increasing DMI, but, it depends non-monotonically on the magnetic anisotropy.

(a) Schematic device geometry. (b) Magnon band structure with the spin-momentum locking occurring in the shaded region. (c) Temperature dependence of the spin Edelstein coefficient. (d) In-plane anisotropy dependence of the spin Edelstein coefficient at different values of DMI.

CB-13. Investigation of the spin Seebeck effect in an antiferromagnetic insulator. *C. Liu*[1], D. Hong[1], J. Pearson[1] and A. Bhattacharya[1] *1. Material Science Division, Argonne National Laborotory, Lemont, IL, United States*

Recent years have seen rapid development in the area of spin caloritronics. In particular, the spin Seebeck effect (SSE) has been observed in a diverse class of magnetic systems. One interpretation of the SSE is based on thermal excitation of magnons in the bulk. Spin angular momentum is then transferred from those magnons to the normal metal through the local spin pumping process. While other theories for the SSE place more emphasis on the role of spin dependent scatterings at the magnetic material/normal metal interface. To elucidate the mechanism of the SSE, we performed the SSE measurements using an antiferromagnetic insulator. The epitaxial thin films were grown using RF sputtering. The unique response of the magnetic sublattice in this AFM to the applied magnetic field enables us to identify the role of surface magnetic moments in the SSE in an atomic length scale. By taking angular dependence measurement, we observe clear spin-flop transitions and the response of the thermal excitations of magnons owing to the difference in spinwave dispersion induced by the applied magnetic field. We performed the SSE measurements on samples with different thicknesses, which provide further insights on the exact mechanism of the SSE. Nanocontact vortex oscillators (NCVOs) are spin-torque devices, where large current densities drive vortex gyration around a nanocontact on a magnetoresistive multilayer. In contrast to other types of spin torque oscillators, NCVOs exhibit unique dynamical states caused by the self-phase locking between the core gyration and the periodic switching of the core. When the ratio between these two frequencies is irrational, chaotic dynamics appears [1]. Because of the random-like feature of chaotic signals, much effort has been devoted to understanding how to exploit these waveforms for information technologies, such as random number generation, encryption, and encoding information via symbolic dynamics [2-4]. In this work, we investigate experimentally the chaotic time series of an NCVO at 77 K. From the signals, we are able to identify a well-defined series of patterns (Fig. (a)). The patterns are the building blocks of the time series and denoted by their *pn* number, where *p* is the vortex-core polarization, and *n* is an integer number of required core gyration for the switching. We analyze the pattern sequence by reconstructing the attractor (Fig. (b)), and then extract symbolic dynamics (Fig. (c)) from a suitable Poincaré surface (Inset of Fig. (b)). Bit sequences generated from the symbolic dynamics (Fig. (c)) are found to be maximal complexity in the chaotic regime, which is suggestive of a chaotic state subject to thermal noise. This is confirmed by the computation of the Shannon block entropy and the Lempel-Ziv complexity [5, 6]. Finally, we show that the characteristics of the chaotic sequences can be controlled electrically. These results support the feasibility of chaos-based information processing using spintronic nanodevices.

Magnetic films that come into contact with heavy metals have a wealth of interesting interfacial phenomena that include interfacial Dzyaloshinskii-Moriya interaction (DMI), which may lead to chiral magnetic structures. Most work on interfacial DMI is based on films that exhibit C_{3v} symmetry. Such a high-symmetry interface is known to only support Néel type spin helices and skyrmions. [1] Here, the DMI is isotropic and can be described by exactly one micromagnetic parameter. This is different for systems exhibiting C_{2v} symmetry like the (110) surface of an fcc crystal, for which is predict to show anisotropic DMI leading to various scenarios of topological pattern formation. [2] Here, we report a spin-polarized scanning tunneling microscopy and spectroscopy study that reveals a magnetic stripe phase, due to a spin helix with a period of 1.2 nm along the [-1 1 0] direction in a monolayer of Fe on unreconstructed Ir(110). On the basis of our detailed magnetic field dependent measurements we conclude that the chirality of the spin helix is surprisingly of Bloch type, where the rotation is perpendicular with the propagation direction. This contradicts the spin helix induced by an interface in-plane DMI vector. Combined with theoretical insights, we discuss our findings in terms of the formation energy in systems with C_{2v} symmetry. The work is supported by the CRC 1238 of the Deutsche Forschungsgemeinschaft (DFG).

A Bloch point (BP) is a singularity in a ferromagnetic material at which the local magnetization vanishes. BP has a novel physical character such as pining in between atomic lattices, and the spin-Cherenkov effect [1, 2]. Furthermore, it has been known that the switching of vortex and skyrmion cores is mediated by the injection and propagation of the BP with changing the local topological number of the spin structures [3, 4]. However, the experimental study on the basic physics of BP such as atomic-scaled pinning and dynamics has not yet been elucidated due to difficulties of generating a stable BP in magnetic nanostructures which is easy to measure. In this presentation, we report experimental observations of the BPs stabilized in a magnetic vortex structure in an asymmetrically shaped permalloy ($Ni_{80}Fe_{20}$) nanodisks [5] by using the magnetic transmission soft X-ray microscopy (MTXM) at the Advanced Light Source [6]. We figured out clearly the types of BPs according to its surrounding structures. Furthermore, we observed the stable movement of the BPs under the static magnetic field. Our findings provide a way to stabilize a BP in a patterned nanostructure and it is expected to stimulate the experimental study on fundamental static and dynamic behaviors of BP.

One of the most fascinating topics in current quantum physics are hybridized systems, in which resonators of different quantum systems are strongly coupled. Prominent examples are circular resonators with high quality factors that allow the coupling of optical whispering gallery modes to microwave cavities or magnon resonances. However, the coupling to magnons with finite azimuthal wave vectors has not yet been achieved due to the lack of efficient excitation schemes. I will present the generation of whispering gallery magnons with unprecedented high azimuthal wave vectors via nonlinear 3-magnon scattering in a µm-sized magnetic vortex state disc [1]. These modes exhibit a strong localization at the disk's perimeter and practically zero amplitude in an extended area around the vortex core. They originate from the splitting of the fundamental radial magnon modes (see Figure), which can be resonantly excited in a vortex texture by an out-of-plane microwave field. I will shed light on the basics of this non-linear scattering mechanism from experimental and theoretical point of view. Using Brillouin light scattering (BLS) microscopy, the frequency and power dependence of this nonlinear mechanism is investigated. The spatially resolved mode profiles give evidence for the localization at the disk's boundaries and allow for a direct determination of the modes' wavenumber. Furthermore, time resolved BLS in combination with pulsed microwave excitation revealed the temporal evolution of the 3-magnon splitting and its dependence on the applied microwave power.

CC-05. Three-Magnon Splitting in Vortex-State Magnetic Nanodots. *R.V. Verba*[1], L. Korber[2,3], V. Tiberkevich[4], K. Schultheiss[2], H. Schultheiss[2,3] and A.N. Slavin[4] *1. Institute of Magnetism, Kyiv, Ukraine; 2. Helmholtz-Zentrum Dresden–Rossendorf, Dresden, Germany; 3. TU Dresden, Dresden, Germany; 4. Oakland University, Rochester, MI, United States*

Spin waves in ferromagnetic micro- and nanostructures demonstrate a great variety of nonlinear phenomena at moderate excitation power. In particular, using the nonlinear effect of 3-magnon splitting it is possible to built frequency-selective power limiters [1], and excite highly non-uniform magnon modes, which are not accessible to direct linear excitation [2]. Also, properties of 3-magnon interaction drastically depend on the geometry of the ferromagnetic structure, and on its static magnetic configuration. In this work, we present a theory of 3-magnon splitting in a *vortex-state* magnetic nanodot. Using vector Hamiltonian formalism [3], we demonstrate, that 3-magnon spitting of a magnon mode with radial and azimuthal numbers (n_3, m_3) into modes (n_1, m_2) and (n_2, m_2) obeys the following selection

rules: conservation of the azimuthal number $m_3=m_1+m_2$, and, for a radially symmetric initial mode ($m_3=0$), inequality of the radial number of resultant modes, $n_1 \neq n_2$. The last rule, however, is relaxed in small dots due to the increasing role of the vortex core. The coefficient $V_{12,3}$ describing the efficiency of the 3-magnon interaction significantly depends on the resultant modes, as it is shown in Fig, 1b for the example of splitting of the second radial (2,0) mode of a vortex-state Permalloy disk (50 nm thickness, 5 μm diameter). Although the resonance condition for the 3-magnon splitting (zero detuning, Fig. 1a) is satisfied for several pairs of the resultant modes, the larger efficiency $V_{12,3}$ requires splitting into (0,5)+(2,-5) modes, in full accordance with the experiment [2]. Varying the driving frequency, one can control the splitting process, and the resultant modes can be changed e.g. to (1,*m*)+(2,-*m*) at 8.9-9 GHz. Thus, the developed theory allows one to predict both the splitting channels and the splitting thresholds. Also, this theory is useful for the investigation of the stimulated sub-threshold 3-magnon processes in magnetic vortices.

Magnetic skyrmions are nano-scale chiral spin configurations which present fascinating physical behaviors due to their topological qualities, and are attractive for next-generation data storage and logic devices. These chiral structures can support long-range dynamic modes, including breathing modes and gyration modes which can be excited using ferromagnetic resonance (FMR) [1]. The frequency of these dynamics – typically in the gigahertz range – presents additional opportunities for microwave frequency electronics. In this work, we us small angle neutron scattering (SANS) as a real-space, in-situ probe to capture the dynamics in hybrid skyrmion structures under RF applied fields. Specifically, our team has recently demonstrated magnetic skyrmions with a hybrid configuration – with a flux-closure defined Néel caps on the top and bottom, and Bloch configuration at the equatorial band – in Gd/Fe multilayer films, which are stable at ambient conditions [2, 3]. Using an in-plane RF field with an out-of-plane static field, dynamic gyration modes are excited in the skyrmions. These gyration modes were probed using Doppler-shift contrasted SANS. In this technique, we recognize that neutrons scattering from a moving object pick-up an additional energy. In the case of the gyration mode, the dynamics occur in a plane that is orthogonal to the neutron beam. As a result, the neutrons pick-up a transverse velocity, proportional to the speed and direction of the skyrmion motion at the time of scattering. For the case of gyrating skyrmions, this manifests as a broad ring on the detector, with a radius proportional to the velocity. By analyzing the distribution of the scattering pattern the speed and path of the gyration is extracted. Work at UCSD supported by DOE award No. DE-SC0003678.

The concept of topological protection in a continuum model precludes a continuous deformation between topologically inequivalent configurations[1]. Motivated by this concept, there has been a great expectation that nontrivial magnetic structures at a nanoscale, i.e. magnetic skyrmions, can stay robust against thermal agitations, providing a breakthrough in ultrahigh density magnetic memory applications[2]. Despite the substantial importance of the concept of topological protection, however, the experimental assessment

has remained elusive due to difficulties in evaluating the stability of topologically inequivalent magnetic textures in the same material at the same conditions[3]. Here either the skyrmion state or the topologically trivial bubble state is selectively prepared, and we experimentally show that the magnetic skyrmions, of which decay involves surpassing a topological barrier, exhibit far longer lifetime τ than topologically trivial bubbles (Fig. 1), directly evidencing the topological stability in a real discrete system. Our work has far-reaching implications for taming and exploiting the topology of magnetic materials towards the ever-dense and more-stable magnetic devices.

Ultra-fast coherent magnetization reversal within a picosecond, which will be an essential technique for ultra high-speed spintronics in the future, is expected to be realized by irradiation with a nearly monocyclic terahertz pulse. Till now, coherent magnetization modulation by terahertz pulses has been reported for several ferromagnetic thin films; however, the modulation ratio reported so far has been typically less than 1% of the saturation magnetization even with extraordinarily strong terahertz electric fields. Here, we demonstrate a large modulation up to 20% of the magnetization with terahertz pump-pulse irradiation to MnAs ferromagnetic nanoparticles embedded in a semiconductor GaAs (GaAs:MnAs) (Figs. 1,2) [1]. We show that, when using semiconductor-based ferromagnetic materials, the influence of the "electric field" component of the terahertz pulse has much more dominant than that of the magnetic-field component [2], unlike in metallic materials. In GaAs:MnAs, a strong electric field can be applied to each nanoparticle, leading to the large modulation. This work was partly supported by Grants-in-Aid for Scientific Research (No. 26249039, 18H03860, ISHO1011, 16H02095), Spintronics Research Network of Japan, and CREST, Japan Science and Technology Agency (Grant No. JPMJCR1661, JPMJCR177).

Spin-wave (SW) dynamics in lithographically patterned nanomagnet arrays have attracted huge interest to the scientific community due to their rich physics and potential applications in magnetic memory, sensors, logic and on-chip communication devices. Here, we present the efficient modulation of SW spectra in 200-nm wide triangular shaped $Ni_{80}Fe_{20}$ antidot lattices (ADL) arranged in different symmetry, namely square, rectangular, hexagonal, honeycomb and octagonal symmetry with different lattice constants of 400, 500, 600 and 700 nm. Further, the anisotropy properties of the square and octagonal lattices have been studied by varying the orientation of the in-plane bias magnetic field. The triangular holes create inhomogeneous internal magnetic fields resulting in effective pinning centres for SWs created by the asymmetric demagnetized regions. This is mainly responsible for the observed tunability of the SW dynamics and the configurational anisotropy. Experimental studies with Time-Resolved Magneto-Optical Kerr Effect (TR-MOKE) microscopy show a rich variation of the SW spectra

with the variation of the lattice symmetry as well as the lattice constant. The SW modes in both square and octagonal lattices possess strong anisotropic behaviour as a function of the in-plane bias field orientation, which originates from the variation of the asymmetric demagnetized regions around the triangular shaped holes. The square lattice shows a four-fold anisotropy with superposition of a weak six fold anisotropy. On the other hand, for the octagonal lattice a mixture of eight-fold and six-fold anisotropy is observed. Micromagnetic simulations qualitatively reproduce the experimentally observed modes and the simulated mode profiles reveal the presence of different types of extended and quantized standing SW modes in these samples. The simulated magnetostatic field distributions underpinned the observed variation in the SW spectra leading towards an extensive understanding of SW dynamics in this new type of magnonic crystal.

CC-11. Stimulated, continuous, and wave vector selective magnon excitation using rapid demagnetization from high repetition rate femtosecond laser pulse trains. *S. Muralidhar*[1*], A. Aleman[1], A.A. Awad[1], R. Khymyn[1], D. Hanstorp[1] and J. Åkerman[1,2] *1. Department of Physics, University of Gothenburg, Gothenburg, Sweden; 2. KTH Royal Institute of Technology, Stockholm, Sweden*

Magnonics provides interesting prospects in miniaturization and optimization of high frequency devices where magnons/spin waves (SWs) are the information carriers. Optical excitation of SWs in thin magnetic films was first observed in 2002 using rapid demagnetization from femtosecond (fs) laser pulses [1]. However, due to the high damping coefficients of magnetic materials, continuous emission of SWs using this approach has not yet been possible. With fs-laser repetition rates being typically 80 MHz and lower, the time duration between pulses is much longer than the time constant of SW damping. However, this has recently changed with 1 GHz repetition rate fs-lasers now being available, which allows magnetic excitation every 1ns, i.e. on the same time scale as the SW decay [2]. We here use μ-focused Brillouin Light Scattering (μ-BLS) as probe, which affords us excellent spatial resolution and high sensitivity to both thermal and optically excited SWs. The results using a 20 nm NiFe thin film are shown in Fig.1(a) where the BLS counts are plotted on a logarithmic scale as a function of SW frequency for four different laser powers and together with the laser off (thermal SWs only). As the laser power is increased, we find a pronounced exponential enhancement of the BLS counts when the SW frequency matches harmonics of the 1 GHz rep-rate. While the enhancement is the strongest around the ferromagnetic resonance (~8 GHz), substantial additional SW intensity is observed also at 7 and 9 GHz. To study the spatial extent of the generated SWs, we acquired line scans of the BLS counts. At 7 GHz the SWs appear localized to the pump region. The SWs at 8 and 9 GHz instead show propagation along the direction perpendicular to the in-plane component of the applied magnetic field (H_{in}). By changing the in-plane component angle and the strength of the magnetic field, we can control the direction and spatial pattern of the SW emission.

CC-12. Investigating optically excited THz spanding spin waves in noncollinear magnetic heterostructures. *T. Lichtenberg*[1], M.H. Janssen[1], R. Lavrijsen[1] and B. Koopmans[1] *1. Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands*

In recent years, spin waves have received significant interest due to their potential use as information carriers in Joule-heat-free data transfer and processing. Recently, it was discovered that fs laser pulses can be used to excite THz standing spin waves in noncollinear magnetic heterostructures [1, 2]. The basic principle of this phenomenon is sketched in the inset of fig. 1. A fs laser pulse generates a spin current between the two neighboring ferromagnetic layers, allowing for interlayer angular momentum transfer. The injected spin current is absorbed on a relatively short length scale (~1 nm). This causes a depth dependence of the spin-transfer torque and thus the magnetization canting, which creates the ideal environment for higher order spin wave excitation. In this work, we study the excited first order THz spin waves in a $[Co(0.2)/Ni(0.6)]_{4x}$/Co(0.2)/Cu(0-30)/Co(5)/Pt(2) stack

using optical pump-probe experiments. More specifically, we investigate the influence of the Cu spacer layer on their damping and phase. The first order modes are presented for several spacer thicknesses in fig. 2. Micromagnetic simulations have been performed in support of these experiments. These simulations accurately predict the spin wave dispersion, and extensions to extract phase information are on the way. We report that the typical length scale for interlayer angular momentum transfer in this stack is ≈13 nm, which is much smaller than the spin diffusion length of Cu. This indicates a simple picture of a demagnetization induced diffusive spin current is insufficient to fully describe the observed spin transfer. By measuring the phase of the first order rather than the homogeneous mode, a higher resolution is obtained for studying the injected spin current in the time domain. Preliminary results indicate that the current absorption time increases from 50 to 300 fs within the studied range (fig.2). This experiment thus allows us to further elucidate the spin transfer mechanism in our experiments.

CC-13. Terahertz Magnonics on Garnet Ferrite Thin Films and their Neuromorphic Application. *H. Tabata*[1] *1. School of Engineering, University of Tokyo, Tokyo, Japan*

Spin-waves in magnetic insulators maintain several centimeters [1]. Because there are no conductive electrons in magnetic insulators, spin-wave of magnons, which are the collective motion of spins angular momentum, can be propagated over a long distance. In addition, spin pumping technique enables to convert the spin-wave spin-currents into conduction electron spin-currents [2]. High-energy magnons which are called as electromagnons (EMs) is expected to be excited by the electric field component of THz wave [3]. In this study, samarium ferrite garnet (SmIG) was selected as the target material. The epitaxial strain rate of SmIG is largest in all of rare-earth iron garnets (RIGs) because the lattice constant of SmIG is largest in all of RIGs. RIGs are ferrimagnetic and dielectrics at RT, and transparent in a wide range of THz region. Moreover, spin fluctuation because the spin fluctuation can be observed in THz region and it is expected to mimetic neuromorphic signal processing [4]. Figure shows the THz spectroscopy of the SmIG films. The complex permittivity of the film in THz regime was extracted using the way described in [5]. Because the phonons do not change their excitation energy in accordance with magnetization strength, these absorption peaks are considered to be EMs. The higher energy peak is due to the Brillouin Zone-edge magnon mode (EMBZ), and the lower energy peak is due to the harmonic magnon mode (EMH) [6]. The EMs were observed only in the strained SmIG film, whereas they were not observed in the relaxed SmIG film, as we designed. The increment of excitation energies of EMs is saturated above 0.35 T, being coherent with a MCD result. We estimated the spin-wave spin-current properties of Ems using D'yakonov-Perel (DP) model; $\Gamma \propto \omega^2\tau$, where Γ is the scattering probability of spin precession, ω is the resonant angular frequency and τ is the relaxation time of the electrons. Electromagnons are detected in the strained Sm3Fe5O12 ultrathin film, using a transmittance THz time-domain spectroscopy.

Spin polarized currents are employed to efficiently manipulate the magnetization of ferromagnetic ultrathin films (below 2 nm) by exerting a torque on them. When these spin currents are generated by means of the spin-orbit interaction it is known as spin-orbit torque (SOT)[1,2]. In this work, we present a new technique to quantify the SOT efficiency based on the measurement of the non-linearities of dc current-voltage characteristics in Hall bar devices. We have experimentally studied the SOT TaOx/Co/Pt asymmetric stack with perpendicular magnetic anisotropy and compared the results with the second harmonic technique. The presented technique requires a lesser current than the used in the second harmonic technique, see reference [3] and yields directly the effective field per unit of current density in a single experiment. The results obtained show large torques due to the different Spin Hall angles of platinum and tantalum that induce a large spin current density in the cobalt layer [4].

CD-02. Spin orbit torque arising from the interfacial scattering in an Fe/Ru Interface. *Q. Liu*[1], K. Meng[1], Y. Wu[1], J. Chen[1], Z. Li[1], J. Miao[1], X. Xu[1] and Y. Jiang[1] *1. University of science and technology Beijing, Beijing, China*

Controlling magnetization of nanodevices through the spin-orbit torque(SOT) offers a wide spectrum of opportunities to integrate magnetic functions[1]. However, up to now, the study of SOT is limited to systems consisting of heavy metal (HM), where the HM has a strong spin-orbit coupling (SOC) (such as Pt, W, etc.)[2-4]. In this work, samples of Ru/Fe/HfO_2 structures were deposited at room temperature on oxidized silicon wafers. According to the magnetic field H dependence of the out-of-plane magnetization M and anomalous hall resistance R with temperature as shown in Fig. 1 (c) and (d), We found that the Ru/Fe/HfO_2 films has better perpendicular magnetic anisotropy and thermal stability. Then, the current-induced magnetization switching behaviors in Ru/Fe/HfO_2 films were measured with applying a non-zero in-plane field H. Although the spin Hall angle (SHA) of Ru is small as compared with those from Ta- or W-based heterostructures, reversible current-induced SOT switching of a thermally stable Ru/Fe/HfO_2 heterostrutures can still be achieved as shown in Fig. 2 (a) and (b). To quantitatively determine the strength of the spin-orbit effective fields, the non-adiabatic harmonic Hall voltage measurements were carried out at room temperature. The harmonic measurements by applying a sinusoidal AC current with the amplitude of 5×10^6 A/cm^2 at 300 K are taken as an example as shown in Fig. 2 (c). According to the calculated H values plotted with respect to the applied current in Fig. 2 (d), the SHA in Ru/Co/HfO_2 is calculated to be 0.045. The effective field induced in Ru/Fe/HfO heterostruture is comparable with that generated by SHE of Pt. In conclusion, our results suggest a new opportunities for fundamental study of spin dynamics and transport in ferromagnetic systems.

CD-03. Characterization of field- and current-induced magnetization switching in epitaxial Au/Fe/MgO(001). P. Gospodaric[1], E. Mlynczak[1], A. Kakay[2], *L. Plucinski*[1], I. Soldatov[3], R. Schäfer[3], D. Buergler[1], J. Fassbender[2] and C.M. Schneider[1] *1. PGI-6, FZ Juelich, Juelich, Germany; 2. HZDR, Dresden, Germany; 3. IFW, Dresden, Germany*

We have studied an epitaxial Fe(001) ultra-thin film sandwiched between the MgO substrate and an epitaxial Au thin film. We performed a thorough characterization of the field- and current induced magnetization reversal in the Au/Fe bilayers using magneto-transport measurements and Kerr microscopy. The magnetic properties of the Fe film were studied in the Hall bar geometry via the planar Hall effect. The analysis shows the characteristic four-fold in-plane magneto-crystalline anisotropy of Fe(001) layers, present due to the high crystalline quality of the films. We observe changes in the hysteretic response of the magnetization to the external magnetic field when a high current density is applied to the Au/Fe Hall bar wire. Kerr microscopy of the Hall bars reveals further details on the switching mechanism in presence and absence of a high current density. By comparing field- and current-induced magnetic hystereses the information on the current-induced effective fields can be obtained. Previously we have investigated the magnetization dependent spin-orbit gaps in Fe thin films on Au(001) using angle-resolved photoemission [1], and the growth of Fe on Au using LEEM/PEEM [2]. The spin-orbit torque (SOT) is considered as one of the most promising ways of current-induced switching of ferromagnets and antiferromagnets. In heavy metal/ferromagnet bilayers for example, the spins in the ferromagnetic layer can be manipulated via SOT with an in-plane electric current. Our study points out the considerable effect of the Oersted field for the switching mechanism in Au/Fe heterostructures. Figure shows the evolution of in-plane domains in the Au/Fe Hall bar after applying current pulses monitored by Kerr microscope. Our results demonstrate that only the area close to the Hall cross contributes significantly to the transverse magnetoresitance signal.

CD-04. Manipulating exchange bias by spin–orbit torque. P. Lin[1], H. Lin[2] and *C. Lai*[1] *1. Department of Materials Science and Engineering, National Tsing Hua University, HsinChu, Taiwan; 2. Department of Physics, National Tsing Hua University, HsinChu, Taiwan*

Inspired by the success in switching FM magnetization by various electrical means, AFM spintronics has received a great deal of attention in recent years. While most efforts have focused on electrical manipulations of a bulk AFM, interfacial effects between FM and AFM layers are also vitally important for spintronic devices. Here we demonstrate that applying current pulses to heavy metal/FM/AFM trilayers causes concurrent switching of FM magnetization and exchange bias (EB), shown in Fig. 1, but with different underlying mechanisms[1]. This implies that the FM magnetization and EB can be manipulated independently. When comparing with the conventional field-annealing approach to generate EB, SOT determines the FM magnetization direction and further provides effective disturbance to align the interfacial spins between the FM/AFM layers to the FM magnetization. We further develop a time-resolved resistance measurement technique to eliminate the possibility of EB reversal due to joule heating effects. Not only the direction of the exchange bias can be reversed, but its strength can also be controlled by electric current pulses, which can be correlated to the alignment of interfacial spins and current-induced reorientation of N'eel ordering. With further investigation and optimization along this direction, the current-pulse-induced EB shall have significant impacts on the SOT-MRAM and other spintronic devices.

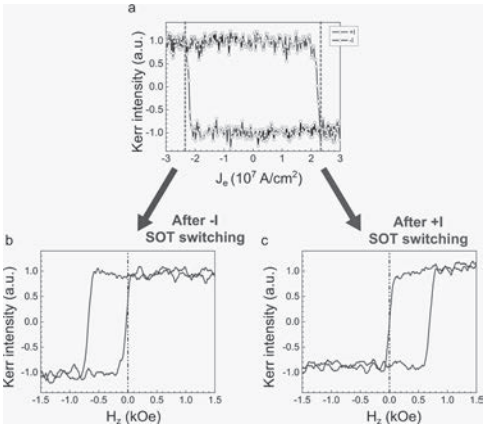

Fig. 1: Concurrent SOT switching for FM magnetization and exchange bias. a. SOT switching curves of FM magnetization in the presence of a longitudinal field Hx=300 Oe for sample Pt 2 nm/Co 1.2 nm/ IrMn 8nm. Dotted lines denote the current density thresholds in the Pt layer for the concurrent SOT switching. b,c. After the concurrent SOT switching, not only is the FM magnetization flipped, but the exchange bias is also reversed. The negative pulse (red line) flips the magnetization (from negative to positive) and the exchange bias (shifted easy-axis loop to the left) at the same time. The opposite SOT switching is observed when the positive pulse (blue line) is applied.

CD-05. A magneto-optical study of spin-orbit torque acting on a nano-ellipse with in-plane magnetization. P.S. Keatley[1], *P. Androvitsaneas*[1], K.O. Chatzimpaloglou[1], T. Manago[2,1], G. Mihajlovic[3], L. Wan[3], J. Katine[3] and R. Hicken[1] *1. University of Exeter, Exeter, United Kingdom; 2. Fukuoka University, Fukuoka, Japan; 3. HGST, San Jose, CA, United States*

In-plane magnetized elements activated by spin-orbit torque (SOT) show great promise for future magnetic memory applications. SOT switching of in-plane magnetized ellipses at the centre of a Pt Hall cross has been studied via the differential planar Hall effect [1]. Time-resolved (TR) scanning Kerr microscopy (SKM) revealed the action of SOT on GHz frequency magnetization precession [2]. The SOT generated by a sub-nanosecond current pulse can yield relaxation that depends on field history, and a transient out-of-plane deflection. However the presence of an associated Oersted (Oe) field prevents full characterisation of the SOT [3]. Here, SKM was used in quasi-static (QS) and spin torque ferromagnetic resonance (ST-FMR) modes to explore the SOT and the Oe-field effects in different sized ellipses. The polar Kerr effect was used to detect the change in the magnetization in response to (i) a modulated DC current (QS mode), and (ii) a combination

of microwave (RF) and DC current (ST-FMR mode). The current passes through a Pt (6 nm) Hall cross parallel to the ellipse minor (hard) axis. The associated Oe-field and the polarization of spins traversing the Pt/CoFeB interface due to the spin Hall effect are parallel to the major (easy) axis. Ellipses with size 0.4×1 to 2×5 μm² were studied. In QS mode, the out-of-plane deflection was found to be maximum, when the magnitude of the applied field was close to the anisotropy field, and perpendicular to the spin polarization and Oe-field. This is in agreement with analytical calculations. ST-FMR mode spectra reveal a shift to the resonance field as a function of magnetic field angle, but little change in the spectral shape when the DC current is zero. A DC current of 10 mA yields marked differences in the amplitude and linewidth that are ascribed to SOT enhancement or compensation of the magnetic damping. A shift in resonance field, of opposite sign to either side of the hard axis, is ascribed to a combination of the DC Oe-field torque and the field-like SOT. Detailed analysis is in progress to disentangle the Oe-field and SOT contributions.

Spin-orbit toque (SOT) has been widely investigated because it allows efficient manipulation of the perpendicular magnetisation in HM/FM heterostructures using an in-plane current [1,2]. Since then, much effort has been devoted to finding materials with a large SOT-induced switching efficiency, which however has to be further enhanced for the realisation of energy-efficient SOT-based spintronic devices. In this study, we have successfully achieved two folds enhancement in SOT and resultant switching efficiency in Pt/CoFeB systems by an interfacial modification involving Ti insertion (Fig. 1). Our spin pumping and X-ray magnetic circular dichroism experiments reveal that such significant enhancements originate from improved spin transparency by suppressing Pt proximity effect at the interface and/or an additional spin current generated of non-magnetic interface. Two significances of our results can be summarized. 1) The perpendicularly magnetised Pt/CoFeB system is a promising candidate for SOT-based spintronic device application because Pt is a highly conductive material with a sizable spin Hall angle and CoFeB has a large spin polarization in conjunction with crystalline MgO, thereby resulting in a large tunnel magnetoresistance. However, SOT in the Pt/CoFeB layer has been reported to be smaller than other Pt/FM bilayers systems so far. Therefore, our result of the enhancement in effective spin Hall angle of Pt/CoFeB promises potential applications in high-performance SOT devices. 2) And more, our result is the first observation that SOT can be enhanced by 100% by an interfacial engineering involving 3*d* metal insertion whereas other studies have shown that SOT decreases by the insertion of a 3*d* metal interfacial layer [4, 5]. In this work, we clearly demonstrate that interface engineering affords an effective approach to improve SOT and thereby magnetisation switching efficiency.

CD-07. High Thermal Stability of Perpendicular Magnetic Anisotropy and Current Induced Spin-orbit Torque in Zr/CoFeB/MgO Stacks. *T. Zhu*[2] and X. Zhan[1] *1. Dongguan Neutron Science Center, Dongguan, China; 2. Institute of Physics, Chinese Academy of Sciences, Beijing, China*

The manipulation of the magnetization in an energy efficient and fast way can be achieved in a magnetic multilayer with perpendicular magnetic anisotropy (PMA) [1-3]. Among the PMA material systems, the heavy metal buffered or capped CoFeB/MgO multilayer, such as Ta/CoFeB/MgO, is of frequently employed owing to its advantage in excellent PMA property [1]. The manipulation of magnetization in CoFeB can be realized through both spin transfer torque or spin orbit torque generated in heave metal underlayer. However, the commercialization of such structures requires PMA to be compatible with COMS integrated circuits, which generally can endure the annealing above 400°C. Here, we reported that the PMA in Zr/CoFeB/MgO, which was used 4d metal as the underlayer, is found to be robust up to 450°C. The origin of PMA is investigated by using polarized neutron reflectometry (PNR) [4], which is a technique sensitive to the compositional and magnetic depth profiles of thin film samples which enables us to discuss the role of boron in the formation of PMA. Meanwhile, we have investigated the spin-orbit torques in the perpendicularly magnetized Zr/CoFeB/MgO stacks.

CD-08. Current-Driven Magnetization Switching and Large Spin Orbit Torque in Ferrimagnet $GdMn_{2.5}Ge_{1.5}$ Thin Film. *L. Ren*[1], L. Liu[1], K. Cai[1], Y. Liu[1], J. Chen[1], H. Yang[1] and K. Teo[1] *1. National University of Singapore, Singapore*

Antiferromagnets have attracted lots of attentions because of no stray fields and faster spin dynamics than ferromagnets. [1, 2] Unfortunately, the challenges of operating the antiferromagnets impede their applications. However, compensated ferrimagnets combine the advantages of the low magnetic moment of antiferromagnets and the ease of realizing magnetic reading and controlling of ferromagnets. [3, 4]. Especially some investigations on spin-orbit torque of have been reported, which provide a promising platform for high-speed spintronic applications [5-7]. Here we report that compensated $GdMn_{2.5}Ge_{1.5}$ films were deposited on MgO substrates. The structure of the film was characterized by XRD and HRTEM. The results indicate that the films are tetragonal with (001) preferred orientation. Magnetic properties indicate that the T_{comp} is about 115 K and the coercivity decreases with increasing or decreasing temperature for either above or below T_{comp}, and that the maximum H_C reaches larger than 7 T near T_{comp}, while the magnetization reaches zero moment. Besides, the transport properties and Harmonic Hall voltages of the film were also measured using Hall bridge method. Some of the results are shown in Figures (a) and (b), from which we can find that the sign of anomalous Hall resistance above compensation temperature is opposite to that bellow the T_{comp}, and that the spin orbit torque effective field are evaluated as 9.54mT/10^{10}Am^{-2} at 300K, which is much higher than reported values in heavy metal/ferromagnet systems and is attributed to the bulk spin orbit torque effect in our film here. Moreover, at 300K we also found the Hall resistance switching at a current density of 4×10^{10}Am^{-2} under an external magnetic field, as shown in Figure (c). With temperature decreasing, the switching threshold of current density and the Hall resistance switching ratio both increase. Our experiment results provide alternative candidate for the compensated ferrimagnet spintronic applications.

CD-09. Large Spin Orbit Torque Generated by Mn_3Sn Weyl Semimetal Thin Films. *S. Hu*[1] and X. Qiu[1] *1. School of physics science and engineering, Tongji University, Shanghai, China*

Non-collinear antiferromagnet Mn_3Sn has attracted great attention for its novel properties, such as large anomalous Hall effect [1], unique spin Hall physics [2], and negative magnetoresistance in association with Weyl nodes [3]. As Weyl semimetals are predicted to possess efficient charger-spin conversion due to their intriguing band structure and spin-momentum locking in both the surface and bulk states [4-6], the Weyl semimetallic character of Mn_3Sn shows great prospects for spin-orbitronic memory and logic applications Here, we report the large spin orbit torque (SOT) and its driven efficient perpendicular magnetization switching in Mn_3Sn/Cu/$[Ni/Co]_n$ heterostructures at room temperature. Mn_3Sn (0001) thin film was deposited on single crystalline MgO (111) substrates by dc magnetron sputtering. Figure 1(a) shows the X-ray diffraction spectrum of 40 nm-thick Mn_3Sn films, which exhibits strong (0001) preferred orientation. The positive magnetoconductance, an important feature of Weyl semimetal, is shown in Fig. 1(b) [3]. Figure 2(a), (b) are the first and second harmonic measurements of Mn_3Sn/Cu/$[Ni/Co]_n$ and β-Ta/Cu/$[Ni/Co]_n$ heterostructures to quantify the SOT effective fields. We observe that the spin orbit torque generated by Mn_3Sn is nearly one order larger than β-Tantalum [7]. Figure 2(c) shows the corresponding SOT-induced magnetism switching curves. A much lower critical J_C of 4.17×10^6A cm^{-2} is needed to switch the magnetization in Mn_3Sn heterostructure when comparing to the β-Ta heterostructure. Our results demonstrate the Mn_3Sn Weyl semimetal for highly efficiency spin-orbitronic applications.

CE-01. Non-Reciprocal Short-Wavelength Spin Waves in Thin YIG Films. *A. Khan*[1], T. Liu[2], M. Wu[2] and I. Krivorotov[1] *1. Physics, University of California, Irvine, Irvine, CA, United States; 2. Physics, Colorado State University, Fort Collins, CO, United States*

Non-reciprocal microwave devices such as circulators, isolators and phase shifters based on field-biased bulk ferrites have been extensively used for microwave signal processing over many decades. However, these magnetic device designs cannot be scaled down to chip-integrable, nanoscale dimensions. An alternative route towards non-reciprocal nanoscale magnetic devices is based on non-reciprocal short-wavelength spin waves in thin magnetic films [1]. Here we report observation of strongly non-reciprocal propagation of short-wavelength spin waves in 40 nm thick films of yttrium iron garnet (YIG). For these measurements, we employed e-beam lithography to pattern two coplanar strip Ti/Au microwave antennas on top of the YIG film as shown in Fig. 1a, which can excite spin waves with wavelengths as short as 420 nm. Spin wave propagation between the antennas is measured using a microwave network analyzer as a function of magnetic field applied in the sample plane perpendicular to the spin wave propagation direction. Fig. 1b shows magnetic field derivative of the measured S_{21} and S_{12} parameters as a function of frequency [2]. The data reveals significant non-reciprocity of the spin wave dispersion relation. Using this data, we calculate group velocities of 668 m/s and 583 m/s for the left and right propagating spin waves, respectively. Fig. 2 shows the dependence of field derivatives of S_{21} and S_{12} parameters as a function of magnetic field and frequency. These data reveal that spin wave non-reciprocity is observed over a wide range of magnetic fields and frequencies. We will discuss possible origins of the observed non-reciprocity of short-wavelength spin waves in these thin YIG films [3].

CE-02. Nuclear Quantum Phase Control by Transient Magnons. *L. Bocklage*[1,2], J. Gollwitzer[1], C. Strohm[1], C.F. Adolff[1,2], K. Schlage[1], I. Sergeev[1], O. Leupold[1], H. Wille[1], G. Meier[3,2] and R. Röhlsberger[1,2] *1. DESY, Hamburg, Germany; 2. The Hamburg Centre for Ultrafast Imaging, Hamburg, Germany; 3. Max-Planck Institute for the Structure and Dynamics of Matter, Hamburg, Germany*

Quantum optics requires coherent light-matter interactions. Recently, quantum optical concepts have been established in the hard X-ray regime utilizing nuclear resonances of Mössbauer isotopes [1,2]. However, direct coherent control is still a great challenge at hard X-ray energies and its corresponding sub-attosecond time scales. Here, we show that the quantum phase of 57-Fe Mössbauer nuclei embedded in a thin ferromagnetic film can be coherently controlled with zeptosecond temporal accuracy via a transient magnon. We use this collective spin excitation to modulate the magnetic hyperfine interactions of the nuclei in the sample [3]. In this way, the phase of a collectively excited nuclear state, the nuclear exciton, can be controlled on the zeptosecond time scale, as monitored via quantum beats between different hyperfine-split levels. The nuclei are excited with a resonant synchrotron pulse at an energy of 14.4 keV. The quantum beat in the X-ray emission of the nuclei is shown in Fig. 1. The temporal beat on a nanosecond scale results from the interference of the nuclear dipole transition moments of two interacting nuclear levels. When a transient magnon is excited during the lifetime of the nuclear excition (blue bar in Fig.1) a phase shift is induced in the quantum beat. This phase shift directly relates to the phases of the involed dipole transition moments, where we determine phase shift down to one zeptosecond. Our quantum control method opens new perspectives for precision phase control of X-rays in extreme metrology applications. Furthermore, magnonic applications, such as spin wave logic or spin-caloritronics, can be extended to the field of quantum state control.

CE-03. Introducing Coherent Time Control to Cavity-Magnon-Polariton Modes. *T. Wolz*[1], A. Stehli[1], A. Schneider[1], I. Boventer[1,2], R. Macedo[3], A.V. Ustinov[1,4], M. Kläui[2] and M. Weides[1,3] *1. Institute of Physics, Karlsruhe Institute of Technology, Karlsruhe, Germany; 2. Institute of Physics, Johannes Gutenberg University, Mainz, Germany; 3. James Watt School of Engineering, University of Glasgow, Glasgow, United Kingdom; 4. Russian Quantum Center, National University of Sicence and Technology MISIS, Moscow, Russian Federation*

By connecting light to magnetism, cavity-magnon-polaritons (CMPs) [1-3] can build links from quantum computation to spintronics. As a consequence, CMP-based information processing devices have thrived over the last five years, but almost exclusively been investigated with single-tone spectroscopy. However, universal computing applications will require a dynamic control of the CMP on demand and within nanoseconds. In this work, we perform fast manipulations of the different CMP modes with independent but coherent pulses to the cavity and magnon system. We change the state of the CMP from the energy exchanging beat mode to its normal modes (Fig. 1) and further demonstrate two fundamental examples of coherent manipulation: First, a dynamic control over the appearance of magnon-Rabi oscillations, i.e., energy exchange, and second, a complete energy extraction (Fig. 2) by applying an anti-phase drive to the magnon. Our results show a promising approach to control different building blocks for a quantum internet and pave the way for further magnon-based quantum computing research.

CE-04. Excitation Vector Field and Polarization Effect on Cavity-Magnon-Polaritons. *R. Macedo*[1], D.A. Bozhko[1], R. Holland[1], J. Barbosa[1] and M. Weides[1] *1. James Watt School of Engineering, University of Glasgow, Glasgow, United Kingdom*

In recent years we have witnessed a growing interest in cavity-magnon-polaritons. These are hybrid light–matter quasiparticles originating from the strong coupling between magnons and cavity photons [1,2]. Thereby, combining light and magnetism in such way, it is possible to combine quantum information with spintronics. By using this emergent phenomenon, it is possible to engineer devices including, gradient memory and radiofrequency-to-optical transducers. In order to enable more functionality, it is particularly interesting to engineer and understand the coupling strength between elements of a hybrid system – a property which works as a measure for coherent information exchange. This coupling is strongly dependent on the field configuration within the cavity, and hence, the position at which the magnetic sample is placed. In this work, the importance of the field configuration within the cavity is demonstrated but also shown, how different polarisation states can affect the behaviour of cavity magnon polaritons. In Figure 1 we show the measured reflection (S_{11}-parameter) of a YIG sphere placed inside a square microwave cavity, which exemplifies how the coupling can change as a function of the field profile at the sample position. We also show how the polarisation states within different cavity geometries can affect said coupling strength and behaviour of the overall hybrid system. We use the perturbation method to verify our experimental findings. This is done by finding analytical expressions for the field profiles inside the cavity which couple with specific permeability tensor components – these can be calculated through classic LLG equations. Finally, we expect that by being able to control and understand the behaviour of cavity-magnon-polaritons will open up new avenues for, and better manipulate, exchange of information as well as bridging the gap between quantum information and spintronics applications.

CE-05. Parametric Pumping of Forward Volume Spin Waves by Surface Acoustic Waves. *N. Nujhat*[1], A. Jander[1] and P. Dhagat[1] *1. Electrical Engineering and Computer Science, Oregon State University, Corvallis, OR, United States*

We demonstrate the parametric pumping of forward volume magnetostatic spin waves (FVMSW) by surface acoustic waves (SAW) in a yttrium iron garnet (YIG) thin film. Parametric pumping of spin waves has application in magnonic signal processing devices, where forward volume modes of spin waves are preferred due to their single-valued dispersion characteristics. Although parametric pumping of spin waves can also be achieved using microwave magnetic fields [1, 2], such pumping of the FVMSW modes is precluded by their circular precession. We have predicted theoretically [3], and now show experimentally, that SAW can pump FVMSW in a magnetostrictive film such as YIG. The experimental device, illustrated in Fig. 1, consists of aluminum interdigitated transducers with an overlying piezoelectric ZnO film for generating SAW, and coplanar waveguide antennas for exciting and detecting spin waves, both fabricated lithographically on a 1μm thick YIG film on a gadolinium gallium garnet (GGG) substrate. A magnetic bias field directed perpendicular to the film plane supports FVMSW propagation between the antennas. The SAW generated by the interdigitated transducers propagate in the YIG film, transverse to the spin waves. The acoustic transducers are driven at a pump frequency of f_p=*2366* MHz while the spin wave antenna is driven near half of this frequency to generate a spin wave signal at f_s=*1183* MHz+Δf. By the energy and momentum conservation rules for parametric interactions, an idler spin wave is generated at $f_i=f_p-f_s$. This idler wave travels counter to the direction of the signal spin wave and is picked up by the same antenna. As shown in Fig. 2a, the observed idler frequency varies with Δf, an evidence of the nonlinear parametric interactions between the spin and acoustic waves. The intensity of the generated idler is plotted as a function of signal wave power and acoustic pump power in Fig. 2b showing that the idler power is a product of the signal and pump powers.

CE-06. Code Correlation of Binary-Phase-Shift-Keying Microwave Signals Using Parametric Pumping of Spin Waves. M. Hansen[1], I. Lisenkov[2], H. Liu[1], P. Dhagat[1] and *A. Jander*[1] *1. Electrical Engineering and Computer Science, Oregon State University, Corvallis, OR, United States; 2. Winchester Technologies LLC, Burlington, MA, United States*

We demonstrate the cross-correlation of binary code words, up to 16 bits in length, using a simple microwave device based on parametric pumping of spin waves. With two binary-phase-shift-keying (BPSK) microwave signals applied at the inputs, the correlator generates an output that is a BPSK microwave signal encoded with the cross-correlation of the input codes. Microwave correlators [1-3] are useful for radar and communications systems employing code division multiple access (CDMA) schemes. The correlator device, illustrated in Fig. 1a, consists of a narrow microstrip antenna and wider pumping strap for respectively generating and parametrically pumping spin waves in an adjacent yttrium iron garnet (YIG) film. A BPSK microwave signal with carrier frequency 1.2 GHz applied to the microstrip antenna generates a backward volume magnetostatic spin wave which travels beneath the pumping strap. A second BPSK microwave signal, with twice the carrier frequency, applied to the pumping strap produces a microwave magnetic field which parametrically pumps the spin wave, generating a counter-propagating idler spin wave. The modulation of the input waveforms depends on the binary code signal and reference codes, where the pump code is time-reversed and compressed by a factor of two for proper operation. As shown in Fig. 1b, the resulting idler wave is modulated with the cross-correlation of the two inputs. With an estimated time-bandwidth product of 22, the correlator should be able to process binary code words of up to 22 bits in length. As shown in Fig 2, we have tested all possible combinations of 7 bit codes with the results closely matching the theoretically expected correlation. We have further demonstrated the correlation of 16 bit code words using a subset of possible codes, specifically the Walsh-Hadamard codes often used in CDMA systems. Agreement between the correlator output and the expected results is excellent.

Karazin Kharkiv National University, Kharkiv, Ukraine*

The field of magnonics considers the operations with data carried by spin waves and their quanta, magnons [1]. Nowadays, the new direction of cryogenic magnonics attracts increasing attention. The decrease in temperature, in particular, results in the reduction of thermal population *n* of magnons below 1 opening access to single-magnon quantum physics [2, 3]. Moreover, this allows for combining magnonics with superconductivity [3-6]. Ferromagnetism and superconductivity are fundamental cooperative phenomena in condensed matter physics. Entailing opposite spin orders, they share an essential conceptual similarity: Disturbances in magnetic ordering in magnetic materials can propagate in the form of spin waves (magnons) while magnetic fields penetrate type II superconductors as a lattice of magnetic flux quanta (fluxons). Despite a rich choice of wave and quantum

phenomena predicted, magnon-fluxon coupling has lacked experimental scrutiny so far. In this talk, a selection of our recent results [6] on the interaction of spin waves with the flux lattice in ferromagnet/superconductor Py/Nb bilayers will be presented - see Fig. 1. In this system we found the magnon frequency spectrum to exhibit a Bloch-like band structure (as shown in Fig. 1(b)) which can be tuned by the biasing magnetic field. Furthermore, the frequency spectra of spin waves scattered on the flux lattice moving under the action of a transport current in the superconductor exhibit Doppler shifts. The resonance absorption of spin waves is explained by their inelastic scattering on the vortex lattice constituting a reconfigurable magnonic crystal [7]. The observed Doppler shifts arise due to the modified dispersion relation for spin waves scattered on the moving vortex lattice constituting a moving Bragg grating. In addition, manipulation of spin waves and tailoring of their transmission spectra in Py will be exemplified by using adjacent Nb layers with nanofabricated pinning potential landscapes.

Spin waves, and their quanta magnons, are of great interest as potential data carriers in future low-energy computing devices [1]. The phase of a spin wave provides an additional degree of freedom, while the scalability of structures and wavelengths down to the nanometer regime [2, 3] are further advantages. Recently, a set of magnonic data processing units was demonstrated. Nowadays, the challenge is the realization of an integrated magnonic circuit [4]. Such a circuit requires the development of a universal reconfigurable unit for performing different logic operations with a nonlinear functionality to cascade multiple units. Here, we present the experimental realization of a nanoscale magnonic directional coupler which fulfills all these criteria [4]. A SEM image of the structure fabricated from an 85 nm thick Yttrium Iron Garnet (YIG) is shown in Fig. 1a. The two spin wave waveguides, each of 350 nm width, are separated by a gap of 320 nm. A U-shaped antenna is used to excite spin waves and space-resolved Brillouin Light Scattering (BLS) spectroscopy is exploited for detection. It is shown experimentally [4] and numerically [5] that the data is coded into the spin wave amplitude is guided towards one of its two outputs depending on the signal frequency, magnitude, and on the magnetic field. By controlling these degrees of freedom, the multi-functionality and reconfigurability of the device is achieved. The nonlinear switching of the output by changing the spin wave amplitude is demonstrated in Fig. 1b. Particularly, this ability opens a path for the realization of all-magnon integrated circuits. The operation of the directional coupler as a multiplexer, fan-out, AND, and XOR logic gates, as well as a half-adder, is demonstrated. This research has been supported by ERC Starting Grant 678309 MagnonCircuits, FET-OPEN project CHIRON (801055), by the DFG through the SFB/TRR-173 "Spin+X" (B01) and DU 1427/2-1 and by the Ministry of Education and Science of Ukraine (0118U004007).

CE-09. Creating Rogue Waves in Magnetic Thin Films. *M. Copus*[1] and R. Camley[1] *1. Physics, Center for Magnetism and Magnetic Nanostructures, University of Colorado at Colorado Springs, Colorado Springs, CO, United States*

Rogue waves in oceans are a well-known phenomenon where a large wave that can overturn a ship spontaneously arises. We study whether it is possible to create a rogue wave in a magnetic system. We do this in micromagnetics by starting the system initially with a rogue wave configuration, for example where the spins in the center of the film are raised out of plane by a few degrees (see Fig. 1), and then letting the system evolve in time. Instead of collecting data over the entire sample and using time reversal to produce the rogue wave[1], we collect time-dependent magnetic data at a small number of receiver sites in the sample. Playing back the time reversed signal at the receiver sites from a system beginning in equilibrium we can create rogue waves which are several times larger than the average amplitude of the noise. By playing back just the fields above the film, but with larger amplitudes, one can get large angular deviations at the initial site, over 10 degrees. Fig. 1 shows the initial rogue wave and the regenerated wave produced by four sites. In our example the intial rogue wave has a diameter of 50 nm and the calculation is for a Permalloy film 5 nm thick in a field of 1 kOe. In addition, we find that it is possible to create multiple rogue waves and we can create more rogue waves than the number of recording sites. Unlike the ocean, magnetic systems are anisotropic and tunable. The reconstruction can be influenced by several variables including saturation magnetization, damping, exchange stiffness, external field strength, dynamic field strength, sensor placement, and material size and shape. Because of the large angular deviations possible at the rogue wave, we discuss the effect of nonlinearities in the reconstruction. To finish, we discuss potential applications.

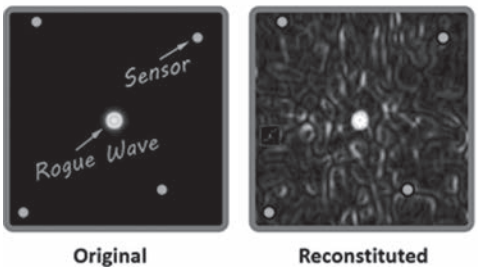

Fig. 1. An example of an initial rogue wave and its reconstruction. The system is initially in an equilibrium state with all the spins in the plane of the film except those near the center which are raised by a few degrees in angle. The system is released, evolves in time and the motions and fields are recorded (for about 2 ns) at the receivers. When the signals at the receivers are time reversed and played, a reconstructed wave appears.

CE-10. Chiral Spin Waves in Obliquely Magnetized Magnetic Films. *C.A. Trevillian*[1] and V. Tiberkevich[1] *1. Physics, Oakland University, Rochester Hills, MI, United States*

Recently, the chiral properties of spin waves (SWs) became a subject of intensive research [1-4]. SW chirality may lead to a frequency splitting of counter-propagating SW excitations [1] and might be important for effective SW excitation [3, 4] and propagation [2] in nano-scale magnetic systems. Here, we studied chiral SW properties in a simple, yet not fully understood magnetic system lacking mirror symmetry—obliquely magnetized (OM) magnetic film with SWs propagating along the direction of projection of the bias field (see Fig. 1 (a)). Using numerical simulations, we investigated spectra and profiles of dipole-exchange SWs propagating in OM films under varying bias field orientations. We found that for all magnetization angles $0° < \theta < 90°$, the propagating SWs possess a definite chirality that reverses upon the mirror reflection of the bias field direction. Fig. 1 (c) and (d) show the instantaneous profiles of dynamic SW magnetization across the film thickness for "original" (H) and "mirror-reflected" (H′) systems, respectively. The two SW profiles have a clearly visible spiral character with opposite chiralities. The chiral nature of SWs is most pronounced for $\theta \approx 80°$ and gradually diminishes when the bias field approaches in-plane or normal-to-plane directions. It is interesting to note, that, in the considered geometry, other usual manifestations of SW chirality are absent. In particular, frequencies and time-averaged amplitude profiles of SWs remain unchanged upon mirror reflection (see Fig. 1 (b)). One of the direct consequences of the chiral nature of SWs is the presence of transversal exchange spin currents carried by SWs. Such transversal spin currents in OM films have been reported previously [5, 6] and might be important for spintronic applications. The natural SW chirality in OM geometry may also be used for more efficient SW excitation and detection [3, 4].

CE-11. Extracting the Dzyaloshinskii–Moriya interaction from propagating spin waves. *J. Lucassen*[1], C. Schippers[1], M. Verheijen[1], R. Duine[1,2], H. Swagten[1], B. Koopmans[1] and R. Lavrijsen[1] *1. Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands; 2. Institute for Theoretical Physics, Utrecht University, Utrecht, Netherlands*

Thin film magnetism has seen a large increase in the investigations of the interfacial Dzyaloshinskii–Moriya interaction (iDMI) because of its ability to stabilize complex chiral spin textures. This interaction can be quantified by investigating the frequency difference between oppositely propagating spin waves. [1] However, as the films become thicker this frequency difference reduces and quantification becomes more difficult. Moreover, other effects such as a differences in the interfacial anisotropies between the top and bottom of the ferromagnetic layer start playing a role. [2] Here, we disentangle different contributions to spin wave frequency non-reciprocity utilizing all-electrical Propagating Spin Wave Spectroscopy (PSWS) to extract the iDMI. [3] Non-reciprocities as a function of Co thickness in Pt/Co/Ir, Pt/Co/Pt and Ir/Co/Pt are investigated to separate the different contributions to this non-reciprocity. In fig. 1 we show our measured data including fits based on a model we have developed. The striking correspondence allows the extraction of the individual components to the spin-wave frequency non-reciprocity. From the fits we find a DMI that demonstrates the expected sign change when going from Pt/Co/Ir to Ir/Co/Pt. The model also provides us with the difference in interfacial anisotropies, and a large new contribution from a thickness dependent change in the crystalline phase of Co, the presence of which is confirmed using transmission electron microscopy data. These insights will open up new avenues to investigate, quantify and disentangle the fundamental mechanisms governing the iDMI, and pave a way towards engineered large spin-wave non-reciprocities for magnonic applications.

CE-12. Electrical Study of Spin-Wave Propagation in Nanoscale CoFeB Waveguides. *F. Ciubotaru*[1], D. Narducci[1,2], G. Talmelli[1,2], I. Radu[1] and C. Adelmann[1] *1. Imec, Leuven, Belgium; 2. Department of Materials Engineering, KU Leuven, Leuven, Belgium*

Spintronic devices are promising candidates to complement CMOS technology to improve both throughput and energy consumption. Especially spin-wave-based majority gates show potential for functional scaling, circuit simplification, and ultralow power consumption. For competitive applications, spin-wave devices need to be miniaturized down to the nanoscale. Hence, the characteristics of spin waves in sub-μm structures are of crucial importance. Moreover, scaling the magnetic volume leads to low spin-wave intensities which are a challenge for the electrical characterization of such devices. Here, we report on electrical characterization of spin waves in nanoscale waveguides. The width of the investigated CoFeB waveguides range from single μm-wide structures to multiple waveguides with widths down to 160 nm. Spin waves are excited and detected by inductive antennas (*cf.* Fig. 1a). By all-electrical spin-wave spectroscopy, we investigate the spin-wave propagation characteristics in different types of waveguides in the Damon-Eschbach geometry. We demonstrate that the spin waves can be efficiently detected in 160-nm-wide waveguides even after 1.5 μm propagation (*cf.* Fig. 1b). The shift of the FMR frequency, the changes in the spin-wave band, and the decay characteristics are studied in devices with different waveguide width, gap between waveguides, and propagation distance. The results are explained by modifications of the internal effective field, the dipolar coupling between adjacent waveguides, and the dispersion relation. The obtained results are crucial for the understanding of propagating spin wave modes in ultra-scaled waveguides and open paths to use spin waves in applications, where dimensions in the order of 100 nm and parallel processing are required. The funding from the European Union's Horizon 2020 research and innovation program within the FET-OPEN project CHIRON under grant agreement No. 801055 is acknowledged.

Magnonic crystals receive a lot of attention in spintronics, due to their great potential for information processing technologies [1]. The main features of these crystals are the presence of bandgaps in the spin-wave spectra. The bandgaps are formed due to the Bragg reflections on the artificially created periodic structures. It is possible to influence the properties of the crystals using different designs of these structures within a magnetic material. Recently, potential of edge- and width-modulated waveguiding structures for creation of macro- and micro-sized magnonic crystals was demonstrated [2-5]. In this work, we studied spin-wave propagation in longitudinally magnetized width-modulated yttrium-iron-garnet (YIG) waveguides by means of both Brillouin light scattering and microwave spectroscopies. The waveguides were produced by chemical etching of a YIG film of 8.5 μm-thickness. Short pulses (30 ns) of backward volume magnetostatic spin waves (BVMSW) were excited, close to the ferromagnetic resonance frequency and their propagation was visualized and measured, both in pass and rejection frequency bands (see Fig. 1). We found, that the width-modulated magnonic crystal shows a new underlying mechanism for the formation of a band gap structure, where no back reflection of the spin-wave pulse is observed. Such a reflection-less magnonic crystal is a promising candidate for the realization of frequency selective or multi-component devices.

CF-01. Epitaxial magnetic tunnel junction with Co_2MnGa Heusler alloy electrode on a large-sized Si wafer. *T. Nakano*[1], S. Miwa[2], T. Higo[2], A. Fukushima[1], S. Yuasa[1], S. Nakatsuji[2,3] and K. Yakushiji[1] *1. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan; 2. The Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan; 3. Department of Physics, The University of Tokyo, Tokyo, Japan*

Magnetic tunnel junctions (MTJs) have been intensively explored for various device applications. We recently realized a fully epitaxial MTJ on a large-sized Si wafer, thanks to the development of a NiAl seed layer and a Mg-Al-O barrier [1]. This technology is compatible with CMOS process, and simultaneously enables us to employ novel single-crystalline materials such as ordered alloys. Here, we focus on Co_2MnGa Heusler alloy which is classified as a Weyl magnet exhibiting topological functions such as giant anomalous Nernst effect [2,3]. Films were deposited on an 8" bare Si(001) wafer using a mass-production sputtering apparatus (Canon-Anelva C-7100). Prior to the film deposition, a native oxide layer on the wafer was removed with hydrofluoric acid. Microstructural analysis was carried out by high-resolution transmission electron microscopy (TEM). MTJ films were microfabricated by electron beam lithography process and then its tunnel magnetoresistance (TMR) properties were measured by dc four-probe method. Figure 1 shows a cross-sectional TEM image of an MTJ consisting of substrate/NiAl (25)/Cr (20)/Fe (3)/Co (0.4)/Mg-Al-O/Co_2MnGa (7.5)/capping layers (unit in nm). All the layers, up to the Co_2MnGa electrode, epitaxially grew on the Si wafer. The Co_2MnGa layer was found to contain $B2$- and $L2_1$-ordered structures by electron beam diffraction. Figure 2 shows an TMR curve of an MTJ with a 10-nm-thick Ir-Mn layer inserted on the Co_2MnGa electrode under the magnetic field parallel to the Fe[100] (Co_2MnGa[100]) direction. Parallel and antiparallel magnetization alignments are realized, where the Fe/Co bilayer has a smaller coercivity than that of the Co_2MnGa layer. The TMR ratio was higher than 130% and the resistance-area (RA) product was 123 Ωμm^2. Such a performance of the MTJ supports a high degree of order in the Co_2MnGa electrode. These results demonstrate that this epitaxial growth technology is applicable to an Heusler alloy and can open up utilization of other novel spintronic materials. This work was in part supported by CREST (No. JPMJCR18T3), Japan Science and Technology Agency.

CF-02. CMOS-compatible $L1_0$ FePd perpendicular magnetic anisotropy thin film via a fcc Ru seed-layer for spintronic applications. *D. Zhang*[1], D.M. Lattery[2], R. Wu[3], J. Liu[1], D.B. Gopman[4], A. Mkhoyan[3], X. Wang[2] and J. Wang[1] *1. Department of Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States; 2. Dept. of Chemical Engineering & Materials Science, University of Minnesota, Minneapolis, MN, United States; 4. Materials Science and Engineering Division, National Institute of Standards and Technology, Gaithersburg, MD, United States*

$L1_0$ FePd is a promising candidate for applications in ultralow energy and ultrahigh density spin memory devices, such as spin-transfer-torque magnetic random-access memory (STT-MRAM) due to its high PMA (K_u~ 2×10^7 erg/cm^3), low damping constant (α~0.002), and low processing temperature which are the key features for satisfying the demand of high thermal stability and low critical current spintronic devices (1-4). In order to obtain high-textured FePd thin films with better performance, the seed layer plays a significant role. In this work, $L1_0$ perpendicular FePd thin films on MgO (001) single crystalline substrates were developed with the fcc phase Cr/Ru seed layer by a magnetron sputtering system with the base pressure less than 5.0×10^{-8} Torr. After the sample deposition, the FePd samples were post-annealed at 400 ^{o}C and 500 ^{o}C, respectively, using a high-vacuum furnace. Then their crystal structures were investigated as a function of the post-annealing temperatures, as shown in Fig. 1 It is clearly found that the (001) and (002) diffraction peaks are observed for all of the FePd samples, which indicates that the Cr/Ru seed layer can induce the high-textured crystalline structure of the FePd thin films. We also found that the intensity of these two peaks slightly increases with the increase of the post-annealing temperature, suggesting the crystallinity of the FePd thin films improves. In addition, the damping constant of these Cr/Ru-seeded FePd thin films are investigated by the TR-MOKE and FMR technologies. The ultralow damping constant~0.009 is obtained for the Cr/Ru-seeded FePd thin film. These results demonstrate that the Cr/Ru-seeded FePd thin films can be used to develop the spin memory devices, which can integrate with the current CMOS technology.

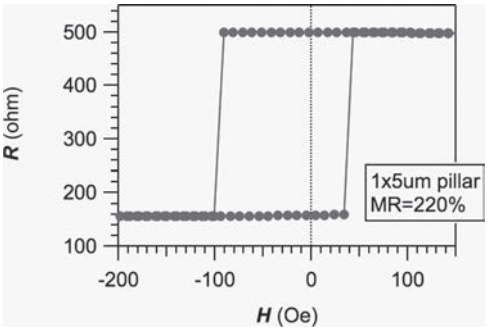
CF-03. Low-Frequency Electronic Noise and Charge Transport Dynamics in Electrically Tunable AlO_x-based Magnetic Tunnel Junctions. *J. Hong*[1], C. Hung[2], I. Martinez[3], C. Gonzalez-Ruano[3], F.G. Aliev[3], D. Ling[1] and M. Lin[2,4] *1. Department of Physics, Tamkang University, New Taipei City, Taiwan; 2. Department of Physics, National Taiwan University, Taipei City, Taiwan; 3. Depto Fisica de la Materia Condensada, Universidad Autonoma de Madrid, Madrid, Spain; 4. Institute of Atomic and Molecular Sciences, Academia Sinica, Taipei City, Taiwan*



Voltage-controlled charge transport properties of AlO_x-based magnetic tunnel junctions (MTJs) have been revolutionized to generate emergent functionality capable of reversibly manipulating resistive switching and tunneling magnetoresistance in a single device, which is promising for multibit nonvolatile memory applications. We demonstrate that the AlO_x-based MTJs can be reversibly tuned by the voltage switching, which causes the change in device resistance and magnetoresistance. The I-V curve, resistance-temperature (R-T) characteristics and low-frequency noise spectroscopy have been experimentally investigated to understand the charge transport dynamics. The Hooge's parameter extracted from the measured 1/f noise varies significantly as the MTJs are tuned from the high resistance state to the low resistance state. This distinct feature can be qualitatively explained by an empirical formulation of mobility fluctuations, indicating that the (re)distribution/(re)migration of oxygen ions and inevitable oxygen vacancies in the AlO_x barrier play an important role in manipulation of the resistance states of the device. Our work develops a phenomenological model of the microscopic charge transport dynamics associative with the resistive switching in the AlO_x-based MTJs.

CF-04. Fully epitaxial magnetic tunnel junction with a spinel-type Mg-Al-O barrier on an 8″ silicon wafer. *K. Yakushiji*[1], T. Nakano[1], A. Fukushima[1], A. Sugihara[1] and S. Yuasa[1] *1. AIST, Tsukuba, Japan*

So far, standard MTJs consist of a CoFeB/MgO-based textured stack for its high MR ratio and low resistance-area (RA) product. Despite such favorable results, the performance has nearly reached a ceiling due to restrictions imposed by the characteristics of the materials and the poly-crystallinity. The use of single-crystalline stacks can likely overcome these difficulties. However, the fully epitaxial MTJs to date have not been deemed practical, because they must be fabricated on a small piece of single-crystalline substrate. That is, none as yet have been fabricated on commercial silicon wafers. In this study, we fabricated a fully epitaxial MTJs on a large Si wafer for the first time [1]. An MTJ stack was fabricated on an 8″ bare Si wafer with (001)-oriented single crystal. A wafer was wet-etched in 1% DHF acid for 10 sec. Films were deposited using a PVD apparatus (C-7100, Canon-Anelva). First, we developed a B2-type Ni-Al seed layer [2] as a (001) oriented template on a Si wafer. The best smoothed surface with Ra ~ 0.15 nm was obtained at Ni = 44 at%. Although similar B2-type alloys such as Co-Al, Fe-Al and Ru-Al were also developed, their surfaces were not so smooth as that for Ni-Al. Then, in-plane magnetized MTJ stacks were fabricated as follows: Si-wafer/ Ni-Al (25) / Cr (20) / Fe (3.0) / Co (0.4) / Al (0.4-0.6) / RF-sputtered MgO (0.6-1.5) / Co (0.4) / Fe (2.5) / Ir-Mn (10) / capping (nm). The benefit of the Al insertion before RF-MgO is that it maintains epitaxy while avoiding plasma damage to the underlying ferromagnetic layer. The bilayer Al/MgO was annealed (in-situ at 480°C for 7 min.), which formed the Mg-Al-O barrier layer. Figure shows a typical R-H minor loop for an MTJ with 1x5 um rectangle shape. It exhibited high MR ratio of 220% with sharp magneto-flips. HR-TEM image revealed a nearly perfect epitaxial stack with a (001) orientation. The lattice constant of the spinel-type Mg-Al-O barrier was 0.410 nm. A wafer-level fully epitaxial MTJ is now a reality. It will affect the performance of every spintronics device to come. This work was supported by the ImPACT Program of the Council for Science, Technology, and Innovation.

CF-05. Spin-Polarized Coherent Tunneling in Fully Epitaxial Magnetic Tunnel Junctions with SrO Tunnel Barrier. *A.M. Spiesser*[1], S. Kon[1,2], Y. Yasukawa[2], S. Yuasa[1] and H. Saito[1] *1. Spintronics Research Center, AIST, Tsukuba, Japan; 2. Department of Electrical and Electronic Engineering, Chiba Institute of Technology, Narashino, Japan*

An efficient way to induce a large spin polarization in Si is to take advantage of the spin filtering effect in epitaxial ferromagnet/crystalline oxide tunnel barriers. With this method, we recently demonstrated the creation of a giant spin accumulation in Si using epitaxial Fe/MgO tunnel contacts[1,2] and found that the tunnel spin polarization (*P*) of Fe/MgO on Si can reach up to ~ 90% at 10 K[2]. However, for MgO thicknesses below 1 nm, we observed a rapid drop of the *P* to values below 25 %[2], which might be attributed to the lower crystalline quality of thin MgO layers due to the large lattice mismatch between MgO and Si (22%). This can suppress spin-dependent coherent tunneling transport near the interface and limit the *P* of the Fe/MgO tunnel contact. A low *P* for thin tunnel barrier thicknesses would be a major obstacle for achieving large magnetoresistance (MR) in a two-terminal Si-based lateral device. From a crystal growth viewpoint, rock-salt type SrO is better lattice-matched to Si than MgO (the lattice mismatch between SrO and Si is 4.9%). Thus, if spin-polarized coherent tunneling through SrO can be achieved, SrO might be a more suitable tunnel barrier for achieving high MR ratio in Si devices. Here, we fabricate magnetic tunnel junctions (MTJs) with an epitaxial SrO tunnel barrier and examine its ability for spin-dependent tunneling by measuring MR effect. The structure of the MTJ consists of Au (10 nm) / Co (20 nm) / SrO (1.5 nm) / MgO (1.0 nm) / Fe (30 nm) on a MgO(001) substrate. From the scanning transmission electron microscopy (STEM) image of the MTJ (Fig. 1), we observe a fully epitaxial Fe(001)/SrO(001)/MgO(001)/Fe(001) structure without significant diffusion or intermixing. Magneto-transport measurements reveal high MR ratios up to 90% at room temperature, indicating that spin-polarized coherent tunneling occurs through SrO. In addition, for equivalent barrier thicknesses, the resistance-area products of the MTJs with SrO are comparable to that of epitaxial Fe/MgO/Fe MTJs. Therefore, SrO presents valuable properties as a novel tunnel barrier for high MR ratio in Si-based lateral devices. This work was supported by JSPS KAKENHI (Grant No. 18K13807, A.S.).

CF-06. Towards highly customized GMR and TMR sensors via oblique-incidence deposition. *M. Ramin Moayed*[1], S. Willing[1,2], T. Gurieva[1], L. Bocklage[1,3], K. Schlage[1] and R. Röhlsberger[1,3] *1. Deutsches Elektronen-Synchrotron DESY, Hamburg, Germany; 2. PIER Helmholtz Graduate School, Hamburg, Germany; 3. The Hamburg Centre for Ultrafast Imaging, Hamburg, Germany*

Giant magnetoresistance (GMR) and tunnel magnetoresistance (TMR) as the heart of spintronics have attracted much interest. Magnetic sensors based on these effects have shown to be of great importance since they are small, robust, energy-efficient, and capable of providing accurate data without physical contact. Such sensors have been employed for many applications including information technology, automotive control, and industrial process management. One major issue of these sensors is the control of the easy axis and the coercive field of one or both magnetic layers without the limitations of interlayer exchange or exchange-biased pinning. Here we present an easy and highly flexible method to address this problem: oblique-incidence deposition (OID) [1]. By adjusting the polar and azimuthal deposition angle, an additional and definable shape anisotropy is induced into the system that tailors the magnetic properties of each layer (Figure 1). Based on this technique we are able to realize custom-designed GMR and TMR sensors which exhibit high performance and novel functionalities. For these sensors, the signal strength, temperature stability, and system reliability have been optimized by comprehensively investigating the stack configurations and preparation steps (Figure 2) in order to exploit the method on industrial scales [2]. Our insight opens new pathways to further expand the use of magnetoresistive systems, especially GMR and TMR sensors.

CF-07. Analysis of the spin-dependent transport in CPP-GMR devices with self-organized Ag-In:Mn-Zn-O nanocomposite spacer.
T. Nakatani[1], T. Sasaki[1], Y. Sakuraba[1] and K. Hono[1] *1. Research Center for Magnetic and Spintronic Materials, National Institute for Materials Science, Tsukuba, Japan*

We studied the mechanism of the improved MR ratio ($\Delta R/R$) of the current current-perpendicular-to-plane giant magnetoresistance (CPP-GMR) devices with a Ag-In:Mn-Zn-O nanocomposite spacer. Polycrystalline pseudo spin-valve structures with Cu-lead / Ta(2) / Ru(2) / CoFe(0.5) / CoFeBTa(1.5) / $Co_2(Mn_{0.6}Fe_{0.4})Ge$ (CMFG)(5) / CoFe(0.4) / spacer / CoFe(0.4) / CMFG(5) / CoFeBTa(1.5) / Ru(8) (thickness in nm) were fabricated with Ag(0.4 nm)/IZO(1.30-1.75 nm) and AIZO (Ag 20-36 at. %)(1.2 nm) films as the spacer layers. As shown in Fig. 1, the devices with AIZO showed much larger $\Delta R/R$ (*e.g.* ~50% at RA ~0.08 Ω μm^2) than those with Ag/IZO bi-layer (*e.g.* $\Delta R/R$ ~30% at RA ~0.1 Ω μm^2). Scanning transmission electron microscopy revealed that for both AIZO and Ag/IZO cases the actual spacer layers were a heterogeneous Ag-In:Mn-Zn-O nanocomposite, where Ag-In alloy paths are distributed in a Mn-Zn-O matrix. This structure is considered to form by an oxidation-reduction reaction between Mn in CMFG and In_2O_3 in IZO as reported recently [2]. In this nanostructure structure, electric current is thought to flow through the Ag-In paths, which gives rise to enhancements of RA and $\Delta R/R$ known as current-confined-path (CCP) CPP-GMR [2]. However, the lateral size of the Ag-In CCP formed from the AIZO precursor layer was found to be larger (~7 nm in diameter) than that from the Ag/IZO precursor (~3 nm). We analyzed the spin-dependent transport in these devices from the point of view of effective spin resistance [3]. The ratio of the effective spin resistance of the CMFG ferromagnetic layer (r_F) to that of the Ag-In CCP (r_{CCP}) are plotted as a function of the resistivity of Ag-In (ρ_N) which cannot be deduced from these experiments. As shown in Fig. 2, r_F/r_{CCP} for AIZO is closer to 1 for a wide range of ρ_N than that for Ag/IZO, indicating a better matching of effective spin-resistance between ferromagnetic layer and spacer for the case of AIZO precursor. This explains the larger $\Delta R/R$ for the devices with the AIZO precursor.

CF-08. Thermally Assisted Magnetisation Reversal in Giant Magneto-Resistive Junctions. *A. Hirohata*[1], W.J. Frost[1], T. Kubota[2], R. Ramos[2], E. Saitoh[2,3] and K. Takanashi[2] *1. Department of Electronic Engineering, University of York, York, United Kingdom; 2. Institute for Materials Research, Tohoku University, Sendai, Japan; 3. The University of Tokyo, Tokyo, Japan*

The wide range of spin-caloric effects, such as the spin-Seebeck [1], Peltier [2] and Nernst [3] effects, have great potential to improve device efficiency by utilising waste heat. Ferromagnetic insulators (FMI) can generate spin-waves via the spin-Seebeck effect when exposed to a thermal gradient. These gradients are ubiquitous in current operated devices, such as giant magneto-restive (GMR) devices and tunnelling magnetoresistance junctions (MTJs). In this study, an unconventional current-perpendicular-to-plane (CPP)-GMR device has been fabricated where the insulating AlO has been replaced with the FMI Fe_2O_3. A Heusler-alloy GMR multilayer of $Co_2Fe_{0.4}Mn_{0.6}Si$ (CFMS) (5)/$Ag_{0.78}Mg_{0.22}$ (5)/ CFMS (5) (thickness in nm) was grown via ultra-high-vacuum sputtering on a MgO(001) substrate with a Cr (20)/Ag (40) seed layer and was capped by Ag(2)/Au (5) layers. The seed and Heusler alloy layers were annealed at 650ºC and 500ºC respectively. Photo- and electron-beam lithography followed by Ar-ion milling were used to fabricate a series of elongated pillars with major axes between 100 - 800 nm. As shown in Fig. 1, the milling was stopped ~1 nm into the bottom CFMS layer. For adhesion a Cr (1)/AlO (2) insulating layer was deposited underneath a 5 nm Fe_2O_3 channel around the GMR pillar. Figure 2 shows a typical MR sweep for one of these devices. When the field is swept from negative-to-positive a wide anti-parallel switch is seen with a small rotational component and a GMR of (10.2 ± 0.1) %. However, when the field is swept from positive-to negative a sharp, narrow reversal is observed with a much larger GMR of (32.8 ± 0.1) %. The difference is due to the spin-wave generated in the FMI enhancing the reversal in one direction. Furthermore the magnetisation of the Fe_2O_3 does not reverse due to its higher coercivity, and therefore couples with some moments in the free-layer, preventing a complete reversal. The asymmetry can also be observed in current-driven reversal, with switching currents as low as (3 ± 0.5) x10^7 A/cm^2. More details will be presented at the meeting.

CF-09. Tunable Long-Term and Short-Term Memories in a Single Magnetic Tunnel Junction Based Synapse. *N. Prasad*[1*], S. Banerjee[1] and L. Register[1] *1. Electrical and Computer Engineering, University of Texas at Austin, Austin, TX, United States*

In this paper, we present an artificial synapse design based on a magnetic tunnel junction (MTJ)-based spin transfer torque random access memory (STTRAM), as depicted in Fig 1. This device is intended to function as a single stochastic electronic synapse for long-short term memory (LSTM) networks (Fig. 1(a)). LSTM networks have been shown to have a distinct edge over other neural networks when processing sequences of data, such as time-ordered video frames, speech, or connected hand-writing recognition [1]. Changes in the synaptic strength are mapped to the MTJ conductance, which is stochastically varied via spin-transfer torque resulting from input current stimuli [2]. This snowman-shaped free ferromagnetic (FM) layer (Fig. 1(b)) provides a meta-stable intermediate magnetic state (Fig. 2, center) to provide short term plasticity (STP) and associated forgetting behavior, as in a biological synapse. Repeated spin-current stimulations, while the MTJ remains in the STP state, then can cause a permanent change in the magnetic state and associated MTJ conductance to provide long-term potentiation (LTP). For the device with magnetic domains shown in Fig. 2, the room temperature lifetime of the STP state is estimated to be ~10 microseconds, while the lifetime of the LTP state is estimated to be ~100 years, based on the minimum-energy paths for switching obtained through micromagnetic simulation. The snowman shaped FM offers the advantage of tailoring the barriers to switching, along with their associated lifetimes, through variation of the device dimensions (Fig. 1(b)). We also analyze the stochastic switching characteristics of the synapse and demonstrate image recognition behavior on a cross-bar array of these synapses.

CF-10. Electrical Control of Magnetoresistance in 2D van der Waals Spin Valve. *W. Yang*[1], X. Wang[1], X. Lin[1] and W. Zhao[1]
1. Microelectronics School, Beihang University, Beijing, China

Spintronics in two-dimensional (2D) van der Waals (vdW) heterostructure is one of the research hotspots recently. With the advent of two-dimensional ferromagnetism and two-dimensional tunneling magnetoresistance (TMR), further explorations of magnetoresistance in 2D van der Waals spin valve and investigations of the modulation effect have been key issues in this field. In this work, we report a large magnetoresistance effect in 2D vdW spin valve of $VSe_2/WSe_2/VSe_2$, where VSe_2 and WSe_2 are adopted as 2D ferromagnetic layer and 2D spacer layer, respectively. A TMR ratio up to 10^{6}% can be achieved in such a device at room temperature, which originates from the interfacial enhanced spin filtering effect. Electrical gating effect further implements voltage control of magnetoresistances in this spin valve (ranging from -15% to about 10^{6}%), which highlights the gate tunability feature of 2D spintronics and enables innovative device applications such as spin logics.

CF-11. TMR Detection of Skyrmions: Simulations of Current Spreading and Spin Polarization. *H. Chen*[1] and S. Majetich[1] *1. Physics, Carnegie Mellon University, Pittsburgh, PA, United States*

Skyrmions have potential interest for sensing, memory, and logic devices [1-2]. Here we have used simulations to investigate electrical detection of skyrmions through vertical tunneling. When current passes through regions with different spin orientations, it can obscure the contrast in the local tunnel magnetoresistance (TMR). A spin polarized current needs to be strongly localized around the contact. The model system used a cylindrical contact 30 nm in diameter, separated by a thin oxide tunnel barrier from a multilayer stack that can support skyrmions or magnetic bubbles. We divided a 180 nm diameter skyrmion with a 20 nm core into 9 cylindrical layers, with uniform spin orientation inside each shell (Fig. 1a). For clarity only two of the twenty horizontal repeat units in the stack are shown and 3 of the shells. Fig. 1b shows the vertical component of the current density through a cross-section of the stack corresponding to the dashed red box of Fig. 1a. Current is injected vertically, but some travels out laterally (orange arrows), so the footprint of the skyrmion bubble will be larger than the contact diameter. The conductivity at the edge of skyrmion is set at the bulk value σ_0 for it has the same spin direction as the contact. At the center, spins antiparallel to the contact spins are characterized by a conductivity σ_c. The shells were fit by an empirical cosine relation based on the relative spin orientations. Fig. 2 shows the resistance measured when the contact is at different locations relative to the skyrmion. Anisotropic conductivities of σ_c=0.6σ_0, 0.8σ_0 yielded TMR contrast of 66.2%, and 25.7%, respectively. This same approach is used to simulate with asymmetric skyrmion stacks and chirality detection in Bloch skyrmions.

CF-12. Phenalenyl-based Organic Barriers for Tunnel Junctions.
N. Jha[1], *C. Denker*[1], A. Pariyar[2], P.K. Vardhanapu[2], H.S. Mohamad[1], A. Azinfar[1], A. Ahrens[3], T. Meyer[3], J. Walowski[1], C.A. Helm[1], M. Seibt[3], S. Mandal[2] and M. Münzenberg[1] *1. Institut für Physik, Universitaet Greifswald, Greifswald, Germany; 2. Department of Chemical Sciences, IISER, Kolkata, India; 3. IV. Physikalisches Institut, Georg-August Universtitaet Goettingen, Goettingen, Germany*

Phenalenyl (PLY) based molecules are appealing for spintronic applications as demonstrated by the formation of a spinterface, showing tunnel magneto-resistance close to room temperature (RT). The spinterface formation leads to the unique property, that a magnetic tunnel junction (MTJ) with a PLY barrier requires only one ferromagnetic metal layer (FM), while the other magnetic layer is formed in the organic barrier directly at the FM/organic barrier interface [1]. In the present study, we compare three different kinds of PLY molecules (PLY, zinc methyl phenalenyl (ZMP), PLY-Cu[2]) as a barrier material for tunnel junctions. In addition, we introduce a new 3-D shadow mask technology allowing for reducing the junction size of in-situ structured devices down to 3 x 6 μm^2 (Fig. 1). Further investigations reveal an AFM rms-roughness of less than 0.7 nm and TEM imaging indicates sharp and well-defined interfaces. Consequently, the current depends non-linearly on the voltage for average barrier thicknesses exceeding 4.8 nm measured by a calibrated quartz microbalance (QCM), the resistance depends exponentially on the barrier thickness and the resistance shows no significant temperature dependence. This evidences tunneling as a conduction mechanism. Magneto-resistive characteristics appear applying a few mV, while memristive properties require voltages in the Volt range. The memristive resistance change is found for all three types of PLY and can be up to a factor of 2. Furthermore, it is stable and reproducible for at least about 100 cycles. Extremely high MR signals are observed at room temperature up to 1000% for FM/PLY-Cu/FM and FM/PLY-Cu/non-magnetic metal layer (NM), but only for some junctions and with improvable stability (Fig. 2).

CF-13. Very Fast Current-Induced Domain Wall Motion with Speed of over 2.5 km s^{-1} Driven by Spin Orbit Torques in Ferrimagnetic GdFeCo Wires. *P. Van Thach*[1,2], S. Sumi[1] and H. Awano[1] *1. Toyota Technological Institute, Nagoya, Japan; 2. Institute of Materials Science, Vietnam Academy of Science and Technology, Hanoi, Vietnam*

Current-induced domain wall motion (CIDWM) in magnetic nanowires has been of great attention in spintronic field during a past decade due to its potential applications such as magnetic memory and logic devices [1]. Previous studies showed that CIDWM-driven by spin-orbit torques (SOTs) is more effective than that driven by conventional spin-transfer torques (STTs). In addition, SOTs can move the DWs along and against the current-flow direction, while STTs only move the DWs against the current-flow direction [2, 3]. Recently, the CIDWM with very high DW velocities of around 1 km/s at current densities of 2 - $3.5x10^{12}$ A/m^2 has been observed in magnetic wires based on antiferromagetically-coupled structures [4, 5], which made these antiferromagetic structures more promising for realizing CIDWM-based magnetic memory devices with low-power consumption and high-speed operation. In this work, we investigated the CIDWM in ferrimagnetic GdFeCo wires having Gd antiferromagnetically coupled with FeCo. Thin films with a structure of Pt(5 nm)/$Gd_{1-(x+y)}Fe_xCo_y$(8 nm)/SiN(10 nm) were deposited on thermally-oxidized Si substrates using a magnetron sputtering system. Magnetic properties of the films were examined by polar Kerr effect. As shown in Fig. 1, the films exhibit the perpendicular magnetic anisotropy. The CIDWM in the GdFeCo wires is investigated by a polar Kerr microscopy. Fig. 2 (a, b and c) show the polar Kerr images taken before, after applying a current to the wire, and in a differential mode, respectively. The DWs were moved in the current-flow direction, which indicates that SOTs are responsible for the CIDWM. We found that the CIDWM with a very fast DW speed of over 2.5 km/s at a current density < $2x10^{12}$ A/m^2 was observed in these GdFeCo wires, and it is strongly dependent on Gd and FeCo compositions. This research was partially supported by the Ministry of Education, Culture, Sport, Science and Technology, Japan - Supported Program for Strategic Research Foundation at Private University (2014-2020) and JSPS KAKENHI (Nos. 17H03240 and 18K14128).

CG-01. Dzyaloshinskii-Moriya interaction in Pt/Co/Ta multilayers with engineered interfacial roughness. *A. Mora Hernandez*[1], A. Hindmarch[1], M. Belmeguenai[2], Y. Roussigné[2] and A. Stashkevich[2] *1. Physics Department, Durham University, Durham, United Kingdom; 2. Physics Department, Université 13 Paris, Villetaneuse, France*

The Dzyaloshinskii-Moriya Interaction (DMI) determines the type and symmetry of non-uniform magnetic structures. The DMI comes from the spin-orbit-interaction, and arises as a result of broken inversion symmetry in bulk magnetic crystals with low symmetry or at interfaces between a ferromagnet and a nonmagnetic material with strong spin-orbit coupling. DMI is important for spintronics as it stabilizes Néel domain walls with high velocities under current excitation, and stabilizes magnetic skyrmions which are potential candidates for new data storage and processing technologies. As that DMI depends of the symmetry of the system, interfacial roughness further breaks the symmetry at the interface in a heterostructure. Here, we describe how controlled induced interfacial roughness can be used to tailor the DMI in model Pt/Co/Ta thin-film multilayer structures. In thin-films, the effect of the DMI is to act as in-plane magnetic field. This influences both the slow, field-driven, dynamics of magnetic domain walls, and the faster, thermally driven, motion of spin-wave excitations. Magneto-optic Kerr effect (MOKE) microscopy is used to quantify the strength of the DMI indirectly (figure, left) via the asymmetric growth of bubble-like domains. Brillouin Light Scattering (BLS) is also used to directly quantify the DMI from the asymmetry induced in the spin-wave dispersion. The influence of engineered interface roughness on DMI as measured by BLS is shown in the figure (right).

CG-02. Reversible control of Dzyaloshinskii-Moriya interaction at graphene/Co interface via hydrogen absorption. *B. Yang*[1], Q. Cui[1], J. Liang[1], A. Hallal[2], M. Chshiev[2] and H. Yang[1] *1. Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China; 2. Univ. Grenoble Alpes, CEA, CNRS, Grenoble INP, IRIG-SPINTEC, Grenoble, France*

Chiral order magnetic structure such as domain wall and skyrmion are attractive for the development of future information storage. The Dzyaloshinskii-Moriya interaction (DMI), which originates from spin orbit coupling (SOC) in inversion symmetry broken system, plays a crucial role in the formation of these spin helix magnetic textures. Therefore, tuning the magnitude and chirality of DMI is beneficial for creation and manipulation the magnetic textures for spintronic applications. Recently, it was found that graphene could induce DMI in Co/Gr heterostructure due to the Rashba effect [1]. Hydrogenated graphene can enlarge the spin-orbit coupling of carbon atoms. Therefore, we suppose that a larger DMI may appear in the hydrogenated graphene system. Moreover, hydrogen has smaller size, lower atomic weight and weaker binding energy, indicating the possibility for devices with faster speed by hydrogen migration. Recently, A. J. Tan *et al*. found that a 90° magnetization switching with H^+ insertion at Co/GdO_x interface by external electric field [2]. Whether the hydrogen can influence the DMI has not been reported. In this paper, using first principles calculations, we find that the DMI oscillates with a period of 2 monolayer (ML) as the function of Co thickness ranging from 1ML to 5ML. This oscillation may come from the quantum well states of Co-d_{xz} and d_z^2 orbitals between graphene and vacuum. Moreover, the DMI gradually decreases as a function of H concentration. In most of the cases, anti-clockwise chirality of Co/Gr could be tuned to clockwise one. For Co(2ML)@Gr-4/8H, the strength of DMI can reach -1.0 meV/cell. Our analysis using density of states combined with first order perturbation theory reveals that the spin-splitting and the occupation of Co-*d*

orbitals, especially the d_{xz} and d_{z^2} states, play a crucial role in changing the magnitude and the chirality of DMI in hydrogenated graphene/Co system. Our understanding of the DMI will provide guideline for experimental and theoretical investigations on the chiral related magnetic systems.

Magnetically coupled nanomagnets have many potential applications including nonvolatile memories, logic gates, and sensors. For these applications, the most effective magnetic couplings have been found to occur between the magnetic layers in a vertical stack. However, in order to realize functional two-dimensional networks of coupled nanoscale magnetic elements such as those used for magnetic logic devices [1] and artificial spin ices [2], it is desirable to engineer the lateral magnetic couplings in a controllable way. Up to now, this has been achieved by exploiting the long-range dipolar interaction. This interaction is nonlocal and scales inversely with the magnetic volume, which limits its use in applications involving nanometer sized structures and thin films. In this work, we demonstrate an alternative method to control the lateral coupling between adjacent magnetic nanostructures [3] based on the interfacial Dzyaloshinskii-Moriya interaction (DMI), which emerges from the combination of spin-orbit coupling and broken inversion symmetry at the interface of ferromagnets and heavy metals. This coupling is mediated by chiral domain walls between out-of-plane and in-plane magnetic regions and dominates the behavior of nanomagnets below a critical size (Fig. 1a). We have exploited this concept for various applications, making use of the fact that the chiral coupling is much stronger than the dipolar coupling. For example, we have created stable synthetic lateral antiferromagnets (Fig. 2a), skyrmionic structures with different numbers of concentric rings (Fig. 2b), and artificial spin ices based on either a square lattice (Fig. 2c) or a kagome lattice (Fig. 2d). In addition, we have demonstrated field-free current-induced switching between multistate magnetic configurations in the chirally coupled nanomagnets via spin-orbit torques. Our work therefore provides a platform to design tailor-made arrays of correlated nanomagnets with a future perspective to achieve all-electric control of planar logic gates and memory devices.

CG-05. Interfacial magnetic properties in 3*d*-transition metal alloy thin films with Pt underlayer. *N. Kim*[1], J. Kim[1], E. Baek[1], J. Kim[1] and C. You[1] *1. Daegu Gyeongbuk Institute Science & Technology, Daegu, The Republic of Korea*

The Slater-Pauling curve explained successfully the magnetic moment variation as a function of the number of electrons for wide range of *3d*-transition metal alloys system[1]. The interfacial magnetic properties of ultra-thin *3d*-transition layers such as Co, Fe, CoFe, and CoNi with Pt underlayer are investigated as a function of the number of electrons, they are important in the spin-transfer-torque and spin-orbit-torque device applications[2-4]. In this work, we investigated the interface perpendicular magnetic anisotropy (PMA) and interfacial Dzyaloshinskii-Moriya interaction (iDMI) of ultra-thin Fe_xCr_{1-x}, Co, Fe, Ni, and Co_xNi_{1-x} alloys on the Pt under layer whose strong spin-orbit coupling is important. By employing Brillouin light scattering (BLS) measurements, we obtained the interface PMA and iDMI energy density as shown in the Fig. 1 (a) and (b). Surprisingly, they show very similar tendency to the Slater-Pauling curve, it increases with the number of electron, and shows maximum between Fe and Co. After the maximum, it decreases linearly. We already reported that the interface PMA and iDMI showed strong correlations in our previous studies[5] because of their common physical origin, the strong spin-orbit coupling. Furthermore, it has been already reported that the iDMI is proportional to the exchange stiffness, which is also related with the saturation magnetization[6]. Therefore, it is not surprising that the interface PMA and iDMI showed the similar dependence with the Slater-Pauling curve. Based on our finding, we can claim that the interface PMA and iDMI can be finely tuned by adjusting the Fermi level of the ferromagnetic layers.

CG-06. Perpendicular magnetic anisotropy of Cu_2Sb-type (Mn-Cr)AlGe films onto thermally oxidized silicon substrates. *T. Kubota*[1,2], Y. Kota[3], K. Ito[1,2], R.Y. Umetsu[1,2], M. Sun[1], M. Mizuguchi[1,2] and K. Takanashi[1,2] *1. Institute for Materials Research, Tohoku University, Sendai, Japan; 2. Center for Spintronics Research Network, Tohoku University, Sendai, Japan; 3. National Institute of Technology, Fukushima College, Iwaki, Japan*

Perpendicularly magnetized films with high uniaxial magnetocrystalline anisotropy energy, K_u, and small saturation magnetization, M_s, are of the interest for developing magnetoresistive random access memories with giga-bit class memory capacity for future. Cu_2Sb-type MnAlGe is a material showing relatively large K_u of 5×10^6 erg/cm^3 and small M_s of about 300 emu/cm^3[1][2]. MnAlGe possesses a merit that the films exhibit (001)-orientation also onto amorphous substrates, e.g. glass substrates[3], which is suitable for applying to magnetic tunnel junctions using MgO barrier with (001) orientation. On the other hand, the moderate K_u is a drawback which is necessary to be improved. Substitution of Cr for the Mn site is a way to manipulate the magnetic properties of MnAlGe. The enhancement of ferromagnetic Curie temperature was reported for poly-crystalline bulk (Mn-Cr)AlGe [4,5], however, there has been no report on K_u so far. In this study, Cr concentration dependence of magnetic properties was investigated for (Mn-Cr)AlGe films onto thermally oxidized Si substrates. The films were fabricated using ultra-high vacuum magnetron sputtering machine, and the stacking structure was as follows: Si, SiO_2 sub.|(Mn-Cr)AlGe 100 nm|MgO 2 nm|Ta 3 nm. All layers were deposited at room temperature, and after the deposition of the capping layers, annealing was carried out using a vacuum furnace at 500 °C. The Cr concentration was changed from 0 to 0.45 in the stoichiometry. The (001)-textured Cu_2Sb-type structures were confirmed by x-ray diffraction profiles for all samples, successfully. Magnetization curves were measured by using vibrating sample magnetometer for the out-of-plane and in-plane directions at room temperature, and all samples exhibited perpendicular magnetization. Values of M_s and K_u are summarized in Table I. The K_u is successfully enhanced by the Cr-substitution. First principles calculations were also carried out for evaluating K_u, and the possible mechanism of the enhancement will be discussed in the presentation. This work was partially supported by the Murata Science Foundation.

IFW Dresden, Dresden, Germany*

Antiferromagnets (AFs) are of emerging interest due to their wide variety of useful properties at the micro and nanoscale. Despite the macroscopically vanishing magnetic remanent moment and therefore high stability with respect to external magnetic field, AFs may provide other unique magnetic static states as well as promising characteristics for dynamic applications like high domain wall velocities and excitation frequencies up to the THz regime [1, 5]. Synthetic antiferromagnets (SAFs), consisting of AF-coupled ferromagnetic layers via thin non-magnetic spacer layers [2], maintain the main characteristics of intrinsic AFs. Additionally, SAFs offer a high degree of tunability and easy integration, thus making them interesting for a wide range of applications [3-5]. One unique AF phenomenon, whose observation became possible through the emergence of SAFs, is the Surface Spin Flop (SSF) [6, 7]. Here, for an even number of AF-coupled layers at sufficiently high field, a vertical AF domain wall is nucleated at one of the surfaces of the SAF and then, as the external field is further increased, propagates

towards the center of the SAF. For even higher fields, the vertical AF domain wall expands into the Bulk Spin Flop state with a canting between adjacent magnetic layer moments [8]. So far, the observation of the SSF in SAFs was limited to epitaxial systems with in-plane uniaxial magneto crystalline anisotropy. We will present the SSF for the first time in SAFs with perpendicular magnetic anisotropy caused by the interfaces of Co/Pt multilayers (Fig. 1). The fact that single crystalline substrates are no longer needed, paves the way for further investigations of the SSF state as well as for applications. Furthermore, we demonstrate the possibility to stabilize the vertical AF domain wall even at remanence, thereby making it readily available also for low field investigations and applications.

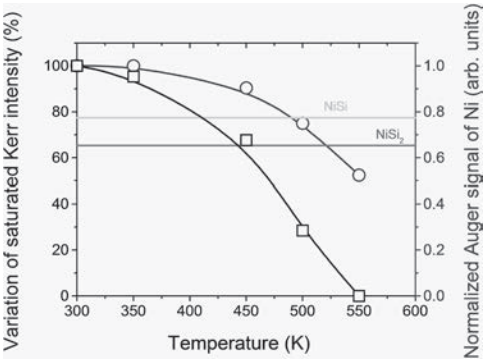
Novel spin-electronic devices require electrodes that inject electrons with both high in-polarization and perpendicular magnetic anisotropy (PMA). We investigate structural origins of PMA using a test case of ultra-thin Co2MnSi films prepared by magnetron sputter-deposition, adjacent to a MgO layer to represent a tunneling barrier, and to a Pd buffer layer. We measure PMA, with an energy density of 7.8 ± 1.8 Merg/cc at 5 K, when a Pd layer is adjacent to Co2MnSi, following annealing in a narrow temperature range, around 350 °C. This ferromagnetism originates from nanometer scale regions, below 5 nm in size, having a relatively low saturation magnetization, 550 ± 50 emu/cc at low temperatures. Following thermal annealing, significant compositional interdiffusion between Co2MnSi films and adjacent layers, Co with Pd and Mn with MgO, was observed by electron energy-loss and angle resolved X-ray photoelectron spectroscopies. Aberration-corrected transmission electron microscopy shows that Co2MnSi does not crystallize while at the interface with Pd, nanometer-scale crystallites of FCC solid solution CoPd with {1 1 1} texture are identified. We conclude that these Pd rich CoPd crystallites, characterized by large magnetostriction, are a source for PMA.



M-H loops measured at 5 K for Pd/CMS/MgO/Pd multilayer annealed at 350 °C. The notations "perpendicular" and "parallel" refer to directions of the applied external magnetic field with respect to the plane of the film.

CG-09. Evolutions of magnetic phases driven by compositional changes for ultrathin Ni/Si(111). C. Chang[1], Y. Chow[1], C. Hsieh[1], P. Jiang[1] and *J. Tsay*[1] *1. Department of Physics, National Taiwan Normal University, Taipei, Taiwan*

Metal-semiconductor interfaces have attracted considerable interest because of their promising applications as semiconductor devices and possible use as new functionalities in semiconductor technology [1,2]. As a magnetic material, nickel has an advantage of a relatively low Curie temperature, which permits it to be used in studies of critical phenomenon near room temperature. There are relatively few reports dealing with the magnetic properties of ultrathin Ni layers on silicon surfaces and chemical compositions of these materials at the interface. We report herein on the correlation between the morphology, composition, and magnetic properties of ultrathin Ni/Si(111) films. At room temperature, the dominant species produced at the interface is NiSi, which is produced by the spontaneous formation of strong bonds between Ni and Si atoms. We established a chemical shift-related concentration model for determining the amount of ultrathin Ni silicides by assuming that a Ni layer is formed over a NiSi layer with the total coverage as a constraint. At elevated temperatures, the compositional changes as monitored using Auger electron spectroscopy shows a strong correlation with the magnetic responses (Figure 1). From systematical explorations, a magnetic phase diagram for Ni/Si(111) was established showing three regimes. The interdiffusion of Ni and Si atoms at the interface as well as the morphological characteristics play important roles on the boundaries of phase transitions.

CG-10. Alternate monoatomic layer deposition of Fe and Ni on Al_2O_3 (0001) using PLD. *T. Miyashita*[1], H. Ito[1], T. Kumagai[1], T. Koganezawa[2], T. Miyamachi[3], F. Komori[3] and M. Kotsugi[1] *1. Tokyo University of Science, Tokyo, Japan; 2. JASRI, Hyogo, Japan; 3. ISSP of The University of Tokyo, Chiba, Japan*

Development of novel magnetic materials is an important issue in the realization of spintronics devices or electric vehicles. Recently, huge attention has been focused on rare-earth-free high-performance magnetic materials from the viewpoint of elemental strategy. Our proposed FeNi ordered alloy shows strong magnetization and large magnetic anisotropy without rare earth elements, and it is a potential candidate satisfying these requirements [1]. A number of studies have been carried out on FeNi ordered alloys such as material fabrication, functional analysis and theoretical calculation so far [2, 3]. Here, we focused on the $L1_1$-FeNi ordered alloy, which is expected to show a higher uniaxial magnetic anisotropy K_u by the first principle calculation. In this study, we attempt to construct $L1_1$-FeNi by alternate monoatomic layer deposition of Fe and Ni by using pulsed laser deposition (PLD). We analyzed the crystal structure and magnetic properties, and discussed their correlation [4]. Experimentally, Al_2O_3(0001) substrate was heat-treated to obtain a clean surface. Thereafter, Cu was vapor-deposited using a PLD apparatus using an Nd: YAG laser (266 nm) as a light source as an underlayer. The preparation of $L1_1$-FeNi was performed using monoatomic alternate deposition on the optimized underlayer. Evaluation of surface crystallinity was RHEED, evaluation of surface flatness was AFM, evaluation of crystal structure was Synchrotron radiation-based X-ray diffraction, evaluation of magnetic characteristics was SQUID magnetometer was used. Fig. 1 shows the magnetic hysteresis by SQUID. Fig. 1 (a) shows the magnetic hysteresis of FeNi/ Cu/ Al_2O_3, and Fig. 1 (b) shows the magnetic hysteresis of $L1_0$-FeNi. The figure shows that the spontaneous magnetization is oriented in the in-plane direction in both samples. At this time, calculate the magnetic anisotropy energy K_u. The evaluated K_u was 9.8×10^6 erg/cc for FeNi/ Cu/ Al_2O_3 in (a) and 8.4×10^6 erg/cc for $L1_0$ FeNi in (b). From the above, it was confirmed that the FeNi alloy on the Al_2O_3 substrate fabricated this time had high magnetic anisotropy.

Physics, Georgetown University, Washington, DC, United States*

Molecular spintronics has become a very promising field for the next generation of spin-valve based devices due to their chemical tunability,[1] low spin relaxation mechanisms[2] and novel interfacial interactions between ferromagnets and organic molecules.[3] When small organic molecules are in contact with more reactive metals such as ferromagnet films, the interactions at the interface may lead to the formation of chemical bonds between the molecular adsorbates and the film, creating new hybrid metal-organic interface states that directly affect the electronic and magnetic properties of the adsorbed molecule.[3] In this work, we study small organic molecules/ferromagnets interface effects by imaging the magnetization vector at the surface using spin-polarized low-energy electron microscopy (SPLEEM). We found that the out-of-plane to in-plane spin reorientation transition occurs at thicker Ni films in the presence of bathocuproine (BCP) overlayer compared to bare Ni films, indicating that a significant perpendicular magnetic anisotropy (PMA) is induced at the BCP/Ni interface at room temperature. Systematic Ni thickness dependent measurements allow the quantification of PMA induced by the BCP overlayer. This is somewhat similar to what has been reported in the graphene/ferromagnet system.[4] Our experimental observations suggest that the metal-organic interface plays a fundamental role in inducing the PMA. In addition, this work opens up possibilities for studying the adsorbed molecule's composition and morphology that may lead to new insights in designing novel organic spin-valve devices with tunable anisotropy. CG-12. Evolution of Bulk Perpendicular Magnetic Anisotropy and AHE in CoFeBGd Alloy Films: Composition and Temperature Dependence. O.A. Inyang[1], B. Nicholson[1] and *D. Atkinson*[1] *1. Physics, Durham University, Durham, United Kingdom*

Thin-film ferrimagnetic rare earth-transition metals (RE –TM) alloys have been studied and used in technology over decades. Research interest has re-emerged due to the bulk perpendicular magnetic anisotropy (PMA) and magnetisation response to field and spin-orbit torques around the ferrimagnetic compensation point [1-4] The bulk PMA is hosted by an amorphous microstructure resulting from the addition of sufficient RE into a TM lattice,

and while studies have given insight into the origin of the PMA [5-8], details of the origin and control of bulk PMA are poorly understood. Here the aim is to further understand bulk PMA and AHE with RE content and the temperature dependence around the ferrimagnetic compensation. Previous studies have focused on adding a RE, typically Gd or Tb, into crystalline Fe, Co or CoFe alloy that leads to the amorphous structure. The emerging bulk PMA has been linked to texturing of the amorphous phase. To investigate the link between structure, composition and bulk PMA and AHE, we report, for the first time, on the of addition of Gd to the already amorphous alloy CoFeB, as a function of Gd concentration. We also demonstrate the critical role of the underlayer in developing bulk PMA and show that the anisotropy depends on temperature around the compensation point. Multilayers of NM(5nm)/Gdx(Co20Fe60B20)1-x(t)/Ta were studied as a function of Gd content, thickness and the Non-Magnetic underlayer. Magnetisation was investigated with longitudinal and polar MOKE and Hall magnetometry. Fig. 1 shows the development of the anisotropy in CoFeBGd with Gd content. No magnetic response was observed at the compensation at 21.9 % Gd. Significantly, the role of the underlayer is important, with some cases creating a bulk PMA, while in others the magnetisation is in-plane for the same amorphous ferrimagnetic alloy. Furthermore, temperature measurements show that the anisotropy is also very sensitive to the ferrimagnetic state around the compensation, switching between PMA and in-plane magnetisation.

CG-13. Mapping of Magnetic Metastable States in Synthetic Antiferro- and Ferrimagnets with Perpendicular Magnetic Anisotropy.
R. Salikhov[1], F. Samad[1,2], L. Koch[2], B. Böhm[2] and O. Hellwig[1,2] *1. Institute of Ion Beam Physics and Materials Research, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany; 2. Physical faculty, Chemnitz University of Technology, Chemnitz, Germany*

Magnetic multilayers (MLs) with perpendicular magnetic anisotropy (PMA), such as Co/Pt or Co/Pd, are the host materials for a variety of metastable magnetic configurations, e.g. aligned or labyrinth stripe domains, bubble domains and their mixtures. The magnetic morphology at remanence mostly depends on the specific demagnetization routine using an external magnetic field [1], whereas the characteristic size of the magnetic objects (domain period or bubble radius) is mostly determined by the design parameters of the magnetic MLs (e.g. the thickness of Co layer, periodicity and the number of repeats X) [1,2]. Interleaving the Co/Pt blocks by Ru or Ir layers, which promote antiferromagnetic (AF) interlayer coupling between PMA ML blocks, results in a class of artificial magnetic structures, known as synthetic antiferromagnets (SAFs) with PMA. The AF interlayer exchange energy alters the typical energy balance, thus modifying the morphology and characteristic size of magnetic domain states in PMA SAFs [1]. Stabilisation of magnetic bubble domain states in SAFs is of particular practical interest [3], whereas other new magnetic configurations are of interest for fundamental research. Here we present the mapping of magnetic states in SAFs for different demagnetization protocols and ML parameters by means of monitoring the remanent magnetization M_R during the AC or DC demagnetization process itself and performing magnetic force microscopy (MFM) imaging at the intermediate states of interest (Fig. 1). The aligned stripe domain state is characterised by almost zero M_R, whereas bubble domains [4] and mixed states (Fig. 1) manifest themselves by an enhanced M_R. The magnetic states for SAFs with tuneable parameters such as Co thickness and repetition number X will be presented. We will also discuss the magnetic behaviour in synthetic ferrimagnets, where the two ML block sub-lattices have different magnetic moments.

Crayton Pruitt Family Department of Biomedical Engineering, University of Florida, Gainesville, FL, United States

On-chip power inductors and transformers require ferromagnetic core materials that offer large frequency bandwidth, low loss, and relatively high permeability. Where traditional core materials typically lack one or more of these parameters, magnetic nanocomposites have garnered interest for their hybrid magnetic properties and potential to concurrently meet all device specifications [1]. In this work, the fabrication and characterization of two soft magnetic nanocomposite films are described: ~4-μm-thick nickel/iron-oxide, and ~2-μm-thick permalloy/iron-oxide. These composites are made using electro-infiltration, where a magnetic nanoparticle phase is deposited into a mold, and then a magnetic metal matrix phase is electroplated through the voids between these particles [2]. Testing shows that both composites provide a high permeability attributed to the metal matrix phase, but also an increased bandwidth and modestly low losses attributed to the iron-oxide nanoparticle inclusion phase. At 10 MHz, the nickel/iron-oxide nanocomposite exhibits a relative permeability of ~23, with a loss tangent of ~0.1, and the permalloy/iron-oxide nanocomposite exhibits a relative permeability of ~136, with a loss tangent of ~0.15 (Fig. 1). These materials are also explored structurally through scanning/transmission electron microscopy and energy dispersive x-ray spectroscopy, and results show that the ~31 nm diameter iron-oxide nanoparticles are dispersed throughout both composites. A dense, void-free interface between the nanoparticle phase and metal matrix phase is also observed, suggesting complete infiltration of the voids between particles (Fig. 2).

CH-02. Spray-coated magnetic planar inductor for compact IoT sensor node. T. Hara[1] and *M. Yamaguchi*[2,3] *1. Design center, RICOH Electronic Devices Co., Ltd., Ikeda, Japan; 2. Department of Electrical Engineering, Tohoku University, Sendai, Japan; 3. New Industry Creation Hatchery Center, Tohoku University, Sendai, Japan*

A 'sensor node' typically consists of sensor(s), microprocessor, transceiver and battery power supply [1]. Since a compact IoT wireless sensor node needs a small and high efficiency power supply, this paper reports a magnetic powder composite thin film inductor. The composite is spray-coated at room temperature that offers quick, low temperature and high step coverage microfabrication technology for better mass productivity for integrated DC/DC converter [2], [3]. Ni-Cu-Zn spinel ferrite particles (mean diameter = 0.61 μm, initial permeability = 544 @ 1MHz) and epoxy precursor were mixed and spray-coated on a Si-substrate to the thickness of 62.6 μm. The fraction of ferrite particles was 19.5 wt%. SEM image revealed that the ferrite particles were uniformly distributed and did not sedimented in epoxy precursor. RF measurement by the shielded-loop type permeameter [4] clarified that the real part of relative permeability was 1.32 at low frequency, and the FMR frequency was 3.0 GHz. A 3 x 3 mm^2 planer air-core inductor was firstly made on a Si substrate. The coil was made of 1 μm-thick Al, line/space was 56/9 μm, and had 10 turns. Then, using a spray coater, the diluted magnetic powder composite with solvent was sprayed on to the air-core to the thickness of 62.8 μm without insulator in between. The composite covered entire coil surface well, including the coil height steps, as shown in Fig. 1. The thickness of spray-coat is controllable in a wide range from 0.1 μm to several tens μm. Fig. 2 shows the impedance $R_s + j\omega L_s$ of the inductor measured by an impedance analyzer. The inductance L_s was increased whereas the R_s was constant as frequency increased up to 20 MHz. Magnetic powder composite enhanced the Ls from 157 nH to 205 nH (30%) up to 5 MHz. This enhancement is achieved by low permeability but thick magnetic powder composite film processed by the proposed spray-coating process. The permeability and corresponding inductance can be increased by further process development to increase the volume fraction of ferrite. Collaboration with Junichi Konishi (RICOH Co., Ltd.) is highly appreciated.

CH-03. Microtransformer on Silicon with CoFeB Magnetic Core for High-Frequency Signal Applications. *D. Dinulovic*[1], M. Shousha[1,2] and M. Haug[1] *1. R&D, Würth Elektronik eiSos GmbH & Co. KG, Garching, Germany; 2. Electrical Power & Machines, Cairo University, Giza, Egypt*

One of the important development challenges for monolithic solutions for Internet of Things (IoT), wireless communication, and many portable devices is the integration of on-chip inductors and transformers with magnetic materials on silicon [1-3]. The most recent works in this technical field show not only big improvement in integration technology and magnetic material research but also the development of new micro inductors and microtransformers and their implementation in many electrical applications [4-8]. This paper presents the development of a microtransformer with a bar magnetic core fabricated on silicon substrate using thin-film technology. The microtransformer device can be applied for higher frequencies up to 20 MHz. The microtransformer features a bar magnetic core and primary and secondary windings with a minimum distance between primary and secondary side of 30 μm. Both windings are identical with 12 turns each. The dimension of a single turn is 620 μm x 40 μm x 1 μm (L x W x T) with a 10 μm distance between turns. The winding material is copper fabricated using physical vapor deposition (PVD) process. As magnetic material for microtransformer core, a CoFeB alloy is used, which is also fabricated using PVD process. The magnetic core consists of two layers with dimensions of 1400 μm x 500 μm with a thickness of 0.4 μm and oxide gap in-between of 0.8 μm. The insulation material is a combination of SiO_2 and Si_3N_4. The microtransformer device is remarkably small and the chip size is only 1.6 mm x 0.8 mm. The inductance of the device is about 40 nH. The breakdown voltage is about 1500 V. The thickness of deposited copper material is only 1 μm, therefore, the microtransformer device shows an electrical resistance of about 7 Ω, hence this device is suitable for using in signal applications. Figure 1 shows a fabricated microtransformer. In the full paper, the design, fabrication and evaluation will be presented.

CH-04. Magnetic Hysteresis Phenomena under PWM Inverter Excitation by using Coupled Analysis between Electricity and Magnetism in Circuit Simulator. *A. Yao*[1] and T. Hatakeyama[1]
1. Department of Electrical and Computer Engineering, Toyama Prefectural University, Imizu, Japan

Pulse width modulation (PWM) excitation is often used for control in motor drive system. Many studies have shown that the high frequency components caused by PWM waveforms induce complex dynamic hysteretic magnetic loops in soft magnetic materials (used as a motor core)[1-5]. To realize the high-efficiency motor system, it is necessary to numerically represent the dynamic hysteretic loops of soft magnetic materials. Previous studies have shown that the play model[6] with the Cauer circuit[7-11] (PMCC) can express hysteretic loops. Recently, some researchers have realized a weak coupling analysis of magnetic field and electric circuit by using PMCC[8,11]. However, there has been no report on a strong coupling analysis to express magnetic hysteretic loops by using PMCC. In this study, we develop the strong coupling analysis in a circuit simulator. Figure 1 shows schematic of the strong coupling analysis with the inverter circuit and the hysteresis model. In our study, we apply PMCC to the circuit simulator (PSIM, Powersim) to realize the numerical calculation of magnetic hysteresis properties under PWM inverter excitation by using the strong coupling analysis. See Refs. 10, 11 for details of numerical methods based on PMCC. Figure 2 plots the magnetic hysteresis loops of magnetic materials under PWM inverter excitation with a carrier frequency of 1 and 20 kHz. The experimental results are consistent with the numerical loops calculated by the strong coupling analysis (current method). We realize accurate representations for hysteresis loops especially in high carrier frequency region compared with results of the previous method[11] (weak coupling analysis). The evaluation errors of iron losses calculated by strong and weak coupling analysis are about 3.5 % and 10 % at 20 kHz, respectively. These results open the way to further research in low loss motor system based on coupled studies of magnetic and semiconductor properties.

CH-05. Core loss calculation for power electronics converter excitation from a sinusoidal excited core loss data. *H. Matsumori*[2], T. Shimizu[1], T. Kosaka[2] and N. Matsui[2] *1. Tokyo Metropolitan University, Tokyo, Japan; 2. Nagoya Institute of Technology, Aichi, Japan*

Advances in power semiconductor devices such as SiC, GaN, etc. have significantly enhanced the power-density of power electronic converters. By increasing the switching frequency, the volume of magnetic components, i.e. inductors and transformers can be reduced [1], [2]. However, the reduced surface area of the magnetic component leads to increased thermal resistance and temperature stresses. Therefore, the core loss analysis of magnetic cores is important for high-power-density converter design. The core loss data provided by core manufacturers is usually based on sinusoidal excitations, whereas in most cases the magnetic cores in power converters are under square voltage excitations and the DC bias condition. One solution is to approximate the sinusoidal wave to a square wave [3-7], yet its accuracy is affected by the DC bias characteristic of the core loss. Another solution is

using square voltage and the DC bias excited core loss data [8-12]. However, the square waveforms are described by the amplitude, the frequency, and the duty ratio, which leads to a wide range of test conditions [13]. The authors thus propose a core loss calculation method for power electronics converter excitation from a sinusoidal excited core loss data. This method is based on Brockmeyer's theory shown in [5] and adapts to calculate core loss under DC bias excitation conditions. Furthermore, the core loss test conditions are reduced since the required core loss data used in this method is only to add DC bias characteristics to the sinusoidal excitation core loss data provided by the core manufacturers. In order to validate the proposed method, first, the core losses under sinusoidal and square voltage excitation are measured by BH analyzer with DC bias excitation unit, as shown in Fig.1. And then, the measured values under square voltage excitation and the calculated values from sinusoidal excited core loss data are compared. The evaluation result of the Sendust core (Toho Zinc.corp: HK-08SS) is shown in Fig. 2. The core losses on DC bias Ho= 4000 A/m is calculated within 2.2% error. The detail of the proposed method and the others result are explained in the final paper.

CH-06. Transient Potential Distribution on Transformer Winding Considering the Effect of Core Lamination Stack. *S. He*[1], D. Huang[1], X. Feng[1], Y. Wang[1], J. Deng[2] and J. Li[1] *1. Electrical Engineering, Xi'an Jiaotong University, Xi'an, China; 2. Maintenance and Test Center of EHV Power Transmission Company, China Southern Power Grid, Guangzhou, China*

The potential distribution of windings under impulse voltage is very important for the design of transformer inter-turn insulation especially for large capacity transformers such as UHVDC converter transformer. Quite a lot of equivalent circuit models for transformer winding have been proposed for the potential distribution calculation assuming that the influence of magnetic core is negligible at frequencies higher than 10kHz. However, lightning Impulse or VFTO waveforms usually contain abundant frequency components higher than 10kHz. At above situations the magnetic core plays an important role during the transient procedure. To obtain a more comprehensive model and also to provide a more accurate potential distribution of transformer winding, in this paper, the equivalent circuit representation of UHVDC converter transformer winding is given taking into consideration of comprehensive frequency characteristic of core lamination stack. Considering skin effect and saturation effect, the equivalent relative permeability of lamination stack is studied and implemented in the calculation of frequency-dependent parameters such as resistance, self- and mutual- inductances. The equivalent circuit model is realized in MATLAB and the surge propagation process in the winding, the winding potential distribution under transient overvoltage is studied carefully. The initial potential distribution and Interturn potential gradient distribution are shown in Fig.1 and Fig.2, respectively. The calculation results may provide more accurate winding potential distribution prediction for transformer inter-turn insulation design. Detailed calculation results and analysis will be shown in the full paper.

CH-07. Reduced Basis Finite Element Modelling of Transformers with Stranded Conductors. *I. Gürbüz*[1], A. Lehikoinen[2], U. Aydin[1], P. Rasilo[3], E. Takala[4] and A. Belahcen[1] *1. Department of Electrical Engineering and Automation, Aalto University, Espoo, Finland; 2. Smeklab Oy, Espoo, Finland; 3. Faculty of Information Technology and Communication Sciences, Tampere University, Tampere, Finland; 4. Trafotek Oy, Turku, Finland*

The windings of transformers and electrical machines sometimes consist of several stranded parallel conductors to reduce AC-losses. Although using stranded parallel conductors instead of large conductors reduces the skin effect losses, circulating currents are inevitable because of the uneven distribution of the current among the strands [1]. Several authors with variety of different methods have addressed the issue of modelling individual strands, that is computationally heavy due to large number of unknowns. However, very few of the presented methods are able to model parallel strands [2]. In this paper, a reduced basis approach is proposed to analyze the proximity effect and circulating currents in transformers with stranded parallel conductors while reducing the needed computation time. This method is heavily inspired by the reduced basis approach earlier proposed for rotating electrical machines with multi conductor windings [2]. In the reduced basis approach, the model geometry is divided into non-winding and winding domains. Instead of solving the AVI formulation directly, the vector potential of the winding domains (a_w) and voltages of the windings (u_i) are expressed with a matrix system in terms of the vector potential of the non-winding domain (a_n), its boundary (a_b) and the currents flowing through individual conductors (i_i). Next, this matrix system is inserted into the other rows of the AVI formulation to eliminate a_w and u_i in order to obtain the reduced matrix system, from which a_n, a_b, and u_i are solved first. Finally, a_w and u_i are solved from the initially found matrix system by using the solutions of previous computations. The proposed approach is applicable for both time-harmonic and time-stepping analysis. In case of a non-conforming mesh between the non-winding and winding domains, the method is achieved by using an interpolation (or projection) matrix. Also, having identical winding domains makes the computation efficiency of the approach better as the same matrix system expressions can be used for all identical domains. The method enables to observe eddy-current and circulating current losses in the windings as well as core losses.

CH-08. Modelling and Measurement of Magnetic Properties of Anode Saturable Reactor Under Impulse Excitation. *C. Zhang*[1,2], J. Wang[2], Y. Li[2] and Q. Yang[2] *1. Ohio State University, Columbus, OH, United States; 2. Hebei University of Technology, Tianjin, China*

In high-voltage DC transmission system, the anode saturable reactor is crucial to protect the switching device from over-current fault in the converter valve. Since the core loss of saturable reactor under impulse excitation produce significant heat, which may cause large temperature rise and reduce the lifespan of insulation. The classical Steinmetz model based on the empirical and loss separation technique is only applicable to the perfect waveform at 50/60 frequency[1]. S. Barg developed a new empirical method to estimate magnetic core loss under non-sinusoidal magnetic induction[2]. When using the T-Ω method, the effects of lamination core loss are considered by introducing an additional field component in lamination [3]. It would cost too much computation burden to refine mesh of laminated steel layer by layer considering impulse eddy current effects. In order to reduce the complexity of numerical algorithm, the multi-scale numerical method is introduced into the electromagnetic eddy current[4]. The saturable reactor made of ultra-thin silicon steel is used in the 12-pulse rectifier converter valve, which can limit the changing rate of current in the circuit. Firstly, the magnetic properties of the ultra-thin silicon steel is measured. Based on magnetic properties data, an improved magnetic property simulation model is proposed to estimate core loss under the switch-on and switch-off working condition. The stray capacitor and reactor form a high frequency oscillation as shown in Fig. 1, thus the switching process would cause significant current harmonic and extra core loss. One single core with air-gap is simulated by transient electromagnetic simulation shown in Fig. 2, when the current of the reactor is the same as in the real operating conditions. Eddy current and hysteresis loss are much higher than excess losses. The additional eddy losses in the lamination are calculated by 3D transient magnetic field considering the fringing magnetic flux flowing into the silicon steel lamination plane. Finally, the temperature-rise test is carried out by infrared thermometer in order to verify the proposed core loss model.

CH-09. Influence of magnetization fixture winding on magnet flux profile and performance of isotropic bonded NdFeB motor.

R.C. Angara[1], N.E. Onal[1], K.W. Hsu[1], P. Villar[1] and *N.K. Sheth*[1]
1. Research and Development, Neo Performance Materials (S) Pte Ltd, Singapore

Isotropic bonded NdFeB magnets are used in automotive and home appliance motors due to their superior magnetic properties which helps in achieving increased motor efficiency and power density. The magnetizing fixture winding configuration is critical in achieving the desired performance[1,2] . In this paper the effect of fixture winding configurations on resultant magnet flux profile and motor performance is presented for a 4-pole automotive accessory motor. Magnetizing fixtures are designed using to achieve 3T magnetizing field on the magnet. It is observed that when the number of turns is kept the same, but the conductor diameter reduced by 29%, the magnetization profile becomes more radial and resulting in 20% higher peak to peak cogging torque in motor. Using two-dimensional (2D) finite element analysis (FEA), the magnetization fixtures are designed for six different conductor configurations for the winding. Figure 1 shows four of the conductor configurations evaluated. For each configuration a 2D FEA is performed to arrive at magnetized magnet profile and motor performance. Table I summarizes the flux integral of magnetized magnet profile and corresponding motor perfromence. From this table it is observed that for a 4-pole magnet, the '1-column' conductor arrangement where-in the conductors are arranged along the radial direction resulted in radial flux profile and highest flux integral per pole. On the other side the flux integral per pole is minimum and the flux profile becomes more sinusoidal when '1 row' arrangement in which the conductors are arranged along a concentric arc from fixture core surface is used. The higher flux per pole with radial magnet flux profile, results in higher back-emf and peak to peak cogging torque for '1-column' configuration. The lowest flux integral per pole and the Halbach magnet flux results in lowest back-emf and cogging torque. The designed magnetization fixtures were built, magnets are magnetized, and the motor performance is evaluated. The experimental results are in good agreement with the simulation results.

CH-10. Design of Directing Permanent Magnet of U-Shape Interior Ferrite Permanent Magnet Synchronous Motor for Electric Vehicles.

H. Won[1], Y. Hong[1], M. Choi[1] and W. Lee[1,2] *1. Department of Electrical and Computer Engineering and Center for Advanced Vehicle Technologies, The University of Alabama, Tuscaloosa, AL, United States; 2. RF Product Development Group, Samsung Electro-Mechanics, Suwon-si, The Republic of Korea*

Recently, U-shaped interior permanent magnet synchronous motor (UIPMSM) received much attention due to the possibility of employing rare-earth less ferrite permanent magnet (PM) [1-2]. To further improve the motor performance, the design of UIPMSM with barrier shaping and rotor overhanging method was proposed [1-2]. However, these methods either require high precision tools or reduce torque density. In this paper, we propose a new hybrid directing PM (D-PM) method that enhances the ferrite motor performance without requiring expensive tools and increasing volume. Two types of UIPMSM are rectangular- (R-) and trapezoidal (T-) UIPMSM, having the same dimensions and specification of IPMSM used in Toyota Prius 2010 in Fig. 1 [3]. These UIPMSMs were used to validate our D-PM method and simulated for motor performance using ANSYS Maxwell 2D. While NMF-12F ferrite having B_r of 0.46 T and H_{ci} of 4.13 kOe are used for pillar PM [4], three types of PM having 1) B_r of 0.4 T and H_{ci} of 5.02 kOe, 2) B_r of 0.4 T and H_{ci} of 10 kOe, and 3) B_r of 1.2 T and H_{ci} of 10 kOe were used for D-PM. Fig. 2 shows the resulting efficiency map of R- and T- UIPMSM. As the H_{ci} of D-PM increases from 4.13 to 10 kOe, the maximum torque (T_{max}) of both motors increased from 152.3 to 161 Nm for R-UIPMSM and 159.4 to 167.6 Nm for T-UIPMSM. The size of each efficiency region increased by 1-3% for both motors, while maintaining maximum speed (ω_{max}) of 14,000 revolutions per minute (rpm). By increasing the B_r of D-PM from 0.4 to 1.2

T, the T_{max} and ω_{max} increased from 161 to 166.5 Nm and 14,000 to 16,000 rpm, respectively, for R-UIPMSM, and 167.6 to 171.5 Nm and 14,000 to 16,000 rpm, respectively, for T-UIPMSM. Further, as shown in Fig. 2 (b) and (d), the efficiency region shifted its region to higher torque and lower speed region. As a result, we found that as increasing B_r and H_{ci} of D-PM, T_{max} and ω_{max} of UIPMSM increase without modifying the main motor design. Also, adjustable efficiency regions can be achieved without requiring high precision dies and large motor volume. This work was supported in part by NSF-I/UCRC for EV-STS under Grant number 1650564.

CH-11. An ironless linear permanent magnet generator for the conversion of sea waves energy. *M. Trapanese*[1] and V. Frazitta[1]
1. Dipartimento di Ingegneria, Palermo University, Palermo, Italy

Linear permanent magnet generators are widely considered for the direct conversion of energy contained in sea waves [1-3]. Both planar and tubular structures have been proposed and all these structures present several advantages: relative high efficiency, simplicity of the structures, high sturdiness. However, as all the other linear machines they present some drawbacks: oscillations in the movement, distortion in the generated electromotive force (emf), high level of vibration in the translator. In this paper we focus our attention on the parasitic oscillations of the translator. The oscillation in the movement of the translator are caused by the presence of a high cogging force that is strongly related to the use of iron. Cogging force is generated by the fact that magnetic energy presents a deep minimum when the length of the magnetic flux lines reaches a minimumin the presence of iron. This effect negatively influences the dinamic equations of the generator and strongly reduced the conversion effciency. Thanks to a 3D FEM simulator and in order to reduce the parasitic effects, we have studied the features of a ironless PM generator in a multiphysics approach and we have studied several possible designs of a PM linear generator for the conversion of sea waves energy developing an optimization procedure. Numerical simulations showed that an optimized design can reach efficiency comparable to that of an iron based PM linear generator with a great reduction of parasitic effects. A structure of the stator has been chosen and built. Finally, in order to verify, our optimization approach several structures of rotor have been built and tested. This has led us to validate our approach to the optimization of cogging torque.

CH-12. Optimal Design of a 314kW-class IPMSM for Railway Vehicles Using Hydrogen Fuel Cells. *J. Lim*[1], H. Lee[1], T. Kim[2], J. Lee[1], K. Seo[1], G. Jeong[3] and C. Park[1] *1. Korea National University of Transportation, Uiwang-si, The Republic of Korea; 2. Electrical and Computer Engineering Department, University of Michigan-Dearborn, Dearborn, MI, United States; 3. Electrical Engineering, Hanyang University, Seoul, The Republic of Korea*

Conventional diesel railway vehicles have produced many air pollutants. As a result, studies on the commercialization and development of a diesel/battery hybrid railway vehicles have been conducted in Japan and other countries [1]. However, as disadvantages of the continuous use of diesel such as air pollution, carrying on fuel and low efficiency of internal combustion engine, New type hybrid battery vehicle is needed [2]. One of next-generation railway vehicle technologies is a hydrogen fuel cells vehicle that uses hydrogen as a power source and combines a rechargeable battery that can be charged using regenerative power [3]. Since the hydrogen fuel cell vehicle is equipped with a hydrogen tank and a battery, interior permanent magnet synchronous motor(IPMSM) with a higher output density than an induction motor should be used for heavy-weight components such as traction motors [4]. However, IPMSM have high no-load back electromotive force (back EMF) in high-speed of coasting running sections and are difficult to control. In particular, since it is to the limit value of the phase voltage of the hydrogen fuel cell vehicle much lower than that of the electric railway using the existing catenary, the back EMF is required to be very low (Phase back EMF voltage 866V or less, Conventional phase back EMF voltage 1617V). In order to meet the rated output with low back EMF, high current must be used, but the size of the motor is increased. However, due to the mounting the traction motor on the existing bogie, the constraint of the bogie space must be satisfied. The following table shows the back EMF, electrical and mechanical constraints of this hydrogen fuel cell vehicle. In order to design a IPMSM with high output density under such harsh electrical and mechanical constraints, this paper perform basic design such as characteristic analysis according to various motor parameters. Then, optimal design is performed. It will be also presented to the results of performance analysis of demagnetization, thermal and stiffness of an optimum designed motor in this paper.

CI-01. Enhancing the coercivity and thermal stability of Nd-Fe-B sintered magnets by grain boundary diffusion process. *S. Kim*[1], H. Lee[1], D. Kim[2], J. Kim[1], J. Roh[3] and W. Lee[1] *1. Yonsei University, Seoul, The Republic of Korea; 2. Star Group, Daegu, The Republic of Korea; 3. Kyungpook National University, Sangju, The Republic of Korea*

High-coercivity Nd-Fe-B sintered magnets have been widely used in a variety of practical and industrial applications since their discovery in1984 [1,2], but there is still a need to be able to operate magnets for a long period of time without reducing coercivity in high-temperature environments. In a general way, the coercivity of Nd-Fe-B magnets can be improved by partially replacing Nd with Dy, Tb, or both. However, due to the high cost and scarcity of these heavy rare-earth elements, it is necessary to develop alternatives more economically [3,4]. One of such alternatives is to reduce the use of heavy rare-earth elements and minimize the loss of remanence and energy product through the utilization of the grain boundary diffusion process. [5,6] In this study, we employed consecutive heat treatment-driven Tb-H diffusion to fabricate large-size Nd-Fe-B magnets exhibiting enhanced coercivity without any decrease of B_r and $(BH)_{max}$. In detail, the coercivity of the base magnet increased by 62.7% after grain boundary diffusion process, whereas B_r and $(BH)_{max}$ concomitantly decreased by 1.66% and 1.43%, respectively. To investigate the relationship between Tb-diffused area and coercivity enhancement, we performed a microstructure analysis based on electron probe microanalysis compositional maps. We have found that core-shell structures generated in a stepwise annealing process successfully suppressed the nucleation of reverse domains at Nd-rich phase/main phase interfaces and therefore enhanced magnet coercivity without decreasing remanence and energy product (Fig.1). Furthermore, for practical applications in high-temperature environments, we should consider not only coercivity of Nd-Fe-B magnets but also thermal stability, such as flux loss, temperature coefficients (β), and squareness. For this reason, we have improved thermal stability parameters as well as coercivity through the changes in heat treatment conditions and diffusion materials. As a result, we obtained the Nd-Fe-B sintered magnet with a coercivity lower than the maximum coercivity but with much better thermal stability.

CI-02. Detection of elemental magnetization reversal events in a micropatterned hot-deformed Nd-Fe-B magnet. *T. Yomogita*[1], N. Kikuchi[1], S. Okamoto[1,2], O. Kitakami[1], S. Hossein[2], T. Ohkubo[2], K. Hono[2], K. Hioki[3] and A. Hattori[4] *1. IMRAM, Tohoku University, Sendai, Japan; 2. ESICMM, NIMS, Tsukuba, Japan; 3. Daido Steel Co. Ltd., Nagoya, Japan; 4. Daido Electronics Co. Ltd., Nakatsugawa, Japan*

Although Nd-Fe-B magnets exhibit the highest maximum energy product $(BH)_{max}$ among all of the permanent magnetic materials [1], the coercivity remains as small as about 1/3 of the anisotropy field. Since the coercivity process in permanent magnet includes enormous number of magnetization reversal events, it is essentially important to measure the elemental magnetization reversal events to solve the coercivity problem. For this purpose, ultra-high sensitivity of the magnetization detection for a microsized magnet sample is required. In this study, a hot-deformed (HD) Nd-Fe-B magnet is patterned into a microsized cross-shape using focused ion beam (FIB), and anomalous Hall effect (AHE) is adopted to detect the elemental step of magnetization reversal. The HD magnet consists of well aligned platelet small grains with 300 nm in diameter and 70 nm in thickness [2]. Owing to this unique microstructure, HD magnet has enough high tolerance for process damage. AHE measurement detects electric signal proportional to the perpendicular magnetization component of the cross patterned area with ultra-high sensitivity. Fig. 1 shows the SEM image of the cross-patterned HD magnet with the AHE cross area of 0.9 μm in width and 1 μm in thickness. Fig. 2 shows the AHE curves of the HD magnet repeatedly measured three times. The stepwise AHE signal is clearly confirmed. Taking into account the AHE cross area size and the included grain size, each step height corresponds to the magnetization reversal of a single grain. Moreover, these three AHE curves overlaps, indicating that each step is repetitive. The inset of Fig. 2 shows an expanded part of the AHE curves. The step position slightly fluctuates due to the thermal agitation [3-4]. The thermal activation analysis for these elemental magnetization events will make us to understand the background physics of the magnetization reversal of the HD magnet.

Nd-Fe-B permanent magnets have been intensively studied in order to improve the magnetic properties, especially, coercivity. It has been reported that the lattice strain in the $Nd_2Fe_{14}B$ crystalline grain in the Nd-Fe-B magnet affects the magnetic anisotropy, and hence the coercivity [1-3]. However, there are few experimental reports on the lattice strain in the $Nd_2Fe_{14}B$ phase so far [4]. In our previous synchrotron X-ray diffraction (XRD) study [5], the lattice constants of each constituent phase in an anisotropic Nd-Fe-B-Cu sintered magnet are slightly different from those of the pristine metal or compounds. This result implies the presence of internal strain in sintered magnets. In this study, we have measured temperature dependent synchrotron XRD and determined precise lattice constants of the $Nd_2Fe_{14}B$ phase and secondary phases in the several types of samples: isotropic and anisotropic Nd-Fe-B-Cu as-sintered magnets, their powdered samples, and powder samples obtained from a coarse single crystal which we used as a reference sample without lattice strain. While temperature variations of lattice constants of the $Nd_2Fe_{14}B$ phase are quite similar for all the samples above Curie temperature (T_C), the temperature variations below T_C are different between sintered magnets and their powdered samples. The comparison of the lattice constants of the $Nd_2Fe_{14}B$ phase clarifies the presence and absence of internal strain in sintered magnets and powdered samples, respectively. The internal strain in the isotropic as-sintered magnet is larger than that in the anisotropic magnet. In addition, unit cell volume of each secondary phase in sintered magnets is larger than those of pristine metal or compounds and each secondary phase in powdered sintered magnets below T_C. These results indicate that internal stain in sintered magnets varies lattice constants of all the constituent phases. We thank T. Nishiuchi of Hitachi Metals, Ltd. for supplying the samples. A part of this work is supported by ESICMM under the outsourcing project of MEXT.

CI-04. Determination of Local Magnetic Moments in the Fractured Surface of a Nd-Fe-B Sintered Magnet by a Soft X-ray Microscope. *A. Martín-Cid*[1,2], D. Billington[1,2], K. Toyoki[1,2], Y. Kotani[1,2], S. Kobayashi[1,2], H. Okazaki[1], S. Hirosawa[2] and T. Nakamura[1,2] *1. Japan Synchrotron Radiation Research Institute (JASRI), Sayo, Japan; 2. Elements Strategy Initiative Center for Magnetic Materials (ESICMM), Tsukuba, Japan*

Permanent magnets (PM) used in energy-related applications occasionally operate under strong demagnetizing fields and at elevated temperatures of about 150 °C or more. One of the most desirable properties of PM that operate under such conditions is the coercivity. Nowadays, the main type of PM used in these high demanding applications are the Nd-Fe-B sintered magnets, which usually use the scarce heavy rare earth (HRE) elements such as Tb or Dy to improve their coercivity and thermal stability. In order to avoid the use of the scarce HRE, it is important to have a good knowledge of the effect of the microstructure and the grain boundary (GB) phases on the magnetic properties of a magnet. It has been known that the magnetic properties of the GB phase is associated with the coercivity through nucleation of magnetic domains and the pinning effect of the magnetic domain wall displacement. The evaluation of the magnetic properties of the GB phase is, therefore, crucial for the study of permanent magnets. Soft X-ray magnetic circular dichroism (XMCD) with the total electron yield (TEY) regime is a surface sensitive probe for element specific magnetic moments. XMCD measurements previously showed the magnetic properties of the GB phase exposed in the fractured surface [1]. The estimated values were, however, those averaged over a wide area with significant inhomogeneity. In this work, we present the distribution of the local Fe magnetic moments estimated by the sum rule analysis for XMCD spectra. The local XMCD spectra were recorded using the scanning soft XMCD microspectroscopy technique with the spatial resolution of about 100 nm [2,3] and it was possible to discern the magnetic moment of Fe from the intragranular fracture (related

to the $Nd_2Fe_{14}B$ phase) and the intergranular fracture (related at some extent with the GB phase). The value obtained for the intragranular fracture was ~2 μ_B, similar to that obtained by Mössbauer spectroscopy [4]. We thank T. Nishiuchi of Hitachi Metals, Ltd. for supplying the samples. Part of this work is supported by ESICMM under the outsourcing project of MEXT.

CI-05. Magnetic States of Rare-Earth Atoms in $(Nd,Ce,La)_2Fe_{14}B$ Investigated by Powder Neutron Diffraction. *T. Hawai*[1], M. Yano[2], T. Shoji[2], J.R. Hester[3] and K. Ono[1] *1. High Energy Accelerator Research Organization (KEK), Tsukuba, Japan; 2. Toyota Motor Corporation, Toyota, Japan; 3. Australia's Nuclear Science and Technology Organisation (ANSTO), Lucas Heights, NSW, Australia*

The most popular rare-earth magnet $Nd_2Fe_{14}B$ is necessary for industrial applications because of its strong coercivity originated from anisotropy of Nd. On the other hand, Nd is much costly than Fe and B, so that if a low Nd content magnet as strong as $Nd_2Fe_{14}B$ is realized, its commercial effect should be significant. The most abundant rare-earth elements Ce and La have a much lower cost than Nd, thus they are strong candidates for a low Nd content magnet. In general, Ce is in non-magnetic Ce^{4+} state. However, when Ce^{3+} state is stable, Ce has a magnetic moment and could work as a substitution for Nd. Previous research reported that a rare-earth atom with larger ionic radius prefers a position with a larger volume [1]. The magnetic Ce^{3+} has larger ionic radius (1.15 Å) than that of non-magnetic Ce^{4+} (1.01 Å) [2]. Therefore, to expand a cell for stabilization of Ce^{3+}, La (1.17 Å) is doped as a spacer. Previous study reported that Ce in $(Ce,La)_2Fe_{14}B$ has no moment [3]. Following the previous results, we focused on $(Nd,Ce,La)_2Fe_{14}B$. In this work, powder neutron diffraction experiments were performed to evaluate magnetic moment on rare-earth site and Ce state. The powder samples of $Nd_2Fe_{14}B$, $(Nd_{0.75}Ce_{0.225}La_{0.075})_2Fe_{14}B$, $(Nd_{0.5}Ce_{0.375}La_{0.125})_2Fe_{14}B$, and $Ce_2Fe_{14}B$ were measured on ECHIDNA at ANSTO [4]. Natural B was substituted with ^{11}B due to strong neutron absorption. Figure 1 shows an observed diffraction pattern of $(Nd_{0.5}Ce_{0.375}La_{0.125})_2Fe_{14}B$ together with a result of Rietveld analysis. The experimental data was well explained by the calculated pattern. The magnetic moment on 4*f* site changes almost proportionally to Nd content (Fig. 2). In contrast, the magnetic moment on 4*g* site shows only a little decrease against the decrease of Nd content. The reported magnetic moment on rare-earth sites in $(Nd,Ce)_2Fe_{14}B$ quickly decrease with decreasing Nd content [3]. This result suggests that magnetic Ce^{3+} state is stable thanks to La dope. The details will be discussed.

CI-06. A mixed-valence model for $Ce_2Fe_{14}B$ compounds. *H. Tabata*[1], T. Yoshioka[1,2] and H. Tsuchiura[1,2] *1. Department of Applied Physics, Tohoku University, Sendai, Japan; 2. National Institute for Materials Science (NIMS), ESICMM, Tsukuba, Japan*

Because of the recent intensive use of Nd and Dy for high performance Nd-Fe-B permanent magnets, there is an urgent need to develop novel, economically attractive magnetic materials. Ce-based, or at least Ce-substituted permanent magnets, will be of particular interest because Ce is the most abundant rare-earth element. It is well known, however, that Ce-based magnetic materials such as $Ce_2Fe_{14}B$ usually do not have high magnetocrystalline anisotropy as a consequence of the less tightly-bound 4f electronic clouds in those systems. Theoretically, much less is known about the 4f electronic states of Ce ions in the $Ce_2Fe_{14}B$ because the modern first-principles calculations techniques still have problems to treat them. Thus in this study, we propose an alternative theoretical model to understand how the 4f electrons behave, and how these materials loses magnetocrystalline anisotropy. This model is essentially a cluster-type model which consists of Ce 4f orbital degrees of freedom and several surrounding ligand orbitals. The hybridization amplitude between the 4f and ligand orbitals is given as a parameter V in this model. This model reduces to the localized spin model in a limit with V=0, which has been widely used for rare-earth based permanent magnets [1]. Figure 1 shows the temperature dependences of the magnetic anisotropy constant K_1 obtained by using the present model. We find that the experimental data [2] can be well described at any temperature, when we take V=1100K. The localized spin model extremely overestimates K_1, as also shown in Fig. 1. The V dependences of K_1 and the 4f electronic density N_{4f} are shown in Fig. 2. We can see that N_{4f} first rapidly decreases

but becomes almost independent with increasing V. However, K_1 decreases monotonically even when N_{4f} is nearly constant around 0.5. This results may correspond to the weak magnetic anisotropy of $Ce_2Fe_{14}B$.

Anisotropic bonded NdFeB permanent magnets have wide potential applications in the areas such as brushless DC motors, spindle motors, and stepping motors due to their excellent processing property and high magnetic properties. Anisotropic NdFeB bonded magnets prepared by hydrogen-disproportionation–desorption-recombination (HDDR) process have large energy product at room temperature, however, they are not stable at ~100°C, which is the working temperature of many electric motors. In order to improve their temperature stability, we developed bonded NdFeB/SmCo magnets and investigated the effects of powder particle size and SmCo content on their magnetic properties. We proposed a model to clarify the filling effect of the powder, which played a key role in the enhanced energy product when reducing the SmCo particle size. As for the SmCo content, the bonded magnets showed improved thermal stability with the increase of SmCo mass percent. And through adjusting the SmCo content, the remanence temperature coefficient and coercivity temperature coefficient from 25-150°C were able to be regulated in the range of -0.14%/°C to -0.04%/°C and -0.51%/°C to -0.14%/°C, respectively. This work provides a design strategy and a facile route to improve the magnetic properties and thermal stability of the bonded magnets.

CI-09. Measuring THz Magnons in Metamaterials made of Ultrathin Magnetic Layers. P.M. Yarbrough[1], K. Livesey[1], R. Camley[1] and *R. Macedo*[2] *1. Department of Physics, University of Colorado at Colorado Springs, Colorado Springs, CO, United States; 2. James Watt School of Engineering, University of Glasgow, Glasgow, United Kingdom*

In recent years there has been growing interest in THz magnons as spin waves in this frequency range can be used for applications, such as spin-wave logic devices [1]. Due to their short lifetimes, however, high-frequency magnons can be difficult to measure. THz magnons are common in antiferromagnets, but more difficult to create and measure in metallic ferromagnets. Here we present a calculation showing that infrared magnons can be detected in metallic ferromagnets using standard reflection and attenuated total reflection (ATR) measurements [2]. We consider a layered structure of alternating thin magnetic and nonmagnetic materials. Thin ferromagnetic films have standing spin waves with resonance frequencies in the 100 – 500 GHz range, much higher than those typically found in bulk ferromagnets. We use an entire-cell effective-medium calculation to find the magnetic permeability of our metamaterial. We then calculate reflectivity as a function of frequency. We employ the geometry shown in Fig. 1 where the incident THz radiation is Transverse Electric (TE)-polarised. As can be observed from Fig. 2(a), there are appreciable dips (10%) in the reflectivity at infrared magnon resonance frequencies, for realistic material parameters. Here we have used Fe as the magnetic material composing our layered structure with 343 nm total thickness. The ATR geometry is similar to that pictured in Fig. 1 but we now add a dielectric prism a distance d_{gap} above the magnetic composite material, creating an air gap in which allows for evanescent waves to travel into the composite. The dips at resonance frequencies are now substantial, with reductions of 30% in the reflectivity seen in Fig. 2(c). We note that ferromagnetic and ferrimagnetic elements are widely used for applications in the 1-50 GHz range, and this work opens the way for those applications to be extended to much higher frequencies between 50 GHz and 1 THz.

CI-10. Strongly Absorbing Optic Mode in Ferromagnetic Multilayers: Application to Signal Processing Devices. R. Macedo[1,2], P. Couture[2], R. Camley[2], K. Livesey[2] and *Z. Celinski[2] 1. SUPA School of Physics and Astronomy, University of Glasgow, Glasgow, United Kingdom; 2. Physics, Center for Magnetism and Magnetic Nanostructures, University of Colorado at Colorado Springs, Colorado Springs, CO, United States*

Metallic ferromagnetic layers have been used in signal processing devices to produce microscopic filters and phase shifters [1]. Most of these studies employed a single ferromagnetic film. Here, in contrast, we explore the behavior of a magnetic multilayer system with antiferromagnetic coupling between the ferromagnetic films. This work is motivated by a recent theoretical prediction [2] that such a structure could show significant absorption at higher frequencies in the optic mode, even with no external biasing field. This is very different from the single film results where there is no optic mode, and the operational frequency is generally low for small external biasing fields. While it is possible to use shape anisotropy or internal anisotropy to raise the operational frequency [3, 4] each of these methods has drawbacks. To test the theory, we grew both Fe/Cu and Fe/Cr multilayers embedded into a coplanar waveguide (CPW) structure. The polycrystalline samples had Cu or Cr layers which were 1 nm thick, ensuring an antiferromagnetic coupling between the 1.4 nm thick Fe films with ten repetition of the Fe/ spacer structure. The multilayer stack was covered by a 60 nm thick Cu film. The CPW geometry was defined by photolithography and lift-off. The MOKE measurements, seen in Fig. 1, indicate a weak antiferromagnetic coupling. Network analyzer measurements, shown in Fig. 2, for the Fe/Cu structure show a significant dip in transmission for low biasing fields. As the biasing field is increased, the transmission dip becomes smaller and moves to lower frequencies, in agreement with theoretical calculations. With further increases in biasing, the transmission dip moves to higher frequencies, and in fact is now the, weakly absorbing acoustic mode of a nearly ferromagnetically aligned structure. While the frequencies measured here are relatively small, stronger antiferromagnetic coupling could lead to significantly higher operational frequencies.

CI-11. Injection Locking of Spin-Torque Oscillator with Perpendicularly Magnetized Free Layer. *T. Yamaguchi*[3], N. Akashi[1], K. Nakajima[1,2], S. Tsunegi[3], H. Kubota[3] and T. Taniguchi[3] *1. Graduate School of Information Science and Technology, The University of Tokyo, Tokyo, Japan; 2. JST, PRESTO, Saitama, Japan; 3. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan*

Injection locking of a spin torque oscillator (STO) by alternative current (AC) or microwave field has been studied extensively [1-4]. The main purpose of the injection locking is the reduction of noise in STO, which is preferable for practical devices such as magnetic sensor. Injection locking is also important for new applications, such as phased array radar and reservoir computing [5,6]. For example, the performance of the reservoir computing was shown to be significantly improved recently by a phase control in microwave field [6]. So far, injection locking has been studied for an in-plane magnetized or vortex STO [1-3]. On the other hand, the injection locking of a perpendicularly magnetized STO is not fully understood yet, although STO as such is attractive due to its high emission power [4]. In this work, a theoretical study is developed on the injection locking by AC of an STO consisting of a perpendicularly magnetized free layer and an in-plane magnetized reference layer [7]. Figure 1 shows the frequency detuning between STO and AC. The frequency locking was observed over a wide range, almost 2 mA, of direct current (DC). An explanation for such behavior, contrary to the in-plane magnetized system [1-3] where the locking rage is less than 1 mA, is the orthogonal alignment in the magnetizations of the free and reference layers, since the AC spin torque should have a projection to the precession direction for locking, and thus, the locking range is proportional to the tangent of the relative angle between the magnetizations [8]. Figure 2 shows the temporal magnetization oscillation for several DC values. As phase difference between the STO and AC depends on the free running frequency, the STO phase varies by changing the DC. The wide locking range and phase tunability found in this work indicate that an array of the present STOs can shift the equal phase surface of an injected signal, which guarantees the applicability of STOs to phased array radar. This work was based on the results obtained from a project commissioned by NEDO.

CI-12. Maser operation of two magnetic tunnel junctions with positive gain. *Y. Yamada*[1], M. Goto[1,4], T. Yamane[2], N. Degawa[2], T. Suzuki[2], A. Shimura[2], S. Aoki[2], J. Urabe[2], S. Hara[2], S. Miwa[3,4] and Y. Suzuki[1,4] *1. Graduate School of Engineering Sciences, Osaka University, Osaka, Japan; 2. TDK Corporation, Tokyo, Japan; 3. Institute for Solid State Physics, University of Tokyo, Tokyo, Japan; 4. Center for Spintronics Research Network, Osaka University, Osaka, Japan*

Magnetic tunnel junction (MTJ) is attracting attention for next generation microwave signal sources. Recently, it was reported that the microwave reflection signal from MTJ is amplified by spin-torque from heat-induced magnetic anisotropy change [1]. In addition, we reported that the transmission signal is amplified with a similar mechanism [2]. These results suggest that, using multiple MTJs which amplify the signal at same frequency region, the maser could be excited. In this study, we first investigate the microwave emission from an MTJ with heat induced torque. Then, we put it in a feedback loop circuit and observed auto oscillation of the MTJ. Furthermore, we put two MTJs in the loop and observed strong non-linear increase in the emission power suggesting MASER operation of the MTJs. The film structure is buffer layer / IrMn (7 nm) / CoFe / Ru / CoFeB / MgO barrier (1 nm) / FeB (2 nm) / MgO cap (t_{MgO} =0.3 nm, 0.4 nm) / metal cap. Figure 1 shows the set up for RF power measurement with feedback loop circuit. The DC voltages were applied to the MTJs through bias-tee. The loop signal is measured through the directional coupler. Total gain without sample in loop circuit is adjusted to the negative gain of -0.44 dB by using external amplifier and attenuator. The total cable length of the loop circuit is about 11.5 m. Figure 2 shows the power spectrum density of the loop circuit with two MTJs at the resolution bandwidth of 0.1 MHz. The curve shows sharp peak at 4.809 GHz with side band peaks. The frequency difference between the side peaks is about 19 MHz. The side peaks are observed due to the standing wave in the cavity which is the same mechanism as a multi-mode laser system. In our experiment, the feedback loop acts as microwave cavity and provides the delay. The observed frequency difference of 19 MHz would correspond to a delay line 11.5 m. In addition to this result, the peak intensity amplified by two MTJs is 15 times higher than that amplified by one MTJ. This result suggests MASER operation of the MTJs.

CI-13. Enhanced broadband RF detection in nanoscale magnetic tunnel junction by interface engineering. *L. Zhang*[1,2], B. Fang[1], J. Cai[1], G. Finocchio[3] and Z. Zeng[1,2] *1. Nano Fabrication Facility, Suzhou Institute of Nano-Tech and Nano-Bionics, CAS, Suzhou, China; 2. School of Nano Technology and Nano Bionics, University of Science and Technology of China, Hefei, China; 3. Department of Mathematical and Computer Sciences, Physical Sciences and Earth Sciences, University of Messina, Messina, Italy*

Energy harvesting technologies offer a promising approach to capture energy from ambient sources, such as vibration, heat, and electromagnetic waves. Among them, the ambient radio-frequency (RF) electromagnetic signals provide an attractive energy source for applications in self-powered portable electronics [1, 2]. However, currently available microwave detectors based on semiconductors do not meet the practical requirements for energy harvesting applications. The theoretical work proposed a spin-torque microwave detector with out-of-plane precession for RF energy harvesting [3]. Later on, the experimental work reported a broadband rectifier using magnetic tunnel junction (MTJ) [4]. Our recent work [5] demonstrated that spin-torque microwave detectors based on MTJ with a canted free layer are capable to convert RF power to DC voltage in a broadband frequency. The resulted DC voltage by spin-torque microwave detector can power a nanodevice, suggesting that the spin-torque microwave detectors could be served as building blocks for self-powered nanosystems. In the ambient conditions, there are several high-frequency RF energy sources – e.g. Wi-Fi and 3G/4G mobile signals. Hence a broadband signal detection is essential for energy harvesting applications. Here we show that the bandwidth of RF detection can be tunned by adjusting the perpendicular anisotropy (PMA) in the nanoscale magnetic tunnel junction. We designed an MTJ with a wedge CoFeB free layer to study the effect of PMA on the RF detection performances since the PMA in the free layer is related to the free-layer thickness [6]. An ultra-wide RF detection bandwidth of more than 3 GHz is achieved with the assistance of an external bias magnetic field when the CoFeB thickness is 1.61 nm. Even without external bias fields, a bandwidth of 1.8 GHz is realized under the thickness of 1.65 nm, which covers the most commonly used 3G/4G communication bands. Therefore, our results suggest that the spintronic diode offers a prospective approach for energy harvesting applications.

CI-14. Strong Coupling of Magnons to Microwave Photons in Three-Dimensional Printed Resonators. J. Bourhill[1,2], S. Ben Ammar[1], G. Cochet[3], A. Manchec[3] and *V.M. Castel*[1,2] *1. IMT Atlantique, Technopole Brest-Iroise, CS 83818, Brest, France; 2. Lab-STICC (UMR 6285), CNRS, Technopole Brest-Iroise, Brest, France; 3. Elliptika (GTID), Brest, France*

In recent years, a new light–matter interaction platform has been developed [1-2] by combining microwave (MW) photons residing in a resonant cavity with magnons in magnetic materials with a high spin density, such as yttrium iron garnet (YIG) [3]. The use of a standard three-dimensional (3-D) cavity for MW applications seems difficult to combine with concepts of integration, compactness, cost, and miniaturization. Here, we propose to take advantage of the geometric configuration of a re-entrant MW cavity to counterbalance this problem, which is becoming more and more critical by reducing the working frequency. MW re-entrant cavities offer many advantages in terms of frequency tunability, volume reduction, and control of the MW magnetic field distribution while keeping a high Q factor. Such cavities have been used for decades for a variety of applications, such as high Q resonator or sensors, and in different research area from the observation of spin wave propagation [3] to studies of cavity magnon–polaritons [4]. A range of experimental and simulations results are presented for two YIG/cavity systems, demonstrating the strong coupling signature (see Fig.1) between a YIG thin film resonator and photons generated by a 3-D re-entrant cavity elaborated by additive manufacturing (see Fig.2). A frequency dependence of the coupling strength was observed for both cavities, which differ only with the inner post height. Additive manufacturing opens an innovative path for the development of a new class of 3-D tunable filters based on re-entrant cavities, adjustable inner posts (including exotic shape), iris aperture, and magnon-photon coupling control. Such elaboration procedure combined to re-entrant cavities features improve the integration of YIG/Pt systems without increasing the intrinsic loss rate of the cavity, adding another degree of freedom in terms of tunability [5].

CI-15. 3D Double Post Re-entrant Microwave Cavities as a Powerful Tool for Strong Photon-Magnon Coupling. *J. Bourhill*[1], V.M. Castel[1], M. Goryachev[2] and M. Tobar[2] *1. IMT-Atlantique, Brest, France; 2. University of Western Australia, Perth, WA, Australia*

3D re-entrant cavities offer a unique platform for microwave photon-magnon coupling in magnetic materials. A double post architecture (see Fig. 1) allows RF magnetic field focusing over a magnetic sample placed between the posts, generating orders of magnitude improvements in coupling strength compared to standard TM microwave cavities. These systems have successfully demonstrated achieving the strong coupling regime with coupling strengths equal to a sizeable percentage of the system's total energy [1,2] (see Fig. 2). Futhermore, the spatial separation of E and B fields within the cavity permit the presence of conductive layers, allowing utilisation of Spin-Hall devices [3]. Finally, the possibility of broad in-situ tuneability of the resonant frequency of these cavities results in an extremely versatile device, which will have important ramifications for microwave filtering applications and cavity quantum electrodynamics experiments. A range of experimental and simulation results are presented demonstrating the adaptability of these cavities towards the goals of achieving large coupling parameters, low microwave losses or high field uniformity, the latter being important for the suppression of coupling to higher order magnetic modes [4] for the purposes of clean filtering protocols. Successful manufacturing of these cavities has been demonstrated via 3D printing [5], further adding to their list of benefits through reduced cost and weight, and improved reproducibility, allowing mass production of such systems from a commercial standpoint, but also scalability of experimental tests of fundamental physics such as dark matter detection [6].

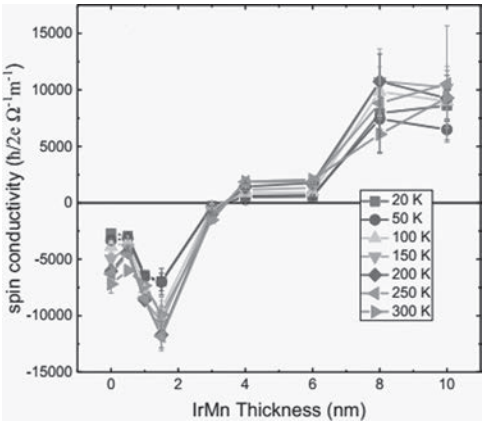
CP-01. Chiral-driven switching of antiferromagnets in a confined thin film. *T. Kim*[1], S. Han[2] and B. Cho[1] *1. School of Material Science and Engineering, Gwangju Institute of Science and Technology, Gwangju, The Republic of Korea; 2. Division of Navigation Science, Mokpo National Maritime University, Mokpo, The Republic of Korea*



In the development of spin-based electronic devices, a particular challenge is the manipulation of the magnetic state with high speed and low power consumption. While many studies have focused on the spin-orbit torque (SOT), based on strong spin-orbit coupling, the torque-driven devices (as well as the charge-based ones) have fundamental limitations: Joule heating, phase mismatching and overshooting. To overcome these limitations, we report alternative switching scenario of antiferromagnetic insulator through theoretical and numerical demonstration. In two-dimensional geometry, as the electric field is applied to the magnetic system, the inversion symmetry of magnetic system is broken, and thereby two magnetic interactions are triggered: Dzyaloshinskii-Moriya (DM) interaction and pseudo-dipole anisotropy. The competition between the DM interaction, the exchange and crystalline anisotropy in thin film results in spiral structure with symmetric and antisymmetric configurations. By tuning DM strength, each symmetric state is energetically determined, which is enable to reverse magnetization. As a result, the switching power is estimated as ~1 pW, which is extremely lower than ~ μW of SOT-driven devices with various magnetic tunnel junction structures. Our finding provides promising opportunities to realize the rapid and energy-efficient electrical manipulation of magnetization for future spin-based electronic devices.

CP-02. Competition between Electronic and Magnonic Spin Currents in Metallic Antiferromagnet. *Y. Wen*[1], F. Zhuo[1], A. Manchon[1] and X. Zhang[1] *1. King Abdullah University of Science and Technology, Thuwal, Saudi Arabia*

We investigate the spin-orbit torque in a Ta/IrMn/Cu/NiFe multilayer heterostructure and relate it to spin current transmission through the IrMn layer. We identify several spin current transport regimes as a function of temperature and thickness of the IrMn layer. To interpret this experiment, we developed a drift-diffusion model accounting for both electron and magnon transport in the heterostructures. This model allows us to discriminate between the contributions of electrons and magnons to the total spin current in IrMn. We find that the electron-magnon spin convertance is one order of magnitude larger than the interfacial electronic spin conductance, while the magnon diffusion length is about ten times longer than the electronic spin relaxation length. This study demonstrates that magnonic spin transport dominates over electronic spin transport even in disorder metallic antiferromagnets.

CP-03. Dirac nodal line metal for topological antiferromagnetic spintronics. *D. Shao*[1], G. Gurung[1], S. Zhang[2] and E.Y. Tsymbal[1] *1. Department of Physics and Astronomy, University of Nebraska-Lincoln, Lincoln, NE, United States; 2. College of Science, Beijing University of Chemical Technology, Beijing, China*

Topological antiferromagnetic (AFM) spintronics is an emerging field of research, which exploits the Néel vector to control the topological electronic states and the associated spin-dependent transport properties. A recently discovered Néel spin-orbit torque has been proposed to electrically manipulate Dirac band crossings in antiferromagnets; however, a reliable AFM material to realize these properties in practice is missing. Here, we predict that room temperature AFM metal $MnPd_2$ allows the electrical control of the Dirac nodal line by the Néel spin-orbit torque. Based on first-principles density functional theory calculations, we show that reorientation of the

Néel vector leads to switching between the symmetry-protected degenerate state and the gapped state associated with the dispersive Dirac nodal line at the Fermi energy. The calculated spin Hall conductivity strongly depends on the Néel vector orientation and can be used to experimentally detect the predicted effect using a proposed spin-orbit torque device. Our results indicate that AFM Dirac nodal line metal MnPd2 represents a promising material for topological AFM spintronics.

CP-04. Structural and Magnetic Property of Co Doped Mn_3Ga Antiferromagnetic Heusler Alloys. Y. Yoshihara[1,2], K. Elphick[2], M. Samiepour[2], H. Uchida[1], M. Inoue[1] and *A. Hirohata*[2] *1. Department of Electrical and Electronic Information Engineering, Toyohashi University of Technology, Toyohashi, Japan; 2. Department of Electronic Engineering, University of York, York, United Kingdom*

Antiferromagnetic (AF) Heusler alloys, especially Mn_2YZ (Y: transition metals and Z: other metals), has been intensively investigated due to their device applicability. Because of their large exchange bias induced at their interface against a ferromagnetic (FM) layer, they can be a potential candidate to replace rare metals, particularly IrMn which commonly used for MR head in HDD or MRAM applications. Fe-doped Mn_3Ga, *i.e.*, $D0_{19}$ Mn_2FeGa, has been predicted to form a collinear spin orientation [1]. Previously we observed both in and out-plane exchange bias experimentally [2]. In this study we study the influence of a FM element doped in an AF Heusler alloy, namely Co doped Mn_3Ga, via the observation of exchange bias and Hall effects. Layer stacks consisting of Ta (5)/Ru (35)/Mn_3Ga (30)/CoFe(3.3) or [Co (1.0)/Pt (1.6)]$_3$/Ta (5) (thickness in nm) were deposited for in- and out-of-plane anisotropy studies, respectively. They were grown by magnetron sputtering at room temperature and doping was achieved by adding Co pegs on the Mn_3Ga target. Blocking temperature (T_B) measurement was performed at activation temperatures T_{act} by the York Protocol [3]. Hall bar devices was fabricated by the lift off method using the stacks consisting of Ta (5)/Ru (35)/Mn_3Ga (30)/Ta (10). Figures 1 and 2 show in- and out-of-plane magnetization curves of $Mn_{2.18}Co_{1.09}Ga$ activated at T_{act} = 100~300 K, respectively. Loops are found to shift to a positive field with increasing T_{act}. Out-of-plane magnetization curves show better squareness than in-plane ones. T_B is estimated to be 197 and 186K for in- and out-of-plane, respectively. These results suggest the Co doped Mn_3Ga transforms the triangular spin configuration into the collinear one as expected. Hall measurements reveal the resistivity is 132 nΩ·m, which is almost the same to bulk Ta. This indicates a current predominantly flows through the Ta capping layer, which is an ideal situation for the spin Hall effect measurements. The details of these results will be presented in our presentation.

CP-05. Degenerated Orthogonal Spin States in Antiferromagnetic NiO(111) on Fe(110). *M. Slezak*[1], P. Drozdz[1], W. Janus[1], J. Korecki[1,2], A. Koziol-Rachwal[1], K. Matlak[1], M. Szpytma[1], M. Zajac[3] and T. Slezak[1] *1. AGH University of Science and Technology, Krakow, Poland; 2. Jerzy Haber Institute of Catalysis and Surface Chemistry PAS, Krakow, Poland; 3. National Synchrotron Radiation Centre SOLARIS, Jagiellonian University, Krakow, Poland*

The aim of antiferromagnetic (AFM) spintronics is to complement or replace ferromagnets (FM) in the active components of spintronic devices [1,2]. For magnetic control of AFMs spin orientation, two main possible routes are application of very strong external magnetic field or to employ the magnetic proximity effects at the AFM-FM interface. Depending on particular AFM-FM interfacial coupling, relatively small magnetic field is required in order to rotate the AFM spins [3]. In this report, we combine interfacial AFM-FM exchange interaction and temperature induced spin reorientation transition (SRT) in FM layer, in order to implement zero-field switching of AFM spins. In epitaxial NiO(111)/Fe(110) bilayers, we take the advantage of intrinsic hysteretic nature of the temperature induced SRT in Fe(110) layer and at given temperature we directly document the existence of degenerated orthogonal magnetic states in AFM NiO(111) sublayer. We used XMLD and XMCD techniques in order to follow the magnetic properties of epitaxial NiO(111)/Fe(110) bilayers. We find that the NiO spins are fully rotatable and always perpendicularly oriented with respect to Fe magnetization that direction can be controlled by external magnetic field or via the thickness or

temperature driven, 90-degree, in-plane SRT of Fe(110) [4,5]. The thickness and preparation recipe of Fe(110) buffer layer can be fine tuned in such a way that temperature driven SRT in Fe takes place at the desired temperature. For example, in Fig. 1 we present temperature dependence of XMCD (rescaled) and XMLD (R_{L2} ratio as defined for example in [6]) in NiO(40 Å)/ Fe(90 Å) bilayer. Fe sublayer undergoes a temperature driven in-plane SRT from [1-10] at high temperature to [001] at low temperature. We observe large thermal hysteresis of the SRT and consequently, in both Fe and NiO layers, at (230, 270 K) temperature range, two degenerated magnetic states can be stabilized at given temperature. Specifically, on the cooling branch within temperature hysteresis the ($FM_{[1-10]}$, $AFM_{[001]}$) magnetic state is stable while on the heating branch the system persists in the orthogonal ($FM_{[001]}$, $AFM_{[1-10]}$) state.

CP-06. Spintronics of magnetoelectric antiferromagnetic thin films. T. Kosub[1] and *D. Makarov*[1] *1. Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany*

Thin film magnetoelectric antiferromagnets (AF) have potential to revolutionize spintronics due to their inherently magnetic-field stable magnetic order and high-frequency operation. To explore their application potential, it is necessary to understand modifications of the magnetic properties and magnetoelectric responses of AF thin films with respect to their bulk counterparts. Our approach is based on the electron transport characterization of magnetic responses of thin film antiferromagnets [1-4]. This task is difficult as minute uncompensated surface magnetization of antiferromagnets needs to be detected, which imposes strict requirements to the sensitivity of the method. We will outline our developments of zero-offset anomalous Hall magnetometry [3] applied to study the physics of insulating magnetoelectric Cr2O3 antiferromagnets. To build a reliable description of the material properties, the analysis of the transport data is backed up by structural characterization and real space imaging of AF domain patterns using NV microscopy [1,2]. Considering grainy morphology of thin films, we address questions regarding the change of the intergranular exchange [2], criticality behavior and switching of the order parameter [3]. The fundamental understanding of the magnetic microstructure of magnetoelectric α-Cr2O3 thin films and the possibility to read-out its antiferromagnetic order parameter all-electrically enabled the entirely new recording concept where a magnetoelectric memory cell can be addressed without using a ferromagnet, the purely antiferromagnetic magnetoelectric random access memory (AF-MERAM) [1]. In addition to the outline of the memory concept, we discuss on the physics of the readout signal in α-Cr2O3 interfaced with Pt [4].

CP-07. Tunnel Magnetoresistance Properties in the Magnetic Tunnel Junctions with the Plasma Oxidized Cr_2O_3 Barrier. *T. Ichinose*[1], K. Elphick[2], A. Hirohata[2] and S. Mizukami[1,3] *1. Advanced Institute for Materials Research, Tohoku University, Sendai, Japan; 2. Department of Electronic Engineering, University of York, York, United Kingdom; 3. Center for Science and Innovation in Spintronics (Core Research Cluster) and Center for Spintronics Research Network, Tohoku University, Sendai, Japan*

There has been growing interest in the antiferromagnetic spintronics due to the high-speed operation, no stray fields etc. [1] Cr_2O_3 known to be the magnetoelectric material with the antiferromagnetic ordering under the Néel temperature of 310 K would show the intriguing spin dependent transport phenomena such as magnetoresistance effects mediated by antiferromagnetic and/or magnetoelectric nature. [2] In this work, the spin-dependent transport properties in the magnetic tunnel junctions (MTJs) with a Cr_2O_3 barrier were investigated. The stacking structures of Cr_2O_3(20)/ Ta(5) and Cr_2O_3(2)/ Co(3)/ $Ir_{22}Mn_{78}$(10)/ Ta(3)/ Ru(7) were prepared on the Si/ SiO_2/ Ta(5)/ Ru(20)/ Co(4) underlayers. (thickness in nm) The structural and transport properties were measured by using the x-ray diffraction (XRD), the 4-terminal prober, and the physical property measurement system. The Cr_2O_3 thin films were prepared by using the 90° off-axis cathode followed by the plasma oxidation to reduce the oxygen vacancies. The MTJs were post-annealed at 523 K under a magnetic field of 2 kOe. The Cr_2O_3 (006) peak could be observed in the XRD profiles of 2θ/ω scans for the 20-nm-thick Cr_2O_3 films. In the corundum oxides, the (006) diffractions were weak in contrast to the (104) peaks: For instance, the intensity ratio $I_{(006)}/I_{(104)}$ in the Cr_2O_3 powder sample was 0.15. On the contrary, sputtered Cr_2O_3 showed the $I_{(006)}/I_{(104)} \sim 8.8$, indicating high orientation of Cr_2O_3 to the (001) direction. The dielectric breakdown strength could be improved from 0.3 V to 1 V via the plasma oxidation, which could originate from the reduction of the oxygen vacancies. The MTJs with the Cr_2O_3 barrier showed the tunnel magnetoresistance (TMR) ratio of 1% (4%) at 300 K (10 K). In the TMR curves at < 100 K, the increase of coercive fields and anisotropy in the Co layers could be observed, indicating antiferromagnetic order of Cr_2O_3. This is the first observation of TMR in MTJs with the antiferromagnetic Cr_2O_3 barrier. The work was partially supported by KAKENHI (JP18H05947) and JST CREST (No. JPMJCR17J5).

CP-08. Crystallographic Structure Dependent Current-induced Switching in NiO/Pt Bilayer. *S. Hu*[1] and X. Qiu[1] *1. School of Physics Science and Engineering, Tongji University, Shanghai, China*

Spintronics mainly focus on manipulating magnetic moments of ferromagnetic materials. Recently, antiferromagnet has drawn a lot of attentions for its self-canceled stray fields, ability to against the external field and ultra-fast spin dynamics [1]. Several works have demonstrated electrical switching of metallic antiferromagnet CuMnAs and insulating antiferromagnet NiO [2-4]. However, more detailed discussions about whether the structure dominates the switching behavior is lacking. Here, we report the current-induced switching of antiferromagnetic insulator and its strong crystallographic structure dependent behavior in NiO/Pt bilayer by probing transvers resistance. Figure 1 (a) and (b) show the cross-sectional HR-TEM of the $SrTiO_3$/ NiO/Pt and the X-ray diffraction spectrum of 30nm-thick NiO films grown on different substrates, indicating epitaxially growth of NiO on $SrTiO_3$ and different crystallographic structures of NiO are successfully obtained. Figure 2 shows the strong crystallographic structure dependent switching behavior for NiO/Pt deposited on four different substrates, which reflected in the aspects of critical and degenerative J_C as well as ΔR_H. Both the crystallographic structure of NiO and the thermal conductivity of substrates can be responsible to the observations. The inset shows the writing and probing

geometry, two orthogonal writing pulses will switch the transvers resistance to different state. Furthermore, electron energy loss spectrum mapping reveals that the redistribution of oxygen in NiO after electrical switching which could be in strong correlation with the current-induced switching of antiferromagnetic insulator. Our works provide a vital way to tune critical switching current density and enhance switching amplitude in insulating antiferromagnet/Platinum bilayer.

CP-09. Magneto-optical Kerr Spectroscopy of Mn_3AN Non-collinear Antiferromagnetic Thin Films. *K. Krizanova*[3], L. Beran[3], J. Zázvorka[3], F. Johnson[2], D. Boldrin[2], A. Mihai[2], B. Zou[2], L. Cohen[2], M. Veis[3] and J. Zemen[1] *1. Czech Technical University, Prague, Czechia; 2. Imperial College London, London, United Kingdom; 3. Charles University, Prague, Czechia*

Mn_3NiN and Mn_3GaN belong to a family of Mn-based antiperovsktie nitrides with general formula Mn_3AN. In the bulk form, this class of materials has attracted much interest due to phenomena such as temperature independent resistivity, abnormal thermal expansion, or barocaloric effects [1, 2] in the last decade. Here we focus on thin films which have shown potential for spintronic applications very recently, e.g., Piezomagnetic effect [3] and Anomalous Hall Effect [4] have been demonstrated on various perovskite oxide substrates. So far there has been one observation of MOKE in the Mn_3AN family [5]. However, the agreement with the available simulated MOKE spectra [6] is relatively poor, possibly due to an intentional N-deficiency in the Mn_3GaN1-x film [5]. We present magneto-optical spectra of Mn_3AN (A= Ni, Ga) thin films on substrates with different lattice parameters (BTO, STO, LSAT) which induce various strain. The samples were grown by pulsed laser deposition. The magneto-optical spectra were measured by rotating analyzer method in the spectral range from 1.5 to 4.5 eV. The samples were cooled down in in-plane field of 0.9 T from the paramagnetic state across the Neel temperature for each polarity of the magnetic field. The Kerr rotation spectra were obtained by the subtraction of the spectra at each polarity. Figure 1 shows a comparison of measured (solid lines) and simulated (dashed lines) spectra in stoichiometric Mn_3NiN thin films on BTO with strain, e_{xx}~ 0.1%, due to lattice mismatch with substrate. Our simulations rely on the Projector-Augmented Wave method (PAW) and linear response theory as implemented in the VASP code [7]. They assume the triangular G^{4g} and canted triangular states are assumed in the simulations for cubic and strained lattices ($|e_{xx}|> 0$), respectively. We observe semi-quantitative agreement of our measured and simulated spectra. Moreover, the amplitude of the measured spectrum is an order of magnitude larger than MOKE measured in hexagonal Mn_3Sn [8]. It is also in agreement with predictions of ref. [6].

CP-10. Modification of Antiferromagnetic State by Spin-Orbit Torque. J. Wu[1], *C. Yang*[1] and C. Lai[1] *1. National Tsing Hua University, Hsing Chu, Taiwan*

The spin-orbit torque (SOT) device with an orthorhombic current/in-plane magnetization geometry has demonstrated its potential on the deterministic switching dynamics and low-power consumption [1]. In this work, we exhibit the field-free SOT switching in a PtMn/CoFeB bilayer studied by using a magnetic force microscope (MFM) and magneto-optical Kerr magnetometer (MOKE). PtMn is an antiferromagnet with considerable spin Hall effect as typical heavy metals, which is capable of triggering the magnetization switching of adjacent CoFeB with a critical current density of 3.9×10^7 A/cm^2. Fig. 1(a) and 1(b) show the MFM images of the two magnetic states driven by pulse current upward and downward, leading to magnetization leftward and rightward, respectively. Furthermore, in Fig. 1(c) the hysteresis loops acquired from the two magnetic states show a clear variation on exchange bias (±160 Oe), suggesting the spin configuration at the PtMn/CoFeB interface can be modified by the spin Hall effect from PtMn itself. The SOT-driven field-free switching captured by exchange bias offers a novel approach for exploring the AFM state modification in FM/AFM bilayer.

CP-11. Tunable Magnetic-Phase Order and Magnetic Anisotropy in FeRh Multilayers: First-Principles Prediction. *D. Odkhuu*[1,2] *1. Department of Physics, Incheon National University, Incheon, The Republic of Korea; 2. Institute of Physics and Technology, Mongolian Academy of Sciences, Ulaanbaatar, Mongolia*

Phenomena originating from spin-orbit interaction such as magnetic anisotropy, Rashba-type interactions, or topological insulators have drawn huge attention for its intriguing physics as well as possibilities for applications. In particular, modern spintronics relies on perpendicular magnetic anisotropy (PMA) and its switchable feature in an antiferromagnetic material. In this presentation, we will report results of our recent first-principles calculations on viable routes by applying electric-field and strain effects that can lead to tunable magnetic-phase order and magnetization direction in recently proposed antiferromagnet-based magnetic tunnel junctions, including FeRh films on MgO(001) and $BaTiO_3$(001) substrates. We will also discuss on the tremendous effects of heavy transition-metal (HTM) contact layers on the magnetic-phase transition from an antiferromagnetic to a ferromagnetic order and large PMA found in HTM/FeRh/MgO and HTM/FeRh/$BaTiO_3$ multilayers.

CP-12. Anomalous Hall effect in antiferromagnetic antiperovskite $Mn_3Ni_{1-x}Cu_xN$ films. *T. Hajiri*[1], K. Zhao[2], R. Miki[1], H. Chen[3], P. Gegenwart[2] and H. Asano[1] *1. Nagoya University, Nagoya, Japan; 2. Augsburg University, Augsburg, Germany; 3. Colorado State University, Fort Collins, CO, United States*

Antiferromagnet (AFM) spintronics is an emergent field of research because AFMs have a great potential to take the place of ferromagnets [1]. However, since the AFM spins align alternating directions of magnetic moments on individual atoms, the resulting zero net magnetization makes hard to detect AFM ordering electrically. Although it is well known that the anomalous Hall effect (AHE) in conventional ferromagnet is proportional to the net magnetization, the large AHE is realized in noncollinear antiferromagnet Mn_3X (X = Sn, Ge, Pt) [2, 3, 4]. The symmetry analysis expects that antiperovskite nitride Mn_3AN can exhibit large AHE [5], and recently, we realize AHE in polycrystalline sintered pieces and epitaxial thin films of $Mn_3Ni_{1-x}Cu_xN$ [6]. In this presentation, we report the thin film growth and AHE of antiferromagnetic $Mn_3Ni_{1-x}Cu_xN$ films. Figure 1 shows the out-of-plane magnetic hysteresis loops of $Mn_3Ni_{0.35}Cu_{0.65}N$ films on MgO(111) substrate. A weak remnant magnetization is clearly observed with the saturation magnetization of ~0.003 μB/Mn above 50 K and 0.01 μB/Mn at 2 K. Figure 2 shows AHE measurements results of $Mn_3Ni_{0.35}Cu_{0.65}N$ films on MgO (111) substrate. The clear AHE signal is obtained below 180 K. Both magnetization and AHE exhibit similar coercive field, indicate that the obtained AHE is directly related to the noncollinear AFM order. The normalized anomalous Hall conductivity by the magnetization exceeds 6000 (Ω●cm●μB/Mn)$^{-1}$ at 50K, which is much larger than that of typical ferromagnet Fe of 135 (Ω●cm●μB/Fe)$^{-1}$. From the symmetry analysis based on noncollinear Γ_{4g} magnetic order, the obtained AHE can be explained by the non-vanishing Berry curvature in momentum space.

CP-13. Spin Transport Properties in Antiferromagnetic $L1_2$-ordered Mn_3Ir Thin Films. *H. Iwaki*[1], T. Moriyama[1], T. Ikebuchi[1], K. Oda[1], Y. Shiota[1] and T. Ono[1] *1. Institute for Chemical Research, Kyoto University, Uji, Japan*

There is a growing interest in spin dependent transport due to the Berry-phase and topological effect often manifested by the anomalous Hall effect (AHE). The magnitude of the AHE has been phenomenologically believed to be proportional to the magnitude of the spontaneous magnetization. However, since the intrinsic AHE emerges due to the interplay between the Berry curvature and the spin-orbit coupling, the spontaneous magnetization is not always necessary to show AHE. One example is the antiferromagnetic Mn_3Sn with a chiral Kagome lattice [1]. While it has negligibly small net magnetization, a sizable AHE has been observed due to the Berry curvature associated with the chiral magnetic structure. Similar giant AHE has been predicted for the Mn_3X family (X = Sn, Ge, Ir, Pt, etc.) [2,3]. In this work, we investigated AHE in $L1_2$-ordered Mn_3Ir. We prepared thin films with the structure: MgO(100) substrate / Mn_3Ir (20nm) / SiO_2(5nm). The Mn_3Ir layer was grown at various substrate temperatures (T_s = 300°C ~ 600°C) to promote the epitaxy as well as the intermetallic ordering. X-ray diffraction (XRD) shows a superlattice (100) peak for the sample grown at T_s > 400°C indicating that the $L1_2$ ordering is established (Fig. 1.). Hall

resistances (R_{Hall}) of each sample were measured with a Hall cross structure using a physical-property measurement system (PPMS) with the magnetic field applied perpendicular to the sample plane. R_{Hall} of the ordered samples varies nonlinearly with respect to the field B and draws a hysteresis curve (Fig. 2.) which is akin to the AHE behavior. In the presentation, we will discuss in more detail the correlation between the $L1_2$-ordering and the AHE-like behavior.

CP-14. Crystal orientation dependence of the spin current transmission in single crystalline NiO thin films. *T. Ikebuchi*[1], T. Moriyama[1], K. Oda[1], H. Iwaki[1] and T. Ono[1] *1. ICR, Kyoto University, Uji, Japan*

Spin current transmission in antiferromagnetic materials is one of the intriguing phenomena in the emerging antiferromagnetic spintronics [1]. We previously investigated the spin current transmission in a polycrystalline NiO by means of the spin pumping effect and estimated the spin propagation length λ_{NiO} to be 22±3 nm [2]. In this work, we prepared single crystalline NiO thin films with various crystal orientations and investigated the crystal orientation dependence of the spin current transmission. NiO (t_{NiO}) / $Fe_{20}Ni_{80}$ (5) / SiO_2 (5) (unit: nm) multilayers were deposited on an Al_2O_3 (0001) and a MgO (001) substrate by magnetron sputtering. From the XRD and RHEED images, the NiO films were found to be epitaxially grown with (111) and (001) orientation on the Al_2O_3 (0001) and the MgO (001) substrates, respectively. Ferromagnetic resonance (FMR) measurements were performed by the homodyne detection technique [3]. FMR spectra were taken at room temperature by sweeping an external field with a fixed frequency. The Glibert damping constant α is estimated from the FMR spectra. We focus on the enhancement of α due to the spin pumping effect with respect to the NiO thickness, which reflects the spin transmission in NiO [2]. α is plotted as a function of NiO thickness (Fig. 1) for (111) and (001) epitaxially grown NiO films. The asymptotic fitting based on the spin pumping model [4] results in λ_{NiO}=68±10 nm for the NiO (111). On the other hand, for NiO (001), α does not change much in the measured thickness range, which may suggest λ_{NiO} could be gigantic. Furthermore, in order to assure that spin current passed through the NiO layer, the enhancement of α in Pt/NiO/Py trilayer thin films was also investigated. The details will be discussed in the talk.

CP-15. Spin transport across antiferromagnent in an ferromagnent/ antiferromagnet/heavy metal trilayer device. *P. Lin*[1], B. Yang[1], P. Lee[1] and C. Lai[1] *1. Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan*

Antiferromagnent (AFM) now become a promising candiate in spintronics research. Here, we study the interaction between spin current and antiferromagnent. The spin diffusion length of metallic antiferromagnent is around 2 nm[1]. However, there is a recent report demonstrating that the spin current can penerate the 12 nm metallic FeMn[2]. The magnon transportation for this thicker region is proposed. In this study, we use ferromagnent (FM) with perpendicular magnetic anisotropy (PMA) for it can achieve higher density, switching speed and thermal stability in futue application[3]. Also, the spin-orbit torque (SOT) switching is performed to probe the spin current transportation. The [Co/Ni] multilayers/FeMn t_{FeMn}/Pt 5 (unit:nm) trylayer structure is fabricated by magnetron sputtering. The FeMn thickness (t) is varied from 0 to 14 nm. Surprisingly, the FM switching is observed through all the FeMn thickness. Fig. 1a exhibits the swiching for t_{FeMn} = 14nm under in-plane magnetic field (Hx) = 300 Oe. Besides the FM swiching, the exchange bias switching is also observed as shown in fig. 1b, c.[4] This shows an unexpected result that the SOT switching could still take place with inserting an thick AFM between [Co/Ni] multilayers and Pt. The magnon transpotation across thick FeMn is a possible explanantion. In summary, by demonstrated the spin-orbit switching in FM/AFM/Pt structure, we provide another mean to study the spin transpotation in AFM.

CP-16. Fabrication of Antiferromagnetic Mn_3Sn Epitaxial Thin Films and Anomalous Hall Effect in Them. *T. Ikeda*[1], M. Tsunoda[2], M. Oogane[1], S. Oh[3], T. Morita[3] and Y. Ando[1] *1. Department of Applied Physics, Tohoku University, Sendai, Japan; 2. Department of Electronic Engineering, Tohoku University, Sendai, Japan; 3. Institute for Super Materials, ULVAC Inc., Tsukuba, Japan*

In bulk single crystals of antiferromagnetic Mn_3Sn, an anomalous Hall effect (AHE) with significant amplitude as large as ferromagnetic materials was observed [1]. For applications of this large AHE to practical devices such as MRAMs, researches for growth techniques and characterizations in thin film form are necessary. Previously, we succeeded in fabricating polycrystalline Mn_3Sn thin films on SiO_2 sub. and observed the large AHE in them [2], [3]. However, its magnitude was smaller than bulk's one because of the existence of grains whose orientations do not contribute to the AHE. Therefore, controlling crystal orientation is essential to obtain larger AHE. The purpose of this research is to fabricate Mn_3Sn epitaxial thin films and to evaluate their properties. 50-nm-thick films were deposited on MgO (111) sub. by sputtering at room temperature (R.T.). After the deposition, thermal annealing was performed to promote crystallization. Diffraction peaks originated from Mn_3Sn phase were observed in the XRD profile for the samples annealed at 400°C or higher as shown in Fig. 1. Detailed structural analyses clarified that the Mn_3Sn phase has epitaxial relationship as Mn_3Sn [110](001) // MgO [110](111), meaning successful fabrication of c-plane oriented epitaxial Mn_3Sn thin films. The *MH*-curve exhibited weak ferromagnetic behavior in the c-plane. Saturation magnetization at R.T. was almost same to the bulk's one. On the other hand, it showed linear behavior against applied magnetic field along c-axis, similar to the bulk's response. The Hall curves measured with a field normal to the film plane are shown in Fig. 2. Negligibly small negative AHE was observed in the present epitaxial sample, differently from the previous polycrystalline sample. This behavior is well corresponding to the *MH*-curve response along c-axis as same as the bulk's one. It thus implies that large AHE comparable to the bulk's one will be obtained when the current flows along the thickness direction. Results for the other oriented films will be presented.

CP-17. Gradual phase transition from ferromagnetic tetragonal to antiferromagnetic cubic states in Mn_xGa ($1.8 \leq x \leq 3.0$) thin films. Y. Jang[1], W. Yoo[1], H. Bang[1], C. Kim[1], Y. Lee[2], K. Lee[3] and *M. Jung*[1] *1. Department of Physics, Sogang University, Seoul, The Republic of Korea; 2. Korea Institute of Science and Technology, Seoul, The Republic of Korea; 3. Mainz University, Mainz, Germany*

The $D0_{22}$ tetragonal structure of Mn_3Ga has a ferrimagnetic state with the net magnetization of about 150 emu/cc [1]. The deficiency of manganese introduces vacancies in the Mn I sites, while maintaining the tetragonal crystal structure. The $D0_{22}$ tetragonal phase in Mn_xGa is formed in a wide range of Mn concentration x from 1.8 to 2.9 [2]. In the case of Mn_2Ga, only Mn II atoms are left and aligned ferromagnetically, so that the magnetization increases up to 400 emu/cc [3]. The cubic phase of Mn_3Ga is anticipated to possess collinear antiferromagnetic order and complete spin polarization as one of the key materials to lower energy loss in spintronic device applications. Our preliminary experiments have demonstrated the cubic phase in Mn_3Ga films displays an antiferromagnetic transition at T_N = 400 K [4]. Thus, one can naturally expect the change of magnetic and electronic properties dependent on the crystal structure from tetragonal Mn_2Ga to cubic Mn_3Ga. In this study, we report the systematic results on the phase change from a ferromagnetic tetragonal structure to an antiferromagnetic cubic structure in a wide range of Mn composition ($1.80 \leq x \leq 3.03$) in Mn_xGa thin films. The structural, magnetic, and electronic properties of Mn_xGa thin films are investigated as varying the Mn composition. The variation of x in Mn_xGa films dramatically changes the crystal structure as well as the magnetic properties. With increasing x, we observe the gradual phase

transition from a ferromagnetic tetragonal state to an antiferromagnetic cubic state. The structural characterization reveals that the $D0_{22}$ tetragonal structure of Mn_2Ga is slowly transformed to the $L1_2$ cubic structure of Mn_3Ga. Two phases coexist around $x = 2.4$. The magnetization is systematically reduced as x increases, ending to an antiferromagnetic state of cubic Mn_3Ga, and the electrical resistivity increases with x. Such highly tunable magnetic and electronic properties in Mn_xGa phase simply by the variation of the Mn/Ga ratio provide advantages to be used for spintronic device applications.

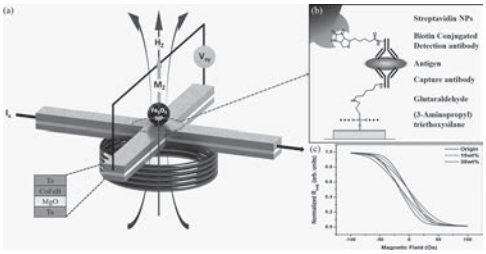
CQ-01. Using repetitive paired-pulse transcranial magnetic stimulation for evaluation of motor cortex excitability. T. Torii[1], A. Sato[1], *M. Iwahashi*[2] and K. Iramina[3] *1. Medical Care and Welfare Engineering, Tokai University, Kumamoto, Japan; 2. Clinical Engineering, Komatsu University, Komatsu, Japan; 3. Graduate School of Sytems Life Sciences, Kyushu University, Fukuoka, Japan*



Transcranial magnetic stimulation (TMS) is a noninvasive human brain stimulation method, in which a magnetic field is used to induce eddy currents in the cortex. TMS has mostly been applied to the treatment of brain or neurological diseases, and studies of brain function. However, there has been relatively little research investigating cortical excitability induced by TMS. Previous studies have used a long duration of magnetic stimulation to evaluate cortical excitability (e.g., 0.1 Hz magnetic stimulation for 15 minutes). The present study examined whether cortical excitability could be evaluated using repetitive paired-pulse TMS for a short duration. The inter-stimulus intervals (ISIs) between the conditioning (first) stimulus and the test (second) stimulus were 1000 ms, 200 ms and 100 ms, and magnetic stimulation intensity was 110% of the resting motor threshold. A total of 20 stimuli were delivered to primary motor cortex using paired-pulse TMS at 10 s intervals. The results revealed no significant correlations between the number of stimulations and average motor-evoked potential (MEP) amplitudes at each ISI. However, weak negative correlations were observed for 200 and 100 ms ISIs. This decreasing tendency indicates a cumulative cortical impact of repetitive paired-pulse TMS with ISIs of 200 and 100 ms. Therefore, repetitive paired-pulse TMS with 200 and 100 ms ISIs may require an interval of 10 s or more to avoid exerting a cumulative impact. In addition, MEP amplitude with an ISI of 200 ms increased in the second stimulation ($p < 0.05$), and MEP amplitude with an ISI of 100 ms decreased dramatically ($p < 0.01$). However, MEP amplitude with a 1000 ms ISI did not change significantly. Previous research suggested that successive stimulation at a frequency of 1 Hz or less inhibited cortical excitability. The current findings suggested that cortical excitability after the first stimulation was facilitated at 200 ms, and inhibited at 100 ms. In contrast, repetitive paired-pulse TMS may appear to not affect the cortex after 1000 ms from first stimulation. Thus, the current findings indicate that repetitive paired-pulse TMS with an ISI of 1000 ms could be used to evaluate cortical excitability.

CQ-02. Immunoassay Using a CoFeB/MgO Perpendicular Magnetic Sensor. *C. Cheng*[1], K. Chang[1], S. Kao[1] and Y. Tseng[1] *1. National Chiao Tung University, Hsinchu, Taiwan*

This work reports on a Hall sensor using CoFeB/MgO perpendicular magnetic structure for immunoassays. Fe_3O_4 nanoparticles (NPs) were used to bind to a biotin-avidin system and conjugated antibody on the sensor surface for antigen capture. The amount of bound NP can quantitatively reflect the antigen concentration by monitoring the R_{AHE}-H (anomalous Hall effect (AHE) resistance vs magnetic field) change of the sensor. This is because the R_{AHE}-H is determined by the stray-field yielded by the attached NPs. The sensor presented reproducible R_{AHE} change with antigen-concentration dependence for H < 100 Oe. This demonstrates the potential of the sensor as an electronic-based immunoassay detector. The sensor's detecting sensitivity was tunable with the interfacial magnetic anisotropy of the state-of-the-art CoFeB/MgO heterostructure [1]. The combination of the CoFeB/MgO stack and a perpendicular magnetic coil is the core of the design, at which the coil is to trigger the NPs' stray field as well as to enable the AHE measurement. COMSOL Multiphysics simulation was combined with experiments to explore the sensor's detection limit. Arduino prototyping platform was employed to test the modularization of the proposed sensor, through which the read-out signal could be magnified by a factor of ten. The proposed sensor may facilitate the idea of digital medicine with spintronic technology.

(a) Illustration for the design and measurement of the proposed Hall bio-sensor. The Hall device is composed of a Ta/CoFeB/MgO/Ta stack. Functionalization is placed at the intersection part of the Hall device, which allows a local binding of Fe_3O_4 NPs. (b) Detail of the functionalization on the sensor surface for biological sensing. 3-Aminopropyl triethoxysilane (APTES) conjugated glutaraldehyde is to bind the antibody, which functionalizes the sensor surface and enables the capture of the antigen. The biotin-conjugated detection antibody binds the antigen to the NPs that are streptavidin-functionalized. (c) R_{AHE} change with various antigen/NP concentrations. Origin refers to the antigen/NP-free condition.

CQ-03. Monophasic pulsed field generation with an optimized switching mechanism. *N. Prabhu Gaunkar*[1], W. Theh[1] and M. Mina[1] *1. Electrical and Computer Engineering, Iowa State University, Ames, IA, United States*

Pulsed magnetic fields play a significant role in the application space of magnetic resonance, medical therapy, and brain stimulation since magnetic moments/neurons produce predictable responses to pulsed fields [1,2]. Specific parameters such as pulsed-field magnitude, frequency and repetition rate, are controlled to observe the different biological phenomena. In essence, all these parameters depend on the pulsed field switching mechanism. Thus, the focus of this work is to evaluate and improve the pulsed field switching process for a monophasic pulsed field generator. The designed pulsed field generator is relevant for low-field magnetic resonance applications. It must be noted that several conventional pulsed field switching

methods exist [3,4] but most of these are designed for high-field systems and aren't directly applicable to low-field applications. In the low-field magnetic resonance application space, localized pulsed fields in the frequency range of 5-10 MHz with fields <0.1 T are used [5]. Switching devices (such as FETs or transistors) are connected to inductive loads to obtain pulsed currents correspondingly leading to the generation of pulsed fields. However, it is observed that the rise time of the switching device affects the pulsed currents and thus lower pulsed fields or delayed responses are obtained [5]. To overcome the impact of the switching rise time on the pulsed fields, simulations were performed to verify rise time minimization techniques such as pre-biasing, charging gate capacitance, and use of gate drivers. Design considerations and improvements presented by these different techniques will be discussed as a part of this work. The design of an improved monophasic pulsed field generator will be presented and compared to prior designs [5,6].

CQ-04. Point-of-care ultrahigh sensitivity magnetic lateral flow assay.
M. Khodadadi[1], J. Trabuco[1], L.V. Chang[1], K. Kourentzi[1], R. Willson[1] and *D. Litvinov*[1] *1. University of Houston, Houston, TX, United States*

Today, many highly quantitative biomarker detection tools for medical diagnostics are readily available in state-of-the-art centralized clinical laboratories. However, there remains a critical need for inexpensive, versatile, and high-sensitivity diagnostic platforms which can bring the performance to the point of care (POC) or doctor's office. Our team has developed an ultrasensitive point of care biosensor based on the miniaturized inductive detector of magnetic reporter nanoparticles (10^{-10} emu detection limit) in a test line of a lateral flow assay (like a pregnancy test). This technology represents a new general biosensor platform that can be broadly useful in various areas of molecular diagnostics, therapy monitoring, biomarker detection, and biomedical research. The biosensor prototype performance was evaluated using a standard hCG model system with well-established LFA immunochemistry based on readily available, well-characterized and inexpensive antibodies. The LFA half-strip was prepared on a nitrocellulose membrane with an absorbent pad. Polyclonal anti-α hCG antibody and anti-mouse antibody (1μg/cm each) were used to functionalize the test and control lines, respectively. hCG model protein was diluted in LFA Buffer and 10 μL of each sample was mixed with 1 μL (~10^8) of conjugated 200nm Adembeads functionalized with mouse monoclonal anti-β hCG and the 3 mm half-strip was dipped in the mixture. The test line and control line on each strip was measured by passing the strip through the femtoMag chip and recording the signal in real-time. For system calibration, each line was cut from the LFA strip to be measured in the AGFM. The Figure compares the test line measurements for an LFA with various concentration of hCG using the biosensor and an AGFM. The number of magnetic nanoparticles reported is estimated from the AGFM measurements using a calibration sample with known amounts of 200 nm Adembeads.

The biosensor (left) and AGFM (right) is used to quantify the number of magnetic nanoparticles immobilized in the test line of an LFA test strip using various concentration of hCG pregnancy hormone. The blank sample (left-most data point) has no hCG and represents the amount of non-specifically bound particles.

CQ-05. Magnetically Activated Cell Capture and Release using Spin Orbit Torque.
V.M. Estrada[1], R. Zheng[1], G. Carman[1] and A. Sepulveda[1] *1. Mechanical and Aerospace Engineering, University of California, Los Angeles, Los Angeles, CA, United States*

Cell sorting has become an indispensable technique for a variety of biological and biomedical applications. With the development of fields such as personalized medicine and new breakthroughs in cancer treatments, more modern cell sorting techniques aimed at addressing the problems at hand are needed now more than ever. Magnetically activated cell sorting (MACS) has quickly become one of the most widely used techniques due to its high performance in throughput, selectivity, and ease of use. Recently, there has been much research and development aimed at creating MACS devices in the microfluidic regime[1]. This is due to the many benefits of using such devices. These benefits include: low cost, the ability to run fast low volume experiments, and the ability to capture and release cells while simultaneously culturing them within a device. In this paper we present a novel method of capturing and releasing magnetically activated cells using spin orbit torque (SOT) to change the magnetization of magnetic films with perpendicular magnetic anisotropy (PMA) placed within a microfluidic device. SOT has been shown to be a reliable method of manipulating the magnetization of magnetic memory devices with PMA[2] and for this reason it was chosen as the method of operation. This device is an improvement on current microfluidic cell sorting approaches due to its simple mechanism and high selectivity. The paper includes both modeling and experimental data to verify the theoretical mechanism proposed.

Microfluidic cell sorting: A review of the advances in the separation of cells from debulking to rare cell isolation. *Lab on a Chip, 15*(5), 1230-1249. doi:10.1039/c4lc01246a [2]Kwak, W., Kwon, J., Grünberg, P., Han, S. H., & Cho, B. K. (2018). Current-induced magnetic switching with spin-orbit torque in an interlayer-coupled junction with a Ta spacer layer. *Scientific Reports, 8*(1). doi:10.1038/s41598-018-22122-1

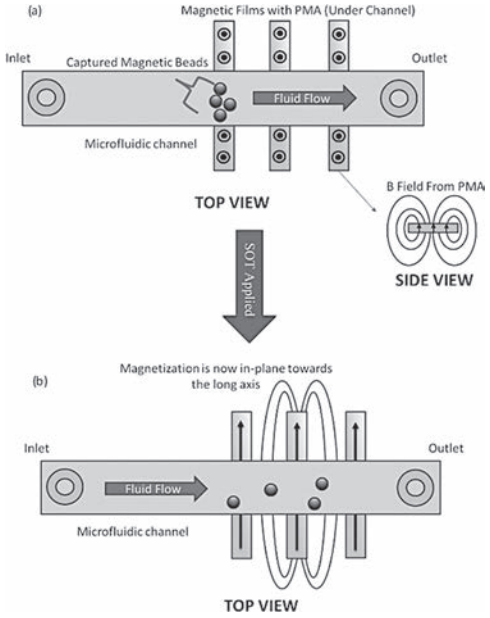

Fig. 1 Schematic of the proposed Device and Operation Principle. (a) The magnetic beads are captured due to a strong magnetic field gradient at the surface of the films due to their PMA. (b) The beads are released due to the drag force of the fluid overcoming the magnetic attraction of the beads to the film. This occurs because the magnetization has changed from out of plane to in-plane. The change in magnetization is performed by running a current that exerts a SOT on the films.

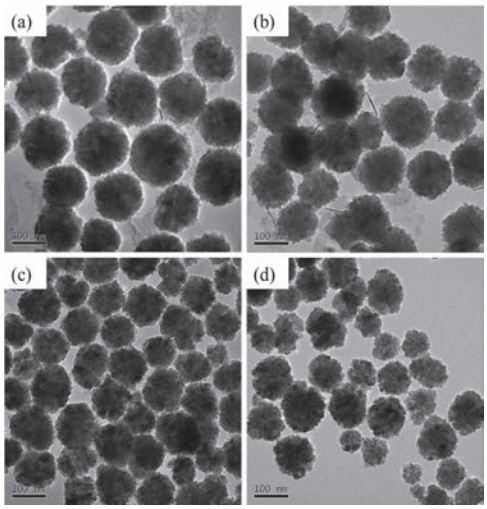
CQ-06. Magnetic Properties and Hyperthermia Behavior of Iron Oxide Nanoparticle Clusters. *S. Pourmiri*[1], V. Tzitzios[2,3], G.C. Hadjipanayis[1], B. Meneses Brassea[4] and A.A. El-Gendy[4] *1. Physics, University of Delaware, Newark, DE, United States; 2. Department of Chemical Engineering, Khalifa University of Science and Technology, Abu Dhabi, United Arab Emirates; 3. NCSR Demokritos, Athens, Greece; 4. Physics, University of Texas at El Paso, El Paso, TX, United States*



Magnetic iron oxide nanoparticles have a great potential for magnetic hyperthermia, due to their low cost, tunable properties, and biocompatibility. In particular, Iron oxide nanoparticle clusters have been found to have higher magnetization and better colloidal stability than individual nanoparticles, making them better suited for magnetic hyperthermia [1]. In this study, Fe_3O_4 nanoparticle clusters have been made from two different sizes of individual nanoparticles. The synthesis was done by adding a CTAB aqua solution to individual Fe_3O_4 nanoparticles, which were mixed in chloroform. It has been observed that the time, temperature and CTAB concentration were the three important factors for controlling the size, shape and collective behavior of the clusters. The impact of each of these three factors on the aggregation behavior of clusters has been studied. Powder XRD studies shows that the clusters have the Fe_3O_4 phase. Dynamic Light Scattering (DLS) shows that the clusters can have a hydrodynamic diameter in the range of 100 to 200 nm. The growth of nanoparticle clusters has been studied by TEM measurements and is in a good agreement with the DLS values. Magnetic measurements show that saturation magnetization of clusters can be changed from 52 emu/g to 68 emu/g by just changing the size of individual particles from 7 nm to 11 nm. Also, the blocking temperature for Fe_3O_4 clusters was increased from 250 K to 300 K which confirms the stronger collective behavior in the case of bigger nanoparticles. The magnetic hyperthermia behavior of the clusters is studied, and it is seen that by increasing the size of nanoparticles, the SAR value for clusters was increased from 14 W/g to 67 W/g.

CQ-07. Investigations of the effective parameters on the synthesis of monodispersed magnetic Fe_3O_4 by solvothermal method for biomedical applications. G.C. Hermosa[1], W. Chen[1], H. Wu[1], C. Liao[1], S. Wang[2], Y. Chen[1,3], C. Koh[3] and *A. Sun*[1] *1. Department of Chemical Engineering and Materials Science, Yuan Ze University, Taoyuan, Taiwan; 2. Department of Materials and Mineral Resources Engineering, National Taipei University of Technology, Taipei, Taiwan; 3. Department of Surgery, Far Eastern Memorial Hospital, New Taipei, Taiwan*

Iron oxide nanoparticles, such as magnetite (Fe_3O_4) is by far the most commonly employed in different fields in particular in biomedical applications. These nanoparticles are especially interesting, because of their excellent chemical stability, low toxicity, readily accessibility, high coercivity and inexpensiveness, which makes it a promising material. All these technological and medical applications require that the nanoparticles are superparamagnetic with smaller sizes and the overall particle size distribution is narrow so that the particles have uniform physical and chemical properties. To apply superparamagnetic nanoparticles for biomedical applications, the nanoparticles should be monodispersed for controlled biodistribution and contrast effects. Therefore, much effort has focused on the development of Fe_3O_4. The solvothermal process is one of the successful methods to obtain Fe_3O_4 fine particles with highly uniform sizes, hydrophilic surface and aqueous dispersibility. These characteristics can be altered by changing certain experimental parameters, including water and stabilizing agent amount and pH. In this study, monodispersed magnetite nanoparticles were obtained by investigating the different synthesis parameters of the solvothermal method. The morphology and chemical structure of the Fe_3O_4 nanoparticles were characterized by FT-IR, XRD, SEM, TEM, DLS and VSM. Results indicated that the without the addition of water as it forms the minor phase of iron instead of magnetite. Furthermore, the size of nanoparticles is tunable in the range of 50 to 150 nm by changing the amounts of water, PSSMA and NaOH. The amount of PSSMA restricts the growth of the nanoparticles and narrow the size distribution and a hydrophilic surface was obtained. Synthesized magnetite nanoparticles were successfully conjugated with carbon dots for bio-imaging application. The resulting nanoparticles exhibited good fluorescence characteristics. Cytotoxicity tests confirmed that nanoparticles are non-toxic. The synthesized monodispersed magnetite nanoparticles are good potential candidates for biomedical applications in the future.

Magnetic beads have gained great interest in recent years for use in biomedical applications such as microorganism detection, hyperthermia therapy, and drug delivery. Currently, ac susceptibility, magnetic relaxation, and remanence-based methods have been developed for microorganism detection by measuring the magnetic field from magnetic nanoparticles bound to microorganisms via detecting antibodies [1]. In this study, we evaluated a simple and rapid detection system of oral bacteria in liquid phase for point-of-care diagnostics using magnetic nanoparticles. We focused on the response of nanoparticles to applied switching magnetic field, i.e. the magnetic moments of the nanoparticles without the bacteria can be easily reversed by switching magnetic field compared to the nanoparticles with the bacteria [2]. Figure 1 shows schematic diagram of laboratory-made system. The system consists of a giant magneto-impedance (GMI) sensor, driving coil (3000 turns), NdFeB magnet (5 mm x 4 mm x 3 mm) and rotor. Firstly, the cultured bacteria sample using magnetic nanoparticles of 500 nm in diameter was magnetized by the NdFeB magnet for 600 sec. Next, a switching magnetic field was applied to the sample for 30 sec by driving coil, then the sample rotated slowly close to the GMI sensor and the magnetic field from magnetic nanoparticles was measured by the sensor. The strength and direction of switching magnetic field were changed to evaluate the response of nanoparticles. Figure 2 shows the relationship of the output signal from the sensor and the number of bacteria with *Porphyromonas gingivalis* and *Pseudomonas aeruginosa* cultured. The results show that the output signal to the switching magnetic field became larger as the number of bacteria increased. Furthermore, it was possible to detect the bacteria in liquid phase with the concentration below 10^5 CFU/ml, which was the same sensitivity as other microbial sensors currently used in point-of-care diagnostics.

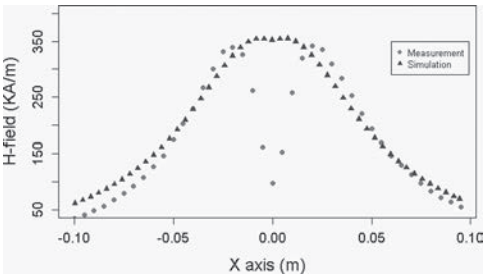
CQ-09. Magnetic Characterization Change by Solvents of Magnetic Nanoparticles in Liquid-phase Magnetic Immunoassay.
K. Jinno[1], B. Hiramatsu[1], K. Tsunashima[1], K. Fujimoto[1], K. Sakai[1], T. Kiwa[1] and K. Tsukada[1] *1. Graduate School of Interdisciplinary Science and Engineering in Health Systems, Okayama University, Okayama, Japan*

Magnetic nano-particles (MNPs) have been studied for medical diagnostic purposes—as the imaging agents of MRI, hyperthermia, and drag delivery. Among them, a highly sensitive magnetic immunoassay (MIA) has been developed. The MIA generally uses polymer-coated MNP beads, on the surface of which antibodies are immobilized to detect conjugation with antigens. Conventional immunoassays need to be washed to remove unbounded antibodies from solutions; however, the MIA can estimate the number of conjugated antibodies without being washed because the AC magnetic properties of MNP beads vary when the antibodies are bounded with antigens. Thus, we studied the AC magnetic properties of MNPs under various conditions and substances using a developed MNP measurement system. Variations in the AC magnetic properties are observed owing to variations in the volume, which results in the moment of rotation of beads by conjugation; therefore, the viscosity of the sample solution is considered to affect the AC magnetic properties. Our study revealed that the MNP beads in the serum solution exhibited AC magnetic properties different from those of MNP beads in the buffer solution though the viscosity of the solution was similar. To investigate the influence of serum on the AC magnetic properties, the concentration dependence of sodium chloride in the solution was first measured, because the sodium (Na^+) and chloride (Cl^-) ions in the serum dominate the ion balance of the serum. Resovist was used as MNPs, and susceptibility as a function of the concentration of Na^+ was measure. The results show that the magnetic properties depend on the concentration of Na^+ in the solution as well as the difference in viscosities. We conclude that this dependence was caused by the aggregation of MNPs by shielding the surface charge of the MNPs by ions, which was supported by our AC susceptibility and light scattering measurements for the same MNPs solutions. In this study, we have also evaluated the difference in magnetic properties for different substances as well as different coating and sizes of MNPs. Evidently, the optimization of substances is required for applying the MIA to practical medical diagnosis.

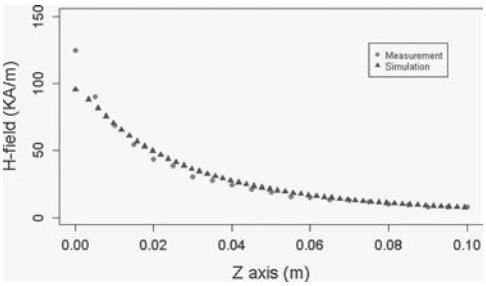
CQ-10. Superparamagnetic gold coated iron nanoparticles for hyperthermia treatment of cancer. M. Sanad[1], B. Meneses Brassea[1], S. Pourmiri[2], G.C. Hadjipanayis[2] and *A.A. El-Gendy*[1] *1. Physics, University of Texas at El Paso, El Paso, TX, United States; 2. Physics and Astronomy, University of Delaware, Newark, DE, United States*

Core/shell iron/gold nanoparticles have been synthesized using wet chemical method. The synthesis conditions have been tailored to obtain monodispersed, biocompatible and high magnetic properties that needed for efficient hyperthermia. The morphology and crystal structure of the prepared core/shell samples have been characterized using SEM, TEM and XRD. The data yielded spherical like shape and identical core/shell morphology with average sizes of 10, 20, 40 nm with FCC structure for iron core and cubic structure for gold shells. The magnetization dependence on external magnetic field exhibited superparamagnetic behavior with saturation magnetization (MS) of 168, 150, and 135 emu/g for sizes of 10, 20, 40 nm respectively. Feasibility of hyperthermia has been measured for particles solution of 5mg/ml under different applied magnetic field and frequencies in the range of 100-500 Oe and 144-304 kHz respectively. The particles showed good dispersion in water and observable increase in the heating rate and the heating power or specific absorption rate (SAR) ranging from 1.5-3.5 C/min and of 20-150 W/g respectively. The data reveal the potential of Fe@Au superparamagnetic nanoparticles for hyperthermia treatment of cancer.



CQ-11. Self-regulating magnetic hyperthermia (SrMH) of Ni_xCu_{1-x} nanoparticles. B. Meneses Brassea[1], S. Pourmiri[2], M. Sanad[1], M. Ortega[1], G.C. Hadjipanayis[2] and *A.A. El-Gendy*[1] *1. Physics, University of Texas at El Paso, El Paso, TX, United States; 2. Physics and Astronomy, University of Delaware, Newark, DE, United States*

NixCu1-x (x=0.2-0.5) nanoparticles have been synthesized with a proper size distribution by reducing a Ni and Cu from metal precursor's using sol-gel route followed by annealing at different temperatures. These particles have been synthesized to be used for controlled self-regulating magnetic hyperthermia applications (SrMH). We have investigated the morphology and crystal structure of the particles revealing spherical shape with average size ranging from 20-50 nm and FCC cubic structure for different compositions of NixCu1-x alloy. The magnetic properties exhibited ferromagnetic behavior with saturation magnetization (MS) ranging from 8-20 emu/g at 300 K and Curie temperature ranging from 42-45°C within the limit of the therapeutic temperature range of 42-46°C. The feasibility of hyperthermia has been performed under the therapeutic limits of alternating magnetic field and frequency. The samples exhibited heating rate and a significant dissipated heating power or measured as specific absorption rate (SAR) ranging from 0.1-1.6 C/min and 20-100 W/g, respectively. The dissipated heating power of the samples saturated after reaching their Curie temperature at 42-45°C revealing their feasibility for self-regulation hyperthermia.



CQ-12. Testing of the prototype of a novel TMS coil with improved focality: Quadruple Butterfly Coil. *X. Zhong*[1], P. Rastogi[1], Y. Tang[1] and D.C. Jiles[1] *1. Electrical and Computer Engineering, Iowa State University, Ames, IA, United States*

Transcranial magnetic stimulation (TMS) is a non-invasive neuromodulation technique that is used or investigated for various neurological disorders such as major depressive disorder, Parkinson's disease, and obsessive compulsive disorder. The design of TMS coil has always been a popular topic in TMS studies as the coil geometry can affect the distribution of induced electric field significantly. A novel coil called Quadruple Butterfly Coil (QBC) has been introduced to improve the focality of stimulation [1]. Recently the prototype of QBC has been fabricated by Jali Medicals which gives us the opportunity to test the validation of this prototype as well as the computational simulation results. A Hall probe and a gaussmeter were used to measure the actual magnetic field strength provided by the prototype of QBC. Measurements were taken along two directions, one is along x axis going through from the center to the end of the two windings of QBC, the other is along z axis moving away from the surface of QBC perpendicularly. The results for the two directions are shown in Figure 2 and 3 from which we can see a good match between the measurements and the simulation results. Therefore, the QBC prototype has shown its success and in turn validate the computational simulations.

CQ-13. A Highly Tunable Skyrmion-based Neurostimulator (SkyNS) for Low-Power Cellular-Level Implantable Magnetic Stimulation. *R. Saha*[1], K. Wu[1], D. Su[2] and J. Wang[1] *1. Electrical & Computer Engineering, University of Minnesota, Minneapolis, MN, United States; 2. Chemical Engineering and Material Science, University of Minnesota, Minneapolis, MN, United States*

Bonmassar *et. al* [1] had explored the possibility of implantable micromagnetic stimulation (μMS) by using commercially available sub-mm sized microcoils to stimulate deep target neuronal tissues. Magnetic field can permeate deep through the biological tissues and the induced electric field from the magnetic neurostimulators are spatially asymmetric, thereby supporting selective activation of neurons [2]. This gives implantable μMS an added edge over deep brain stimulation (DBS) or transcranial magnetic stimulation (TMS). Nevertheless, μMS has been reported to consume 10^3 times greater energy than conventional DBS electrodes which causes detrimental thermal effects on tissues [3]. Here, we propose SkyNS [4], a skyrmion-based neurostimulator of dimension 500 nm × 200 nm × 1 nm with a barrier of higher perpendicular magnetic anisotropy (PMA) situated at the center that operates on a current of 2.71 μA and consumes a power of 1.434 nW. On solving the Landau–Lifshitz–Gilbert (LLG) equation, it was studied that the displacement of magnetic skyrmions in a heavy metal/ferromagnetic metal (HM/FM) bilayer generates a time varying magnetic field (see Fig. 1) which according to Faraday's Law of Electromagnetic Induction, induces an electric field (see Fig. 2) large enough to trigger neuron stimulation. Magnetic material properties including Dzyaloshinskii-Moriya interaction (DMI), PMA of barrier and surrounding thin film and device dimensions on stable skyrmion nucleation and smooth skyrmion dynamics have been extensively tuned to meet the therapeutic specifications for cellular-level neurostimulation. This work provides another proof-of-concept to exploit our proposed spintronic neurostimulators [5,6,7,8] as ultra-low power, implantable magnetic nanostimulators.

CQ-14. Magnetic Nanoparticle Relaxation Dynamics-Based Magnetic Particle Spectroscopy for Rapid and Wash-Free Molecular Sensing.

K. Wu[1], J. Liu[1], D. Su[2], R. Saha[1] and J. Wang[1] *1. Department of Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States; 2. Department of Chemical Engineering and Material Science, University of Minnesota, Minneapolis, MN, United States*

Magnetic nanoparticles (MNPs) have been extensively used as contrasts and tracers for bioimaging, heating sources for tumor therapy, carriers for controlled drug delivery, and labels for magnetic immunoassays. Here, we describe a MNP Brownian relaxation dynamics-based magnetic particle spectroscopy (MPS) method for the quantitative detection of molecular biomarkers. In MPS measurements, the harmonics of oscillating MNPs are recorded and used as a metric for the freedom of rotational motion, which indicates the bound states of the MNPs. These harmonics can be collected from microgram quantities of iron oxide nanoparticles within 10 seconds. Since the harmonics are largely dependent on the quantity of the MNPs in the sample, the MPS bioassay results could be biased by the deviations of MNP quantities in each sample, especially for the very low concentration biomarker detection scenarios. On the other hand, the ratios of the 3rd to the 5th harmonics (R35) at different drive field frequencies have also been used as a MNP quantity-independent metric for characterizing the biomarker concentrations/quantities from samples. Fig. 1 summarizes the harmonic ratios, R35, from six samples as we vary the drive field frequency from 500 Hz to 20 kHz. The harmonic ratios R35 increases as the concentrations/quantities of streptavidin increases. Herein, we report three MNP concentration/quantity-independent metrics for characterizing the bound states of MNPs in MPS. Using a streptavidin-biotin binding system as a model, we demonstrate the feasibility of using MPS and MNP concentration/quantity-independent metrics to sense these molecular interactions, showing this method can achieve rapid, wash-free bioassays, and is suitable for future point-of-care (POC), sensitive, and versatile diagnosis [1].

CR-01. Dynamic magnetic property in Pt/Co/Cr_2O_3/Pt stack films with perpendicular magnetic anisotropy. *T. Nguyen*[1,2], Y. Shiratsuchi[3], H. Sato[4,1], S. Ikeda[4,1], T. Endoh[4,1] and Y. Endo[5,1] *1. Center for Science and Innovation in Spintronics, Tohoku University, Sendai, Japan; 2. Center for Spintronics Research Network, Tohoku University, Sendai, Japan; 3. Graduate School of Engineering, Osaka University, Suita, Japan; 4. Center for Innovative Integrated Electronic Systems, Tohoku University, Sendai, Japan; 5. Graduate School of Engineering, Tohoku University, Sendai, Japan*

Ferromagnetic (FM)/non-magnetic (NM) stack films with perpendicular magnetic anisotropy (PMA) are of increasing interest in spintronics devices with various enriched functionalities [1]. To realize these devices, understanding their dynamic magnetic properties such as the Gilbert damping constant (α) is one of the most important requests. Until now, the relationship between PMA and α for these films was reported, and the results were, however, dispersed among the variation of layered structure [2,3]. Herein, we choose the perpendicularly magnetized Pt/Co/Cr_2O_3/Pt stack films, where Cr_2O_3 is insulating at room temperature with a weak spin-orbit coupling, which enabled us to focus on the dynamic magnetic properties at the Pt/Co interface. Then, we investigate the change in PMA and α with the thickness of Co (t_{Co}) and Pt (t_{Pt}) layers, and discuss their correlation in these stack films. The changes in the perpendicular magnetic anisotropy energy density (K_U) and α of Pt(t_{Pt})/Co(t_{Co})/Cr_2O_3(200 nm)/Pt stacks with t_{Co} and t_{Pt} are shown in Fig. 1 (a) and (b), respectively. In case of the fixed t_{Pt} = 3 nm, K_U decreases as t_{Co} increases except for 0.9 nm. α linearly decreases with the increase of t_{Co} up to 0.9 nm, and saturates for t_{Co} above 0.9 nm. On the other hand, in case of the fixed t_{Co} = 1 nm, as t_{Pt} increases, K_U increases for t_{Pt} below 5 nm, keeps constant for 5 nm ≤ t_{Pt} ≤ 10 nm, again increases for t_{Pt} up to 15 nm, and then saturates for t_{Pt} above 15 nm. α increases as t_{Pt} increases and saturates as t_{Pt} excesses 5 nm. Thus, each behavior of α in the range of thinner t_{Co} (≤0.8nm) and t_{Pt} (≤10nm) is very similar to those of K_U, implying that α is correlated with K_u in these stack films. Therefore, these results reveal that the origin of α is mainly derived from the spin-orbital coupling (SOC) and α value depends on the strength of SOC [4]. In addition, these results could suggest the non-negligible role of the spin-diffusion in the Pt capping layer [5]. CR-02. Optically Detected Spectroscopy of Magnons Generated in Nonlinear Ferromagnetic Resonance using NV Centers in Diamond. *B. McCullian*[1], A. Thabt[1], B.A. Gray[2], M.S. Wolf[2], A.S. Ahmed[1], V.P. Bhallamudi[3], D.V. Pelekhov[1], M.R. Page[2] and P.C. Hammel[1] *1. Physics, Ohio State University, Columbus, OH, United States; 2. Materials and Manufacturing Directorate, Air Force Research Laboratory, Dayton, OH, United States; 3. Department of Physics, Indian Institute of Technology Madras, Madras, India*

We have used nitrogen-vacancy (NV) centers in diamond to optically detect and spectroscopically map magnons generated in the nonlinear regime of ferromagnetic resonance (FMR) in thin films of low damping NiZnAl ferrite, a material which shows promise for voltage control of magnetization [1]. The spin-state dependence of fluorescence intensity in NV centers enables sensitive optical detection of fluctuating magnetic fields at NV spin transition frequencies which are in the few-GHz range. Applied to ferromagnetic dynamics, this has enabled local, off-resonant spectroscopy of driven uniform-mode FMR [1-3] by monitoring the field-noise associated with NV-resonant magnons generated by the FMR damping process. The low damping of NiZnAl allows us to increase microwave power and drive into the nonlinear FMR regime. NV measurements at high microwave power show very small NV-resonant magnon population at the uniform mode FMR condition, and instead a large occupation of NV-resonant magnons at the field and frequency of the broadened FMR shoulder. To rule out possible heating and very large cone angle effects, we perform stripline FMR at various temperatures, microwave powers, microwave duty cycles, and static magnetic field sweep rates [4-6]. We attribute both the broadened FMR line and the strong generation of magnons at the FMR shoulder to a spinwave instability process. This direct probe of magnons enables study of nonlinear FMR behavior that may have important implications for magnetic switching in memory applications.

Co/Ni multilayers have been known to exhibit large and tunable perpendicular magnetic anisotropy (PMA) [1] and relatively low intrinsic damping [2]. In this study we investigated a series of Pt/(Co/Ni)xN/Ir multilayers grown on Si/SiO2 with a Ta adhesion layer and Pt/Ta capping layer. Using broadband ferromagnetic resonance (FMR) and elevation angle dependent measurements, we find the presence of a strong fourth-order contribution to the perpendicular anisotropy. We are able to fit the elevation angle resonance field data and extract both the second and fourth-order anisotropy constants (shown in Fig 1) by using the Smit-Beljers relation [3]. Using the frequency dependence data of the linewidth, we are able to determine the effective Gilbert damping parameter. The effective Gilbert damping increases linearly with the inverse thicknesses of the multilayer, indicating an interfacial contribution to the damping process as shown in Fig 2. We find the spin-mixing conductance to be $g_{\uparrow\downarrow,eff} = (3.1 \pm 0.1) \times 10^{19}$ m^{-2}. Acknowledgements: DARPA TEE: D18AP00011 & NSF-CAREER #1452670

CR-04. Non-electronic Contributions to Thermal Conductivity in a Low-Damping Ferromagnetic Metal. *M.R. Natale*[1], D.J. Wesenberg[1], E. Edwards[2], J.M. Shaw[2] and B.L. Zink[1] *1. Physics & Astronomy, University of Denver, Denver, CO, United States; 2. NIST, Boulder, CO, United States*

Low Gilbert damping materials have many potential applications in the field of spintronics and spincaloritronics. While low-damping magnetic insulators have been studied for decades, recent work has shown that carefully engineered metals can achieve similarly low damping parameter [1]. Low damping suggests that spin waves could contribute to heat transport in such metals[2], though this has yet to be conclusively shown[3]. Here we use suspended Si-N thermal isolation platforms to address this issue by careful examination of the Wiedemann-Franz law in two compositions of Co-Fe alloys, $Co_{25}Fe_{75}$(CoFe-A) and $Co_{50}Fe_{50}$ (CoFe-B). This allows us to better understand how damping affects heat transport via charge, magnons, and phonons. CoFe-A, where the lowest Gilbert damping is seen, has large positive "violations" of the Wiedemann-Franz law, showing non-electronic contributions to thermal conductivity. Comparison to temperature- and field-dependenent Seebeck measurements on the sample samples, which show large contributions beyond simple diffusive thermopower, provides further insights on the non-electronic contributions to thermal conductivity.

CR-05. First Principle Calculations for Gilbert Damping Constants of Heusler Alloys in the Consideration of Spin Fluctuation. *R. Hiramatsu*[1], S. Shirakihara[1], D. Miura[1] and A. Sakuma[1] *1. Applied Physics, Tohoku University, Sendai, Japan*

The magnetization damping is of critical importance for development of magnetic devices. In particular, low Gilbert damping are required to achieve high speed and low power consumption devices. Therefore, it has attracted much interest to study magnetic materials with the small damping constants. Especially, because of theoretical prediction about the low damping [1], Heusler alloys have been studied for long time. On the basis of the theory, the low damping comes from the half metallicity of the systems. Thus, it is considered that breaking the half metallicity, such as spin fluctuations, affects on the damping constants. The purpose of our research is to evaluate the effect of spin fluctuations on the damping constants in half metals, on the basis of first principle calculations. To achieve this aim, we assume that the spin direction is restricted to one axis, and the spin fluctuations are expressed by varying the ratio between up and down spins, which was proposed in our previous study [2]. For the calculations of the electronic structures, we employ the first principle tight-binding linear muffin-tin orbital method and apply the coherent-potential-approximation for the spin configurations. The Gilbert damping constants are evaluated on the basis of the torque-correlation model [3]. In addition, to convert spin fluctuations ratio to temperature, we use an experimental results of temperature dependence of magnetization in $L2_1$ structure [4]. Figure 1 and 2 show temperature (T) dependence of the damping constants and the spin polarization at the Fermi level in Co_2MnAl, with $L2_1$, B2 structure, respectively. T_C denotes the Curie temperature of $L2_1$ structure. In the both systems, we can observe that the damping constant is temperature independent in the region of nearly half metal. Whereas, at high temperature range, the damping constants increase with increasing temperature. In the conference, we will also show the property of A2 structure and other Heusler alloys such a Co_2MnSi, and argue its trend in detail.

CR-06. Strain-Induced Perpendicular Magnetic Anisotropy and Gilbert Damping of $Tm_3Fe_5O_{12}$ Thin Films. *O. Ciubotariu*[1], A. Semisalova[2], K. Lenz[2] and M. Albrecht[1] *1. Institute of Physics, University of Augsburg, Augsburg, Germany; 2. Institute of Ion Beam Physics and Materials Research, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany*

Over the past years, iron garnets thin films have attracted a lot of attention in the field of spintronics and magnonics due to the superior magnetic properties of $Y_3Fe_5O_{12}$ (YIG). The insulating nature and low Gilbert damping (10^{-4}) make YIG the prototype material for the investigation of fundamental phenomena with potential applications in spin-wave-based technologies. In this regard, the control of the magnetic easy axis direction would open new potential applications. Tensile strained films grown on largely mismatched substrates or implemented in engineered heterostructures show perpendicular magnetic anisotropy (PMA) [1,2]. Other rare-earth iron garnets can also possess PMA when grown under tensile or compressive strain depending on the sign of the magnetostriction constant. Such an example is $Tm_3Fe_5O_{12}$ (TmIG) [3]. However, despite contradicting reports, no systematic study was performed to investigate the effect of TmIG film thickness grown on sGGG(111) substrates on the structural and magnetic properties. In this study, TmIG films with thicknesses between 20 and 300 nm are epitaxially grown by pulsed laser deposition on sGGG(111) substrates. Structural characterization shows that films thinner than 200 nm show in-plane tensile strain, thus exhibiting PMA due to strain-induced magnetoelastic anisotropy. However, with increasing film thickness a relaxation of the unit cell is observed resulting in the rotation of the magnetic easy axis towards the sample plane due to the dominant shape anisotropy. Furthermore, the Gilbert

damping parameter is found to be in the range of 0.02 for the entire film series. Our results show promising properties needed for the integration of TmIG films in heterostructures designed for spin-wave propagation.

CR-07. Ferrimagnetic Domain Wall Dynamics through the Compensation Points. *E. Haltz*[1], J. Sampaio[1] and A. Mougin[1] *1. Laboratoire de Physique des Solides, Orsay, France*

The manipulation of magnetisation via spin current offers new perspective for processing and storage of non-volatile information. To increase the efficiency of spin torques on magnetic texture (by Spin-Transfer-Torque (STT) or Spin-Orbit-Torque (SOT)), it is proposed to use materials mixing different magnetic sub-lattices antiferromagnetically coupled (AFC) [1]. The conventional mechanisms involved in this new dynamics have to be revisited. Here, new simulations or analytical approaches are developed in rare earth-transition metal amorphous ferrimagnetic alloys whose properties are tuneable changing the temperature or the chemical composition [2]. At so-called compensation points, the net magnetisation or the net angular momentum vanishes. Recent experimental studies, including our work, show very interesting properties as the fast Domain Wall motion (DW,) driven by field or SOT [3] crossing compensation points. The magnetic properties of GdCo ferrimagnetic alloy are simulated using mean field theory. Quantitative values are used in micro-magnetic simulations to investigate DW dynamics under field, STT or SOT. To mimic the magnetic alloy structure, micro-magnetic simulations consider two magnetic momentums of Gd and Co interacting each other by AFC. Field acts on both sub-lattices whereas, as expected, the spin injection interact only with the Co population. DWM driven by field and spin current simulated for a large range of chemical composition reveals translational or precessional modes separated by Walker-like threshold (including DMI [4]). As a further support, two analytical approaches are used. First, in a strong AFC approximation, it is possible to consider the alloy as a ferromagnet with effective parameters. Calculations using standard q-φ model (q, the DW position, and φ its internal magnetisation angle) explain most of results. However, few of the effective parameters exhibit non-physical divergences at compensation points. The laters are solved considering an eventual tilt between magnetic moments of both sub-lattices. In a new model, 2 couples of coordinates (q1- φ1 and q2- φ2, one for each sub-lattice) describe two AFC DWs and a tilt can arise from any a difference (q1-q2) or (φ1-φ2).

Antiferromagnetic spintronics has been gaining much attention in both fundamental and practical points of view [1,2]. Antiferromagnetically-coupled ferrimagnets have recently been emerging as useful material platforms for studying antiferromagnetic dynamics since we can use conventional techniques for ferromagnets to investigate them. Both field-driven [3] and current-driven [4,5] domain-wall dynamics in ferrimagnets are found to be fastest at the angular momentum compensation temperature T_A, indicating that the magnetic dynamics becomes antiferromagnetic-like. In the context of the antiferromagnetic-like dynamics, however, the ferrimagnetic resonance (FiMR) has not been fully clarified. In this presentation, we revisit the FiMR in ferrimangetic GdFeCo compounds theoretically and experimentally, and show the rigorous analysis for the FiMR. For this study, we used a 5-nm SiN/10-nm $Gd_{25.0}Fe_{65.6}Co_{9.4}$/5-nm Pt/100-nm SiN/Si substrate. We measured spin-torque induced FiMR spectra at several temperatures T between 220 K and 295 K by using the homodyne technique. It is found that the spectral linewidth of the resonance peak strongly depends on T. From those FiMR spectra, we calculate the two versions of the effective Gilbert damping parameter: α_{FM} based on the conventional expressions of ferromagnetic resonance [6] and α_{FiM} based on our theory for FiMR that accounts for the difference between the net spin density and the saturated total spin density in ferrimagnets. As shown in Fig. 1, α_{FM} increases significantly as T approaches T_A, in good agreement with Ref. [6], while α_{FiM}(≈0.01) is insensitive T to in sharp contrast to α_{FM}. This indicates that the T dependence of the spectral linewidth in FiMR is attributed to the T dependence of the net spin density instead of that of α_{FM}. Our results provide a clear evidence that properly defined Gilbert damping parameter α_{FiM} of ferrimagnets is insensitive to T, which is consistent with some recent reports [7,8].

CR-09. Thermal intermixing effect on Gilbert damping of sputter-grown Pt/$Ni_{80}Fe_{20}$/Pt sandwich trilayers. *Y. Kim*[1], B. Kim[1], B. Bhoi[1], Y. Kim[1] and S. Kim[1] *1. Material science, Seoul National University, Seoul, The Republic of Korea*

In this work, we investigated the intermixing effect on the Gilbert damping constant of sputter-grown Pt/Py/Pt trilayer films. In order to enable intermixing at both Pt/Py interfaces, we post annealed them in the same vacuum environment for 30 min by varying the annealing temperature up to 800 K. We examined the structural changes among all of the samples by X-ray diffractometry (XRD), at the interfaces using TEM, and the magnetic properties using VSM measurement; then, we obtained the Gilbert damping constant by the VNA-FMR technique. According to the VNA-FMR results, = 0.0206 for the as-deposited sample and = 0.0932 for the sample annealed at 800 K. In the annealing temperature range up to 600 K, the Gilbert damping constant was nearly unchanged, ranging from 0.0206 to 0.0212. This can be explained by the competition between the spin pumping effect and the sharp interface effect on the Gilbert damping constant. Above the 600 K annealing temperature, the Gilbert damping constant began to increase, and in the annealing temperature range of 700 – 800 K, it showed a drastic increase, from 0.0329 to 0.0932. Such an increase in the Gilbert damping constant could be accounted for by intermixing, the stoichiometric compound, and the formation of the non-magnetic dead layer at the interface. The XRD data revealed that the crystallinity of the interface increased up to the 600 K annealing temperature, but that above it, there was increased interface roughness as well as degradation of the crystallinity and texture of the Pt phase. Additionally, above the 700 K annealing temperature, formation of the stoichiometric compound between Py and Pt and the structural transformation from ordered L12-FCC to disordered A1-FCC[2] were observed. Furthermore, the average diffusion length[3,4] of the atoms imparted a consistency of structural change, as observed by XRD. This research establishes that the intermixing effect on Gilbert damping, allows for understanding of the interfacial effect and provides insight into the optimization of complex low-damping-constant multi-layer spintronic devices with various interfaces.

The effective Gilbert damping constant for all samples annealed at different temperature for 30 minute.

CR-10. Enhanced damping effect of FeNiN film due to two magnon scattering. *Z. Zhu*[1], H. Feng[1], J. Wang[1] and Q. Liu[1] *1. Key Laboratory for Magnetic and Magnetic Materials of the Ministry of Education, Lanzhou University, Lanzhou, China*

The magnetic damping behavior of soft magnetic films have been widely investigated due to their application in high frequency microwave devices, spintronic devices or magnetic random access memory. Generally, effective damping is divided into intrinsic Gilbert damping and extrinsic relaxation mechanisms. The doping is considered as an effective method to adjust the magnetic damping. Meanwhile, the static magnetic properties of thin films will also change. In order to suppress the impact of dopant on static magnetic properties. The light element Nitrogen was used as dopant to adjust magnetic damping. we prepared FeNiN films by magnetron sputtering technology. Five different samples were prepared by varying the Nitrogen partial pressure with 0, 5%, 10%, 15%, 20%, and we will represent the samples with symbols S1~S5, respectively. Ferromagnetic resonance (FMR) was used to study the enhanced magnetic damping. The experimental results show that nitrogen doping significantly affects the magnetic damping of the samples, while its effect on the coercivity is negligible. The analysis of angular dependence of FMR indicates the enhanced damping is mainly from two magnon scattering (TMS). Fig. 1 presents angular dependences of FMR linewidth and theoretical fitting curves. θ is the angle between applied magnetic field and film plane. With the rise of Nitrogen partial, TMS (the green diamond) gradually become a very important part of FMR linewidth. Gilbert damping of samples increases, and TMS increases more sharply. The shape of angular dependent FMR linewidth curves even transforms from "field dragging type" to "TMS type". Our experiments and analysis point out that one can strictly distinguish the types of damping stemmed from doping process. The prepared FeNiN films maintain the excellent soft magnetic properties with large effective damping, which meet the requirements of many devices, such as spin-torque nano-oscillator, etc.

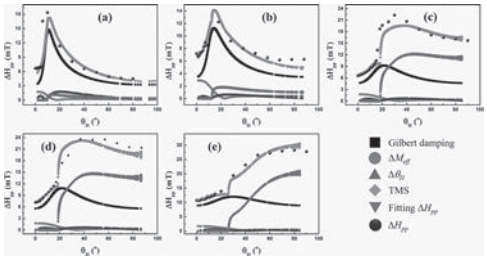

FIG. 1. The measured angular dependences of FMR linewidth (dark blue dots) and the fitting data of different samples. (a) ~ (e) represents the results of S1 ~ S5, respectively

CR-11. Manipulation of Magnetic Anisotropy by Pt Under-Layer Thickness in Pt/Co/Pt Films. *J. Yu*[1], D. Kim[1], J. Chang[1], J. Park[1], Y. Park[1,2], D. Kim[3], B. Min[2] and S. Choe[1] *1. Physics and Astronomy, Seoul National University, Seoul, The Republic of Korea; 2. Spin Convergence Research Center, Korea Institute of Science and Technology, Seoul, The Republic of Korea; 3. Institute for Chemical Research, Kyoto University, Kyoto, Japan*

Magnetic domain-wall (DW) dynamics has received a substantial attention owing to its academic interest as well as its possibility to state-of-the-art application of magnetic memory and logic devices [1]. In the creep regime, it has been known that the DW dynamics strongly depends on the creep-scaling constant that is directly correlated to the magnetic anisotropy [2]. Here, we show that the magnetic anisotropy can be systematically manipulated by adjusting the thickness of non-magnetic Pt under-layer in Pt/Co/Pt films and consequently, the DW dynamics can be finally controlled. In this study, 5.0-nm Ta/t_{Pt}^{u}-nm Pt/0.3-nm Co/1.5-nm Pt films were fabricated on a Si/100-nm SiO_2 substrate by using dc and ac magnetron sputtering, where t_{Pt}^{u} varied from 1.5 to 8 nm. Then, the magnetic anisotropy field H_K was characterized by the extraordinary-Hall-voltage measurement scheme [3] and the creep-scaling constant was measured by observing the DW motion through a magneto-optical Kerr effect (MOKE) microscope equipped with an out-of-plane electromagnet [2]. Figure 1 shows the plot of H_K and with respect to t_{Pt}^{u}, respectively. The figure unambiguously shows that H_K and are closed correlated: both increases as t_{Pt}^{u} increases and then, saturates at a critical value of t_{Pt}^{u}. Examination based on the x-ray diffraction suggests that the close correlation between H_K and is possibly attributed to their common relation to the crystallinity of the Pt under-layers.

CR-12. Gilbert Damping Variation via Disorder in B2 Ordered Co_2MnAl Full Heusler Alloy System. *V. Barwal*[1], N. Behera[2], S. Husain[2], A. Kumar[2], P. Svedlindh[2] and S. Chaudhary[1] *1. Physics, Indian Institute of Technology Delhi, New Delhi, India; 2. Department of Engineering Sciences, Uppsala University, Uppsala, Sweden*

Co-based Heusler alloys are in demand due to their half-metallicity, high spin polarization, high Curie temperature T_c and low damping constant, etc. Co_2MnAl (CMA) is one of the Co-based full Heusler alloys which exhibits high T_c~697 K and large spin polarization (~78%). CMA has considerable research interest due to its compatibility with the most semiconducting substrates and topological properties. In the present work, the Mn concentration dependent magnetization dynamic properties of *B2* ordered CMA full Heusler alloy are investigated.$Co_{2+x}Mn_{1-x}Al$ (CMA) Heusler alloy thin films grown on Si (100) by varying Co/Mn concentration at fixed growth temperatures (T_s) of 400 deg.C using DC-magnetron sputtering are investigated. XRD patterns revealed the formation of *B2* ordered phase in the film with exact stoichiometry. Ferromagnetic resonance (FMR) technique is employed to determine the Gilbert damping constant, which is found to be 0.0045±0.0002 for the perfect stoichiometric film which is a record low value in the CMA Heusler alloy thin films. The Co/Mn concentration based tunable Gilbert damping constant in CMA Heusler alloy is investigated and the lowest value of damping constant is found to be 0.0045. The tunability of Gilbert damping provides the opportunity to apply Heusler alloy materials in different fields of the spintronic devices. The low damping constant is inevitably important for spintronic applications.

CR-13. Paramagnetic resonance in $La_{0.6}Ca_{0.4}MnO_3$ detected by magnetoimpedance method using a copper 'stripcoil'. U. Chaudhuri[1], A. Chanda[1] and *R. Mahendiran*[1] *1. Physics, National University of Singapore, Singapore*

Electron paramagnetic resonance (EPR) and ferromagnetic resonance (FMR) in colossal magnetoresistive Mn-oxides have been extensively studied using the microwave cavity perturbation technique at a fixed resonance frequency of the cavity, typically 9.8 GHz. [1] Conventional EPR/FMR spectrometers record the field derivative of the microwave power absorbed by the sample while *dc* magnetic field (H_{dc}) is swept through resonance. Here, we show detection of EPR signal $La_{0.60}Ca_{0.40}MnO_3$ by measuring the effective changes in magnetoimpedance of a copper stripcoil surrounding the sample. In our method, *rf* current from an impedance analyzer flows through a stripcoil surrounding the sample which creates an *rf* magnetic field inside it, along its axial direction, [2] which excites t_{2g} core electrons of Mn^{3+}/Mn^{4+} ions to make Zeeman transitions between spin split levels upon sweeping *dc* magnetic field. Fig. 1 (a) shows a plot of magnetization (M) versus applied magnetic field (H) and M vs T in the inset for the sample. These curves indicate that the sample is paramagnetic at 300 K and it undergoes a transition to ferromagnetic state below 260 K. Fig. 1 (b) illustrates the percentage changes in magnetoresistance ($\Delta R/R_0$) and magnetoreatance ($\Delta X/X_0$) at 2.5 GHz which are the apparent resistance and reactance changes of the sample as picked up by the stripcoil. $\Delta R/R_0$ decreases gradually and shows an abrupt increase at a critical field H_{cr} which corresponds to a pronounced dip in $\Delta X/X_0$. In Fig. 1 (c) and (d) display the evolution of $\Delta R/R_0$ and $\Delta X/X_0$ respectively, from 0.5 GHz to 2.5 GHz. We can see that the H_{cr} increases linearly with frequency (f) of the current in the stripcoil which follows the relation $f = (g/2\pi)H$, where g is the gyromagnetic ratio as expected for EPR. The electrical detection of spin dynamics in the paramagnetic sample shown here urgently needs theoretical explanation.

We analyze the ferromagnetic resonance field H_r and linewidth of pulsed laser ablation deposited, amorphous Fe-B films based on the characteristics of their film-substrate and film-capping interfaces. Two pairs of films (20 nm thick) were deposited onto MgO (001) (M films) and Corning® glass (C films) substrates, respectively. A film out of each pair was capped with a 5 nm Au layer whereas the other was kept uncapped. All films exhibit a uniaxial dc MOKE hysteresis with the easy axis (e.a) parallel to one substrate side (C) or to one diagonal (M). The in-plane (IP) angle dependence of H_r in the C films (Fig. 1a) showed a uniaxial anisotropy component typical of amorphous alloys, with no traces of higher order components. The magnetoelastic coupling with the stresses at the substrate-film interface is proposed as the source of this anisotropy and of the extrinsic contribution to the linewidth, showing the same angle dependence as H_r (Fig. 1b). The origin of a peak splitting observed in the angular region associated to the linewidth maxima is discussed in terms of different mechanisms, based on magnon scattering [1, 2] or local resonance [3]. The larger linewidth of the uncapped C film, in comparison to the capped C one, can be attributed to the oxide layer formed at its free surface. The M films present, in addition to a uniaxial anisotropy, a weaker cubic (biaxial IP) component (Fig. 2a), due to the presence, observed by transmission electron microscopy, of a 1 nm thick Fe epitaxial layer at the Fe-B/MgO interface. The extrinsic linewidth contribution exhibited by the capped M film (Fig. 2b) has a four-fold angle dependence, which, consequently, must be associated to the occurrence of exchange coupling between the Fe epitaxial layer and the amorphous Fe-B layer. In contrast with this result, the linewidth of the uncapped M film (Fig. 2b) shows an angle evolution correlated neither to the cubic nor to the uniaxial components of the anisotropy, and which is likely ruled by the oxide layer present at the deposit free surface.

CR-15. Time dynamics and magnetic viscosity measurements in inhomogeneous $La_{0.7}Sr_{0.3}MnO_3$ films. *N. Mottaghi*[1], S. Kumari[2], M.S. Seehra[1] and M. Holcomb[1] *1. Physics and astronomy, West Virginia University, Morgantown, WV, United States; 2. Department of Physics, The Pennsylvania State University, University Park, PA, United States*

Recently we have reported on the role of so-called magnetic dead layers/regions in the bulk magnetic properties of a 7.6 nm thin of $La_{0.7}Sr_{0.3}MnO_3$ (LSMO) grown on $SrTiO_3$ (STO) substrate[1, 2] showing that this sample was magnetically inhomogeneous containing spin clusters embedded in a ferromagnetic phase.[2] It was suggested that these spin clusters are responsible for the observed hysteresis loop inversion and negative magnetization in the temperature dependent magnetization (*M*-*T*) measurements and these spin clusters act like a superparamagnetic phase.[1, 2] Here we report a systematic study of the magnetic relaxation ($M(t)$) in similar magnetically inhomogeneous LSMO/STO (001) thin films but with thickness = 12, 21.2, 32 and 37 nm. As before[1, 2], these films were fabricated by pulsed laser deposition (PLD). Measurements of magnetization were done as follows: Samples are cooled in magnetic field $H = +50$ Oe to the measuring temperature. After the temperature becomes stable, H is set to zero and time dependence of $M(t)$ is recorded for t up to 2 hours yielding the long-time logarithmic relaxation rate shown in Fig. 1. Similar measurements were repeated for other temperatures after warming the sample each time to $T > T_C$ and then cooling back to the measuring temperature in $H = +50$ Oe. The data of M vs. t follows the Eq. $M(t) \approx M_0 - S(H, T) \ln(t)^3$, with S being the magnetic viscosity and M_0 the magnetization at $t = 0$. In addition to the temperature dependence of S, we also report the temperature of M_{stable}, the final value of the magnetization the system reaches after 2 hours. Temperature variations of M_{stable} and S for the four films (Fig. 2) show that S has the maximum values for all the samples at the temperature where M_{stable} switches sign from positive to negative values. These results of peaks in S and sign change in M_{stable} are interpreted in terms of co-existence of multiple magnetic phases in these inhomogeneous films.

Spin pumping effect in FM/NM bilayers attracts more interests because it can tailor magnetization dynamic damping. Interface and NM layer play crucial roles in spin current generation based on the effect. For Permalloy (Py), the magnetization dynamic damping (α) is quite small due to the quenched orbital magnetic moments, which restricts the applications in spintronic devices. Spin pumping occurred on the interface between Py and the NM films with larger L-S coupling could improve the α of Py indirectly. Rare earth materials as NM layers have showed a stronger spin pumping effect, such as Tb(Terbium)[1]. Ho is also a heavy rare earth material with paramagnetism at room temperature and larger orbital moment L. In this paper, we investigate the α by spin pumping in Py/Ho bilayers by frequency dependence of Ferromagnetic Resonance (FMR). Various thicknesses of Ta(5)/Py(10)/Ho(d)/Ta(2) films are fabricated by magnetron sputtering. Results show that the α increases with the increasing thickness of Ho layer and then tends to a stable value at about 0.03828 as shown in Fig.1, which agrees with the trend of the spin pumping behavior. By fitting the experimental data based on spin pumping principle, the spin diffusion length of Ho and spin mixing conductance are obtained, which indicate that a stronger L-S coupling in the Ho layer than that in heavy metal Pt gives main contributions of α enhancement. From the saturation magnetization, it decreases with the function of the thickness of Ho layer d, which may tell us that an antiferromagnetic interface in Py/Ho exists. The magnetic moments Py may induce the non-zero magnetic moment of Ho during atomic layers near adjacent Py layer. This non-zero magnetic moment is possibly anti-parallel to the one of Py layer. It is reported that an antiferromagnetic interface can increase the damping coefficient [2]. Therefore, in our research, antiferromagnetic interface also plays an important role in the damping enhancement in Py/Ho bilayer. The detailed discussion and analysis will be described in the full text. This work was supported by NSFC (Grant No 61427812, 51571062).

CS-01. Exploring magnetic resonance with a compass. *D. Nelson*[1], E. Cookson[1], M. Anderson[1], D. McKinney[2] and I. Barsukov[1] *1. Physics and Astronomy, UC Riverside, Riverside, CA, United States; 2. Santa Rosa Academy, Menifee, CA, United States*

Magnetic resonance plays an important role in today's science, engineering, and medical diagnostics. Learning and teaching magnetic resonance is challenging since it requires advanced knowledge of condensed matter physics and quantum mechanics. Driven by the need to popularize this technologically impactful phenomenon, we develop an inexpensive table-top demonstration experiment. It unveils the magnetic resonance of a hand-held compass in the magnetic fields of a permanent magnet. The setup provides an immediate visualization of the underlying physical concepts and allows for their translation to broad student audiences. This work was supported by the National Science Foundation under Grant No. ECCS-1810541.

CS-02. Magnetic Fields Web Series: Engaging Middle School Students in STEM. *P. Pena Martin*[1], J. Isberg[1], E. Ertekin[1,3], V. Lorenz[1,2] and N. Mason[1,2] *1. Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 2. Department of Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, United States*

Web based media can make scientific content accessible to audiences far beyond the scientific community. We created a web series called "Magnetic Fields" that aims to introduce materials science, particularly concepts related to magnetism, and promote themes more general to STEM fields, such as persistence and the scientific process, through use of characters and a story geared towards a middle school audience. The goal is to build and maintain interest in science at an age where this tends to drop off. The four-episode arc follows a group of high school characters as they encounter a strange new material during a class field trip to a laboratory. The series is directed by John Isberg, with professional actors making up most of the cast. The series was initiated by scientists in the Illinois MRSEC, and the storyline was developed in collaboration with MRSEC students and faculty. The episodes were released in May 2019 through Youtube. We report on the process of creating this series, response to it upon release, and discussion of its use as an educational tool. The authors acknowledge primary support of the NSF through the University of Illinois at Urbana-Champaign Materials Research Science and Engineering Center DMR-1720633.

CS-03. In-class experiments with smart phones for teaching upper-level electricity and magnetism. A. Davidson[1], A. Ranjan[2] and *X. Fan*[1] *1. Physics and Astronomy, University of Denver, Denver, CO, United States; 2. Cherry Creek High School, Greenwood Village, CO, United States*

Interactive-engagement method such as studio physics [1, 2], has demonstrated higher learning gains than traditional lecturing in intro-level physics classes. However, there have been limited applications in upper-level classes, such as Electricity and Magnetism (E&M), possibly because experiments on E&M topics can be too costly and sophisticated to be carried out in the classroom. Smart phone, which is equipped with magnetic field sensors, radio signal detectors and light sensors, provides a convenient platform for carrying out E&M-related experiments. In this poster, we will present three examples of the implementation of smart-phone-based studio physics in an E&M class for Physics majors: (1) Detection of earth magnetic field inclination; (2) quantifying skin depth of aluminum foil with cellphone tower signals; and (3) Measurement of Brewster's angle. Besides sensitive sensors, smart phone also has computational power, which can be explored to further expand the breadth and depth of the smart-phone-based studio physics. Due to the wide accessibility of smart phones and the simplicity of experimental setup, we expect this teaching technique can be easily transferred to other institutes in the world.

CS-04. The Use of Virtue Modules in Physics Lab Teaching. *W. Zhang*[1], R. Bidthanapally[1], T. Sebastian[2], Y. Xiong[1,3], H. Qu[3] and J. Sklenar[4] *1. Physics Department, Oakland University, Rochester, MI, United States; 2. THATec Innovation GmbH, Mannheim, Germany; 3. Electronic and Computer Engineering, Oakland University, Rochester, MI, United States; 4. Physics Department, Wayne State University, Detroit, MI, United States*

Lab sessions in physics education connect the fundamental concepts to practical examples and are effective measures of the students' understanding and reasoning through ultimate real-world tests. Many topics in condensed

matter physics are known to be challenging to convey in both lectures and labs. In addition, these topics are usually resource demanding, which has been one of the challenging issues. Here, we introduce and demonstrate the use of virtue lab modules for teaching physics labs and for effectively integrating research and education. Experiments that are relevant to magnetism and spintronics include, but not limited to, spin current detecting, microwave energy harvesting, and spin-based thermoelectric effects. An important highlight of these modules is the highly-interactive laboratory learning platform. In the class, each piece of experimental hardware (e.g. electrometers, oscilloscopes, etc) will be paired with a computer-based virtual module. The individual modules mimic the hardware, which the students can use to become familiar with the hardware, acquire real-time feedback, and visualize the data acquisition dynamics, on-demand and risk-free. The virtual component is also helpful for demonstrating delicate, shared hardware in class, without risk of damaging the actual instrumentation. These individual components are connected to a central operating system and the experiment can be re-programmed by simple coding and user-interfaced commands [1]. Work at Oakland University is supported by NSF DMR-1808892.

CT-01. Microwave absorption properties of Y-Co_2Z/PANI composites. *N. Tran*[1], H. Nguyen[1], Y. Choi[1], M. Lee[1], T. Phan[1] and B. Lee[1] *1. Department of Physics, Hankuk University of Foreign Studies, Yongin, The Republic of Korea*

In recent years, the growing development of wireless devices has caused microwave polluted environment. Therefore, the demand for microwave absorbers in the GHz range is much increasing. Ferrites are concerned to be the best choice for industrial purpose because of their high resistivity, high saturation as well as excellent electromagnetic properties [1-3]. Z-type hexaferites have high resonance frequency f_r and large permittivity μ in the GHz range. Furthermore, the composites of Z-type hexaferrites/conductive polymers can be used to enhance the microwave absorption in the minimum reflection loss (RL) as well as effective bandwidth absorption. To understand the role of doping and composite on the microwave absorption properties of Z-type hexaferites, composites of Y-doped $Ba_3Co_2Fe_{24}O_{41}$ and polyaniline (PANI) were prepared. $Ba_{3-x}Y_xCo_2Fe_{24}O_{41}$ (x = 0, 0.2 and 0.4) samples were synthesized by solid state reaction method. Their composites with PANI were then prepared with hexaferrites (H) and PANI (P) ratio H/P = 9/1. The composites together with 7%wt. epoxy were ground and pressed into the toroidal shape (with D = 7 mm and d = 3 mm) then dried at 170 °C/0.5 h. Electromagnetic wave absorption properties of these composites were studied by a PNA-X Network Analyzer in the frequency range of 0.1 – 18 GHz. The absorption properties versus the toroidal thickness (t) were also carried out. RL of the composites was strongly dependent on x and t. With t decreasing, the absorption frequency moved toward the high frequency range. All the samples had minimum RL < –10 dB, which represented capacity of incident wave absorbing of materials up to 90%. The largest bandwidth of microwave RL < –10 dB was obtained in the range of 13.8 – 17.8 GHz for x = 0.4. Considering microwave RL < –8 dB (~84% of incident wave being absorbed), the sample x = 0 can be covered for a huge frequency range of 3.95 – 16.54 GHz at t = 2 mm. Meanwhile, the minimum RL = –29.5 dB (~99.9% of incident wave being absorbed) was archived at frequency of 11.4 GHz for x = 0.2 with t = 2.5 mm. These results suggest that Y-Co_2Z/PANI composites are potential candidates for microwave absorption.

CT-02. Microwave absorption properties of core-shell structured FeCoNi/PMMA filled in composites. *K. Kim*[1], W. Jang[1], S. Mallesh[1] and S. Lee[2] *1. Physics, Yeungnam University, Gyeongsan, The Republic of Korea; 2. Composites Research Division, Korea Institute of Materials and Science, Changwon, The Republic of Korea*

The electromagnetic (EM) absorbers have been required the essential factors such as high absorption ability, broad bandwidth, and lightweight [1, 2]. To enhance the ability of EM absorption, the permittivity and permeability of absorber should be controlled for impedance matching. In general, the carbonyl Iron particles (CIP), ferrites and carbon based materials have been widely employed in EM absorber for tuning the permittivity and permeability. Especially, the specific gravity of the metallic and ceramic fillers is relatively high. In order to reduce the weight of EM absorbers, the core-shell structured fillers synthesized by electroless plating that the 100 nm thick-FeCoNi shell was coated on the surface of PMMA beads (approximately 3 μm) as shown in Fig. 1. To verify the enhancement of EM properties of FeCoNi@PMMA, which were compared with those of the spherical CIP (BASF, EW) with similar size of PMMA. The magnetization values of FeCoNi@PMMA and CIP were 170 emu/g and 191 emu/g, respectively.

The FeCoNi@PMMA and the CIP were dispersed in paraffin matrix, respectively, which composites were pressed into the toroidal shape to measure EM properties by using 7 mm coaxial line with vector network analyzer up to 18 GHz. The real part of permittivity of FeCoNi@PMMA of 55 wt.% in composite exhibited from 15 to 12 although the CIP with same weight ratio was 4. The real part of permeability of FeCoNi@PMMA and CIP composites were slightly decreased from 1.5 to 1 with the increment of frequency. The minimum reflection losses (RL) of FeCoNi@PMMA composites exhibited from -21.4 dB@13.3 GHz for 1.5 mm to -19.3 dB@6.1 GHz for 3 mm, which values were much larger than those of CIP with the same weight ratio as shown in Fig. 2. As results, the core-shell structured lightweight FeCoNi@PMMA is one of good candidate filler material for EM absorber. We'll present the analytical results in detail and discuss in presentation.

CT-03. In-detailed Study of Magnetic, Dielectric and Microwave Properties on $MnFe_2O_4$ Nano-Hollow Spheres. *D. Mandal*[1] and K. Mandal[1] *1. Condensed Matter Physics & Material Sciences, S.N.Bose National Centre for Basic Sciences, Kolkata, India*

From the detail studies of structural, magnetic, dielectric and microwave properties, $MnFe_2O_4$ (MFO) nano-hollow spheres (NHS) are found interesting towards its application in high-frequency devices as well as in bio-medical fields. Single crystal MFO NHS of size ~ 250 nm is synthesized in one step template free solvothermal method and the morphology is analyzed through FESEM and TEM micrographs. The crystallographic phase is determined using profile analysis of XRD pattern. Room temperature magnetization (M) study on MFO NHS displays its soft ferrimagnetic nature with H_C, M_R and M_S values of 127.7 Oe, 15.3 emu/g and 57.8 emu/g respectively. Domain structures of NHS and temperature dependence of M are predicted from the Day plot and Bloch's power law. Variation of dielectric properties such as permittivity (ε), and ac conductivity (σ) of these NHS with frequency (1 Hz – 1MHz) is explained on the basis of Maxwell-Wagner two-layer model for space charge and cationic interactions in between tetra- and octahedral sites. Permeability (μ), ε, and Reflection loss (RL) are studied in widely used X-Band (8-12 GHz) frequency range on composites filled (20 wt% and thickness of 2 mm) with sample. Hollow cavity of NHS leads to a lower density as well as multiple internal reflections enhances Electro-Magnetic wave absorption (optimal RL ~ - 32 dB at 11.7 GHz) and a broad band-width (W) of ~ (9.4 – 12) GHz having RL < -10 dB (absorption > 90%) [1]. These properties ensure its potentiality as light-weight, size efficient microwave absorbing material.

CT-04. Magnetic and microwave absorption properties of Co-doped $SrFe_{12}O_{19}$ M-type hexaferrites. *H. Nguyen*[1], N. Tran[1], Y. Choi[1], J. Ahn[1], T. Phan[1] and B. Lee[1] *1. Department of Physics, Hankuk University of Foreign Studies, Yongin, The Republic of Korea*

Many studies have demonstrated that strontium hexaferrite (SrM) is a potential candidate for radar-absorbing materials (RAMs) [1-3]. By substituting either Sr^{2+} or Fe^{3+} with other elements, changing the permittivity (ε_r) and permeability (μ_r) [1, 2], one can improve the magnetic and microwave absorption (MWA) properties of SrM, prticularly for the Co doping because it is a fast relaxer with high magnetocrystalline anisotropy. Basing on this suggestion, we have prepared $SrCo_xFe_{12-x}O_{19}$ (x = 0 - 1) samples and studied their magnetic and MWA properties. The results obtained from magnetization measurements indicated an increase of the saturation magnetization (M_s) with increasing x in $SrCo_xFe_{12-x}O_{19}$, namely from ~36 emu/g for x = 0 to 46 emu/g for x = 1, see Fig. 1. Meanwhile, excepting for x = 0, the coercivity (H_c) reduces from ~3.7 kOe for x = 0.1 to 1.7 kOe for x = 1. These changes are related to the replacement of Co^{2+} for Fe^{3+} in different polyhedral sites of the M-type structure that changes the local geometrical structures and exchange interactions between Fe ions. Such changes influence directly the MWA properties. To investigate the MWA properties, we selected typical samples (x = 0, 0.4, and 0.8), pressed into toroid-shaped devices, and performed frequency (f)-dependent measurements of ε_r and μ_r in the range f = 0.1-18 GHz. After recording the ε_r and μ_r data with different toroidal thicknesses (t, 1.75-2.75 mm), we calculated f- and t-dependent reflection loss (RL). We have found that while x = 0 does not show the MWA possibility (RL ≈ 0), the others with x = 0.4 and 0.8 show good MWA possibility at frequencies f = 9-17 GHz. The best MWA performance has been found for x = 0.4 with t = 2 mm. For this sample, two absorption ranges at 9.8~12 and 13~17 GHz with RL < -10 dB are observed. Particularly, the minimum RL obtained at 10.9 GHz is about -49 dB,

corresponding to >99.99% microwave absorption (see Fig. 2), which is much larger than absorption values reported previously. These features demonstrate that the Co doping improved remarkably the magnetic and MWA properties of $SrCo_xFe_{12-x}O_{19}$ at high fequencies, above 9 GHz.

CT-05. Improved microwave properties of C-axis oriented La-Co substituted barium hexaferrite thick films for high frequency device applications. *S. Mahadevan*[1] and P. Sharma[1] *1. School of Physics and Materials Science, Thapar Institute of Engineering & Technology, Patiala, India*

M-type barium hexaferrite (BaM) has gained considerable attention in high frequency device applications due to its intriguing magnetic and microwave properties. The large uniaxial magnetocrystalline anisotropy (H_a ~17 kOe) associated with self-bias nature overcome the requirement of an external biasing field, which miniaturize the size of devices[1]. The operational frequency of microwave devices was strongly depended on intrinsic magnetic properties[2], i.e., saturation magnetization and H_a. Over the decades, large efforts have been made to tailor the magnetic properties by partial cationic substitution for Fe or Ba. However, magnetic and microwave studies related to simultaneous substitution for Fe and Ba is scarcely investigated. In the present work, $Ba_{0.85}La_{0.15}Fe_{12-x}Co_xO_{19}$ (x = 0 - 1) samples were prepared by solid-state ceramic method. Their structural, magnetic and microwave properties were investigated with micro Raman, VSM and VNA. We observe that cobalt substitution (x = 0.20) shows drastic increase in reflection loss (RL < -20 dB; absorption >99%) at K_u-band, which is 50% improved as compare to unsubstituted BaM shown in fig. 1. Our results suggest that the improvement is ascribed to dilution of H_a associated with cobalt substitution. Further, the material was utilized to fabricate oriented screen printed thick films of ~74 μm, which is a 26% reduction in thickness with respect to the previous reports[3,4]. Its morphological and magnetic properties were investigated by SEM and VSM respectively. Fig.2 shows the VSM plot of oriented thick film sintered at 1275 °C.

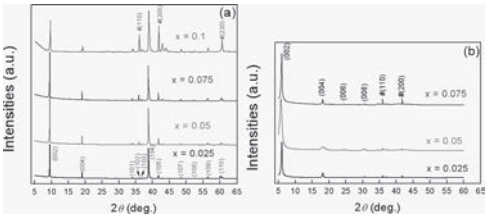
CT-06. Magnetic properties and microstructures of Fe-doped $(Ti_{1-x}Fe_x)_3AlC_2$ MAX phase and their delaminated MXene. N. Zhao[1], T. Chen[2], *J. Chen*[3], P. Jia[1], W. Cui[1] and Q. Wang[1] *1. Northeastern University, Shenyang, China; 2. Lanzhou University of Technology, Shenyang, China; 3. Institute Of Electronics, CAS, Beijing, China*

MAX phases, with with a chemical formula of $M_{n+1}AX_n$ (n= 1~3), are a family consisting of inherently nanolaminated compounds. Here M is the early transition metal, A is an A group elements and usually Al, and X is C and/or N. Al can be easily etched by acid, leading into the delaminated emerging 2D MXene by sonication. Some studies have been focused on the magnetic substitution on M site of MAX phase. But there are seldom reports on the further delamination to MXene of magnetic doped MAX phase. The $(Ti_{1-x}Fe_x)_3AlC_2$ (x = 0, 0.025, 0.05, 0.075, 0.1) powders were prepared by the conventional solid state reaction. The MXene samples were prepare by the typical etching process. The structural evolution was characterized by X-ray diffraction, TEM and SEM. Magnetic properties were characterized by Cryogenic VSM. XRD patterns of (Ti1-xFex)3AlC2 (x = 0.025, 0.05, 0.075 and 0.1) are compared in Fig. 1. For small doping amount x ≤ 0.05, all peaks corresponds to 3:1:2 MAX phase. More doping leads into the (Ti,Fe)C cubic phase for x = 0.075 and 0.1. By etching and delamination, a broadened (002) peak at 2θ ≈ 6o and a weak (004) peak at 2θ ≈ 18o are observed due to the expanded c lattice parameter. The SEM images after acid etching show the typical accordian-like morphology. While, after sonication and delamination, the 2D nanosheets are formed and show the six-fold symmetry of diffraction patterns. The Curie temperature of (Ti1-xFex)3AlC2 (x = 0.025, 0.05, 0.075) is measured by M-T curves and gradually increased from 210 K to 260 K, indicating the weak ferromagnetism. The MXene "paper" can be

prepared from all three MXene. The excellent electromagnetic shielding properties were obtained for the frequency between 2-18GHz and the The best electromagnetic interference of ~ 35 dB is achieved, which means that more than 99.9% of the incident energy is reflected by the prepared "paper".



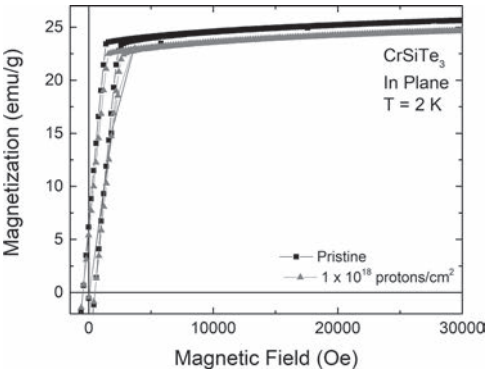


Fig.1 The XRD patterns of (Ti1-xFex)3AlC2 (x = 0.025, 0.05, 0.075 and 0.1) MAX phase and the corresponding MXene.

CT-07. Fluence Dependent Magnetic Properties of Proton Irradiated van der Waals CrSiTe. *H. Iturriaga*[1], R. Olmos[1], D.S. Blazer[1], L.M. Martinez[1], K. Gandha[2], C.I. Nlebedim[2], Y. Liu[3], C. The research on van der Waals magnetic materials is rapidly progressing after the discovery of monolayer ferromagnetism in CrI_3 two years ago. Proton irradiation is an effective tool in manipulating the magnetic properties of these materials. The main goal of this work is to study the magnetic properties of $CrSiTe_3$ (CST), which is a layered ferromagnetic material associated with the Curie temperature of 32 K. We find the Curie temperature for the 10^{18} protons/cm^2 irradiated sample to be 37 K. A comparison between a 10^{18} protons/cm^2 irradiated sample and a pristine sample showed a 4% change in magnetization at 2 K in the in-plane direction. Furthermore, comparing isothermal magnetization in different crystal orientations confirms the presence of magnetocrystalline anisotropy and reveals that the easy axis is along the in-plane direction. We will present and discuss our comprehensive experimental findings on the magnetic properties of CST such as saturation magnetization, coercive field, and Curie temperature by varying the proton fluence from 10^{15} to 10^{18} protons/cm^2.

CT-08. Preparation and characterization of flexible FeRh thin films. *Y. Xie*[1], B. Wang[1], H. Yang[1] and R. Li[1] *1. Ningbo Institute of Industrial Technology, Chinese Academy of Sciences., Ningbo, China*

Flexible magnetic devices are one of the indispensable flexible devices.[1] Meanwhile, CsCl-type FeRh alloy have been used widely as one of the magnetic layers in magnetic devices.[2-4]. Therefore, it is essential to develop a method to fabricate flexible FeRh films. In this work, we present a convenient method to fabricate flexible wrinkled FeRh films via coating and transfer process. From the curvature radii dependent magnetic measurement, it can be obtained that the magnetic properties of FeRh is stable under different bending strain. As schematically illustrated in Fig. 1(a), the substrates used in this work were cleaved NaCl single crystals that can be dissolved in water. FeRh films were deposited on the top of soluble NaCl crystal by dc magnetron sputtering, as shown in Fig. 1(b). During deposition, there are great disparities in the thermal expansion coefficient of FeRh and NaCl crystal substrates. Consequently, the grown films display random wrinkles. Subsequently, polydimethylsiloxane (PDMS) were coated on the top side of the wrinkled film surface using spin coating technique, as schematically shown in Fig. 1(c). After the spin coating process, the NaCl crystal is peeled from the FeRh films, by means of dissolution, leading to a PDMS elastomeric template covered with the FeRh film (Fig. 1(d)). Fig. 2(a) shows the temperature dependent magnetization of FeRh/PDMS. With decreasing of curvature radii from ∞ to 1.5 mm, the temperature dependence of magnetic behaviors of FeRh/PDMS keeps almost unchanged, indicating that the magnetic properties are stable when the sample is under different strains generated via bending of the simple. Fig. 3(b)-3(c) show the hysteresis loops of FeRh/PDMS with different curvatures radii, which were measured at 250 and 400 K, respectively. Similarly, the magnetic hysteresis loop is almost unchanged as the curvature decreased from ∞ to 1.5 mm.

CT-09. Spectral reflectivity crossover and direct-write of ferromagnetic patterns in FeRh thin films. *O. Van't Erve*[1], M. Currie[1], I. Mazin[1], C.D. Cress[1], J. Prestigiacomo[1] and S.P. Bennett[1] *1. Naval Research Lab, Washington, DC, United States*

Metamagnetic transition in FeRh, the transition from antiferromagnetic (AF) to ferromagnetic (FM) above room temperature, has been subject to many investigations. Several methods have been employed to investigate the various structural, magnetic, and electronic characteristics as the material undergoes this transition. In this work, we investigate the frequency dependent reflectance, which is a fast and easy probe and is found to display a clear and distinct signature coincident with this transition. Complimenting these experimental finds, our first principle calculations reveal that the dramatic difference in electronic structure between the ferro- and antiferromagnetic phases of FeRh leads to a characteristic crossover in the energy dependence

reflectivity, whereby the reflectivity difference between the two phases changes sign at E=~0.79 eV (1400 nm). Developing means to control the metamagnetic transition is also of high interest. To this end, we will demonstrate the successful direct write of ferromagnetic patterns in FeRh. For this we utilized a He-ion microscope to implant He ions with a specific dose, as determined by the microscope settings, into arbitrarily shaped regions. This sample was then transferred to a Magneto Optical Kerr Effect Microscope to characterize the local magnetic properties and study the effects of He implantation (energy and dose) on the metamagnetic properties of FeRh.

CT-10. On the magnetic interactions and spin dynamics in 3d transition metal doped 3C-SiC. *G. Moharana*[1], S. Singh[2] and H. Narayanan[1] *1. Physics, Indian Institute of Technology Madras, Chennai, India; 2. IMMT BBSR, BBSR, India*

We have synthesized Cr, Mn, Co and Ni (1, 3, 5) % doped 3C-SiC polycrystalline samples by Thermal Plasma technique. X-Ray Diffraction (XRD) revealed that the structure is Cubic (space group F4-3m) for all the three samples. XRD and Raman spectra indicates that the samples have crystallized in single phase and confirms the incorporation of the dopants into the host matrix. The temperature variation of Raman spectra reveals the roles of the defects in the structural stability and its effect on magnetic properties of the materials. The variation of Longitudinal Optical Mode (LO) and transverse Optical mode (TO) with temperature and different concentration has been analysed. The Site occupancy and valence state of dopant ions were investigated by variable Temperature Electron Spin Resonance spectroscopy (VT-ESR) and XPS study. The spectrum of pure SiC sample has shown the feature of resonance at resonance field Hr= 338.05mT, corresponding to g value of 2.00 which could be due to defects present in the sample (Vsi,Vc).

CT-11. Spin Reorientation in $R_XSm_{1-X}FeO_3$ Perovskites (R= Pr or Nd). *F.E. Lurgo*[1], C. Martin[2] and R.E. Carbonio[1] *1. Departamento de Fisicoquimica, Facultad de Ciencias Quimicas, Universidad Nacional de Córdoba, INFIQC-UNC-CONICET, Córdoba, Argentina; 2. Laboratoire CRISMAT, Centre National de la Recherche Scientifique (CNRS)/ENSICAEN/UCBN, Caen, France*

Design, development and understanding of novel functional magnetic materials are essentially important for numerous applications such as magnetic data storage devices, sensors and in the field of biomedicine [1,2]. Lanthanide orthoferrites and orthocromites have been under exhaustive study for several decades. These materials show a variety of striking effects resulting from the coupling between the two magnetic sublattices. This strong interations between these two sublattices could produce a phenomenon vastly studied: spin reorientation (SR). The orthoferrites $SmFeO_3$, $NdFeO_3$ and $PrFeO_3$ present reorientation of spin at temperatures already reported (470-490K for Sm, 66-158K for Nd and 50-85K for Pr) [3-6]. If one of these lanthanides, Pr or Nd are mixed with Sm in a composition such that the T_{SR} decreases to 300 K would be fantastic, because it could be potentially observing magneto-electric properties at room temperature. In the present work, three different compositions of two different perovskites of the $R_xSm_{1-x}FeO_3$ family (R=Pr, Nd) have been synthesized to obtain magneto-electric materials at room temperature. All these compounds crystallize in a *Pbnm* orthorhombic unit cell. ZFC and FC dc magnetic susceptibility curves as a function of temperature were measured in warming for all the members. The magnetic behavior depends on the rare earth. The study of the magnetic structure vs temperature showed the occurrence of a progressive spin orientation in all the compositions and is possible switch the T_{SR} with different compositions of rare earth cations on A site.

CT-12. A comparison between Al and Si substitution effects on structural and magnetic properties of Mn_3Ge with tetragonal $D0_{22}$ structure. *H. Okada*[1,2] and Y. Syoji[2] *1. Faculty of Engineering, Tohoku Gakuin University, Tagajo, Japan; 2. Graduate School of Engineering, Tohoku Gakuin University, Tagajo, Japan*

Mn-based alloys with tetragonal structure have attracted much attention in the field of spintronics and permanent magnet [1,2]. Mn_3Ge with $D0_{22}$ structure exhibits a ferrimagnetic ordering and strong uniaxial magnetocrystalline anisotropy without 4*f* elements. It has been known that magnetic properties of the Mn-based alloys are strongly influenced by number of the valence electron. On the other hand, theoretical investigations have predicted that

the magnetic state is sensitive to structural properties [3,4]. In this work, we have investigated structural and magnetic properties of Al- and Si-substituted Mn_3Ge to clarify the relationship between structural and magnetic properties of the alloys. It is known that Mn-rich composition is required for obtaining a single phase of the $D0_{22}$ structure in Mn-Ge alloys. In this work, the single phase is obtained at x = 0.0-0.2 for $Mn_{3.03}Ge_{0.97-x}Al_x$ and y = 0.0-0.4 for $Mn_{3.09}Ge_{0.91-y}Si_y$. The lattice constants a and c estimated from the X-ray diffraction data linearly decreases with increasing Si content. This is due to the substitution with Si atom having smaller ionic radius than Ge atom. As the result, the unit cell volume shrinks with the increasing Si content. The axial ratio c/a is mostly constant, indicating that the unit cell volume is isotropically contracted by the Si substitution. On the other hand, the replacement of Ge with Al leads to an increase in the parameter a and a decrease in the parameter c. Consequently, the unit cell volume is slightly expanded. The Al substitution effects are consistent with the results of the Ga-substituted Mn_3Ge [5]. Therefore, it is considered that the structural properties are influenced by number of the valence electron in addition to ionic radius. As shown in Fig.1, Spontaneous magnetization estimated using the law of approach to saturation increases with increasing Al content, whereas the magnetization decreases with increasing Si content. These results imply that the structural properties such as the unit cell volume and the atomic distance between Mn atoms play an important role for the magnetic properties of the alloy.

CT-13. Investigation of the structural and magnetic phase transition of Ga-doped $Eu_3Ir_4Sn_{13}$. *R.M. Grossi*[1], A. Fahl[1], K.R. Pakuszewski[1], J.C. Souza[1], A. Ribeiro[1], C. Adriano[1] and P. Pagliuso[1] *1. Unicamp, Campinas, Brazil*

$Eu_3Ir_4Sn_{13}$ is an intermetalic compound, the so-called Remeika cubic phase $R_3M_4Sn_{13}$ (R = rare earth, M = transition metal). $Eu_3Ir_4Sn_{13}$ presents a structural distortion at T* ~ 57K with a propagation vector (0 1/2 1/2). In addition it presents an antiferromagnetic (AFM) order below T_N ~ 10K where we observe a commensurate magnetic propagation vector (0 1/2 1/2) identical to the one observed for the structural distortion [3]. In this work we present the evolution of the magnetic and structural properties of $Eu_3Ir_4Sn_{13-x}Ga_x$ studied by electrical resistivity, specific heat and magnetic susceptibility. The results have shown that the Ga doping suppresses the structural transitions and barely changes de magnetic one. We will also present results of X Ray powder diffraction under applied pressure of the undoped compound were we found a change of the powder pattern of the super lattice peaks for pressure higher that 3.2 Gpa.

CT-14. Preparation of Highly Magnetic and Dispersible FeCoNi-Graphene Hybrid Materials using a Low Temperature Process for Electromagnetic Absorbing Film. K. Lee[1], *S. Lee*[1], K. Kim[2], B. Jung[1] and T. Kim[1] *1. Korea Institute of Materials Science, Changwon, The Republic of Korea; 2. Yeungnam University, Gyeongsan, The Republic of Korea*

Magnetic metal and graphene hybrid is a suitable material for electromagnetic wave absorbing film due to high electric and magnetic properties [1, 2]. However, hydrothermal process and heat treatment at high temperature decreases the productivity of the hybrid material. In this work, a strategy for preparation of FeCoNi and graphene hybrid materials without heat treatment and hydrothermal method is described. Electroless plating is used to grow the magnetic metal particles on the surface of graphene without reduction by heat treatment at high temperature. We find that the conventional electroless plating method is inappropriate for the synthesis of FeCoNi@graphene hybrid materials with high saturation magnetization. Therefore, we propose a new electroless plating method and observe the morphological, structural and magnetic properties of the synthesized FeCoNi@graphene hybrid materials. The FeCoNi@graphene prepared by the new synthesis method has a different morphology (see Figure 1) and crystal structure from that prepared by the conventional one. Saturation magnetization value of the hybrid material is 63.1 emu/g when the ratio of FeCoNi to graphene is 1:1, and the maximum is 171.6 emu/g when the FeCoNi ratio is increased. When the ratio of FeCoNi to graphene is 4:1, both magnetic property (120.4 emu/g) (see Figure 2) and dispersion stability of the hybrid material can be achieved. The FeCoNi@graphene hybrid is well dispersed in tetrahydrofuran, and thus it is fabricated into a free-standing and flexible composite film by mixing with thermoplastic polyurethane. High permeability of the FeCoNi@graphene film results in high EM wave absorbing performance due to impedance matching. These results provide important progress not only towards the commercialization of EM wave absorbing film for healthcare, electronic reliability, and tactical security applications, but also towards the development of magnetic metal and graphene hybrid materials based on a scalable process.

CT-15. First-principles study of magnetic properties of NO_2 absorbed on $SnSe_2$ monolayer. W. Cheng[1], H. Fuh[2] and *C. Chang*[3] *1. Graduate Institute of Applied Physics, National Taiwan University, Taipei, Taiwan; 2. Department of Chemical Engineering & Materials Science, Yuan Ze University, Taoyuan, Taiwan; 3. Department of Physics, National Taiwan University, Taipei, Taiwan*

Recently, two-dimensional transition metal dichalcogenides (2D-TMDs) materials has gained great attention due to its weak van der Waals type layer structure. Moreover, the flake and few-layers $SnSe_2$ have also been used as high performance photodetector[1] and high-mobility field-effect transistor[2] applications. Moreover, $SnSe_2$ is also a good candidate for gas sensing. This study simulates the interactions of NO_2 and NH_3 gas molecules absorbed on $SnSe_2$ monolayer respectively via a first-principles approach based on density-functional theory (DFT). The calculation includes both the van der Waals force interaction and spin polarization. Fig. 1 (a) and (b) show the crystal structures of monolayer $SnSe_2$ adsorbed with NO_2 and NH_3 molecules, respectively. The distances between gas molecules and $SnSe_2$ are about 3Å means the interaction between gas molecules and $SnSe_2$ monolayer is in the range of physisorption. Fig. 2 (a)~(d) represent the band structures of NO_2 and NH_3 adsorption on $SnSe_2$ monolayer. The magnetic moment of NO_2-$SnSe_2$ system is about $1.0\mu_B$. In Fig. 2(a) and (b) are the spin decomposed band structure of SnSe2 adsorbed with NO_2. Firstly, there are two flat bands between the E_F which located in about -0.2eV and 0.8eV. The spin-up electrons are occupied below the E_F and the spin-down electrons are occupied up the E_F. This kind of band structure distribution also induces the magnetic moment after NO_2 adsorbs on the $SnSe_2$ monolayer. However, the magnetic moment of NH_3-$SnSe_2$ system is about $0.0\mu_B$. Due to the band occupation of the spin-up and spin-down electrons of NH_3 are the same location which shown in Fig.2 (c) and (d). The difference of magnetic moment induced by different gases sensing is similar with graphene-based gas sensor[3][4]. In conclusion, the magnetic moment would be induced when NO_2 adsorbs $SnSe_2$ monolayer which provides experimental researcher to further investigation.

CT-16. A Study on the Improvement of Torque Density and THD Performance through the Injection of Ferrofluid into the Magnet Tolerance of IPMSM. *I. Yang*[1], D. Kim[1], S. Song[1], S. Lee[1], K. Kim[2] and W. Kim[1] *1. Gachon University, Gyeonggi-do, The Republic of Korea; 2. Halla University, Gangwon-do, The Republic of Korea*

When inserting a permanent magnet into a rotor core of IPMSM (Interior Permanent Magnet Synchronous Motor), it is ideal that the size of the permanent magnet and the insertion space correspond to each other. However, it is difficult to insert the permanent magnet when the sizes of insertion space and the permanent magnet are the same. Magnet tolerance between the rotor core and the permanent magnet is necessarily required. Increased magnet tolerance can reduce the performance and there is a problem with driving motor at high speed that can cause vibration between the permanent magnet and the magnet tolerance. And vibration causes noise. In order to prevent vibration in the magnet tolerance, an adhesive is inserted into the magnet tolerance to fix the permanent magnet. In this case, the magnet tolerance doesn't contribute to performance improvement. In this paper, a method to improve performance by injecting ferrofluid into the magnet tolerance of IPMSM for 4WD hydraulic control system and changing the rotor shape. The ferrofluid is a magnetic liquid which consists of water or oil mixed with ultrafine powder. The ferrofluid has a higher permeability than vacuum. Therefore, it is possible to improve the performance by reducing magnetic resistance when the ferrofluid is injected into the magnet tolerance. To verify the proposed rotor configuration, two rotor parameters and four target functions were set for the proposed model which the shape of the barrier and the position of the magnet were changed while the ferrofluid was injected in and the conventional model. And the rotor design was proceeded respectively through FEM (Finite Element Method). It was confirmed whether the conventional model and the proposed model satisfied the target specification of IPMSM for 4WD hydraulic control system or not. The design process was verified through prototype manufacture and testing. The proposed model had higher performance than the conventional model in terms of torque, THD and efficiency except cogging torque. This study is expected to be applied to robot, aviation, medical, and other fields requiring high performance and high efficiency motors.

Systems comprising magnetic nanoparticles (MNPs) are unique in both structure and properties, thus allowing different applications. However, interactions among MNPs are difficult to address in real systems. Regarding MNPs interactions, several experimental results have been reported in the literature, but few theoretical approaches have been proposed to explain the behavior of such a complex system. In this study, we report on the morphological, structural and magnetic investigation of cobalt ferrite nanoparticles (CFN) synthesized by co-precipitating Co^{2+} and Fe^{3+} in alkaline medium at increasing temperatures, from 25 to 95 °C [1,2]. X-ray diffraction data of the as-synthesized CFN revealed samples with high degree of crystallinity and average crystallite size in the range of 5 nm to 11 nm as the synthesis temperature increases [3]. Hysteresis cycles (*M* versus *H*) were recorded at 5 K, 100 K and 300 K whereas field-cooled (FC) and zero-field-cooled (ZFC) magnetization curves (*M* versus *T*) were obtained in the range of 5 K to 300 K while varying the applied field in the range of 50 Oe to 100 Oe. The room-temperature *M* versus *H* data were well described by averaging out the first order Langevin function with a lognormal distribution function of magnetic moments [4]. However, at low temperatures, deviations from the classical superparamagnetic regime are observed and generally attributed to single-particle blocking effects and/or random interactions among MNPs [5,6]. The dependence of the magnetization in different temperatures is herein reported and explained using a new phenomenological approach. Three samples are tested, and the results are discussed in terms of such a new empirical model. The proposed interpretation is thought to be applicable to other MNPs systems.

CU-02. gFORC: A GPU Accelerated First-Order Reversal-Curve Calculator. F. Gross[1], J.C. Martínez García[2], S.E. Ilse[1], G. Schütz[1], E. Goering[1], M. Rivas[2] and *J. Gräfe*[1] *1. Max Planck Institute for Intelligent Systems, Stuttgart, Germany; 2. University of Oviedo, Gijón, Spain*

First-order reversal-curves (FORCs) [1] are a powerful tool, increasingly used in material science as well as nano-magnetism [2-4]. Ideally, it can access microscopic interactions and coervities without the need for lateral resolution [5]. Unfortunately, the conventional fitting algorithm requires lots of computational effort to overcome noise, inherently present in the measurement data. Here we present a fast Fourier transform (FFT) evaluation approach exploiting the manifold of Fourier space to decrease the computing time by a factor of 200. Comparing baseline resolutions of the conventional and the FFT algorithm, we are able to deduce an analytical equation to transform the smoothing factor *SF* of a FORC diagram into real field resolution *R*. To validate the proposed algorithm we compare three representative FORC measurements evaluated with both approaches (Fig. 1). All of the FORC densities show exceptionally good agreement. Not only does the FFT algorithm show the typical *reversal ridge* [6] for fully reversible processes (*cf.* Fig 1c) & d)), it also perfectly recovers the behavior of a multi-phase system with complex interactions between soft and hard magnetic phases [7] (*cf.* Fig 1e) & f)) over a wide range of smoothing factors. The achieved speed up allows us to utilize an autocorrelation approach [8] which was previously computationally prohibitive. This autocorrelation allows us to judge objectively whether a FORC diagram is under- or oversmoothed at a given smoothing factor (Fig. 2). In the first part (gray box, left), the noise of the FORC diagram is reduced which increases the correlation (undersmoothing). The last part (gray box, right) is highly oversmoothed which causes destruction of information. The part between noise and signal reduction (green box) illustrates the region of optimum smoothing in which noise is suppressed sufficiently but no information destroyed. In summary, the proposed algorithm speed up FORC calculations and allows to replace the *SF* concept with real field resolutions. It automatically determines the optimum smoothing and enables unprecedented advanced FORC evauation.

CU-03. Study of Mechanical Resonance Induced by Magnetostriction in Cyclic Structures Based on FeSi. *J. Li*[1], B. Qu[2] and K. Yu[3] *1. State Key Laboratory of Control and Simulation of Power System and Generation Equipments, Tsinghua University, Beijing, China; 2. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China; 3. Global Information and Telecommunication Institute, Waseda University, Tokyo, Japan*

The noise produced by motors and power transformers is harmful and its reduction is the hot subject in continuous research. Such systems are likely to be in resonance and become more vociferous, and the resonance may be mechanical or magnetic forces. The interaction between the deformation due to magnetostriction and mechanical resonance of a structure made up of laminated steel sheets is investigated in this paper. The resonance phenomena are generally studied and analyzed by considering that the frequency and the spatial distribution of the electromagnetic forces coincide with the natural frequency and the modal shape of the corresponding structure. It is observed that the magnetostriction may induce a resonance without the need to combine these two conditions. Two cyclic sheets structures of square and circular consisting of cold-rolled grain-oriented (GO) and non-grain oriented (NO) electrical steels are used to confirm this assumption. Finite element (FE) calculations and measurements are made and compared with vibration displacements. The results of the mechanical resonance induced by ferromagnetic magnetostrictive strain are shown, as well as the corresponding vibration spectrums. 1. The mechanical resonance induced by magnetostrictive deformation has been studied. The resonance occurs when the natural frequency of the laminated steel sheets structure corresponds to the multiple of the excitation frequency. The vibration behavior of the laminated structure shows a ferromagnetic behavior which similar to the modelling. 2. The study confirms that the magnetostriction is likely to cause the resonance of a ferromagnetic materials even at very low amplitudes of excitation, and may be even more important for high power devices. Due to the presence of harmonics in the magnetizing field, so, the consideration of their influence on the deformation is necessary. 3. This paper has shown that the magnetostriction can be involved in the mechanical resonance of a laminated structure, and should be considered in the design stage.

CU-04. Ultra-broadband and ultra-high sensitivity permeability measurements by transformer coupled permeameter. *S. Tamaru*[1], H. Kubota[1], N. Kikuchi[2] and S. Okamoto[2] *1. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; 2. IMRAM, Tohoku University, Sendai, Japan*

Many high frequency magnetic components are made of magnetic particles, which are first prepared by crashing an ingot, next undergo various processes such as micro-forging and annealing, then are either sintered or dispersed into polymer resin and solidified into the final form. Its permeability is measured on the final form due to limited sensitivities of permeameters currently available[1-3]. Therefore, one can only infer the effect of each of the processes on the permeability from the measurement result on the final form, which is very inefficient and often misleading for the development of high frequency magnetic components. For this reason, a technique to measure the permeability of magnetic particles with a sufficiently high sensitivity has been strongly sought. To accomplish this goal, we have developed a permeability measurement technique, which we named as "transformer coupled permeameter (TC-permeameter). Figure 1 shows the block diagram. A magnetic particle is sandwiched by two short terminated coplanar waveguides (CPWs). These two CPWs are electrically insulated by Kapton tape, thus this structure forms a loosely coupled transformer. Each CPW is connected to the port 1 and 2 of a vector network analyzer that measures S_{21} twice, first under the magnetic field of interest, and second under a sufficiently strong magnetic field to saturate the magnetic particle. The difference of S_{21} under these two magnetic fields reflects the permeability. Figure 2 shows the permeability of a single Permalloy particle with a lateral size of approximately 100 μm and thickness of 0.5 μm, which is similar to the size of magnetic particles contained in commercial noise suppression sheets, measured by the TC-permeameter. The figure shows that the permeability can be measured from 10 MHz up to 20 GHz with a high signal-to-noise ratio. In the presentation, the measurement principle of the TC-permeameter, including the jig structure, the reason why this technique can enhance the sensitivity and how to calibrate the system to give the absolute value will be explained.

CU-05. Inexpensive Setup for Accurate Characterization of the Ferromagnetic Linewidth of Garnet Spheres. *A. Pacewicz*[2], J. Krupka[2], P. Aleshkevych[1], B. Salski[2] and P. Kopyt[2] *1. Institute of Physics, Polish Academy of Sciences, Warsaw, Poland; 2. Warsaw University of Technology, Warsaw, Poland*

The theory, design and operation of an inexpensive but accurate setup for ferromagnetic linewidth (ΔH) measurement of garnet spheres is presented. The fixture consists of a microwave Q-meter, rectangular cavity, hand-adjustable magnet, quartz sample tube and personal computer. From a single Q-factor measurement, as well as the diameter and saturation magnetization of the sample, the linewidth is obtained based on the recently proposed characteristic equation for a spherical gyromagnetic resonator placed in a metal enclosure [1]. The setup can handle any coupling regime between the sample and cavity. For strong coupling, which occurs for sufficiently narrow ΔH, the magnet is positioned in such a way that the Q-factors of the sample and cavity modes are similar [2]. For weak coupling, i.e. when the cavity mode is perturbed, the minimum value of the Q-factor is sought. In either case ΔH is quickly obtained with the aid of a precomputed database. The influence of factors such magnetic anisotropy or dielectric losses on ΔH is shown to be negligible in most practical scenarios. A variety of mono- and polycrystalline yttrium iron garnet samples have been measured in two TE_{102} cavities operating at ca. 5 GHz and 10 GHz. Where possible, the obtained results are compared to a perturbation theory approach.

CU-06. Measurement uncertainties of complex permeability effects in ferrite material under compressive stress. *J. Le Gallou*[1] *1. DMAT, CEA, Monts, France*

To achieve non-destructive control of materials properties, a general broad band measurement technique of complex permeability under stress has been demonstrated some years ago, based on a short-circuited line (one-port measurement/reflection only) [1]. Despite the fact that the application of an external stress can change drastically the values of the permeability, most of the studies have evidenced the influence of a stress on static magnetic properties only, but few works have led into the field of the dynamic magnetic properties. As shown figure 1, the sample is inserted between an alumina layer of already characterized EM spectral permittivity and the short circuit. Broad band measurement of the complex reflection coefficient S_{11} is performed using a vector network analyzer, in a coaxial line geometry. The complex permeability of the MUT sample is retrieved using the one-to-one well described Nicholson and Weir correspondence procedure, from this two-phase material configuration formed by the alumina cylinder placed side-by-side of the sample. To apply a compressive, uniaxial controllable state of stress, the mechanical setup, as shown in figure 1, allows the alumina layer to apply the designed force on the whole surface of the parallel sides of the sample, to create an uniform stress. Such applied pressure is monitored by a force sensor connected to the computer. The developed programs allow to define the VNA and extensometer measuring conditions and to calculate the complex permeability as a function of stress (see figure 2). The dynamic permeability measurements versus stresses are carried out in a standard APC7 sample, in a coaxial wave guide, between 1 MHz and 6 GHz at room temperature. The configuration presented allows to determine accurately the microwave properties of the material under compressive and uniaxial stress. This technique is used to investigate the properties of a soft NiZn ferrite. Many new results on the permeability under mechanical stress of this material will be presented at the conference (example: sensitivity of the permeability as a function of stress speed).

CU-07. Determination of Anisotropy Constants of a Magnetic Thin Film Sample Using Ferromagnetic Resonance (FMR) Spectra. *K.I. Masood*[1], P. Dhagat[1] and A. Jander[1] *1. EECS, Oregon State University, Corvallis, OR, United States*

An experimental procedure, using angle- and strain-dependent ferromagnetic resonance (FMR) spectra to[J1] determine anisotropy constants (K_u, K_1, K_2) and magnetoelastic constants (B_1, B_2) of crystalline thin films, is illustrated in this work. Application of FMR spectra for determining anisotropic constants of magnetic thin films is a well-researched topic [1-5]. Experimental field vs. resonant frequency data are fitted with the theoretical model to extract the anisotropy constants. However, determination of all five constants requires measurements as a function of magnetization angle and strain. Our experimental setup is designed to do this by providing full vector control of the applied magnetic field as well as the ability to apply a bending moment to the sample under test. The arbitrary magnetic field vector is applied by an orthogonal pair (y and z direction) of superconducting electromagnets coupled with automated sample rotation about the z axis as illustrated in Fig. 1(a). Simultaneously, a custom sample-holder is used to bend the sample as shown in Fig. 1(b). A four point bending mechanism is used to generate uniform strain, which can be calculated from the sample geometry, the applied force, the distance (shown as ‘c’ in Fig. 1(b)) between the fulcra, and the elastic modulus of the substrate. The push rod is connected to a voice-coil actuator to modulate the strain in the sample. An example measurement in our instrument is shown in Fig. 2(a), where the angle dependence of the FMR frequency for a Mn doped YIG film is shown. This figure also demonstrates the effect of out-of-plane magnetic field (labeled as ‘Bz’). The effect of applied strain is shown in Fig. 2(b). A gradient descent method is used to fit the FMR data with the Smit-Beljers model and thereby extracting the unknown constants.

CU-08. Displaying FORC Distributions without Information Loss.
P.B. Visscher[1] *1. MINT Center, University of Alabama, Tuscaloosa, AL, United States*

The First Order Reversal Curve (FORC) method[1] is designed to extract more information about a magnetic system than a simple M(H) loop. Specifically, in a system of irreversible Preisach hysterons (each characterized by a down-switching field H_R and an up-switching field H) FORC gives the distribution $\rho(H,H_R) = -\frac{1}{2}\partial^2 M(H,H_R) / \partial H\, \partial H_R$. However, existing programs for displaying this FORC distribution lose much of the information in the FORC measurement. Specifically, (1) By construction, the FORC distribution ρ contains no information on reversible components. (2) There may be nonzero density ρ beyond the maximum H of the FORC curves. (3) The most common (Princeton Measurements) protocol for FORC measurement does a calibration measurement at saturation before each FORC curve which cannot be recovered from the display. We have written a public-domain display program ("FORC+")[2,3] which is designed to preserve all of the information in the FORC measurement, in the sense that the FORC curves $M(H_R, H)$ (where H_R is the reversal field), as well as the calibration measurements $M(H_R, H_{cal})$ can be exactly recovered from the displayed data. Fig. 1 shows a schematic view of the display. The density is displayed as a color plot. However, to recover the original M, we also need some first derivatives as boundary conditions – physically these are the reversible switching field distribution[4] and a Lost Hysteron distribution $\partial M(H,H_R)/\partial H_R$ at the end of the FORC and at the calibration field H_{cal} that indicates how much density was lost by not measuring to high enough field H.

CU-09. Suspension Force Modeling and Electromagnetic Performance Analysis on the Integrated Five Degrees of Freedom DC Four-Pole Hybrid Magnetic Bearing. *X. Ye*[1], Q. Gu[1] and T. Zhang[1] *1. Huaiyin Institute of Technology, Huai'an, China*

Modern ultra-high speed power transmission system puts forward new performance requirements for magnetic suspension motor [1], such as high power density, high suspension force density and high critical speed. The existing magnetic suspension motors usually use 1-DOF axial magnetic bearings, 2-DOF radial magnetic bearings and 3-DOF radial-axial magnetic bearings to form a 5-DOF magnetic suspension support system to support the rotor [2], which results in the longer axial length, lower critical speed, lower power density and suspension force density. Moreover, compared with AC HMB, DC HMB are uncoupled in every direction and easy to control. Therefore, to solve the above problems, an integrated DC HMB which can achieve 5-DOF stable suspension is proposed in this paper. The proposed 5-DOF DC HMB integrates the functions of two radial magnetic bearings and one axial magnetic bearing. It can realize 5-DOF stable suspension in one unit, which is of great importance to improve the critical speed, power density and suspension force density of magnetic suspension motor. Firstly, the structure and suspension mechanism of the integrated 5-DOF four-pole DC HMB are analyzed. Then, the mathematical models of suspension force are deduced by the equivalent magnetic circuit method. Thirdly, the three-dimensional finite element model is established according to the prototype parameters, and the three-dimensional magnetic circuit is analyzed. The relationships between the suspension forces and the control currents are calculated, and the experimental prototype has been manufactured. The simulation and experimental results verify the correctness of the suspension mechanism and the mathematical models. The structure of integrated 5-DOF DC HMB is shown in Fig. 1(a). Fig. 1(b) shows the magnetic circuits. Fig. 2(a), Fig. 2(b) and Fig. 2(c) show the distribution of bias flux density. Fig.2(e), Fig.2(f) and Fig.2(g) show the distribution of resultant magnetic flux density. The force-current relationships are shown in Fig. 2(h). It can be seen that the calculated values of the finite element method agree with those of the mathematical models.

CU-10. Effects of an external magnetic field on the hyperfine parameters in RE_2O_3 (RE = Gd, Er) nanoparticles measured by perturbed angular correlation spectroscopy. *E. Correa*[1,2], B. Bosch-Santos[3], R.N. Saxena[2], G. Cabrera-Pasca[4] and A.W. Carbonari[2] *1. Material Measurement Laboratory, National Institute of Standards and Technology, Gaithersburg, MD, United States; 2. Nuclear and Energy Research Institute, Sao Paulo, Brazil; 3. NIST Center for Neutron Research, National Institute of Standards and Technology, Gaithersburg, MD, United States; 4. Federal University of Para, Abaetetuba, Brazil*

The RE_2O_3 (RE = rare-earth) oxides present three different structures depending on the RE ionic radii: hexagonal (A-type), monoclinic (B-type) or cubic (C-type). In the latter, RE ions occupy two non-equivalent cation sites: asymmetric 24d sites and symmetric 8b sites. Gd_2O_3 and Er_2O_3 crystallize in this structure and have a paramagnetic behavior, although Er_2O_3 also orders antiferromagnetically below 4 K. Due to the high magnetic moment of Gadolinium ions, Gd^{3+} chelates have been used as a contrast agent for magnetic resonance imaging[1]. An investigation of the localized magnetic moment behavior on Gd and Er sites in Gd_2O_3 and Er_2O_3 nanoparticles (NPs), within an atomic resolution, under the influence of an external magnetic field (EMF), is very necessary mainly because the high neutron absorption cross-section of Gd prevents the use of neutron diffraction[2]. In this paper, hyperfine interactions, measured by Perturbed Angular Correlation (PAC) spectroscopy using $^{111}In \rightarrow ^{111}Cd$ as probe nuclei, were used to investigate the behavior of each RE site in Gd_2O_3 and Er_2O_3 NPs with and without the application of an EMF of 0.5 T. NPs were synthesized by thermal decomposition and characterized by transmission electron microscopy and X-ray diffraction. Results show that the contribution of RE atoms at 24d sites is invariant with temperature whereas the contribution from RE atoms at 8b sites is so that the hyperfine magnetic field (B_{hf}) increases in Er_2O_3 and decreases in Gd_2O_3 when temperature decreases indicating an opposite alignment of Gd magnetic moments at the 8b symmetric sites.

CU-11. Macroscopic magnetization tunneling in the Josephson φ_0 junction. *G. Kim*[1] *1. Physics and Astronomy, Sejong University, Seoul, The Republic of Korea*

A quest to understand the quantum tunneling of magnetization(M) in nanomagnets has been a topical issue of intensive theoretical and experimental studies. At extremely low temperature the magnitude of M is frozen out and its orientation becomes an interesting dynamical variable. Since the direction of M is intrinsically determined by the anisotropy energy, there are two or more equilibrium orientation of M. Many studies have focused on the switching rate of individual nanoparticles for observing magnetic tunneling in the magnetic field. In recent years special interest has emerged in the tunneling rate manipulated by a Josephson current. As is well known, an influence of ferromagnetism on superconductivity is much stronger than the opposite one of the superconductivity on the ferromagnetism because the exchange interaction for ferromagnet (~100 K) is much larger than the order parameter for conventional superconductor (~ 1K). However, relativistic interactions responsible for the direction of M in nanomagnets (~ 1 K or less) are expected to be of the same order as the superconducting order parameter. Such a possibility was recently studied by Chudnovsky[1] who investigated the tunneling rate of M in the Josephson φ_0 junction. In fact, such a junction was proposed by Buzdin[2] who studied the Josephson junction between superconductors with a weak link formed by a noncentrosymmetric magnetic metal, and present the current-phase relation, $j=j_c\sin(\varphi-\varphi_0)$ where the phase φ_0 is proportional to M perpendicular to the gradient of the asymmetric spin-orbit potential. However, in the previous works they considered the spin dynamics controlled only by the bias current. In this work we consider quantum tunneling of M in the Josephson φ_0 junction with an external magnetic field as well as the bias current, and present diverse features of the tunneling rate which depends on two external controlling parameters. Spin-coherent-state path integrals are used to obtain analytic expressions for the tunneling rate for various crystal symmetries, with special attention to the field effect of currents. We will discuss optimal conditions giving the possibility of observing quantum tunneling of M coupled with Josephson current.

CU-12. Research on High Frequency Magnetic Properties for Nanocrystalline Alloys Under Alternating and Rotational Magnetizations. M. Yang[1,2], *Y. Li*[1,2], Q. Yang[1,2], S. Yue[1,2], C. Zhang[1,2] and H. Sun[1,2] *1. School of Electrical Engineering, Hebei University of Technology, State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Tianjin, China; 2. School of Electrical Engineering, Hebei University of Technology, Key Laboratory of Electromagnetic Field and Electrical Apparatus Reliability of Hebei Province, Tianjin, China*

Compared with silicon steel sheets, nanocrystalline alloys have higher permeability and lower conductivity, and it can be made into thinner strips, which makes it more easily magnetized and have lower eddy current loss. Therefore, nanocrystalline alloys have great high frequency performance. Compared with ferrite, nanocrystalline alloys have higher saturation magnetic density, which can further reduce the volume of electrical equipment and effectively improve power density. The rotating magnetic field will exist at the corner joint of laminated and blocky cores, and the rotating loss will be quite different from the alternating loss. In order to improve the accuracy of loss prediction, it is necessary to measure the rotational magnetic properties of related core materials [1]. At present, electrical equipment is gradually developing towards high frequency and miniaturization, and the application of novel materials such as nanocrystalline alloys is more extensive. In order to widen the application of nanocrystalline alloys in engineering practice, it is necessary to measure and analyze the magnetic properties of these materials and to make their physical properties clearer so as to give full play to their application value [2]. In this paper, a novel high-frequency 2-D magnetic tester for nanocrystalline alloy is proposed. The alternating and rotating magnetic properties of this material are studied from 1 kHz to 20 kHz. And the differences of magnetic properties between easy and difficult magnetization directions of nanocrystalline alloy in alternating magnetic fields are systematically investigated, and combined the experimental data of 2-D rotating magnetic properties, the macroscopic phenomenon of the magnetic anisotropy is analyzed from the view of the microstructure of the material. The relationship between rotation loss and alternating loss of nanocrystalline alloys under different axial ratios of elliptical magnetic field excitation is analyzed.

CU-13. Independent Control of Anti-parallel and Parallel State Thermal Stability Factors in Magnetic Tunnel Junctions for Telegraphic Signals with Two Degrees of Tunability. *B.R. Zink*[1], Y. Lv[1] and J. Wang[1] *1. Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States*

Magnetic tunnel junctions (MTJs) with low thermal stability at room temperature have been proposed as read units in probabilistic-bits, or p-bits [1]. However, networks of multiple interconnected MTJs may be particularly sensitive to device-to-device variations of thermal stability from design targets [2]. Recently, we generated tunable telegraphic signals using a thermally stable MTJ through proper control over an external bias field and a DC voltage bias [3], which is illustrated in Fig. 1. Not only does this provide a solution to issues associated with device to device variations, but it also introduces the possibility of p-bit designs that are compatible with state of the art MRAM technology. Furthermore, our results demonstrated that the average anti-parallel (AP) and parallel (P) state dwell times could be tuned independently, giving a second degree of tunability to the signals generated. In this work, we expand on this method in two important ways. First, we demonstrate the applicability of our method to p-bit designs by modelling the transfer function using existing p-bit models. Fig. 2 shows that the device's transfer function can be adjusted with slight modifications to the bias field, where the bias voltage is treated as the input and the percentage of time that the MTJ spends in the AP-state (referred to as the AP-rate) is treated as the output. This allows for the possibility of p-bit circuits capable of on-chip

corrections against device-to-device variations of their thermal stabilities. Second, we identify the physical mechanisms that allow for two degrees of tunability in the output signal, which is explained via the Néel-Brown model. This study provides both applicability and predictability to the dual-biasing method.

CU-14. Based on Transient Current Analysis a Measurement Method of Residual Flux Density Used in Single-phase Power Transformer.
H. Cailing[1] *1. Hebei University of Technology, Tianjin, China*

With the rapid development of AC/DC ultra-high voltage (UHV) transmission technology, large capacity transformer has been more and more widely used [1]. As the transformer closes without load, if there is residual flux in the core, the magnetic saturation of the core will be accelerated, resulting in larger inrush current (the peak value can reach 6-8 times of the rated current) [1]. To avoid large inrushing current the study of residual flux in the power transformer is particularly necessary. Gauss meter and fluxgate sensor are used to measure the residual flux of iron core [2-3], but there is a lot of interference and some error in the instrument itself. Some scholars have proposed that residual flux by integral of the measured voltage at switching-off time of transformer can be calculated [4]. Other scholars judge the residual flux by establishing the relationship between residual flux and measurable current [5]. However, none of the methods mentioned in the above references can accurately measure the residual flux. Therefore, this paper proposes a new residual flux density measurement method used in the single-phase power transformer through establishing the basic relationship between residual flux density Br and time constant T of winding transient current i(t) under different Br when loading positive and negative constant voltage signals Us to measuring winding. Basic model of the single-phase power transformer core is shown in Fig.1. N_1 and N_2 are the turn number of preset residual flux winding (winding1) and measuring winding (winding2). The residual flux is preset by loading current excitation im in winding 1, and Us is loaded in winding 2 to detect $i_1(t)$ and $i_2(t)$. The basic principle of the proposed method is shown in Fig. 2. It can be seen that T is different when the flux increases or decreases. Through theoretical analysis and 3-D finite element simulation analysis. The direction of Br is judged by comparing T, and the magnitude of Br can be calculated by the establishing empirical formulas of Br and T. Finally, the validity and accuracy of the proposed residual flux density measurement method are verified by experiments.

CU-15. Effect of Uniaxial and Biaxial Stress on Alternating Magnetic Properties of Silicon Steel Sheet.
Y. Dou[1,3], *Y. Li*[1,3], C. Zhang[1,3] and J. Zhu[2] *1. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China; 2. School of Electrical and Information Engineering, University of Sydney, Sydney, NSW, Australia; 3. Key Laboratory of Electromagnetic Field and Electrical Apparatus Reliability of Hebei Province, Hebei University of Technology, Tianjin, China*

Laminated silicon steel sheet, which is widely applied in electrical engineering, such as cores of power transformers and electrical machines, usually subject to mechanical stress. Magnetostriction will occur once mechanical stress exists, and therefore additional power loss is produced [1, 2]. In general, stress is caused by a number of factors such as material processing, machine manufacturing and operating conditions. To optimize the utilization of silicon steel, the measurement of magnetic properties is required, especially under stress. Although the effect of stress on magnetic properties has been extensively studied, the experiments were always conduct at power

frequency which was not enough to separate the iron losses and study the stress effects on different loss components. This paper focuses on the effect of uniaxial and biaxial stress on hysteresis loop shape, maximum permeability of the material and power loss characteristics. In addition, based on the measurements under different stress situation under various frequency, the total loss can be separate into three loss component, hysteresis loss, classical eddy loss and excess loss using conventional loss separation te chnique. Detailed loss separation process will be presented in the full manuscript.

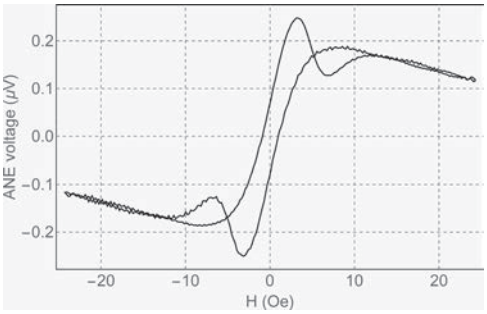
CU-16. Hysteresis loop tracer based on the anomalous Nernst effect induced by the asymmetric dissipation of Joule heating.



C.A. Gonzalez-Fuentes[1], C. Romanque[1], C. Orellana[1] and C. Garcia[1]
1. Physics, UTFSM, Valparaiso, Chile

Magneto-transport measurements techniques, often imply the application of an electrical current on ferromagnetic thin film stripe. As collateral effect, there is always a generation of some amount of Joule heating on the stripe. Given the typically orders of magnitude differences between the thermal conductivities of the ambient and the substrate, this results in an out-of-plane thermal gradient originated by the asymmetric dissipation of Joule heating [1]. This, in turn, may give origin to Anomalous Nernst Effect (ANE) voltages. This effect is normally an unwanted artifact that must be removed from the data analysis, being specially relevant in Second Harmonic Detection of Spin-Orbit Torques [2]. In this work we demonstrate that the above mentioned effect can be conveniently exploited for the study of ANE on thin ferromagnetic films. We test this idea on a NiFe thin film (20nm) shaped into 4-terminal Hall bar, in which the heating current is injected through 2 extremes of the Hall bar and the ANE generated voltages are measured at the two other extremes. As expected, the results showed an excellent linearity between the power applied and the ANE voltage. However, the H-loop curve presents some distortion that we attribute to the non-uniform thermal gradient across the thickness of the film. Our method is very attractive from the experimental point of view given that only electrical connections to the sample are required to study the ANE, without the needing of an external heating or cooling hardware.

CV-01. Strain effects on the magnetotransport properties of transition metals. *R.J. Gonzalez Hernandez*[1], B. Dupe[2] and J. Sinova[2] *1. Department of Physics, Universidad del Norte, Barranquilla, Colombia; 2. Institute of Physics, Johannes Gutenberg University Mainz, Mainz, Germany*

The Anomalous Hall Effect (AHE) is a phenomenon which consists of an extra anomalous transverse voltage developing when current is passed through ferromagnetic material in a magnetic field [1]. In this work, we studied the dependence of strain and magnetization effect on the intrinsic anomalous Hall conductivity (AHC) in 3d metal Fe-bcc, Co-fcc, Co-hcp, and FeCo structure. For Fe-bcc case, the AHC shows a slightly decreasing with the increase of pressure, being this associate to the magnetization dependence with the lattice constant. However, the AHC for lattices constants above of 2.95A shows a downturn around 70%, even when the magnetization has increased. This decreasing seems to be related to a transition of d-states occupations above this lattice constant. The computation of the anomalous Hall conductivity was carried out using ab-initio calculations (included the effect of spin-orbit interaction for the ferromagnetic state) and the Wannier interpolation technique for the application of the Kubo-Greenwood formula [2].

CV-02. Perfection of theoretical model for high frequency MI effect of ferromagnetic amorphous microwires. Y. Wang[1], *F. Qin*[1], Y. Zhao[1], D. Estevez[1], D. Makhnovskiy[1] and H. Peng[1] *1. Zhejiang University, Hangzhou, China*

The Co-based amorphous microwires have a significant magnetoimpedance effect (MI) effect for the excellent soft magnetic properties, nearly zero negative magnetostriction coefficient and the unique magnetic domain structure. Based on the MI effect, the material has excellent sensing properties and can be widely used in the field of sensors, especially high frequency sensors for its high magnetic permeability. However, there is currently a lack of research on high frequency MI effect. And in high frequency, the interaction between the amorphous wire and the electromagnetic field is complex, and the existing theoretical models cannot match the high frequency MI experiment results very well. We developed an accurate method, broadband impedance measurements, for measuring the magnetoimpedance effect (MI) of ferromagnetic microwires from 100 kHz up to 15 GHz. Through the measurements, we obtained the MI curves at different frequencies and the impedance spectrums under different magnetic fields of the amorphous microwires with a nominal composition of Co68.7Fe4Si11B13Ni1Mo2.3, fabricated by Taylor–Ulitovsky method. The MI profiles (Fig.1(a)) shows that a new maximum of impedance appears with the frequency increasing from a few hundred MHz to GHz; its value and the corresponding magnetic field also increase with increasing frequency. In contrast, the magnetic field corresponding to the original maximum in relatively lower frequency remains almost unchanged. The phenomenon cannot be expressed by the existing theoretical model. The impedance spectrum (Fig.1(b)) indicates that the microwires undergo the transition from natural resonance to ferromagnetic resonance with the magnetic field increasing. A multilayer planar domain model is therefore proposed herein to describe these experiment results, which introduces the effect of axial domains (inner layer) on impedance at relatively higher frequency. The new maximum of impedance results from the ferromagnetic resonance of the inner layer based on the analyses of the model on the experimental results.

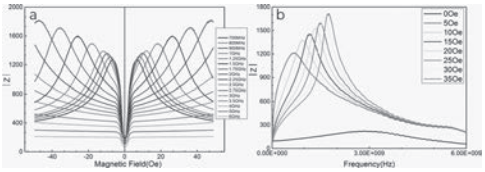

Fig. 1 (a) The MI curves at different frequency. (b) The impedance spectrum of the sample at different magnetic field.

CV-03. The Effects of Annealing Rate and Temperature on Ta/TbFeCo bilayers. *L. Ye*[1,2], C. Lee[1,2], R.C. Bhatt[1,2], S. Chang[1,2], J. Wu[3] and T. Wu[1,2] *1. Graduate School of Materials Science, National Yunlin University of Science and Technology, Douliou, Taiwan; 2. Taiwan SPIN Research Center, National Yunlin University of Science and Technology, Douliou, Taiwan; 3. Department of Physics, National Changhua University of Education, Changhua, Taiwan*

Among various perpendicularly anisotropic magnetic materials, amorphous rare-earth-transition metal RE-TM alloys have attracted much interest due to the advantages of tunable magnetic properties and suitable perpendicular magnetic anisotropy (PMA) strength. Furthermore, RE-TM alloys are anti-parallel coupled systems that can be switched by spin-orbit torques (SOT). In this study, the magnetic properties of the structure Ta/TbFeCo/MgO with various Tb contents, annealing rise rate and temperatures are explored. The film stack consists of structures SiNx/Ta(4 or 10nm)/TbFeCo(10nm)/ MgO(4nm). The samples were then annealed at different annealing rate from 10 ^{o}C/min to 50 ^{o}C/min and holding time from 10 min to 30 min with temperatures ranging from 100 to 150 °C. We found that fast rise rate and low temperature annealing could help to improve PMA and significantly increase the saturation magnetization and squareness. The best Tb composition ratio for the required PMA depends on the annealing conditions. Figure 1 and Figure 2 show the magnetic hysteresis loops for the TM-rich and RE-rich samples under various annealing conditions, respectively. One can see that the both the squareness and coercivity increase with temperature rise rate, but decrease with temperature and holding time. In additions, the anomalous Hall Effect (AHE) measurements on Hall bar were carried out with a series of dc sensing currents. PMA, The AHE measurement results and TEM microstructure properties will be presented and meticulously discussed. This work was supported by the National Science Council of Taiwan, Republic of China, under Contract No. NSC 107-2112-M-224 -001 -MY2.

CV-04. Magnetotransport Properties of Epitaxial Terbium Nanowires. *G.A. Newman*[1], C.S. Taylor[1], L.J. Calvano[1], P.D. Sparks[1], J.C. Eckert[1], S.K. Patel[2] and E. Fullerton[2] *1. Physics, Harvey Mudd College, Claremont, CA, United States; 2. Center for Memory and Recording Research, University of California, San Diego, La Jolla, CA, United States*

Rare earth materials are of great interest because of their rich magnetic properties that play a critical role in current technology and are of potential use in future technologies such as antiferromagnetic spintronics [1]. The high orbital moment and strong spin-orbit interactions make rare-earths appealing for spin-Hall and inverse spin-Hall effects. Further, as materials are scaled down in size for technological application, finite-size effects emerge which alter the properties in confined structures and illuminate the nature of the magnetic transitions [2, 3]. We are interested in studying thin epitaxial films grown on ultrathin seed layers, making the films appropriate for magnetotransport and spintronic measurements. Bulk terbium exhibits ferromagnetic (FM) and weak helical antiferromagnetic (AF) phases [4]. Here, we study these phases in Tb that has been confined in one or more dimensions to magnetic length scales. Thin films of Tb (0001) were deposited by DC magnetron sputtering on MgO (100) and MgO (111) substrates with W seed and capping layers and patterned by electron beam lithography into wires with widths ranging from 100 nm to 4 μm and voltage lead gaps ranging from 100 nm to 16 mm. The FM, AF, and paramagnetic (PM) phases were measured in moment vs. applied field measurements (see Fig. 1) by vibrating sample magnetometry. In magnetoresistance measurements, anomalies in resistance vs. temperature and resistance vs. field (see Fig. 2) determined the phase diagrams for different wire widths and applied field directions. As the wire widths are decreased to magnetic length scales, we are able to measure the transition in individual domains. Work at HMC was funded in part by the Jean Perkins Foundation, Florida State University, and Los Alamos National Laboratory. Work at UCSD supported by DOE award No. DE-SC0003678.

CV-05. Electron transport and magnetoresistance in highly oriented epitaxial magnetite nanorods. *R. Das*[1,2], V. Kalappattil[2], M. Phan[2] and H. Srikanth[2] *1. Faculty of Materials Science and Engineering, Phenikaa University, Hanoi, Vietnam; 2. Department of Physics, University of South Florida, Tampa, FL, United States*

Recent advancements in miniaturization of devices are motivating research at nanoscale. Fe_3O_4 is a promising material for room temperature spintronic device application due to its 100% spin polarization, half metallic behavior and high Curie temperature (T_C = 850 K). Numerous fascinating properties arise from the spin-polarized transport, particularly the magnetoresistance (MR) [1]. At room temperature, MR of 10% has been observed in bulk and polycrystalline Fe_3O_4, which is well below the theoretical value [2]. This could be due to defects, off-stoichiometry, strain effects and interfaces. Moreover, in nanoscale random distribution of tunneling barriers, complex transport channels and crystallite orientations further affect the spin transport properties. One-dimensional nanostructures with unique electron transport properties have shown potential for nanoelectronic devices [1]. However, there has been no report on magnetotransport of an oriented array of magnetite nanorods. In this study, we report the electron transport and MR

in chemically grown highly oriented epitaxial Fe_3O_4 nanorods on a (001) $SrTiO_3$ substrate. Resistance vs. temperature (R-T) data exhibited a sharp increase in the resistance at 120 K, which can be attributed to the Verwey transition whose presence affirmed the high crystallinity of the Fe_3O_4 nanorods. Negative MR values of 0.8% and 2.2% at 0.4 T were observed at 300 and 100 K, respectively. This can be ascribed to the spin-polarized electron transport across the antiphase boundaries. The sharp MR peaks of 200, 410 Oe at 300 and 100 K, respectively, are close to the coercive field as observed from the M-H loop. Recently, we have shown that the epitaxial nanorods exhibit biaxial magnetic anisotropy at room temperature [3]. The results obtained identify epitaxial nanorods as useful materials for room temperature data storage and spintronic devices that necessitate tunable anisotropic magnetotransport property.

The anomalous Hall effect (AHE), as a consequence of spin-orbit coupling, occurs in ferromagnetic material and plays an important role in the experimental research. The AHE in molecular-beam epitaxy L10 FePt thin films has been measured and the side jump mechanism was proven to be dominating. [1] On the other hand, magnetic properties of core/shell FePt/Fe3O4 Nanoparticles has been studied and the hysteresis loops showed that the magnetic hard core and the magnetic soft shell were exchange-coupled. [2] We synthesized FePt/Fe3O4 Core/Shell Nanoparticles with shell thickness 0-5 nm using two steps high temperature organic phase method. The synthesized Nanoparticles were spin coated onto Si/SiO2 substrates and annealed under UHV to obtain a nanoparticle film. The as-made thin films were characterized by SEM, AFM, EDS and XRD. The AHE as a function of film thickness and annealing temperature were systematically investigated. The mechanisms of the AHE in such nanoparticle systems were also investigated.

CV-07. Perpendicular magnetic anisotropy in TbFeCo/MgO structure with underlayer Ta/Hf. *L. Ye*[1,2], R.C. Bhatt[1,2], C. Lee[1,2] and T. Wu[1,2]
1. Graduate School of Materials Science, National Yunlin University of Science and Technology, Douliou, Taiwan; 2. Taiwan SPIN Research Center, National Yunlin University of Science and Technology, Douliou, Taiwan

To attain perpendicular magnetic anisotropy (PMA) for MRAM structure, a number of material systems like RE-TM alloys, Co/Pt and FePt multilayers etc. have been explored as a magnetic recording layer in pMTJs. The RE-TM alloys, in particular the amorphous TbFeCo alloys have advantage of low saturation magnetization, large PMA and significant thermal stability, therefore, are expected to have low critical current density for spin-torque-induced magnetization switching. The heavy-metal underlayer has strong spin-orbit coupling (SOC) which can provide a lower critical current and fast magnetization switching. In this study, the interfacial PMA in (Ta or Hf)/TbFeCo/MgO/Ta structures are investigated and the effectiveness of two kinds of heavy-metal Hf and Ta underlayers are explored. The PMA of TbFeCo are found to be critically relied on several aspects like Tb-concentration (Tb sputtering power), underlayer material (Hf/Ta), annealing temperature and heating rate of annealing. The crystalline phase of the underlayer was optimized by changing the film thickness and observed by XRD and resistivity measurements. It is observed that for the Hf underlayer the PMA can be obtained in as-deposited samples irrespective of the Tb-concentration with squareness close to 1. To see the heat treatment effect, samples were annealed at different (i) heating rate, (ii) annealing temperature and (iii) holding time. We found that fast heating rate and low temperature annealing improves PMA in FeCo-dominant films; however, the PMA reduces when Tb-concentration is increased. Figure 1 and Fig. 2 show the magnetic hysteresis loops for as-deposited and annealed Hf (4nm)/TbFeCo/MgO/Ta structure, respectively. To further investigate the effect of Tb composition and annealing conditions on PMA, the anomalous Hall effect, XRD, and TEM characterizations will be presented and meticulously discussed. This work was supported by the National Science Council of Taiwan, Republic of China, under Contract No. NSC 107-2112-M-224 -001 -MY2.

CV-08. First-principles study of anomalous Nernst effect in 2D ferromagnet and materials with nontrivial spin textures. *F. Ishii*[1], R. Syariati[2], S. Minami[2] and H. Sawahata[2] *1. Nanomaterials Research Institute, Kanazawa University, Kanazawa, Japan; 2. Graduate School of Natural Science and Technology, Kanazawa University, Kanazawa, Japan*

We are interested in getting higher thermoelectric conversion efficiency by magnetic materials. We have been studying Berry-phase-mediated thermoelectric effects, namely anomalous Nernst effect (ANE), which is a heat-to-electricity conversion observed in magnetic materials and directly related to he contribution of the anomalous Hall conductivity (AHC) [1-4]. We discussed AHC mainly driven by an effective magnetic field, Berry curvature, induced by spin-orbit interaction and spin chirality. We performed first-principles density functional calculations[5] for hypothetical

2D materials[1-2], half-metallic 2D ferromagnet[3] and and 3D half-metallic half-Heusler alloys[4]. We found that the spin-orbit interaction and spin chirality driven Berry curvature indeed generates large ANE. We predicted that the carrier tuning enhances thermoelectric efficiency. We will discuss how to find new materials with large Berry-phase-mediated thermoelectric effects in mainly 2D materials.

There is increasing interest in studying materials that exhibit complex magnetic order and phase transitions that couple electronic, magnetic and electronic degrees of freedom. MnRh and FeRh are such materials that show an antiferromagnetic (AF) low-temperature phase to a ferromagnetic (FM) high-temperature phase transition for potential applications such as in magnetic recording, magneto-calorics or antiferromagnetic spintronics.[1-3] In bulk, the binary alloy MnRh undergoes a transition to the AF state during cooling at approximately 150 K and to the FM state during warming near room temperature.[4] In this work, we fabricate epitaxial MnRh thin films on MgO substrates (see Fig. 1) using DC magnetron sputtering. These films exhibit an AF-FM transition with a broad thermal hysteresis that can be seen in magnetometry measurements, as shown in Fig. 2. We conduct a systematic study in these films, showing a shift in the transition to higher temperature with larger Mn:Rh ratios. We also make transport measurements, which demonstrate a dramatic change in resistivity between the AF and FM states. By fabricating nanowires using electron-beam lithography, we confine the system in multiple dimensions to domain size length scales and are able to probe the transition more carefully in individual domains.[3] Work at UCSD funded by Award # DE-SC0019273. Work at HMC funded by the Jean Perkins Foundation, Florida State University, and Los Alamos National Laboratory.

CV-10. Anomalous Hall effect in Hexagonal Magnetic Alloy Fe_5Sn_3.

H. Li[1,2], J. Chen[1,2], B. Ding[1,2], E. Liu[1,3], H. Zhang[1], X. Xi[1], G. Wu[1] and W. Wang[1,3] *1. Institute of Physics, Chinese Academy of Sciences, BeiJing, China; 2. University of Chinese Academy of Sciences, BeiJing, China; 3. Songshan Lake Materials Laboratory, Dongguan, China*

Anomalous Hall effect (AHE) has been explored for a long time in ferromagnetic materials and there are some different origins which relate to AHE in different materials [1]. In general, there are three origins of AHE which can be classified into intrinsic and extrinsic mechanisms, respectively. The former is originated from influence of Berry phase generated from momentum-space[2] and the latter is from scattering which also can be divided into side jump[3] and skew scattering[4,5] because of the different scattering reasons. In hexagonal magnet Fe_5Sn_3, the AHE is investigated during the current flows along c-axis and magnetic field parallels to ac-plane. As shown in Fig.1, with temperature reduced, the slopes of the Hall resistivity ρ_{xy} carves in saturation region changes from positive to negative, which means the species of charge carriers change at low temperatures. This special phenomena could be originated from the influence of magnetic structure on Fermi surface.

CV-12. Fabrication of $D0_{19}$- and B2-type Fe_3Sn epitaxial films and comparison of magneto-transport properties. A. Maeno[1], Y. Goto[1], M. Tsujikawa[2,3], M. Shirai[2,3], T. Yanase[4], T. Shimada[4] and *T. Nagahama*[4]
1. CSE, Hokkaido University, Sapporo, Japan; 2. RIEC, Tohoku University, Sendai, Japan; 3. CSRN, Tohoku University, Sendai, Japan; 4. Graduate School of Engineering, Hokkaido University, Sapporo, Japan

The alloys consisted of 3d-transition metals and Sn has attracted much attention because of novel characteristics. For example, Mn_3Sn was reported to show large anomalous Hall effect (AHE) or anomalous Nernst effect (ANE) [1]. Fe_3Sn_2 also expected to exhibit large AHE because of the crystal structure involving Kagome lattice[2,3]. So far, most of the experiments were performed using single crystal samples. To use them in the devices, thin film fabrication technique is indispensable. Recently, we succeeded in the fabrication of B2 type Fe_3Sn epitaxial films[4] which exhibited large ANE. On the other hand, $D0_{19}$ type Fe_3Sn phase was also reported in the literature. In this study, we fabricated the epitaxial growth of $D0_{19}$ Fe_3Sn and compare the magneto-transport characteristics to B2-type Fe_3Sn. The samples were prepared by Molecular Beam Epitaxy (MBE) method. Stacking structures were as follows: Al_2O_3 (0001) substrate / Pt (111) 6nm (buffer layer) / $D0_{19}$-Fe_3Sn (0001) 30 nm/ Al_2O_3 5nm (cap layer). The temperature of substrates during the depositions were 673 K for $D0_{19}$-Fe_3Sn. B2 Fe_3Sn layer was deposited at a temperature of 373 K on MgO(001) substrate, then the films were annealed at 573 K for 30 min. The epitaxial growth was confirmed by RHEED and XRD θ-2θ measurements. Figure 1 shows the anomalous Hall effect of B2 and $D0_{19}$ Fe_3Sn thin films. Both Fe_3Sn films exhibited clear Hall effect because they were ferromagnetic materials. The Hall resistivity of B2 was 7 times larger than that of $D0_{19}$ Fe_3Sn. Such small Hall effect for $D0_{19}$ alloy could be attributed to the anisotropic crystal structure[1]. The saturation fields of AHE were very different between B2 and $D0_{19}$ because $D0_{19}$ Fe_3Sn has in-plane magnetic anisotropy. The longitudinal MR will be also discussed.

CV-14. Enhanced MR Raio and Low Coercivity in Dual-Spin-Valve GMR Stack with Synthetic Antiferromagnetic Couplings. *N. Fukatani*[1], M. Ichimura[1] and J. Hayakawa[1] *1. Hitachi Ltd., Hikigun, Japan*

In recent years, giant magnetoresistance (GMR) effect has been used in many application such as low magnetic field sensor, current sensor, and read heads in hard disc drives due to their small size, high sensitivity, low power consumption, and low cost[1, 2]. Except for a reading heads in hard disc drives, GMR sensors are required to show high MR ratio and low coercivity (H_c) with low stray field regardless of their thickness because the thickness of GMR stacks is not critical for the performance of GMR sonsors. Important design parameters are number of spin-dependent electron scattering layers, crystallinity, and the interface sharpness. In this study, we fabricated dual-spin-valve GMR stacks with synthetic antiferromagnetic couplings in order to enhance GMR ratio with low H_c in a current-in-plane configuration toward the sensitive magnetic sensor applications. The dual-spin-valve GMR stack is composed of Si/SiO sub.//seed layer/IrMn(6)/ CoFe(2.6)/ Ru(0.85)/CoFe(2.6)/Cu(2.5)/CoFe(1)/NiFe(3.5)/CoFe(1)/ Cu(2.5)/CoFe(2.6)/Ru(0.85)/CoFe(2.6)/IrMn(6)/capping layer (all thickness in nm), which were deposited by magnetron sputtering technique. The micro structure was investigated using scanning transmission electron microscope (STEM) with a energy dispersive X-ray spectroscopy (EDX). The MR curves were measured by a four-probe method by applying magnetic field. Figure 1 shows a vertical STEM-EDX element mapping image of the GMR stack. The layered film structures which consist of a few nm films are clearly observed. The crystal structure of the GMR stack is identified to be highly oriented (111) structure from the fast Fourier transformed diffraction patterns. Figure 2 shows MR curves for the dual-spin-valve and the conventional single-spin-valve GMR stack. The MR ratio in the dual-type is increased up to 13.1 %, which is about 1.3 times higher than that of the single-type of 9.8 %. The H_c estimated from Fig.2 is below 10 Oe, which is comparable to that of the practical GMR sensors. Therefore, present dual-spin-valve GMR stack is promising for realizing high sensitive magnetic sensors.

CV-15. Magnetotransport Properties Probed by Terahertz Time-Domain Spectroscopy on Ferromagnetic Thin Films.
L. Huang[1], S. Lee[1], D. Kim[1], Y. Zhao[1], S. Kim[2], H. Shin[2], J. Park[2], H. Kim[3], J. Hong[3] and D. Kim[1] *1. Chungbuk National University, Cheongju, The Republic of Korea; 2. Pohang Accelerator Laboratory, Pohang, The Republic of Korea; 3. Daegu Gyeongbuk Institute of Science & Technology, Daegu, The Republic of Korea*

Terahertz (THz) properties of various materials have drawn a great attention recently. Since THz time-domain-spectroscopy (TDS) is used to investigate optical conductivity, under external magnetic fields, THz TDS could reveal useful information regarding magnetotransport behavior of ferromagnetic samples. For TDS, a beamsplitter is used to split one ultrafast pulse from Ti:sapphire regenerative amplified laser system into two pulses and different portions of the THz pulse can be measured at the detector and thus, mapping out the THz pulse in the time-domain[1]. Here, we report our experimental investigation on spin-dependent conduction behavior in ferromagnetic Fe metallic films with different thickness by means of TDS developed at Pohang Accelerator Laboratory. It is considered that, in case of ferromagnetic transition metals, carriers are mostly taken by sp-band Fermi-level electrons, while localized electrons scatter with spin-dependent momentum at spin-split d-band, where the spin-dependent transport behavior occurs. The spin-dependent optical conductivity is analyzed based on the Drude model[2]: $\sigma(\omega) = \sigma_0(1\text{-}i\omega\varsigma)^{-1}$ with consideration of the spin-dependent density and momentum scattering/relaxation time of conducting electrons at Fermi levels[3]. THz-TDS under various external magnetic fields in the range 0 – 150 Oe for different thickness have been analyzed, where the amplitude of transmitted signal showed an obviously increasing trend with respect to the external magnetic field, as seen in Fig. 1, which can be understood based on the sample conductivity and number of spin/charge carriers[4]. This research has been supported by [Grant No. 2018R1A2B3009569] and by Max Planck POSTECH/KOREA Research Initiative Program [Grant No 2016K1A4A4A01922028] through the National Research Foundation of Korea (NRF).

CV-16. Large Magnetoresistance at Small Magnetic Field and Reconfigurable Boolean Logic Functions Based on Diode-enhanced Giant Magnetoresistance Effect.
J. Nan[1], K. Zhang[1], S. Yan[1], Z. Zhang[1,2], Z. Zheng[1,2], G. Wang[1], Y. Zhang[1], Y. Zhang[1,2] and W. Zhao[1] *1. Fert Beijing Research Institute, BDBC, School of Microelectronics, Beihang University, Beijing, China; 2. School of Electronic and Information Engineering, Beihang University, Beijing, China*

Magnetoresistance (MR) plays a key role for spintronic devices [1-3]. Recently, diode-enhanced MR has been reported to achieve large MR ratio [4-6]. In this paper, we proposed an alternative to realize large MR at small magnetic field by combining giant MR (GMR) effect with the nonlinear transport property of the diode. The GMR film stack (Fig. 1(a)) [7] is patterned into a strip and then connected to a Zener diode and two resistors R_1, R_2 (Fig. 1(b)). The apparent resistance R is defined as R=V/I, where V is the voltage measured by the voltmeter and I is the applied current. The MR ratio is defined as MR=(R(H)-R(0))/R(H), where R(H) is the apparent resistance under magnetic field H. The MR of the GMR strip (Fig. 1(c)) is amplified by the switching behavior of the diode, resulting in a dramatic change in the apparent resistance of the system (Fig. 1(d)). MR ratio up to 5389% is realized with a magnetic field as small as 50 Oe. This proposal has the potential for realizing reconfigurable Boolean logic functions. As shown in Fig. 2(a), two GMR strips are connected in series. The aligned low-resistance state and anti-aligned high-resistance state of the GMR strip are regarded as logic input "1" and "0", respectively. The pinning direction of the two strips should be opposite to each other, thus the two logic inputs can be set to (0,1), (1,1), (1,0) and (0,0) by applying different magnetic fields (see Fig. 2(b)). Fig. 2(c) shows the I-V curves of the proposed circuit with these four sets of logic inputs. The critical voltage separating logic output "0" and "1" is 0.13 V. For example, setting the working current to 6.1 mA can achieve logic function AND. The working current for logic function OR is 6.4 mA. The details are summarized in Fig. 2(d). This work can help to build future high-performance computing systems.

CV-18. Magnetic and Transport Properties of Multilayered EuO/Pt Thin Films. *N. Shrestha*[1], J.R. Murphy[1], W.D. Rice[1] and J. Tang[1] *1. Physics and Astronomy, University of Wyoming, Laramie, WY, United States*

Research on europium monoxide (EuO) has been done extensively in the last decade because of the physics of this interesting magnetic semiconductor and its potential applications in spintronics. In order to examine the spin-orbit proximity effect, we have prepared multilayered EuO/Pt thin films on Si (001) substrates by pulsed laser deposition (PLD) using europium (Eu) metal as target. The magnetic and transport properties of the EuO/Pt films have been studied as a function of temperature and magnetic field with a Physical Property Measurement System (PPMS). The magnetic data show increased Curie temperature from 70 K to 140 K which is characteristic of oxygen deficient samples (Fig. 1) and is described by a magnetic polaron model [1]. The transport measurements (Fig. 2) reveal contributions from various conducting channels including the interface between EuO and Pt [2]. At the lowest temperatures, the resistivity ρ exhibits an exp ($1/T^{1/2}$) temperature dependence for some samples. The transport measurements reveal both positive magnetoresistance (PMR) and negative magnetoresistance (NMR) originating from spin-orbit scattering and weak localization effect. There is a strong enhancement in the magnetic anisotropy from its bulk value, which results from strong spin-orbit coupling across the EuO/Pt interface.

CW-01. Uniaxial magnetic anisotropy and bcc-bct-fcc transformation of FeCo caused by the addition of V and N elements. *T. Hasegawa*[1], C. Shirai[1] and Y. Takemasa[1] *1. Department of Materials Science, Akita University, Akita, Japan*

The energy utilized by the magnets depends on the magnitudes of the saturation magnetization (Ms) and uniaxial magnetic anisotropy (Ku). FeCo with the body-centered cubic (bcc) structure is a well-known magnetic material characterized by the highest Ms and very high Tc values among various transition metal alloys. Although FeCo-based materials exhibit the strong magnetic properties, their low Ku magnitudes make them unsuitable for the fabrication of permanent magnets. However, if the Ku of FeCo could be increased to a sufficiently high value, one of the strongest permanent magnets would be obtained. Recent our studies[1] revealed that the epitaxial FeCo thin films with the body-centered tetragonal (bct) structure and thicknesses of several nanometers exhibited Ku values of 10^6 J/m^3 due to epitaxial stress, which required further stabilization. Two methods can be used to stabilize the bct structure: (I) applying a uniaxial stress to the FeCo lattice via epitaxial effects and (II) adding a third element to the FeCo structure. The addition of certain third elements (II) is expected to generate a tetragonal distortion in the FeCo lattice leading to the relaxation of the local stress in their vicinity. In our previous study,[2] we focused on the use of the combination of V and C, N elements as the third additive element because of its ability to form a bcc, which was subsequently transformed into the fcc with an increase in the third element content. We expected that a stabilization of the bct structure occurs at the boundary between the bcc phase and the fcc phase. In this study, the effect of the N addition into FeCoV films on their tetragonal deformation was investigated. Figures 1(a) and 1(b) shows the in-plane XRD and the out-of-plane XRD patterns of the FeCoVN films deposited directly on the MgO substrate, respectively. The bcc-bct-fcc transformation depending on the N content (x) is observed. At x = 2.0 at% in the bct region, a high Ku of 10^6 J/m^3 are obtained. This work was supported by NEDO.

CW-02. Large perpendicular anisotropy of highly (001) oriented MnAl film fabricated on CoGa buffer layer. *D. Oshima*[1], T. Kato[2] and S. Iwata[1] *1. Institute of Materials and Systems for Sustainability, Nagoya University, Nagoya, Japan; 2. Department of Electronics, Nagoya University, Nagoya, Japan*

$L1_0$-phase MnAl is one of promising candidates for the memory layer in spin transfer torque magnetic random access memory since it exhibits a large perpendicular magnetic anisotropy and a small Gilbert damping [1]. In previous reports, (001) oriented MnAl films were grown on Cr or Cr alloy buffer layer [1]. Recently, highly (001) oriented MnGa films were grown on CoGa buffer layers which exhibit an excellent magnetic property even for the thickness < 5 nm [2]. In this study, we prepared MnAl films on CoGa(001) buffer layers by magnetron sputtering. The film stack was Cr (2 nm) / MnAl (5 or 15 nm) / CoGa (0 or 30 nm) / Cr (20 nm) / MgO(001) sub. Cr and CoGa buffer layers were deposited at 400 °C and annealed at 600 °C after the deposition. The MnAl layer was grown at T_s and annealed at T_a after the deposition. Figure 1 shows *M-H* loops, atomic force microscope (AFM) images, and x-ray diffraction (XRD) profiles of the 5-nm-thick MnAl films grown on the Cr or CoGa buffer layer. In this case, T_s was set to be 200 °C and post-annealing was not carried out. By using the CoGa buffer layer, MnAl film exhibited a saturation magnetization of 400 emu/cc and almost unity squareness ratio. The value of the perpendicular anisotropy was roughly estimated to be 7 Merg/cc from the in-plane curve. The surface flatness was also improved by using the CoGa buffer layer. In XRD profiles, 001 and 002 MnAl peaks were clearly observed and intensities of these peaks were larger for the sample with the CoGa buffer than that without the CoGa buffer. Further improvements of the magnetic property and the surface flatness by post-annealing at T_a = 500 °C were confirmed, it is concluded that the insertion of the CoGa buffer layer was effective to improve the (001) orientation and magnetic property of MnAl.

CW-03. Structural and magnetic properties of $Mn_{53.3-x}Al_{45}C_{1.7}Ti_x$ (x = 0, 0.5, 1.0, 1.5) melt spun ribbons. *J.S. Trujillo Hernandez*[2,1], J.A. Tabares[1] and G.A. Pérez Alcázar[1] *1. Physics Department, Universidad del Valle, Cali, Colombia; 2. Facultad de Ciencias Naturales y Matematicas, Universidad de Ibagué, Ibagué, Colombia*

The binary Mn-Al alloy is a promising rare-earth free hard magnetic materials due to its intrinsic magnetic properties and low cost of the raw materials. The effect of Ti addition on the magnetic properties and the phase stability of the Mn-Al system is investigated. For this purpose, $Mn_{53.3-x}Al_{45}C_{1.7}Ti_x$ (x = 0; 0.5; 1.0; 1.5) alloys were subject to melt spinning at 20 m/s wheel speeds and annealing under different temperatures. The X-ray diffraction patterns and scanning electron microscope images indicates that was possible to obtain pure ε-phase after melt spinning at 20 m/s for all compositions. For all the other solidification conditions, the melt spun ribbons show undesired secondary phases (T, β and γ_2). Annealing the single phase ribbons above 550°C has shown a clear transformation from the high temperature e-phase to the desired τ-phase. Magnetic measurements indicate a slight increase in the coercivity values with increasing Ti concentration and an increase in Curie temperature by 20 K with addition of Ti. The highest values of magnetic properties were obtained for $Mn_{51.8}Al_{45}C_{1.7}Ti_{1.5}$ alloy: M_s(3T) = 93.6 Am²/kg, μ_oH_c = 0.198 T, M_r = 43.3 Am²/kg, and T_c = 650 K.

CW-04. Effect of Al doping on magnetic properties of LTP-MnBi alloys. *H. Lee*[1], M. Kang[1], G. Lee[1] and J. Kim[1] *1. Materials Science and Chemical engineering, Hanyang University, Ansan, The Republic of Korea*

Recently, there has been much interest in the development of rare-earth free permanent magnets. Among several candidates, a low temperature phase (LTP) MnBi intermetallic compound has been attracted much attention due to its high magneto-crystalline anisotropy coefficient (K = 10^7 erg/cm³), curie temperature (T_c = 775 K) and positive coercivity temperature coefficient.[1-2] Up to now, most studies have focused on increasing the ratio of the LTP phase in MnBi powders due to its low processing temperature but few studies have been conducted to improve its magnetic properties. The first principle calculation showed that addition of Al could increase the saturation magnetization (M_s).[3-4] Therefore, in this study, LTP-MnBi alloys doped with Al were fabricated in order to investigate the effects of Al on the magnetic properties. In this experiment, Mn, Bi and Al raw materials were arc-melted under an argon atmosphere to prepare $(Mn_{54}Bi_{46})Al_x$ (x = 0, 1, 3, 5) alloys. Then, MnBi-Al ingots were inductively re-melted to obtain homogeneously mixed ribbons through the melt-spining process. These melt-spun ribbons were annealed at 573 K for 24 hours under an argon atmosphere to finally produce high quality LTP-MnBi alloys. Figure.1 shows the XRD patterns of annealed MnBi-Al alloys. It can be clearly seen that only LTP-MnBi single phase is developed in specimens containing less than 1 at.% Al. The further increase of the Al concentration results in the formation of the Al_8Mn_5 phase, which remains excess Bi. Figure.2 shows the M-H curves of the alloys measured by VSM at 2.5 T. This demonstrates that the addition of 1 at.% Al increase the M_s of the MnBi alloy from 60.9 to 62.2 emu/g. As expected, the further increase of Al concentration decreases the M_s due to the formation of the non-magnetic phases. The above results suggest that the addition of Al can increase the saturation magnetization of the LTP MnBi phase as the single phase of LTP-MnBi is maintained. This increase may be due to that Al atoms occupy the interstitial sites of the hexagonal MnBi phase. In order to clarify the effects of the Al addition, the microstructural analysis is under investigation.

CW-06. α″-$Fe_{16}N_2$ Foils with a Positive Temperature Coefficient of Coercivity. *J. Liu*[1], G. Guo[1], F. Zhang[1], B. Ma[1] and J. Wang[1] *1. University of Minnesota, Minneapolis, MN, United States*

α″-$Fe_{16}N_2$ has been getting more attention as a candidate of rare-earth-free magnets due to its unique magnetic properties, such as high saturation magnetization (M_s ~ 2.9 T),[1], [2] relatively large magnetocrystalline anisotropy (~1.0×10^7 erg/cm³) [3]–[5], and low coercivity temperature dependence. [6] Nanoparticles (NPs) are widely used to prepare α″-$Fe_{16}N_2$ by a low-temperature method (<200 °C) because of the higher nitrogen diffusivity for NPs.[7] However, several challenges remain for NPs approach such as easy to be oxidized, difficult to handle, and relatively low packing density. Bulk form α″-$Fe_{16}N_2$ like foils or ribbons could potentially address those challenges. However, the nitrogen diffusivity in the bulk forms needs to be enhanced to obtain high phase volume ratio of α″-$Fe_{16}N_2$. Here, we proposed to use Fe foils and tune the microstructure of these Fe based foils to make them suitable for fabricating α″-$Fe_{16}N_2$ foils by a low-temperature nitridation process. The Fe foils (~25 μm) were oxidized in air and then reduced by H_2. A porous structure was formed in these foils, in which the nitrogen diffusivity was enhanced significantly. After the reduction, a nitridation was proceeded using ammonia gas at the temperature lower than 200 °C, and nitride foil with a high phase volume ratio of α″-$Fe_{16}N_2$ were obtained. Magnetic properties of these nitride foils were characterized with coercivity around 1.1 kOe and M_s around 222 emu/g higher than the reduced Fe foil (~ 205 emu/g). The achieved magnetic anisotropy of these nitride foils is up to 7×10^6 erg/cm³. Temperature-dependent hysteresis loops indicated that the nitride foils have a small coercivity temperature coefficiency (positive) from 300 K to 425 K. It is about an order of magnitude smaller than that of commercial NdFeB magnets (negative). This could allow new applications for α″-$Fe_{16}N_2$ magnets. The good magnetic performances of α″-$Fe_{16}N_2$ foils make it a promising candidate for rare-earth-free magnets.

CW-07. Synthesis and magnetic properties of α″-$Fe_{16}N_2$ nanowires using an electrospinning method. *M. Kang*[1], G. Lee[1], J. Lee[1], Y. Choa[1] and J. Kim[1] *1. Hanyang University, Ansan, Ansan, The Republic of Korea*

In recent decades, there have been many attempts to develop new hard magnetic materials with high energy product ($BH_{(max)}$) and rare-earth free elements. An iron nitride phase, α″-$Fe_{16}N_2$, has received much attention due to the giant magnetic moment. Using this high magnetic moment, the α″-$Fe_{16}N_2$ phase was estimated to have a theoretical energy product of the 135 MGOe [1]. However due to the low crystalline anisotropy constant, the coercivity of α″-$Fe_{16}N_2$ magnetic materials was reported to be less than about 2.2 kOe. This means that the coercivity must be increased to use α″-$Fe_{16}N_2$ as a permanent magnet. In this study, one-dimensional α″-$Fe_{16}N_2$ nanowires with high aspect ratios were fabricated to induce the shape anisotropy for high coercivity using an electrospinning method. [2] In this experiment, electro-spun Fe/PVP precursor nanowires were prepared by electrospinning and then annealed at 700°c for 1 hr to obtain iron oxide nanowires in air. These annealed iron oxide nanowires were reduced in a hydrogen atmosphere at 300~400°c for 2 hr. The reduced iron nanowires were then nitrided at 140~170°c for 6~24 hr using ammonia gas. Figure 1 shows the morphology of fabricated nitrided nanowires. As shown in the figure, the wires with a diameter of 150 ~ 350 nm are successfully fabricated and their aspect ratio is also higher than 50. The XRD analysis of the wires indicated that the fraction of the α″-$Fe_{16}N_2$ phase reached 93.7 wt.%. Figure 2 shows the magnetic properties of the nitrided nanowires. The magnetization and coercivity of the nanowires measured 176.2 emu/g and 1215.5 Oe, respectively. It is considered that this low coercivity is caused by the fine grains of the nitrided nanowires. Thus, in order to improve the magnetic properties, various pre-heat treatment conditions before the nitridation of the iron wires have been examined. As a result, the pre-heat treatment is found to be an effective way to increases their initial grain size.

CW-08. Design of $Fe_{16}N_2$ magnets assisted with antiferromagnetic matrix. *X. Hang*[1] and J. Wang[2,1] *1. Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, MN, United States; 2. Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States*

Permanent magnets have traditionally been made with rare-earth (RE) elements. However, the environmental cost of RE mining and processing, as well as RE supply risks make it urgent to develop RE-free permanent magnets. $Fe_{16}N_2$, with its high saturation magnetization (M_s), is a promising candidate material for such purpose. However, even though $Fe_{16}N_2$ has decently large uniaxial anisotropy (K = 1.0 – 1.8 x 10^7 erg/cm^3), bulk $Fe_{16}N_2$ magnets made so far are limited with low coercivity (1200 – 2000 Oe), so are $Fe_{16}N_2$ nanoparticles (1000 – 3000 Oe). Thus, it is desirable to search

for new approaches to enhance its coercivity to make practical iron nitride magnets for a broad range of applications. Here, we propose the use of exchange coupling to an antiferromagnet (AFM) as a means to increase coercivity of $Fe_{16}N_2$ magnets. We studied nanometer-sized single-domain AFM-FM bilayers, using material constants of $Fe_{16}N_2$ as input. The dependence of coercivity on the two key parameters, AFM anisotropy and interface coupling strength, is reported within a simplified two-spin model, assuming uncompensated interface. We showed that, by proper choice of AFM materials, coercivity and $(BH)_{max}$ can be effectively enhanced. Our results guide the design of AFM-FM composite magnets and apply well to semi-hard materials like $Fe_{16}N_2$.

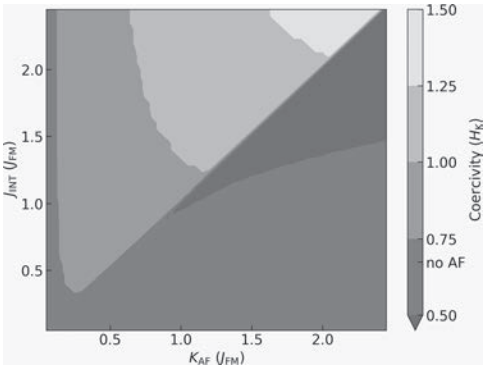

Fig. 1. Coercivity of the AFM-FM composite magnets as a function of AFM anisotropy and interface coupling strength. The coercivity of a single FM is marked on the scale bar.

CW-09. Characteristics of a rare earth free $L1_0$-FeNi hard magnet developed through annealing of FeNiPC amorphous alloys. J. Kim[1] and *H. Yim[1] 1. Sookmyung Women's University, Seoul, The Republic of Korea*

The rare-earth-free hard magnetic $L1_0$-FeNi phase found in cosmic meteorites demonstrates potential as a nextgeneration permanent magnet. However, it is very difficult to artificially produce the $L1_0$-FeNi phase due to the low atomic diffusion coefficients of Fe and Ni near the order-disorder transition emperature (~320 °C). Therefore, FeNiPC amorphous alloy systems exhibiting crystallization temperature (T_x) near the transition temperature were investigated. The amorphous alloys were annealed at T_x, resulting in high atomic diffusion. The structural and microstructural characterizations of annealed ribbons revealed the formation of $L1_0$-FeNi phase through observation of the superlattice peak. The magnetic property, such as coercivity (H_c), also indicated the formation of $L1_0$-FeNi phase, because the maximum H_c value is 641 Oe after the annealing process.

CW-10. Magnetic domain wall pinning and rapid thermal annealing in $L1_0$ -FePt/SiO_2 thin films. *J. Chiou*[1], H. Chang[2], C. Chi[1], C. Hsiao[1] and A. Ranjan[1] *1. National Tsing Hua University, Hsinchu, Taiwan; 2. National Chung Cheng University, Chia-Yi, Taiwan*

Highly ordered $L1_0$ FePt thin films with a strong (001) texture were successfully fabricated on amorphous silicon substrate by co-sputtering and rapid thermal annealing. The main focus of this work is to obtain the preferred orientation structure on amorphous SiO_2. The growth of thin films with controlled texture on the amorphous substrate would be beneficial for economic consideration as compared to with the MgO underlayer, which is pretty expensive. The perpendicular coercivity was enhanced by increasing the heating rate by increasing dislocation densities induced from strain. Dominant pinning sites to restrict the domain wall motion are the strain field of dislocation in FePt $L1_0$ films, because the domain wall width are similar to the range of strain field associated with dislocations. Higher in plane tensile stress was induced in the film by increasing the heating rate during the RTA. Structures were identified by X-ray diffractometer (Simadzu-6000) with the Cu Kα radiation, the strain mapping was performed using the GPA-Phase software (HREM Research Inc.). A spherical aberration corrected (scanning) TEM (JEOL JEM-ARM 200F) operated at 200 kV equipped with an energy-dispersive X-ray spectroscopy (EDS) was used for chemical composition and microstructural analyses. Magnetic hysteresis loops of samples were measured by SQUID, (Quantum Design MPMS-XL). Keyword: GPA-graphical phase analysis, SQUID-superconducting quantum interference device, RTA-rapid thermal annealing.

CW-11. High-temperature properties of Fe-Pt film-magnets prepared by electroplating method. T. Yanai[1], *Y. Omagari*[1], S. Furutani[1], A. Yamashita[1], M. Nakano[1] and H. Fukunaga[1] *1. Electricity and Electronics, Nagasaki University, Nagasaki city, Japan*

An $L1_0$ ordered Fe-Pt alloy is one of the well-known hard-magnetic materials, and active studies on Fe-Pt films with high coercivity have been carried out in the field of recording media. Although the saturation magnetic polarization of the Fe-Pt films is smaller than that of Nd-Fe-B films, the Fe-Pt films show relatively high remanence due to a remanence enhancement effect [1], suggesting that the Fe-Pt films are hopeful materials as isotropic permanent magnets. Taking advantage of high remanence and high coercivity of the TM-Pt alloy, some researchers have reported TM-Pt thick-films as small magnets [2-3], and we also reported the Fe-Pt thick-films prepared by an electroplating method [4]. For applying the films as magnets to small electric devices, we need to consider the thermal stability of the magnetic properties. In the present study, we, therefore, evaluated the high-temperature properties of the electroplated Fe-Pt thick-films. We carried out electroplating to obtain

the Fe-Pt thick films by using a direct current. Almost the same bath composition and the plating condition were used as our previous study [4]. The compositions of the as-plated Fe-Pt films were determined by SEM-EDX, and the hysteresis loops were measured with a VSM in the temperature range from 25 to 200°C. Figure 1 shows the coercivity of the annealed Fe-Pt thick-films as a function of the measurement temperature. As shown in Fig.1, the coercivity of all films decreased with increasing the measurement temperature. The thermal coefficient of H_c was approx. -0.21 %/K and this value is superior to that for typical Nd-Fe-B [5]. Figure 2 shows the demagnetization curves of annealed $Fe_{50}Pt_{50}$ and $Fe_{55}Pt_{45}$ films at 25°C and 200°C. Although high coercivity could be obtained for the $Fe_{55}Pt_{45}$ film compared with that for the $Fe_{45}Pt_{55}$ one, the squareness was inferior. Thus, we consider that the $Fe_{50}Pt_{50}$ thick-films are preferable to operate the films under high-temperature. The coercivity at 150°C was 700 kA/m, and this value is higher than that of some reports for Nd-Fe-B-system magnets [6]. From these results, we confirmed that the electroplated Fe-Pt film-magnets can be applied to small magnets required high thermal stability.

CW-12. Effect of chloride ion on crystal structures and magnetic properties of electroplated Fe-Pt film-magnets. *S. Furutani*[1], Y. Omagari[1], R. Hasama[1], A. Yamashita[1], T. Yanai[1], M. Nakano[1] and H. Fukunaga[1] *1. Nagasaki University, Nagasaki-shi, Japan*

$L1_0$ Fe-Pt films are attractive film-magnets for medical devices since they have good hard magnetic properties and high biological safety [1], and we reported some Fe-Pt thick-films (>10 μm) with a high coercivity (> 700 kA/m) prepared by an electroplating method [2]. In the recent study, we investigated the effect of NaCl concentration in plating baths on the coercivity of the films and pointed out that a possibility of enhancement in the coercivity by the Na ion [3]. When varying the NaCl concentration, not only the Na ion concentration but also the Cl ion one varies, suggesting that the Cl ion also has a possibility of coercivity enhancement. In the present study, we electroplated the Fe-Pt films from plating bath with various concentration of the Cl ion and evaluated structural and magnetic properties. We electroplated $Fe_{50}Pt_{50}$ film-magnets using a direct current on Cu plates. The plating bath consisted of $FeSO_4$(1-12 g/L), $Pt(NO_2)_2(NH_3)_2$(10 g/L), $H_6N_2O_3S$(25 g/L), and citric acid(30 g/L). To vary the Cl ion concentration without the change in the Na ion concentration, we used $FeCl_2$ and NH_4Cl. The films were annealed at 700°C for 5-60 min in a vacuum to order the Fe-Pt crystalline phase. Figure 1 shows the coercivity and Δ2θ of the annealed $Fe_{50}Pt_{50}$ films as a function of the Cl ion concentration. Since the diffraction peak of fcc (200) for the as-plated film is split into two peaks of fct (002) and (200) due to the development of the $L1_0$ ordering by the annealing, we can estimate the degree of the $L1_0$ ordering from the peak splitting Δ2θ. The Cl ion concentration was calculated from the amount of $FeCl_2$ or NH_4Cl in the bath. As shown in Fig. 1, the coercivity and the Δ2θ decreased with increasing the Cl ion concentration. This result implies that the Cl ion concentration affects the degree of the ordering and high Cl ion concentration of is not preferable to obtain high coercivity. Figure 2 shows the coercivity of the Fe-Pt films prepared from the Cl-ion-contained baths as a function of the amount of $NaSO_4$. The coercivity was increased by the addition of $NaSO_4$. From these results, we found that the $L1_0$ ordering is prevented by the Cl ion and enhanced by the Na one.

CW-13. Periodic Magnetic Domains in Singlecrystalline Cobalt Dendrites Fabricated by Electrodeposition. *F. Chen*[1], C. Li[1], R. Peng[1] and M. Wang[1] *1. Physics, Nanjing University, Nanjing, China*

The magnetic structure of a singlecrystalline nanostructures can be fundamentally influenced by the magnetocrystalline anisotropy, which is determined by the crystallographic orientation of the material. The competition of the magnetocrystalline anisotropy and the shape anisotropy enriches

the magnetic patterns of micro/nanostructures.[1] The traditional fabrication method to deposit singlecrystalline films such as molecular beam epitaxy is time-consuming and expensive. In this report, we demostrate an easy and cheap electrochemical method to deposit singlecrystalline dendrites in an ultrathin layer of electrolyte. Singlecrystalline cobalt dendrites are fabricated by electrodeposition on surface of any insulating or semi-conducting substrates. The size of the dendrites can be tuned by adjusting the magtitude of the applied voltage. Periodic magnetic domains and stripe domains are imaged by magnetic force microscopy in the dendrites. The periodicity of the magnetic domain is related to the size, the shape and the crystallographic orientation of the cobalt dendrites. We expect that this fabrication approach can be applied to construct singlecrystalline nanostructures with perpendicular magnetocrystalline anisotropy.

CW-14. Buffer layer dependence of magnetic properties and crystal structures for C38-type MnGaGe films. *M. Sun*[1,2], T. Kubota[1,3], K. Ito[1,3], S. Takahashi[4], Y. Sonobe[4] and K. Takanashi[1,3] *1. Institute for Materials Research, Tohoku University, Sendai, Japan; 2. Graduate School of Engineering, Tohoku University, Sendai, Japan; 3. Center for Spintronics Research Network, Tohoku University, Sendai, Japan; 4. Samsung R&D Institute Japan, Yokohama, Japan*

In the society of Internet of Things, the competition of memory development is becoming more and more serious. Among various memories, magnetoresistive random access memory (MRAM) attracts great attention for its non-volatile attribute and high-working-speed, recently. From the viewpoint of data retention for longer than 10 years, thermal stability factor Δ defined as $K_u V/k_B T$ must be larger than 60, where K_u, V, k_B, and T are uniaxial magnetic anisotropy energy, cell volume, Boltzmann constant and temperature, respectively. With the further integration of memory devices, K_u must be high enough to ensure the large Δ for the ferromagnetic layers in tunnel junctions of MRAM cells. According to the above reasons, our group has been working on C38-type MnGaGe films. In our previous study, the saturation magnetization of 260 emu/cm^3 and the K_u of 8.1 × 10^6 erg/cm^3 were found in a MnGaGe film deposited on MgO (100) substrate [1]. The M_s is comparatively small and the K_u is larger than that of CoFeB [2]. However, a problem is relatively large crystalline orientation dispersion which resulted in the poor squareness of magnetization curves. To improve the crystalline orientation of MnGaGe films, we have investigated the buffer layer dependence of magnetic properties and crystal structures for C38-type MnGaGe films. The stacking structure was as follows: MgO (100) substrate/buffer layer(s)/ MnGaGe (*t*)/MgO (2 nm)/Ta (5 nm). The layer thickness, *t* was varied from 5 nm to 100 nm. Different types of buffer layers such as Cr (60 nm), Cr (60 nm)/Pt (5 nm), Cr (20 nm)/Ru (40 nm) and Cr (60 nm)/ MgO (2 nm) were used. A 100-nm-thick MnGaGe sample using the Cr/MgO hybrid buffer layer exhibited the best squareness of 81% for the magnetization curve, and the full-width at half maximum of 002 peak for the rocking curve was reduced to 1.1°. In addition, perpendicular magnetization was observed down to the thickness of 5 nm for the MnGaGe sample using the Cr/MgO hybrid buffer layer. Samples using other buffer layers will also be discussed in this presentation. This work was partially supported by the Murata Science Foundation and Cooperative Research Project of CRDAM-IMR, Tohoku Univ. MS and TK thank Issei Narita for technical supports.

CW-15. Structure and Magnetic Properties for Fe-Mn-Ga-Sn Thin Films Prepared by Alternate Monoatomic Layer Deposition Method. *F. Nakagawa*[1], M. Doi[1] and T. Shima[1] *1. Graduate School of Engineering, Tohoku Gakuin University, Tagajo, Japan*

Since Nd-Fe-B sintered magnets possess high $(BH)_{max}$ of all permanent magnets, they have been used for variety of applications such as motors, sensors and actuators. However, hard magnetic properties are deteriorated with increasing temperature. Accordingly, substitution of heavy rare-earth (HRE) elements such as Dy and Tb for Nd is essential for increasing thermal stability. Recently, due to the scarce and localized natural resources of the HRE elements, HRE-free or less permanent magnet is strongly required. One of the candidate is Mn-based magnet. It is reported that the XA-type Fe_2MnGa alloy, which is formed when Fe is added to the MnGa alloy, has a high saturation magnetization (M_s) as high as 1300 emu/ cc, a high magnetocrystalline anisotropy, and a Curie temperature. Furthermore, it has been studied theoretically that XA-type crystal structure of Fe_2MnGa in which the ferromagnetic phase is stabilized by the partially substitution of Ga with Sn partially. In this study, in order to confirm the enhancement of the magnetic properties for FeMnGa thin films, alternate layer deposition method have used to prepare FeMnGa and FeMnGaSn thin films, and their structure and magnetic properties have been also investigated. The samples were deposited on a MgO (100) single crystal substrate using an ultrahigh vacuum sputtering (UHV) system. The total film thickness was fixed at 20 nm, and the number of stacking period n was fixed at 60 times. The Fe-Mn-Ga-Sn layer was deposited at 100 °C and them annealed at 400 °C. Cr layer of 10 nm was deposited to a thickness of 10 nm for the purpose of preventing oxidation. A X-ray diffractometer (XRD) and a superconducting quantum interference device (SQUID) were used to evaluate the crystal structure and the magnetic properties, respectively. The M_s was slightly increased with increasing Sn content (x), and the largest M_s of 830 emu/ cc was successfully obtained for $[FeMn/ FeGa_{1-x}Sn_x]_{60}$ (x = 0.8) thin films. It was confirmed that the addition of Sn into FeMnGa thin films led to increase M_s by 20 % as compared to the FeMnGa thin films. Effect of N_2 addition (0 to 5 %) on the crystal structures and magnetic properties for the FeMnGaSnN thin films will be discussed at the conference.

CW-16. Compositional dependence of critical temperatures in $Ni_2MnGa_{1-x}In_x$ single crystals. *P. Cejpek*[1], P. Opletal[1], P. Dolezal[1], K. Vlaskova[1] and M. Dopita[1] *1. Department of Condensed Matter Physics, Charles University, Praha, Czechia*

Ni_2MnGa is a good model system of the shape memory alloy family. These materials are frequently studied because of their possible application as micropumps [1], sensors or actuators [2]. Shape memory effect is connected to the martensitic transformation and to the magnetically induced reorientation (MIR). Therefore, the study of these materials under various external conditions is the key to understand the martensitic transformation, which is still not fully described. Previous studies showed that critical temperatures of the Ni_2MnGa related compounds are strongly dependend on their composition. For example, Ni_2MnGa has the martensitic transformation around 200 K [3], but the alloy with the slightly different composition $Ni_{50}Mn_{28}Ga_{22}$ [4] has the martensitic transformation at 338 K. According to abovementioned facts we decided to study properties of Ni_2MnGa single crystals with respect to indium doping (galium is replaced). As the MIR occurs by twin boundary motion, a single crystal is the basic prerequisite for any significant effect as the presence of grain boundaries can block the motion of twin boundaries. The single crystals were prepared by Bridgman method in the induction furnace (growing speed 0.5 mm/h). The material $Ni_2MnGa_{1-x}In_x$ was previously studied in the form of polycrystals [5] but the results obtained on single crystals apparently differ as it is shown in this work. Electrical resistivity, magnetisation and specific heat measurements were performed to obtain the critical temperatures. All obtained critical temperatures (Curie temperatures, temperatures of martensitic and premartensitic transformation) decrease with the increasing indium content (shown in Figure 1). Contrary to the results previously published on polycrystals [5], the decreasing tendency is much faster – the polycrystalline samples exhibited martensitic transformation even in the sample with 15% of indium, but we did not observed any martensitic transformation on single crystals with the indium content above 10%.

CW-17. Electronic, magnetic, and structural properties of Fe_2MnSn Heusler alloy. B.R. Dahal[1], A. Maruf[1], S. Prophet[2], Y. Huh[1], *P.R. Kharel*[1] and P. Lukashev[2] *1. Department of Physics, South Dakota State University, Brookings, SD, United States; 2. Department of Physics, University of Northern Iowa, Cedar Falls, IA, United States*

Recently, Heusler alloys and compounds have attracted much attention because of their interesting properties with prospects for spintronics, energy technology and magnetocaloric applications. Most of the Heusler alloys are cubic in crystal structure but some non-cubic (tetragonal or hexagonal) alloys have shown high magnetic anisotropy with potential for various magnetic applications. We have performed a combined computational and experimental study of one such compound, Fe_2MnSn. Our density functional theory calculation indicates that this compound has two energetically close crystal phases: cubic $L2_1$ and hexagonal $D0_{19}$, with the latter having slightly lower energy (few meV per 16-atom cell). Electronic structure calculation indicates that both the cubic and hexagonal phases are ferromagnetic, with magnetization values of 6.50 μ_B/f.u. in the hexagonal phase, and 6.04 μ_B/f.u. in the cubic phase. The magnitude of spin polarization is relatively small in both cubic and hexagonal phases (~22% in hexagonal, and ~26% in cubic phases). These theoretically predicted structural and magnetic properties are consistent with our experimental investigation carried out on Fe_2MnSn alloy prepared by arc-melting and annealing. The room temperature x-ray diffraction pattern shows that the dominant phase in the alloy is hexagonal $D0_{19}$ (space group: $P6_3/mmc$) with a small amount of cubic impurity phase. The temperature dependence of magnetization *M(T)* measurement displays ferromagnetic behavior with Curie temperature of 338 K, Figure 1. As shown in the inset of Fig. 1, the field dependent magnetization *M(H)* at 100 K shows a high value of saturation magnetization of 122 emu/g. Strong ferromagnetic nature with potentially high magnetic anisotropy in the hexagonal phase, high Curie temperature and saturation magnetization indicates that the Fe_2MnSn has potential for magnetic applications. We will also present the effect of Mn concentration in the structural and magnetic properties of this material.

Spin-orbit torques couple angular momentum from the lattice to the magnetization. The electrons' spin and orbital moments are intermediaries of this angular momentum flow, which is mediated by the crystal field potential, spin-orbit coupling and the exchange interaction. This variety of angular momentum sources and flows complicates the analysis of the resulting torques. The coupling between the magnetization and the spins always occurs through the local exchange interaction in the ferromagnet. However the coupling of the spins to the orbital moments (spin-orbit coupling) can not only occur there but also in the adjacent non-magnetic layer, at the interface between them, or in an additional ferromagnetic layer or its interface. In these latter cases, transport of spins determines the resulting torques in the ferromagnet. The reduced symmetry of the thin films means that torques that result from all of these sources of angular momentum have the same symmetry, making different mechanisms quite difficult to distinguish experimentally. Never-the-less, it is useful to isolate and identify the specific mechanisms of underlying spin-orbit torques because the resulting models can suggest ways to try to optimize the torque. Interfaces are crucially important in spin-orbit torque systems: they provide inversion symmetry breaking; they convert spin currents into torques; and their reduced symmetry gives rise to Rashba-like spin-orbit coupling localized there. Semiclassical models that describe bulk-like transport in the interior of layers coupled with spin-dependent transmission and reflection at interfaces provide a way to discuss various mechanisms that can give rise to torques. Such models also describe how spin currents are converted into torques at the interface, as well as how interfaces generate spin currents which that are converted into torques in an adjacent or remote ferromagnetic layer. One goal of spin-orbit torque research is to identify mechanisms to generate torques that can deterministically switch a ferromagnetic layer with a perpendicular easy axis. A bilayer of materials that can be each treated as isotropic forbids such torques by symmetry. However, if a second ferromagnetic layer is added, its (fixed) magnetization can break the symmetry of the system and allow such torques. These symmetry breaking torques can be driven by spin currents from the bulk of this second ferromagnetic layer or can be generated by its interface with the nonmagnetic spacer layer.

DA-02. Spin-Orbit Torque Driven by Planar Hall Current.
E.A. Montoya[1], C. Safranski[1] and I. Krivorotov[1] *1. Department of Physics and Astronomy, University of California, Irvine, Irvine, CA, United States*

Spin-orbit torques in bilayers of ferromagnetic (FM) and nonmagnetic (NM) materials create potential for energy efficient spintronic devices. Previously studied spin Hall [1] and Rashba [2] torques originate from spin-orbit interactions within the NM layer and at the FM/NM bilayer interface, respectively. In this talk, we report on the discovery of a spin orbit toque arising from planar Hall current in the FM material of the bilayer [3]. This spin orbit torque driven by planar Hall current, or planar Hall torque (PHT) for brevity, exhibits biaxial symmetry in the plane defined by the bilayer normal and the applied electric field (xz plane in Fig. 1) and can act as positive or negative damping. The unusual symmetry of PHT can be deduced from the angular dependence of the planar Hall current [4] in the FM layer and is distinctly different from the uniaxial symmetry of the spin Hall torque (SHT) as illustrated in Fig. 1. We fabricate 40-50 nm wide nanowires from Al_20_3(0001)/Ta(3.0 nm)/NM/FM/Ta(4.0 nm), where FM = [Co(0.85 nm)/Ni(1.28 Nm)]$_2$/Co(0.85 nm) and NM=Au, Pd, or Pt. We characterize spin orbit torques by means of field-modulated spin torque ferromagnetic resonance (ST-FMR) measurements. The antidamping component of the SOTs is deduced from the dependence of the ferromagnetic resonance linewidth ΔH on direct current density J_{dc} applied to the nanowire. The slope of the line $\Delta H(J_{dc})$ quantifies the strength and sign of the anti-damping SOT. Fig. 2 shows angular dependence of the slope of $\Delta H(J_{dc})$ for three different NM materials. This figure shows that the magnitude of SHT depends on the NM material while the magnitude of the PHT is nearly the same for all three NM materials, lending further support to the planar Hall effect in the FM layer being the origin of the novel SOT. Fig. 2 demonstrates that the magnitude of PHT is similar to that of the giant SHT of Pt and that strong PHT can be present in a system with negligibly small SHT (e.g. FM/Au). Finally, we demonstrate that the planar Hall torque is large enough to excite auto-oscillations of the FM layer magnetization, allowing one to create a planar Hall nano-oscillator [4,5]. Furthermore, the magnetization angle that maximizes PHT also maximizes the dynamic change in resistance due to anisotropic magnetoresistance (AMR). This is in contrast to the spin Hall nano-oscillator where the anti-damping action of SHT is maximized at magnetization angles where dynamic response of AMR is minimized. Therefore, we show the efficiency of the PHT nano-oscillator exceeds that of the SHT nano-oscillator. The discovery of the planar Hall torque [3] expands the class of materials for energy efficient manipulation of magnetization by giant SOTs.

DA-03. Iron Garnet Films for Spintronics. *C. Ross*[1], G. Beach[1], E.R. Rosenberg[1], J. Bauer[1], T. Fakhrul[1], C. Avci[1], L.M. Caretta[1] and B. Khurana[1] *1. Massachusetts Institute of Technology, Cambridge, MA, United States*

Ferromagnetic insulator thin films have emerged as an important component of magnonic, spintronic and magnetooptical devices. Yttrium iron garnet in particular is an excellent insulator with low damping, and has been incorporated into heterostructures that exhibit a plethora of spintronic and magnonic phenomena including spin pumping, spin Seebeck, proximity effects and spin wave propagation. Rare earth (RE) garnet films are both magnetic and magnetoelastic, and their properties can be manipulated by choice of composition and substrate. We demonstrate robust perpendicular anisotropy (PMA) in epitaxial films of bismuth, thulium, europium, dysprosium and terbium iron garnets with high structural quality down to a thickness of 2.5 nm, about 2 unit cells, resulting from lattice mismatch strain. PMA was also induced by thermal mismatch stress in polycrystalline films of EuIG grown on quartz or DyIG on silicon, with grain size exceeding 10 μm diameter. Substitution on the Fe sites is also effective in tuning properties, with Sc raising the magnetization and lattice parameter and lowering Curie temperature in Tb(Fe,Sc) garnet. RE garnet/Pt bilayers exhibit efficient spin transmission across the garnet/Pt interface, with a spin mixing conductance that is similar for different RE garnets and for polycrystalline and single crystal films. RE garnet films exhibit a Dzyaloshinskii-Moriya interaction originating at the garnet/substrate interface which stabilizes skyrmions and chiral magnetic textures. Spin orbit torque from a Pt overlayer drives domain wall motion at room temperature at velocities exceeding 2 km/s in TmIG and 4 km/s in Bi-substituted YIG. Iron garnets also exhibit magnetooptical activity and high transparency in the infrared, and we demonstrated integrated optical isolators with isolation ratios of up to 40 dB comprising Bi and Ce garnets. These results illustrate the potential of garnets to provide a path towards devices with combined spintronic and optical functionality. Support of the nCORE SMART Center, NSF and DARPA is gratefully acknowledged.

DA-04. Spin-Orbit Torques in Metal-Based Heterostructures. *K. Ando*[1] *1. Keio University, Yokohama, Japan*

The fundamental building block of spin-orbitronics is the generation of spin-orbit torques, which enable electric manipulation of magnetization. The source of the spin-orbit torques is spin-orbit interaction in solids. When a charge current passes through a heavy metal with strong spin-orbit coupling, electrons with opposite spins are deflected in opposite directions, resulting in the generation of a transverse spin current, which is known as the spin Hall effect. Another source of the charge-to-spin conversion is the Rashba-Edelstein effect, where a charge flow in a Rashba two-dimensional electron gas results in the creation of a non-zero spin accumulation. The generated spin current and spin accumulation give rise to the spin-orbit torques. Here, we discuss recent experimental results on the generation of the spin-orbit torques in metal-based heterostructures [1-3]. We show that oxidation of the most widely used spintronic material, Pt, turns the heavy metal into an electrically insulating generator of the spin-orbit torques, which enables the electrical switching of perpendicular magnetization in a ferrimagnet sandwiched by insulating oxides [2]. The spin-orbit torques generated by the Pt oxide can be controlled electrically through voltage-driven oxygen migration. We also show that the intrinsic mechanism originating from the Berry curvature is responsible for the generation of the spin-orbit torque through the spin-orbit coupling at ferromagnetic-metal/metal-oxide interface [3].

DA-05. Spin-orbit-torques from low-symmetry materials. *D. Ralph*[1], G. Stiehl[1], D. MacNeill[1], V. Gupta[1], J. Mittelstaedt[1], S. Karimeddiny[1], M. Guimaraes[1], N. Reynolds[1], N. Sivadas[1], I. El Baggari[1], L. Kourkoutis[1], C. Fennie[1] and R. Buhrman[1] *1. Cornell University, Ithaca, NY, United States*

In most experiments performed to date, spin-orbit torques have an important limitation -- the component of torque that can compensate magnetic damping is required by symmetry to lie within the device plane and perpendicular to the applied current, i.e. the spin current has a Rashba-type symmetry. This means that spin-orbit torques can drive the most current-efficient type of magnetic reversal (antidamping switching) only for magnetic devices with in-plane anisotropy, not the devices with perpendicular magnetic anisotropy that are needed for high-density applications. In principle, the types of symmetry-breaking within a spin-source material that are necessary for generating other components of spin-orbit torque can be produced in at least two ways: by using materials that have low crystalline symmetry or an appropriate type of magnetic order. Here I will focus on experimental results from the Cornell group using materials with low crystalline symmetries. We have investigated torques generated within bilayers in which a ferromagnetic layer is integrated with different low-symmetry transition-metal dichalcogenide (TMD) semi-metals and metals: WTe_2, $TaTe_2$, $MoTe_2$, and strained $NbSe_2$. The low crystalline symmetries of the TMDs can indeed allow an out-of-plane antidamping torque of the type desired to drive the most efficient switching mode for magnets with perpendicular anisotropy. In WTe_2 and $MoTe_2$, this component has a surprising dependence on the number of TMD layers, being much weaker for 2-layer samples than for either single-layer or thicker samples. This dependence is not yet understood. We have also observed current-induced torques with an unusual Dresselhaus symmetry. This contribution appears to arise primarily from resistance anisotropy rather than a direct spin-orbit torque. The different TMD materials can generate current-induced torques with a surprising range of contrasting properties even though the underlying crystal symmetries are
