similar, indicating that the torques depend not only on global broken symmetries but also on microscopic factors. The same fabrication techniques that allow us to incorporate air-sensitive TMD materials into spin-orbit devices also allow devices made using recently-discovered 2-dimensional magnetic materials. We have combined mechanically-exfoliated thin flakes of the insulating 2D ferromagnet $Cr_2Ge_2Te_6$ into bilayers with the spin-orbit metal Ta. These samples exhibit spin-orbit induced switching of the out-of-plane magnetic moment of $Cr_2Ge_2Te_6$ at record-low levels of current density. I will present initial results to understand the magnetoresistance of these samples and to characterize the strength of the spin-orbit torque. Support from DOE, SRC/DARPA, and NSF.

DB-01. Tunable spin-to-charge conversion in van der Waals heterostructures at room temperature. *W.F. Savero Torres*[1], L.A. Benítez[1,2], J.F. Sierra[1], M. Timmermans[1], J.H. Garcia[1], S. Roche[1,3], M. Costache[1] and S.O. Valenzuela[1,3] *1. Catalan Institute of Nanoscience and Nanotechnology (ICN2), CSIC and the Barcelona Institute of Science and Technology (BIST), Barcelona, Spain; 2. Spin Hall and spin galvanic effects provide a versatile tool for spin-current generation without ferromagnets [1,2]. They have been widely studied during the last years, giving rise to the emergent field of spin-orbitronics and providing new routes for developing spintronic devices [1,3]. However, despite the diversity of existing bulk materials and the recent advent of interfacial and low-dimensional effects, room temperature electric-field control of the interconversion between charge and spin currents remains elusive [1,2]. In this talk, we will show that strong and controllable spin-to-charge (StC) conversion can be obtained in engineered graphene-based heterostructures at room temperature. By using spin precession experiments, we will first demonstrate that large spin Hall signals in graphene/Pt heterostructures enable full characterisation of both spin transport in graphene and StC conversion in Pt [4]. We will then show that StC conversion driven by the spin galvanic and the spin Hall effects can be unambiguously detected in Hall bar devices made of graphene interfaced with a semiconducting transition metal dichalcogenide [5]. Our findings clearly indicate that StC conversion arises from proximity-induced spin-orbit coupling in graphene. Remarkably, the corresponding conversion efficiencies in this heterostructure can be tailored by electrostatic gating in magnitude and sign, with a magnitude that is comparable to the largest efficiencies reported to date. Such unprecedented electric-field tunability provides a novel route for spin generation free from magnetic materials and a new building block for the development of ultra-compact magnetic memory technologies. DB-02. Universal Transfer and Stacking Technique of van der Waals Heterojunctions for Spintronics. *Y. Cao*[1], X. Wang[1], X. Lin[1] and W. Zhao[1] *1. Beihang University, Beijing, China*

Integrating layered two-dimensional (2D) materials into 3D heterostructures offers opportunities for novel material functionalities and applications in electronics[1] and spintronics[2]. The resulting 2D material transfer and high-quality heterostructures construction techniques are crucial to preserve cleanliness and morphology of 2D material surfaces[3] which come in contact with transfer mediator and flexible stacking control of various 2D materials. In this work, we introduce a free standing poly vinyl alcohol (PVA) film to meet the above requirements. The pre-fabricated PVA film enables ultraclean, accurate and selective 2D materials' interface and contact engineering, including a partial transfer with one micron resolution, flexible stacking of both angle and position, and even transfer of 2D materials with pre-deposited metal films. Such a universal and convenient technique is suitable for 2D materials no matter mechanically exfoliated or chemical vapor deposited (CVD) growth. We further illustrate the practical superiority of this method by a WSe2 vertical spin valve device, whose performance verifies the applicability and advantage of such a method for spintronics. Our PVA-assisted transfer process would certainly promote the development of fundamental research and wafer-scale device application of 2D nanostructures.

DB-03. Observation of Ferromagnetic Resonance in Quasi-2D Ferromagnet CrI_3 using Magneto-Raman Spectroscopy. *R. Valdes Aguilar*[1], A. McCreary[2], T. Mai[1,2], J.R. Simpson[3,2], F.G. Utermohlen[1], N. Trivedi[1] and A.R. Hight Walker[2] *1. Physics, The Ohio State University, Columbus, OH, United States; 2. NIST, Gaithersburg, MD, United States; 3. Towson University, Baltimore, MD, United States*

There is a growing interest in the discovery and understanding of the fundamental physics of magnetic materials in two dimensions (2D) [1-3]. In particular, efforts continue on one of the original 2D ferromagnets, CrI_3, in order to understand whether the interlayer interactions are ferro- or antiferromagnetic [4-10]. The interplay of these magnetic interactions and excitations, structural distortions [4], and their response in a magnetic field is important for a fundamental understanding that can drive potential applications [1,2,11]. To this end, we study in detail the structural and magnetic excitations of CrI_3 in single crystalline thin flakes using inelastic light scattering in a magnetic field, i.e. magneto-Raman spectroscopy. We find that for fields above 6 T we observe the scattering from the zone center magnon, the ferromagnetic resonance, with a linear dependence on the magnetic field in this range. This behavior is well explained by the classical Kittel formula [12] that predicts a value of the zero-field resonance at approximately 45 GHz with an effective g-factor of 2. We also find that as a function of the scattered polarization angle with respect to the incoming polarization, the intensity has a two-fold symmetric pattern without nodes (i.e. the signal does not vanish) as shown in the figure. This indicates that some of the components of the Raman response tensor are complex, which is typically only expected for resonant scattering [13]. We will discuss the possible reasons for this behavior and compare it to that expected for the lattice excitations.

DB-04. Efficient magnetization switching and Dzyaloshinskii-Moriya interaction in WTe_2/ferromagnet heterostructures. *S. Shi*[1,2*], Z. Zhu[1], K. Cai[1], S.D. Pollard[1], J. Wang[3,2], P. He[1], G. Eda[3,2], G. Liang[1] and H. Yang[1,2] *1. Electrical and computer engineering, National University of Singapore, Singapore; 2. Centre for advanced 2D materials, National University of Singapore, Singapore; 3. Department of physics, National University of Singapore, Singapore*

Weyl semimetal WTe_2 has been discovered to have strong spin-orbit coupling and a large spin polarization protected by time-reversal symmetry in both the surface and bulk states [1,2]. However, magnetization switching using the above interesting properties has not been demonstrated so far. Utilizing WTe_2 as a spin current source, here we report current-induced magnetization switching without assistive magnetic fields in WTe_2/Py heterostructures at room temperature. An extremely small charge current density of ~1.58×10^5 A cm^{-2} as shown in Fig. 1 and the thickness-dependent charge-to-spin conversion efficiency in Fig. 2 with the current along the b-axis in the WTe_2 layer are found. Furthermore, a strong Dzyaloshinskii-Moriya interaction (DMI) with a DMI constant up to –1.8 mJ m^{-2} is identified at the WTe_2/Py interface from the chiral domain wall tilting. The demonstration of efficient current-driven magnetization switching and sizable interfacial DMI in WTe_2/ferromagnet heterostructures open a new avenue for the Weyl semimetal based spintronic device applications.

DB-05. Spin Filtering in CrI_3 Tunnel Junctions. *T.R. Paudel*[1] and E.Y. Tsymbal[1] *1. Department of Physics and Astronomy & Nebraska Center for Materials and Nanoscience, University of Nebraska-Lincoln, Lincoln, NE, United States*

The recently discovered magnetism of two-dimensional (2D) van der Waals crystals has attracted a lot of attention. Among these materials is CrI_3 – a magnetic semiconductor exhibiting transitions between antiferromagnetic and ferromagnetic orderings under the influence of an applied magnetic field. Here, using first-principles methods based on density functional theory, we explore spin-dependent transport in tunnel junctions formed of fcc Cu (111) electrodes and a CrI_3 tunnel barrier. We find about 100% spin polarization of the tunneling current for a ferromagnetically-ordered four-monolayer CrI_3 and tunneling magnetoresistance of about 3,000% associated with a change of magnetic ordering[1]. This behavior is understood in terms of the spin and wave-vector dependent evanescent states in CrI_3 which control the tunneling conductance. We find a sizable charge transfer from Cu to CrI_3 which adds new features to the mechanism of spin-filtering in CrI_3-based tunnel junctions. Our results elucidate the mechanisms of spin filtering in CrI_3 tunnel junctions and provide important insights for the design of magnetoresistive devices based on 2D magnetic crystals and possibly of using conventional metallic electrode for enhanced performance, thereby broadening design space of such devices beyond 2D Van der Walls heterostructures.

DB-06. Band gaps and 3d-band splittings on the electronic structures in 2D magnetic materials: Application of Quasiparticle Self-Consistent GW method. *Y. Lee*[1], T. Kotani[2] and L. Ke[1] *1. Ames Laboratory, Ames, IA, United States; 2. Department of Applied Mathematics and Physics, Tottori University, Tottori, Japan*

Using (Quasiparticle Self-Consistent GW) QSGW method, we investigate the electronic structures in magnetic 2D van der Waals (m2dvdW) materials, including $CrGeTe_3$, VI_3, CrI_3, and Fe_3GeTe_2 ---four of the most studied m2dvdW systems to date. QSGW yields non-local potential missing in density functional theory (DFT). The non-local potential contains both off-site and inter-site parts. The off-site non-locality is crucial to better describe the band gap for semiconductors while the DFT+*U* like on-site non-locality enhances the band separation within an atom. In comparison with DFT, QSGW enhances the band gaps in $CrGeTe_3$ and VI_3 due to the off-site and on-site non-local potentials, respectively. Mainly because of the occupied 3d is pushed down relative to anion bands, QSGW predicts an entirely different picture for the transport properties in CrI_3 and VI_3. Furthermore, we found that defects such as vacancy and impurity introduce localized states in the bandgap, which may explain the discrepancy between QSGW bandgap and experiments. The effects of spin-orbit coupling on band structures are also discussed. Finally, we discuss the limitation of usual DFT+*U* method from the view of its ability to mimic QSGW.

DB-07. Effect of Random Anisotropy on Magnetic Long Range Order of Two-Dimensional Magnets. *P. Tang*[1,2], X. Han[2] and S. Zhang[1] *1. Physics, The University of Arizona, Tucson, AZ, United States; 2. Institute of Physics, Chinese Academy of Sciences, Beijing, China*

Recent experimental discovery of new classes of two-dimensional magnets demands a revisit of mechanisms of ferromagnetism of 2D materials. Two essential factors limit the long range order of ferromagnetism with short-range exchange interactions. The number of Goldstone magnons excited at any nonvanishing temperature would diverge for isotropic exchange Hamiltonian in two-dimension systems [1] and thus an anisotropy gap is needed to suppress the thermal fluctuation. The random field, which exists for any film with imperfection, is another source of destabilizing the long range order via formation of the domain structure [2]. Furthermore, the random field also reduces the effective anisotropy and thus it always suppresses the Curie temperature. We consider the influence of the random anisotropy rather than the random field on the magnetic ordering. We argue that the model of the random anisotropy is more appealing than the random field since the magnetic anisotropy is due to spin-orbit coupling at the 2D surface and the symmetric breaking occurs in the direction perpendicular to the film. By using the Green's function approach, we find a quantitative relation between the Curie temperature and the random anisotropy, and we show there are distinct differences when compared with the results of the random field.

DB-08. Giant enhancements of perpendicular magnetic anisotropy and spin-orbit torque by a MoS_2 layer. *Q. Xie*[1], W. Lin[1], B. Yang[2], X. Shu[1], S. Chen[1], L. Liu[1], X. Yu[1], M. Breese[1], T. Zhou[5], M. Yang[3], Z. Zhang[3], S. Wang[3], H. Yang[4], J. Chai[3], X. Han[2] and J. Chen[1] *1. National University of Singapore, Singapore; 2. Chinese Academy of Sciences, Beijing, China; 3. Agency for Science, Technology and Research, Singapore; 4. Chinese Academy of Sciences, Ningbo, China; 5. Hangzhou Dianzi University, Hanzhou, China*

The unique properties of two-dimensional transition metal dichalcogenides (2D TMCDs) including a well-defined single atomic layer thickness, inversion symmetry breaking and strong spin-orbit coupling have motivated 2D TMCDs-based research to seek their potential applications in spintronic devices.[1-3] At the same time, magnetic tunnel junction (MTJ) with ferromagnets possessing a perpendicular magnetic anisotropy (PMA) is attracting increasing attention because it is a promising candidate for achieving next-generation high-density non-volatile memory devices with low-energy-consumption.[4,5] To improve the area density of spintronic devices, a large PMA of the storage layer is required to overcome the thermal fluctuation of the magnetic moment in spintronic application.[6] Many efforts have been made to enhance PMA of the ferromagnetic layer. For example, Chshiev. M et al. reported that the PMA at the Fe/MgO interface can be effectively tuned by electric field.[7] Recently, spin-orbit torque (SOT) has been proposed to switch the magnetization of the free layer in MTJs at lower power consumption and faster speed.[8-10] The SOT is generated from the heavy metal, like Pt[8] and Ta[10] or Rashba effect due to the broken structure symmetry. In order to maintain the thermal stability of the cell at the reduced size and reduce the switching current density, it is desirable to enhance the PMA and SOT efficiency simultaneously in the structure of MTJs. In this work, we investigated the effects of 2D MoS_2 as the underlayer on the magnetic properties and SOT efficiency of Pt/$[Co/Ni]_2$. We found that the PMA and SOT efficiency are significantly enhanced after inserting the MoS_2 underlayer, which reaches a maximum at the structure with a 2 nm Pt. The maximum enhancements of PMA and SOT efficiency are around 3 and 17 times higher than those without MoS_2 underlayer, respectively. First principles calculation and XAS reveal that the MoS_2 underlayer results in the modification of the orbital hybridization at Pt/Co interface, which is responsible for the enhancement of both PMA and SOT efficiency.

DB-09. Surface spin-flop transition in CrI_3 probed by Pt. *T. Su*[1,2], M. Lohmann[2], J. Li[2], M. Al ghamdi[2], K. Watanabe[3], T. Taniguchi[3] and J. Shi[2] *1. International Center for Quantum Materials, Peking University, Beijing, China; 2. Physics and Astronomy, University of California, Riverside, Riverside, CA, United States; 3. National Institute for Materials Science, Tsukuba, Japan*

Two-dimensional (2D) magnetic materials have attracted enormous research attention in recent years. As an important member of this family, CrI_3 has been observed to exhibit a soft ferromagnetic behavior in bulk crystals and antiferromagnetic interlayer coupling in ultra-thin flakes. However, how magnetic properties of the surface layers differ from those of the bulk layers is not clear. Because CrI_3 is insulating, in this work, we perform transport measurements in a conducting material such as Pt that is in proximity with CrI3. Due to the short-range nature of the proximity coupling, the acquired magneto-transport properties in the conducting materials reflect the magnetic properties of the surface layer of CrI3. We fabricate the devices by putting exfoliated CrI_3 flake on top of a pre-patterned thin channel of Pt on a bottom flake of BN, followed by covering the heterostructure with a top BN layer to avoid degradation. We observe an unambiguous jump at ~ 2 T in the magnetoresistance of Pt which is confirmed to come from the presence of the CrI_3. We have fabricated similar devices by replacing Pt with few-layer graphene but did not observe the magnetoresistance jump. We have further

explored the current density dependence of the magnetoresistance jump and found that it only appears at large current densities. Since simple spin-flips would not cause any magnetoresistance jump, our results suggest a surface spin-flop transition in CrI3. We will discuss the role of the spin-orbit torque and spin-orbit coupling in the surface spin flop transition.

DB-10. Structural, electrical and magnetotransport properties of layered $FeGe_2$ thin films. *J. Herfort*[1], S. Gaucher[1], D. Czubak[1], B. Jenichen[1] and M. Ramsteiner[1] *1. Paul-Drude-Institute for Solid State Electronics, Berlin, Germany*

The solid-phase epitaxy of Ge thin films over Heusler alloy surfaces was investigated recently as a solution to create lattice-matched ferromagnet-semiconductor heterostructures for vertical spin valves.[1] A persistent challenge in this field is the growth of epitaxial semiconductors over metals by MBE, a limiting factor for a number of envisaged applications in the field of spintronics. In order to solve this issue, amorphous Ge was deposited on ferromagnetic quasi-Heusler compound Fe_3Si and crystallized slowly by annealing. Instead of pure Ge, the resulting single-crystalline films were shown to consist of a new 2D polymorph of $FeGe_2$ with space group P4mm. TEM studies reveal a layered structure with monolayer Fe planes sandwiched between tetragonal Ge bilayers.[2] The material does not exist in a bulk form, its creation being interpreted as an ordering phenomenon induced by minimization of the elastic energy of the epitaxial film.[2] It is possible to isolate the material on an insulating GaAs substrate by first growing a few monolayers of crystalline Fe_3Si, and then an amorphous Ge fim with a thickness ratio such as to obtain the right stoichiometry for $FeGe_2$. Electrical measurements conducted on $FeGe_2$ films indicate a thickness dependence of their resistivity. Magnetotransport at low temperature reveal a strong anomalous Hall effect. In addition, we investigated vertical spin valve structures based on this novel 2D material as an intermediate layer between the two Heusler alloy films Fe_3Si (bottom) and Co_2FeSi (top). At room temperature, these spin valves exhibit a magnetoresistance effect of around 0.3%. A decrease of the operating temperature leads to a reduced magnetoresistance effect due to a phase change in the $FeGe_2$ layer from a non-magnetic into the ferromagnetic state. At cryogenic temperatures, the magnetoresistance value depends in a complex manner on the sample orientation relative to the external in-plane magnetic field. Two spin valve-like signals appear with opposite signs for orthogonal orientations. The analysis of the observed anisotropic behavior allows for the extraction of information on the spin transport behavior of the $FeGe_2$ film sandwiched between two ferromagnetic Heusler alloy films.

DB-11. Current-driven magnetization switching in a van der Waals ferromagnet Fe_3GeTe_2. X. Wang[1], J. Tang[1], X. Xia[2], Y. Liu[1], Z. Han[2], G. Zhang[1], *G. Yu*[1] and X. Han[1] *1. Beijing National Laboratory for Condensed Matter Physics, Institute of Physics, Chinese Academy of Sciences, Beijing 100190, China, Beijing, China; 2. Shenyang National Laboratory for Materials Science, Institute of Metal Research, Chinese Academy of Sciences, Shenyang, China, Shenyang, China*

The recent discovery of ferromagnetism in two-dimensional (2D) van der Waals (vdW) materials holds promises for novel spintronic devices with exceptional performances. However, in order to utilize 2D vdW magnets for building spintronic nanodevices such as magnetic memories, key challenges remain in terms of effectively switching the magnetization from one state to the other electrically. Here, we devise a bilayer structure of Fe_3GeTe_2/Pt, in which the magnetization of few-layered Fe_3GeTe_2 can be effectively switched by the spin-orbit torques (SOTs) originated from the current flowing in the Pt layer. The effective magnetic fields corresponding to the SOTs are further quantitatively characterized using harmonic measurements. Our demonstration of the SOT-driven magnetization switching in a 2D vdW magnet could pave the way for implementing low-dimensional materials in the next-generation spintronic applications.

Among the recently discovered two-dimensional (2D) van der Waals magnets, Fe_3GeTe_2 is of particular interest due to its high Curie temperature, T_c, strong perpendicular magnetic anisotropy, and tunable magnetic properties depending on the concentration of Fe and its thickness. In this work, the magnetic, electronic, and structural properties of van der Waals-layered, Fe-deficient $Fe_{3-x}GeTe_2$ were systematically investigated by application of high pressure. Electrical and magneto-transport measurements show a ~70 K decrease in the T_c with an increasing pressure up to ~14 GPa. The resistivity of $Fe_{3-x}GeTe_2$ shows a change from a metallic ($d\rho/dT > 0$) to a less metallic ($d\rho/dT < 0$) phase at ~8 GPa, while the magnetoresistance (MR) is negative with an increase in magnitude (below T_c) with pressure. High-pressure x-ray diffraction (HP-XRD) shows no phase change in the hexagonal crystal structure for pressures up to ~29 GPa but a clear shift in the lattice spacing. The decrease in the T_c is due to the lattice shrinkage from pressurization which leads to a weakening of the exchange interaction, while the increase in MR may be related to shrinkage of the van der Waals gap leading to a stronger interlayer coupling. These results indicate that the application of pressure can complement other external stimuli such as chemical doping and strain when manipulating the material properties of van der Waals magnets which are of high interest for next-generation spintronic technologies. Prepared by LLNL under contract DE-AC52-07NA27344.

DB-13. Quasi-2D Magnon Identification by Magneto-Raman Spectroscopy in Antiferromagnetic $FePS_3$. *J.R. Simpson*[2,1], A. McCreary[1], T. Mai[1], R. Valdes Aguilar[3] and A.R. Hight Walker[1]
1. National Institute of Standards & Technology, Gaithersburg, MD, United States; 2. Physics, Towson University, Towson, MD, United States; 3. Physics, The Ohio State University, Columbus, OH, United States

The recent discovery that van der Waals-bonded magnets retain long range magnetic ordering down to a single layer opens avenues in fundamental physics and potential applications of these novel materials.[1,2] One such material is $FePS_3$, a high spin (S=2), Mott insulator where the Fe atoms form a honeycomb lattice.[3] In bulk, $FePS_3$ has been shown to be a quasi-two-dimensional, Ising antiferromagnet,[4] with emergent features in the Raman spectra below the Néel temperature, $T_N \approx 120$ K. Using magne-to-Raman spectroscopy as an optical probe of magnetic structure, we report the temperature and magnetic field dependence of a Raman-active magnon in the magnetically ordered state with a low-temperature frequency of 3.6 THz (121 cm^{-1}). Contrary to previous work that interpreted this feature as a phonon[5], our Raman data shows the expected frequency shifting and splitting of the magnon as a function of temperature and magnetic field, respectively. In addition, we measure the symmetry behavior of the magnon using polarization-dependent Raman spectroscopy and explain the result using the magnetic point group of $FePS_3$.

DC-01. New materials and devices in skyrmionics: Skyrmion-based artificial synapse and skyrmion lattice in van der Waals magnets.
S. Woo[1] *1. IBM TJ Watson Research Center, Yorktown Heights, NY, United States*

The field of skyrmionics has been actively investigated across a wide range of topics during the last decade, mainly inspired by the fascinating physical properties of magnetic skyrmions. [1] In this talk, we present our recent experimental achievements on the new material platform and device scheme where magnetic skyrmions can be stabilized and harnessed to realize non-conventional energy efficient future spintronics applications. In the first part of the talk, using ferrimagnetic multilayers, we demonstrate a fully functional skyrmion-based electronic device, where skyrmions are written, driven, read and erased electrically on a single device at room temperature. [2] In particular, we demonstrate a skyrmion-based artificial synaptic device designed for neuromorphic computing and thus artificial neural network (ANN), which could be used in broader technology fields in the future. Figure 1 summarizes the experimental demonstration of such skyrmion-based synaptic devices. Figure 1a illustrates the schematic of a skyrmion-based artificial synapse and its working principle, where skyrmions play the role of neurotransmitters in biological systems. In a skyrmion synapse, the synaptic weights are proportional to the number of skyrmions in synapse. Therefore, the electric current-controlled accumulation and dissipation of skyrmions within an active synaptic device area can imitate the linear variations of synaptic weights during potentiation and depression, respectively. Figure 1b demonstrates the experimentally measured electrical operation of a skyrmion synapse, where the corresponding magnetic configuration of each resistance state is also imaged by scanning transmission X-ray microscopy (STXM) as shown in Fig. 1c. In this talk, we further present an skyrmion synapse-based ANN and the pattern recognition simulation. [2] In the second part of the talk, we present a new novel material platform, van der Waals (vdW) ferromagnetic crystals, where magnetic skyrmions and their lattice structure can be stabilized. Very recently, it has been reported that 2D vdW crystals can also have long-range intrinsic ferromagnetism in few materials with strong magnetic anisotropy [3, 4]. This discovery of 2D magnets opened a whole new door toward 2D heterostructure-based spintronics, as a result, there appeared significant following interests and efforts revealing the possibility of such devices by demonstrating the magnetoresistance effect in 2D magnets [5], gate-tunable 2D magnets [6] and so on. Due to the broken inversion symmetry and expected large spin-orbit coupling of vdW magnets, vdW magnets might permit the presence of Dzyaloshinskii-Moriya (DM) interaction that could stabilize magnetic skyrmions. In this talk, we present such demonstration of magnetic skyrmions and their crystal formation in ferromagnetic vdW crystals, Fe_3GeTe_2 [7]. Figure 2 summarizes the experimental observations. Figure 2a first illustrates the schematic of crystalline structure of Fe_3GeTe_2 vdW crystal. Figure 2b then shows an observed exemplary STXM image taken at T=100 K and B_z=0 mT, showing the ordered skyrmion lattice (SkX) structure. In this talk, we describe the current-induced generation of skyrmion lattice in detail, as shown in Fig. 2b., as well as the underlying physical mechanism behind the formation of skyrmion lattice in vdW crystals. DC-02. Topological Hall Effects and Topological Spin Hall Effects Caused by a Skyrmion and a Skyrmionium. *Y. Ishida*[1] and K. Kondo[1]
1. Research Institute for Electronic Science, Hokkaido Univ., Sapporo, Japan

Magnetic skyrmions are topological solitons which behave like particles and have been paid much attention in the field of spintronics. Since their structures are topologically protected, it is difficult to destroy their structures and deform them to other magnetic structures. Therefore, it is considered that skyrmions can carry one bit of information and are expected to become candidates for high-density memories in the spintronics fields. In order to apply skyrmions to the spintronics devices, it is mandatory to read information by detecting the existence of skyrmions. This can be resolved using the topological Hall effect (THE). THE originates from the fact that skyrmions create an emergent magnetic field affecting itinerant electrons in ferromagnets. Moreover, this field also causes the topological spin Hall effect (TSHE). This is because the emergent fields are opposite to each other for itinerant electrons with different spins. In our study, we investigate THE and TSHE for Néel-type and Bloch-type skyrmions using the tight binding model, respectively. The Hamiltonian consists of the nearest neighbor hopping and the exchange coupling between spins of itinerant electrons and magnetization of a ferromagnet. For simplicity, we set the hopping parameter t and the strength of exchange coupling J_H equal to one. Figure 1 and Figure 2 show joint density of states (DOS) and topological (spin) Hall angles θ_{TH} (θ_{TSH}) for different fermi energy ε_f in the case of a Néel-type skyrmion, respectively. In the case of a Bloch-type skyrmion, we have obtained almost identical results. As shown in Fig. 2, manifestation of THE and TSHE strongly depends on the fermi energy of itinerant electrons. This result implies that the fermi energy is an important factor to apply skyrmions to spintronics devices. Moreover, we have obtained joint DOS and (spin) Hall angles in the case of a skyrmionium and found that they are totally different from those of skyrmions. At the conference, we are going to discuss both the results of the skyrmions and the skyrmioniums in detail.

Electrical detection of topological magnetic textures, such as skyrmions, is currently limited to conducting materials. While magnetic insulators offer key advantages for skyrmion technologies with high speed and low loss, they have not yet been explored electrically. Here, we report a prominent topological Hall effect in $Pt/Tm_3Fe_5O_{12}$ (TmIG) bilayers below, at, and above room temperature. Fig. 1 shows Hall resistivity and topological Hall resistivity versus out-of-plane magnetic field (H) where a prominent peak in the data indicates a strong topological Hall signal for a 1.85 nm thick TmIG film. Secondly, our pristine TmIG epitaxial films down to 1.25 unit cell thickness allow for tuning of topological Hall stability over a broad range of temperatures (T) from 200 to 465 K through atomic-scale thickness control. Fig. 2 shows *H-T* phase diagrams for several TmIG thicknesses with the color scale representing the magnitude of topological Hall resistivity. These regions of skyrmion stability scale with TmIG thickness, and consequently, the thickness dependent Curie temperature of the films. The electrical detection of topological magnetic textures in Pt is made possible by a novel phenomenon: "spin-Hall topological Hall effect" (SH-THE), where the interfacial spin-orbit torques allow spin-Hall-effect generated spins in Pt to experience the unique topology of the underlying skyrmions in TmIG. This novel electrical detection phenomenon paves a new path for utilizing a large family of magnetic insulators in future skyrmion technologies.

DC-04. All Optical Motion of Chiral Domain Walls and Skyrmion Bubbles. *L.M. Caretta*[1], F. Buettner[1], F. Steinbach[2], D. Suzuki[1], B. Pfau[2], C. von Korff Schmising[2], S. Eisebitt[2] and G. Beach[1] *1. MIT, Cambridge, MA, United States; 2. Max-Born-Institut, Berlin, Germany*

Manipulation of magnetism with femtosecond laser excitations began with the observation of ultrafast demagnetization in ferromagnets[1,2] and was soon followed by the discovery of all optical switching (AOS) in GdFeCo[3]. Today, the mechanism of AOS is well understood, enabling low-power, sub-picosecond manipulation of magnetism for spintronics[4]. Deterministic, single shot AOS is limited to rare-earth transition metal ferrimagnets, whereas in transitional metal (TM) ferromagnets, helicity dependent, multi-shot switching occurs through a thermal demagnetization and re-magnetisation process resulting from helicity-dependent propagation of domain walls (DWs)[5]. This gave rise to the study of helicity-dependent optical DW motion in TM ferromagnets and ferromagnetic semiconductors. Simultaneously, it was discovered that the Dzyaloshinskii-Moriya Interaction (DMI) can be present in non-centrosymmetric materials systems, giving rise to new chiral forms of spin textures, such as skyrmions and homochiral Neel DWs[6,7]. Moreover, the same DMI that gives rise to AOS in ferrimagnetic systems also gives rise to ultra-small and ultrafast current-driven spin textures[8], making ferrimagnets the one of the most promising technologies for beyond-CMOS data storage and computing. However, the role of the chirality in all optical domain wall motion (AO-DWM) has been nearly neglected. Here, we systematically study the role of DMI in AO-DWM of ferrimagnetic GdCo. We achieve deterministic, single shot thermally-driven motion of chiral Neel DWs in Co-rich Pt/GdCo/Ta trilayers exhibiting significant DMI. We find that that the DW motion does not depend on light helicity, but rather on the orientation of the DW (Neel versus Bloch), revealing the role of the DMI in AO-DWM for the first time. Micromagnetic simulations, in combination with atomistic simulations, support this observation, indicating that coherent AO-DWM in GdCo necessitates Neel DWs. Moreover, we demonstrate that this same principle can be applied to drive to skyrmion bubbles all-optically for the first time.

Analogous to the Hall effect where electronic charges moving in the presence of a magnetic field acquire a transverse velocity, magnetic solitons with non-zero topological charges (i.e. skyrmions and chiral domains walls) exhibit the skyrmion Hall effect [1], which opens up new possibilities for manipulating the trajectories of these quasiparticles. The skyrmion Hall

effect has been theoretically predicted to vanish for antiferromagnetic skyrmions because of the cancelation of opposite topological charges [2] and experimentally demonstrated to vanish in ferrimagnets at the compensation temperature [3]. We present a study of current driven domain wall dynamics in artificially ferrimagnetic multilayers: Ta(4 nm)/Pt (5 nm)/[Co (0.5 nm)/Gd (1 nm)/Pt(1 nm)]$_{10}$/Al (2 nm). The magnetic texture in different layers of the multilayer films are coherent and antiferromagnetically aligned. Here we experimentally investigate the temperature dependence of the current driven magnetization dynamics from room temperature down to temperatures below the compensation point at around 100 K and show a dependency of the skyrmion Hall angle and domain wall speeds on the applied temperature. *Work at Argonne was supported by the US-DOE, Office of Science, MSED. Antiferromagnetic skyrmions, compared to their counterpart ferromagnetic skyrmions, have richer physics and offer technological advantages for spintronic device applications, because of their insensitivity to stray fields, compensation of skyrmion Hall effects and expected high mobility [1-3]. Here we report the realization of zero-field synthetic ferrimagnetic skyrmions at room temperature in [Co/Gd/Pt]$_{10}$ multilayers and the investigation on the stability of the chiral domain walls of such synthetic ferrimagnetic skyrmions between 33 K and 300 K. Synthetic ferrimagnetic skyrmions, in which Co and Gd layers are antiferromagnetically coupled across the interfaces of the multilayer, were created in a sputtered Ta(4 nm)/Pt (5 nm)/[Co (0.5 nm)/Gd (1 nm)/Pt(1 nm)]$_{10}$/Al (2 nm) multilayer by a well-defined magnetic field treatment. These skyrmions, once formed, are stable at room temperature and zero field. The spin configuration of the Co and Gd layers were imaged by element-specific synchrotron x-ray photoemission electron microscopy (PEEM) at zero field, while the temperature decreased from 300 K to 33 K and then increased back to 55 K. PEEM imaging reveals that the antiferromagnetically coupled Co and Gd skyrmion pairs are stable over a large temperature range from about 300 K to 55 K. At 50 K the magnetization of the core area of the skyrmion pairs starts to rotate from the original out-of-plane direction to in-plane. This spin reorientation transition (SRT) becomes more pronounced when the temperature is decreased further to 33 K. However, the domain wall regions are preserved during this SRT, and after the temperature is increased back to above 50 K, the same skyrmions are recovered to the their identical state before the SRT. Micromagnetic simulations were performed to understand the SRT in context of the presence of chiral domain walls. The observed temperature dependent spin configuration changes in the [Co/Gd/Pt]$_{10}$ multilayers can be attributed to the competition among the ferromagnetic exchange coupling within the Gd spins and Co spins, antiferromagnetic exchange coupling between the interfacial Gd and Co spin, and the interfacial Dzyaloshinskii–Moriya interaction.

DC-07. Magnetic skyrmions, bimerons and antiskyrmions in new materials. *Y. Zhou*[1] *1. School of Science and Engineering, The Chinese Univerisity of Hong Kong (Shenzhen), Shenzhen, China*

In this talk, I will discuss our recent work of magnetic skyrmions, bimerons and antiskyrmion in new material systems, i.e., antiferromagnets, ferrimagnet and frustrated magnets [Nature Electronics, 1, 288-296, (2018); Nature Communications, 9, 959, (2018); Nature Physics, 13, 162–1169 (2017); Nature Communications, 8, 1717, (2017); Nature Communications, 7, 10293 (2016)]. It is shown that the skyrmion Hall effect can be partially or completely suppressed in ferri-, antiferro- or frustrated materials in comparison to ferromagentic materials, making magnetic skyrmions in the new systems suitable for memory applications. In addition, I will discuss the novel physics of these intriguing topological spin textures in the new materials systems and highlight their potential device applications.

DC-08. An accurate model for skyrmion dynamics under spin-orbit torques. *W. Gan*[1], I. Purnama[1], J.C. Martinez[2] and W. Lew[1] *1. Nanyang Technological University, Singapore; 2. Singapore University of Technology and Design, Singapore*

While many experimental works have demonstrated that the spin-orbit torques play a critical role in propelling skyrmions, the phenomenon has not been modelled completely. In this work, we develop an analytical model to accurately describe skyrmion dynamics under the influence of spin-orbit torques by incorporating the contribution from the spin Hall effect and the Rashba effect. We show that the spin Hall effect leads to the emergence of a force with an amplitude that depends solely on the skyrmion size and a direction that depends only on the skyrmion configuration. The result suggests that small skyrmion used for hi-density devices will suffer from deteriorated performance due to their slow speed. Comparison with micromagnetics confirm the accuracy of our model over a wide range of material parameters and skyrmion configurations. Using our model prediction for the helical-type skyrmions, we find that, despite their very low skyrmion Hall angle, they were found to move much slower in nanowires as compared to the high skyrmion Hall angle radial-type skyrmions. The counter-intuitive results were explained by a force amplification effect that arises due to the edge repulsion from the nanowire. We further provide examples on how this

amplification effect can be exploited for higher skyrmion speeds. In conclusion, our work provides a fundamental understanding of skyrmionics and insights for possible exploitation or elimination of the skyrmion Hall effect, while predicting a scalability challenge for skyrmion devices.

Moving skyrmions with non-zero topological charges and finite fictitious magnetic fields exhibit the skyrmion Hall effect, which is detrimental for applications such as skyrmion racetrack memory[1]. Recently, it was predicted that the skyrmion Hall effect vanishes for antiferromagnetic skyrmions because their fictitious magnetic field, proportional to net spin density, is zero[2]. In this work, we experimentally demonstrate the vanishing skyrmion Hall effect in the vicinity of the angular momentum compensation temperature T_A[3] by using ferrimagnetic compound GdFeCo. We measured current-driven transverse elongation of pinned ferrimagnetic bubbles in perpendicularly magnetized ferrimagnetic GdFeCo/Pt film by using MOKE (Fig. 1). And we confirmed that the angle between the current and bubble elongation directions, vanishes at the angular momentum compensation temperature T_A (=287±5 K) where the net spin density vanishes (Fig. 2). To interpret these results, we developed a simple theory for the elongation of a pinned magnetic bubble driven by SOT. Specifically, we modelled an elongated bubble with one pinned end at the origin as a composite object that consisted of a half skyrmion ($Q = \pm 1/2$) at the free end and a straight rod that connected the two ends, and the elongation angle $\theta = \theta_{SkH}$ with $\theta_{SkH} \approx \tan^{-1}(2s_{net}Q\lambda/\alpha s_{total}r)$ where s_{net} is the net spin density, s_{total} is the sum of the sublattice spin density magnitudes, α is the Gilbert damping constant, λ is the domain wall width that forms the bubble boundary and r is the radius of the half skyrmion. As the temperature approaches T_A, s_{net} goes to zero and, consequently, the elongation angle θ_{SkH} goes to zero. This implies the skyrmion Hall effect vanishes at T_A, as was experimentally observed. Combined with theoretical and numerical support, our observation demonstrates that the fictitious magnetic field for magnetic skyrmions is proportional to s_{net} and skyrmion Hall effect vanishes at T_A[4].

In recent years, the manipulation of magnetization solely by the ultrashort laser pulse has attracted attention for future ultrafast and low-energy spintronics devices [1-10]. GdFeCo has been predominant materials system showing all-optical single-shot magnetization switching. The magnetization switching of GdFeCo is driven by a transient ferromagnetic-like states and transfer of angular momentum between Gd and FeCo sublattices [1,2]. However, restriction to Gd-based ferrimagnetic material limits potential spintronics device applications. Moreover, all-optical magnetization switching in magnetic multilayer, in which magnetic layers are decoupled, is unexplored. In this study, we demonstrated that all-optical single shot magnetization switching can be realized even in ferromagnetic film, which is mediated by transfer of angular momentum in spin-valve structure [11]. This demonstration provides new way to deterministically switch ferromagnetic films with a single optical pulse. The spin-valve structure used in this study consists of a ferromagnetic [Co/Pt] layer and a ferrimagnetic GdFeCo layer where the two magnetic layers were magnetically decoupled by a thick Cu spacer layer. The ultrashort laser pulses irradiate sample from the film side (GdFeCo layer) and the magneto-optical Kerr effect images are obtained from the substrate side. It is observed that the ferromagnetic layer is switched by the irradiation of single femtosecond laser pulse to the GdFeCo layer even when we insert a 30-nm-thick Cu layer. When we insert Pt spin scattering layer in the Cu spacer layer, single shot switching of ferromagnetic layer decayed with increasing Pt layer thickness. Thus, we conclude that the all-optical switching of ferromagnetic layer is attributed to the transfer of angular momentum from GdFeCo layer to the Co/Pt layer. In the presentation, we will show the details of the experimental results as well as recent experiments using different ferromagnetic materials. In addition, time-resolved experiments using pump-probe technique as well as electrical detection of all-optical switching in spin-valve will be presented. In the past two decades, researchers have been able to observe ultrafast magnetic dynamics driven by femtosecond laser pulses, revolutionizing our view on magnetism [1,2]. Despite the progress of the last decade in the description of ultrafast magnetism, the understanding of the fundamental physics that allows for the ultrafast transfer of angular momentum is still only partial, historically hampered by the lack of experimental techniques suited to fully explore these phenomena. However, the recent appearance of coherent X-rays generated at free electron lasers (FELs), has given researchers access to a whole new set of capabilities to unveil this elusive phenomenon. With its superconducting linear accelerator, the European XFEL is the only existing high-repetition FEL. The increased number of photons hugely improves the statistics and allows to effectively perform time-resolved imaging experiments with femtosecond resolution. The SCS beamline for soft X-rays has a new state-of-the-art detector (DSSC) that matches the high repetition rate offered by the FEL. We will show the first images taken with the DSSC detector at a record repetition rate of 1.1MHz. Using holographic reconstruction techniques, we were able to image spin structures in a CoFeB nanodot using femtosecond X-ray pulses. Our experiment shows that the European XFEL and hence future superconducting FELs are facilities where it is possible to perform imaging with combined high temporal and spatial resolution. While our first images on ultrathin CoFeB are limited to ~20 nm spatial and ~500 fs temporal resolution due to temporary limitations at the European XFEL, we anticipate that these new machine will open up for achieving combined 10 nm and 10 fs resolution in a single measurement. Such combined resolution will allow for a deeper

understanding of the fundamental processes in the puzzling phenomenon of ultrafast magnetism, directly probing the spatial and temporal length scale of the spin-orbit and exchange interactions.

DD-03. Ultimate Speed Limits for Deterministic All-Optical Toggle Switching. *Y. van Hees*[1], B. Koopmans[1] and R. Lavrijsen[1] *1. Department of Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands*

In order to use single pulse all-optical switching (AOS) for future ultrafast data storage or logic applications, a better understanding is needed of the ultimate switching rates that can be achieved to assure deterministic AOS. In this contribution, we experimentally investigate double pulse AOS behaviour in a Co/Gd bilayer [1] as a function of picosecond time delay between two fs laser pulses which can individually induce AOS (fig. 1). As seen in fig. 2, we demonstrate that there is a clear delay threshold for deterministic switching of 50-100 ps (leading to data rates of 10-20 GHz). We introduce and discuss simulations describing this process using the microscopic three-temperature model (M3TM) [2], which can already qualitatively reproduce single and double switching as well as thermal demagnetization behaviour seen in the experiments (fig. 2). This model allows us to unravel the determining factors for the time-delay threshold. For instance, we find that this threshold is strongly dependent on the relative laser fluence of the incident pulses, which we will also demonstrate experimentally. Interestingly, matching with previous modeling work [3], these simulations show that it is possible to switch the magnetization a second time even when the system has not fully relaxed to saturation yet. Optical double-pump-probe measurements are underway to experimentally investigate the ps-timescale dynamics of this non-equilibrium switching mechanism. This work demonstrates the exciting potential of single pulse AOS for future ultrafast magnetic storage and logic applications. Moreover, the bilayer nature of the system under investigation grants (interface) engineering opportunities which can push this so-called rapid-fire performance of future devices even further.

We demonstrate how femto- or picosecond-long heat pulses enable single-shot all-optical switching (AOS) of magnetization in ferrimagnets[1]. By realistically modelling a generic ferrimagnet as two coupled macrospins[2], we show that the net magnetization can be reversed via distinctly different pathways, using a heat pulse with duration spanning all relevant timescales within the non-adiabatic limit (Fig. 1). This understanding is validated by

experiments studying the material and optical limits at which the switching process in GdFeCo alloys loses its reliability. Specifically, we numerically and experimentally reveal the existence of a critical pulse-duration threshold for $Gd_x(FeCo)_{100-x}$ alloys, whereby thermal pulses with durations below and above t_c are capable and incapable respectively of achieving deterministic AOS. The size of t_c scales monotonically and dramatically with x (Fig. 2) – increasing x from 22 to 27 leads to t_c increasing by a factor of more than 40. Our interpretation and results resolve a significant controversy[3] about how relatively "slow" pulses can achieve magnetization reversal, and also provide new guidelines for how deterministic AOS can be achieved in suitable ferrimagnets using tailored thermal pulses[4].

The interaction of an ultrashort laser pulse with magnetic materials may be used to manipulate spins at the time scale of picoseconds [1, 2]. This provides a feasible way to significantly improve the speed of information storage and operation based on the spins of magnetic materials. However, this manipulation normally originates from the light induced heat effect. Because of the slow heat diffusion, the repetition frequency of this spin manipulation is greatly limited. Therefore, it is important to search nonthermal ways to control the spins at the ultrafast time scale. Although the circularly polarized light was used to nonthermally stimulate the coherent spin rotation in a variety of magnetic materials via the inverse Faraday effect, using linearly polarized light to nonthermally drive the magnetization motion at the ultrafast time scale is much less demonstrated. Here, we present two methods using linearly polarized light to manipulate the magnetization of magnetic materials via the ultrafast nonthermal effect. One way is the excitation of magnetization precession via the inverse Cotton-Mouton effect in undoped yttrium iron garnet (YIG) films [3], as shown in Fig. 1, and the other way is the excitation of magnetization precession via the optical rectification in combination of the inverse piezoelectric effect in a ferromagnetic/ferroelectric heterostructure ($Co/BiFeO_3$). For both effects, the precession amplitude and/or precession phase depend on the polarization direction of the linearly polarized laser pulse.

DD-06. Selective All-Optical Toggle Switching Defined by Spin Currents in FM/Cu/Co/Gd Systems. *Y. van Hees*[1], P. van de Meugheuvel[1], B. Koopmans[1] and R. Lavrijsen[1] *1. Department of Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands*

Single pulse all-optical switching (AOS) of magnetization by fs laser pulses has been proposed as a candidate for future data storage applications. However, in this regard it is limited by being a toggle mechanism, which is independent of the inital magnetization direction. In this contribution, we show that spin currents generated in a magnetic reference layer can significantly impact single pulse AOS in a Co/Gd bilayer. Using this mechanism, we demonstrate selective toggle switching which only depends on the magnetization direction of the reference layer. The system under investigation (fig. 1) consists of a Co/Ni multilayer separated by a Cu spacer from a Co/Gd bilayer, the latter of which shows single pulse AOS [1]. Upon fs laser illumination the Co/Ni multilayer demagnetizes, generating spin currents which flow through the Cu spacer to the top Co/Gd. We conjecture that the additional spin angular momentum deposited into the top Co layer may add as an additional bias to provoke or prevent switching into the reversed state. We find (fig. 2) that the threshold laser fluence for single pulse AOS is lower when the moments of the Co/Ni multilayers and the top Co layer are initially antiparallel. Here the effect is found to be >10%, with more systematic studies underway for further tuning and understanding. Furthermore, we prove that this phenomenon is driven by spin currents by demonstrating that the effect vanishes when inserting a Pt spin sink layer. We show that our mechanism allows for laser fluence dependent deterministic setting of the magnetization state of the top Co/Gd layer based on the reference layer magnetization direction, which could lead to new applications in data storage and logic.

DD-07. Comparing all-optical switching in (synthetic-)ferrimagnetic multilayers and alloys. *M. Beens*[1], M. Lalieu[1], A. Deenen[1], R. Duine[2,1] and B. Koopmans[1] *1. Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands; 2. Utrecht University, Utrecht, Netherlands*

All-optical switching (AOS) refers to the switching of the magnetization by femtosecond laser pulses and has a high potential to be used in future magnetic memory devices. After the discovery of AOS in ferrimagnetic GdFeCo alloys [1], AOS was also demonstrated in Pt/Co/Gd multilayers [2]. The latter allows for easy interface-engineering to optimize its magnetic properties. An important question that arises is to what extent the switching of ferrimagnetic alloys and synthetic ferrimagnets relies on the same physics. Our research shows that the conditions for switching the ferrimagnetic alloys and synthetic ferrimagnets are strikingly different [3]. We experimentally show that Pt/FM/Gd multilayers can be switched for a relatively thick ferromagnetic (FM) layer, which indicates that the switching mechanism in synthetic ferrimagnets is independent of a possible compensation temperature. In contrast, for the alloys it is believed that it is crucial to have a significant magnetization compensation. These different conditions are verified by our microscopic model, which describes the laser-induced dynamics in ferrimagnetic alloys and synthetic ferrimagnets on an equal footing. The model includes Elliott-Yafet spin-flip scattering and exchange scattering between multiple spin sublattices, which correspond to the sublattices of a ferrimagnetic alloy or the atomic monolayers of a synthetic ferrimagnet. In agreement with our experiments, Fig. 1 shows that Co/Gd bilayers can be switched for an arbitrary thickness of the Co layer, i.e., both with and without the presence of a magnetization compensation temperature. In contrast, Fig. 2 shows that GdCo alloys can only be switched near the compensation point. The role of spin transport on the robustness of the switching mechanism in the synthetic ferrimagnets will be discussed.

Electrical Engineering and Computer Science, University of California Berkeley, Berkeley, CA, United States*

Reduction of switching time and energy are the keys to the success of future MRAM devices [1,2]. In recent years, much attention has been given to the material GdFeCo as a result of its unique ability to reverse its magnetization in picosecond timescales in response to only a single femtosecond laser pulse excitation [3-5]. Early attempts to observe this behavior at the nanoscale, however, were impeded by either the weak anisotropy and loss of perpendicular magnetization in nanoscale patterns of GdFeCo alloys [6] or the inhomogeneity of the local, but higher anisotropy in continuous films of TbFeCo alloys [7,8]. In this work, after first demonstrating helicity-independent all-optical switching in GdCo nanoscale patterned dots, we characterize their time-resolved magnetization switching behavior as a function of diameter [9]. GdCo dots of diameter d and spacing 2d were made to fill uniform arrays of size 25 μm x 25 μm, such that the laser probe beam (diameter 15 μm) would measure a summation of the magnetization from many dots of the same size. The time resolved magneto-optic Kerr effect (TR-MOKE) behavior in Fig. 1 indicates clear evidence of faster magnetization reversal for smaller dot sizes, despite increased noise in those arrays resulting from laser interference, edge effects, and other non-idealities. Figure 2 summarizes the switching time as a function of dot diameter, where a 75% reversal threshold was chosen. Increased switching speed at smaller dimensions is believed to be a result of enhanced electron-phonon and spin-lattice coupling, which cause a reduction in the time necessary to transfer heat from the electrons and spins to the lattice, allowing the magnetization to settle faster to its reversed state [9]. These results can be further extrapolated to demonstrate the potential impact in nanoscale integrated systems, where in Fig. 2, a 20 nm dot is expected to switch its magnetization in less than 2 ps, two orders of magnitude less than precessional switching processes [10].

DD-09. Ultrafast helicity-independent all-optical magnetization reversal of Co/Pt multilayers coupled with CoGd. *J. Chatterjee*[1], A. Pattabi[1], M. Ruiz[2], S. Salahuddin[1,3], F. Hellman[2,3] and J. Bokor[1,3]
1. Department of Electrical Engineering and Computer Sciences, University of California, Berkeley, Berkeley, CA, United States; 2. Department of Physics, University of California, Berkeley, Berkeley, CA, United States; 3. Lawrence Berkeley National Laboratory, 1 Cyclotron Road, Berkeley, CA, United States

Ultrafast helicity-independent all-optical switching (HI-AOS)[1] as well as ps current-pulse driven magnetization reversal[2] of a ferrimagnetic GdFeCo illuminated the pathway of realizing ultrafast magnetization reversal of a ferromagnet[3]. Recently, HI-AOS of Co/Pt multilayers (MLs), coupled with GdFeCo has been demonstrated[3,4]. However, as the perpendicular magnetic anisotropy of GdFeCo decreases with device scaling[5], the stacks where a ferromagnet is coupled with GdFeCo are not ideal for applications. Therefore, we have investigated the magnetic properties as well as magnetization dynamics of Co/Pt MLs coupled with CoGd, in which HI-AOS is recently been reported in nano-devices. The stacks studied are configured as "Pt seed /$[Co/Pt]_2$ /Co /Pt (t nm) /CoGd /Pt cap", where the intermediate Pt spacer thickness is varied (t= 0.25, 0.5, 1 and 5 nm). The hysteresis loops of the samples shown in Fig. 1(a) were measured by polar magneto optical Kerr effect (MOKE). The MLs are ferromagnetically coupled with CoGd for t<5 nm. They exhibit single shot HI-AOS with laser pulse widths from 60 fs to 3.5 ps as presented in Fig 1 (b) and (c), which opens up the possibility to reverse the magnetization of Co/Pt MLs using charge current pulses of similar pulsewidth (~ 3.5 ps). The MLs and CoGd are decoupled, for t=5 nm and only the magnetization of CoGd is toggled under successive optical pulses. Hence, we believe that the HI-AOS of Co/Pt MLs is mediated by exchange coupling through the Pt spacer. Finally, the magnetization dynamics of the ferromagnetically coupled stacks are characterized by time-resolved MOKE measurements, which is presented in Fig. 2. The magnetization of the stacks reverse within a ps time-scale irrespective of the spacer layer thickness. Such a fast magnetization reversal of a ferromagnet exploiting the exchange bias with CoGd will be promising for ultrafast memory and storage applications.

DD-10. Field Dependence of Time-Resolved All-Optical Toggle Switching in Co/Gd Bilayers. *M. Peeters*[1], Y. van Ballegooie[1], M. Beens[1], R. Lavrijsen[1] and B. Koopmans[1] *1. Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands*

Originally discovered in ferrimagnetic GdFeCo alloys [1], AOS gives rise to a toggle switch of the magnetization on the picosecond timescale after excitation with an ultrashort laser pulse. Recently, it was shown that single-pulse AOS can also be found in ferrimagnetic Co/Gd bilayers [2], opening up new possibilities for (interface) engineering of the stack, which makes it highly suitable for future spintronic applications [3]. However, up until now only static measurements of AOS in Co/Gd have been reported. We report on the first time-resolved measurements of all-optical switching in Co/Gd for applied fields between 0 and 500 mT, performed with a time-resolved MOKE setup. In order to measure the time-dependence of the toggle switching process, we detect at half the repetition rate of the laser (100 kHz), selecting only every other pulse. Thus, we do not need to rely on a reverse magnetic field to bring the magnetic state back to the original orientation after the switch. We show that in Co/Gd bilayers the switching happens on the same picosecond timescale as in GdFeCo alloys. As visible in Fig. 1, the magnetization recovery on very short timescales displays a strong dependence on the external field, even for fields that are orders of magnitude smaller than the exchange fields that drive the magnetization recovery. We will present numerical simulations using the M3TM applied to alloys and bilayers on equal footing. From comparing our magnetic-field dependent experimental results with those simulations, we conjecture that the magnetization reversal is a strongly non-homogeneous across the exciting laser spot. Also, the recovery process is suggested to be a complex process of local magnetization dynamics and domain wall propagation on longer time scales. Our current efforts are aimed at shedding more light on this non-homogeneous and multiple time scale dynamics. We expect that this research will provide an important next step in the understanding of AOS in ferrimagnets.

DD-11. Light-wave dynamic control of magnetism. *M. Münzenberg*[1]
1. Institute of Physics, Greifswald University, Greifswald, Germany

Ultrafast magnetism, attosecond lasers and methods using x-ray pulses to explore structural dynamics is reaching new limits - attosecond magnetism. Recent major milestones, from hard x-ray bunches to attosecond pulses, are breaking frontiers and time records. This allows the observation and study of coherent spin processes. The phenomena is originating from coherent charge transfer, driven by a few cycle laser pulse. Today, the fully controlled electric field evolution of ultrashort laser pulses permits the direct and ultrafast control of electronic properties of matter and is the cornerstone of light-wave electronics. In sharp contrast, because there is no first order interaction between light and spins, the magnetic properties of matter can only be affected indirectly on the much slower tens-of-femtosecond timescale in a sequence of optical excitation followed by the rearrangement of the spin structure. Here we record an orders of magnitude faster magnetic switching with sub-femtosecond response time by initiating optical excitations with near-single-cycle laser pulses in a ferromagnetic layer stack. The unfolding dynamics are tracked in real-time by a novel attosecond time-resolved magnetic circular dichroism (atto-MCD) detection scheme revealing optically induced spin and orbital momentum transfer (OISTR) in synchrony with light field driven charge relocation. We present the first incarnation of attomagnetism observes light field coherent control of spin-dynamics in the initial non-dissipative temporal regime and paves the way towards coherent spintronic applications with Petahertz clock rates.

DE-01. Thermoelectric signature of individual skyrmions. *A. Fernández Scarioni*[1], C. Barton[2], H. Corte-León[2], S. Sievers[1], F. Ajejas[3], W. Legrand[3], N. Reyren[3], V. Cros[3], O. Kazakova[2] and H. Schumacher[1] *1. Physikalisch-Technische Bundesanstalt, Braunschweig, Germany; 2. National Physical Laboratory, Teddington, United Kingdom; 3. Unité Mixte de Physique, CNRS, Thales, Univ. Paris-Sud, Université Paris-Saclay, Palaiseau, France*

The electrical detection and characterization of individual skyrmions at room temperature is a key requirement both for future devices and fundamental studies. So far, skyrmions in multilayers have been electrically detected by their signature in the anomalous Hall effect (AHE) [1]. While AHE detection is limited to Hall crosses, here we show that the anomalous Nernst effect (ANE) [2], the thermoelectric analogue of the AHE, allows non-invasive detection, counting and characterization of individual skyrmions in complete nanowires at room temperature. We use a combined ANE – in situ magnetic force microscopy (MFM) setup to identify the ANE signature of individual skyrmions in Co|Ru|Pt multilayer nanowires. First, a set of skyrmions is nucleated by a current pulse through the wire. Then, MFM is used to characterize the number, size, and spatial distribution of the skyrmions. A transverse thermal gradient from a microheater induces an ANE signal proportional to the out-of-plane magnetization of the wire, which is electrically detected. To derive the ANE signature of individual skyrmions, the stray field of the MFM tip is used to delete individual skyrmions one by one and the respective ANE signals are compared. We demonstrate the ANE based detection and counting of individual skyrmions and study the field dependence of the ANE signature of individual skyrmions. This new non-invasive tool could prove useful for applications and fundamental studies of the topological Nernst effect.

Magnetic skyrmions are the focus of intense research due to their fundamental qualities as a topologically stabilized pseudo-particle and their potential applications to next-generation magnetic information technologies. These chiral spin structures are frequently presented as 2D projection of a complex 3D topological structure, however, this picture ignores the three-dimensional tube-like structure of the skyrmion. Previous works have suggested interesting physics, including magnetic monopoles, may exist within the depth of the skyrmion. Recently, we have demonstrated the realization of hybrid skyrmions stable at room temperature and zero magnetic field in Gd/Fe multilayers [1]. These skyrmions are stabilized by magnetic dipolar interactions, rather than the traditional Dzyaloshinskii–Moriya interaction.[1,2] As part of the dipolar stability, flux-closure domains form at the top and bottom surfaces of the film; TEM results reveal a Bloch-type azimuthal winding at the equator. In this work, we use grazing incidence small-angle neutron scattering (GISANS), shown in Figure 1, and polarized neutron reflectometry (PNR), to determine the depth profile of the skyrmion. Specifically, in the GISANS and PNR patterns, the specular data capture the depth-dependent magnetic structure of the skyrmions, averaged across the sample plane. Since the structure is highly symmetric in-plane, the depth-resolved average cannot determine the structure alone. The off-specular GISANS data captures the in-plane structure. Measuring both data, we resolve the full depth profile of the skyrmion. To interpret the data, a micromagnetic simulation of the skyrmions was developed; the specular and off-specular patterns were calculated from the model and compared to the experimental results. By iteratively improving the model the simulated pattern was made to accurately reproduce the experiment. For comparison, a prototypical skyrmion thin-film of FeGe is also measured. Work at UCSD supported by DOE (DE-SC0003678); neutron work was performed on VSANS and PBR at NCNR, and supported by CHRNS (NSF:DMR-1508249).

Room-temperature magnetic skyrmions in magnetic multilayers are considered as information carriers for future spintronic applications. Currently, a detailed understanding of the skyrmion stabilization mechanisms is still lacking in these systems. To gain more insight, it is first and foremost essential to determine the full real-space spin configuration. Here, we apply two advanced X-ray techniques, based on magnetic circular dichroism, to investigate the spin textures of skyrmions in $[Ta/CoFeB/MgO]_n$ multilayers[1]. First, by using ptychography, a high-resolution diffraction imaging technique, we determined the two-dimensional out-of-plane spin profile of skyrmions with a spatial resolution of 10 nm. Second, by performing circular dichroism in resonant elastic X-ray scattering, we demonstrate that the chirality of the magnetic structure undergoes a depth-dependent evolution. This suggests that the skyrmion structure is a complex three-dimensional structure rather than an identical planar texture throughout the layer stack. The analyses of the spin textures confirm the theoretical predictions that the dipole-dipole interactions together with the external magnetic field play an important role in stabilizing sub-100-nm-diameter skyrmions and the hybrid structure of the skyrmion domain wall. Our combined X-ray-based approach opens the door for in-depth studies of magnetic skyrmion systems, which allows for precise engineering of optimized skyrmion heterostructures.

DE-04. Controlling skyrmion bubble confinement by dipolar interactions. *T. Lichtenberg*[1], F.C. Ummelen[1], H. Swagten[1] and B. Koopmans[1] *1. Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands*

Magnetic skyrmions are whirls in the magnetization in which neighboring spins are rotated with respect to each other with a specific chirality. They are robust against annihilation, are less hindered by pinning sites or defects than magnetic domain walls (DWs), and their size can be in the order of nanometers. These properties make them suitable for data storage. For the envisioned skyrmion racetrack memory device [1, 2], skyrmions must be stable in small geometrically confined structures. Therefore, understanding and being able to control the interaction between skyrmions and the edge of the magnetic structure is crucial to the development such devices. In this work addressing dipolar interactions in confined structures, we show that it is possible to use focused ion beam irradiation (FIB) to control the stability and confinement of skyrmion bubbles in an entirely novel way [3]. FIB is used to locally decrease the magnetic anisotropy of a Pt/Co/Ir stack, such that skyrmion bubbles are stable within the irradiated region (fig. 1). We observe that skyrmion bubbles are located throughout the entire geometry if the background magnetization within the structure points in the same direction as the surrounding. Conversely, when the magnetization direction is opposite, a clear repelling bubble-edge interaction is observed, indicated by the red dashed line. Thus, we demonstrate it is possible to tune the skyrmion bubble confinement with a magnetic field. Finally, we calculate theoretically how skyrmion bubble stability changes in the vicinity of an edge due to a change in dipolar interactions. The observed behavior matches well with these calculations, indicating that dipolar interactions are dominant in determining the positions of skyrmion bubbles with respect to edges and to each other.

The study of topological objects has emerged as a fascinating phenomenon in solid state research from both the fundamental and the applied perspectives. An exciting candidate in this field of research is the magnetic skyrmion

which is unaltered by certain elastic transformations such as a stretching, bending or twisting [1]. The skyrmion's topology introduces unique characteristics in the way in which it interacts with electrons, other skyrmions and defects and on how it responds to a driving force [2]. This talk will address aspects of skyrmion creation, motion and detection at room temperature in cobalt based multilayer devices. Individual skyrmions are detected using Hall resistivity. A skyrmion size independent contribution to the Hall resistivity was observed which was found to be dependent on the number of skyrmions in the disc [3] (Fig. 1a). Scanning transmission x ray microscopy (STXM) was used to image the devices' out of plane magnetization while the Hall resistance was measured *in situ*. Current driven motion is observed in amorphous cobalt based devices. Recent publications have shown experimental deviations from the rigid skyrmion motion theory in form of a velocity dependence of the skyrmion Hall angle [4,5]. Here, we will discuss the diameter dependence of the skyrmion Hall angle with a constant average skyrmion velocity at 6 ± 1 m/s evaluated from STXM images. Here, we show a skyrmion diameter independent skyrmion Hall angle in systems where moving skyrmions and pinned skyrmions coexist (Fig. 1b). Furthermore, the potential for laboratory based local field assisted skyrmion creation is outlined (Fig. 1c). This work was funded by Horizon 2020 MagicSky, TOPS EMPIR and received funding from the EU H2020 research and innovation programme (grant agreement N 654360), benefitting from the access provided by the Paul Scherrer Institut (Villigen) within the NFFA Europe Transnational Access Activity framework.

We present the nucleation of skyrmions and the formation of skyrmion lattices by magnetic force microscopy (MFM) in "heavy metal/ferromagnet"-based multilayers with PMA and the interfacial Dzyaloshinsky-Moriya interaction. Stray fields induced by a standard magnetic moment tip during a multi-pass scanning result in the spontaneous nucleation of zero-field lattices of skyrmions with size of 100-150 nm, which were observed by MFM using a low magnetic moment tip. Ordered skyrmion lattices have the periodicity of about 150 nm, Fig.1. The physical process of a high dense skyrmion lattice fabrication is supported by the micromagnetic simulations. The appropriate conditions under which a confined skyrmion lattice with the hexagonal arrangement and the desired spatial geometry is formed have been defined. These results open a pathway for a maskless skyrmion nanolithography (SkNL) with sub-100 nm resolution, where each skyrmion plays role of a pixel in a final topological image. SkNL can be used to create regions of complex shape covered with skyrmions, Fig.2. The flexibility and further development of this approach related to the topological modification of the environment will make it possible to obtain regions with a minimum size corresponding to the skyrmion lattice period. The alignment of skyrmions into ordered geometric regions will allow one to fabricate skyrmion-based magnonic crystals and assign trajectories of a complex shape for the propagation of spin waves in a skyrmion lattice. Another promising aspect of tSkNL is the possibility of studying the interaction of skyrmions with a labyrinth domain structure and the features of the dynamic properties of skyrmions and chiral domain walls. The work is supported by RFBR (18-52-53038 and 19-02-00530) and Minobrnauki (state task 3.5178.2017).

DE-07. Nonvolatile creation and annihilation of fixed magnetic skyrmions using VCMA. *D. Bhattacharya*[1], S. Razavi[2], H. Wu[2], B. Dai[2], K. Wang[2] and J. Atulasimha[1] *1. Virginia Commonwealth University, Richmond, VA, United States; 2. University of California, Los Angeles, Los Angeles, CA, United States*

Current control of magnetic skyrmion motion has been investigated widely for its potential to realize racetrack like memory devices [1, 2]. Although Voltage Control of Magnetic Anisotropy (VCMA) has shown great promise to implement low power consuming memory devices by minimizing I^2R loss, control of magnetic skyrmions using VCMA has not been extensively studied yet. Some recent theoretical proposals have shown utilizing VCMA to manipulate skyrmions can be the basis of small footprint energy efficient nanomagnetic memory devices [3-5]. In this work, we demonstrate VCMA induced nonvolatile creation and annihilation of skyrmions in an antiferromagnet/ferromagnet/oxide heterostructure film (Ta/IrMn/CoFeB/MgO/Al_2O_3) [6]. Due to competing interactions (i.e. PMA, DMI and exchange bias), skyrmions and worm domains formed in CoFeB layer of 1.13 nm thickness without requiring any external bias magnetic field (Fig. 1, left column). Thereafter, we applied a negative voltage of -7 V (electric field of -0.16 V/nm) across the stack which resulted in an increase of PMA. We observed that after withdrawing the voltage, the skyrmions (and the worm domains) were annihilated and the magnetization reoriented in the perpendicular direction (Fig. 1, middle column). On the other hand, application of a positive voltage pulse reduced PMA of the system which proved to be a favorable condition for skyrmion formation from a saturated out of plane oriented state (Fig. 1, right column). Furthermore, we observed creation of skyrmions from chiral domains while increasing PMA. Finally, we performed detailed micromagnetic modeling to understand the underlying physics (Fig. 2). This study could provide a future pathway to control single skyrmion in an MTJ like device using VCMA. Magnetic skyrmions have attracted significant attention given their efficient motion in response to electrical currents and their topological stability due to their integer winding number [1]. For applications, the reliable nucleation of skyrmions that are stable in zero field at room temperature is of continued interest. Previously, it has been shown that the Joule heating from electrical current pulses may assist in nucleating skyrmions from stripes in systems with an interfacial Dzyaloshinskii-Moriya interaction (iDMI) [2,3]. In this presentation, experimental studies of Co/Ni/Pt thin-film heterostructures with moderate iDMI will be discussed. Using full-field transmission soft X-ray microscopy, we have observed a current-induced skyrmion phase can be generated at room temperature. We find a complete stripe-to-skyrmion transformation (within the field of view) by applying a 300 μs-long current pulses of density 5 x 10^{11} A/m^2 in an out-of-plane magnetic field of H = 3 kOe in 10 μm-wide wires of the composition $[Co/Ni/Pt]_{30}$. By reducing the moment and effective perpendicular anisotropy in samples of the form $[Co/Tb(0.4\ nm)/Ni/Pt]_{20}$, the current and field necessary to accomplish the same transition reduces to 1 x 10^9 A/m^2 and Hz = 350 Oe, respectively. Furthermore, the Joule heating needed to nucleate skyrmions is also reduced by

orders-of-magnitude. In both systems, the skyrmions remain stable over a range of magnetic fields, including at zero field. By investigating the effect of different current pulse amplitude, pulse duration, and applied magnetic fields, we find a sub-mJ difference in the Joule heating needed to completely transform stripe domains into skyrmions and that which has no action is found – suggesting Joule heating may not completely explain the energetic impetus of the stripe-to-skyrmion transition in these materials (Fig. 1). This work is supported by the US Department of Energy under grant DE-FOA-0001810.

Skyrmions are nanometer-scale magnetic domains which can be attributed a non-trivial topological charge. Their size and stability make them candidates for high-density magnetic memory. Skyrmions have been observed at low temperatures in certain bulk crystals and thin films lacking inversion symmetry. Recently, Ir/Fe/Co/Pt multi-stack films have been shown to host magnetic skyrmions at ambient conditions [1,2]. Here we present magnetic force microscopy (MFM) imaging of skyrmions in the temperature range 5-200K. We studied a sample with 20 repeats of [Ir(1)/Fe(0.5)/Co(0.5)/Pt(1)], where numbers in the parentheses represent layer thickness in nm. Isolated skyrmions in the film appear at an external magnetic field B≈0.3T. The skyrmions shrink and proliferate with temperature. Special care was taken to maintain a constant height of the MFM tip of ≈30nm above the surface, which allowed assessment of the temperature dependence of the skyrmion size. The examples of the MFM scans are shown in Fig. 1. Contrary to expectations [3], we found that skyrmions shrink and proliferate with temperature; the observed skyrmion radius r_m at half maximum decreases from ≈32nm at 5K to ≈24nm at 200K. Due to the blurring effect of the tip, the actual skyrmion radius r_s is much smaller, r_s≈22nm at 5K. For smaller r_m blurring contributes even more, so we expect that r_m=24nm corresponds to r_s<14nm. The reduction of r_s is accompanied by a decrease of the amplitude of the MFM signal, although the decrease, by a factor 3 from 5K to 200K, is significantly smaller than expected due to the decrease of r_s and of the saturation magnetization M_s with temperature. We analyzed skyrmions by minimizing the micromagnetic energy functional [3], which depends on material parameters, from which M_s and the effective anisotropy K_{eff} are known experimentaly [1], and B is set externally. Although K_{eff}, which favors large skyrmions, reduces strongly with temperature, we find its influence on size to be small. In contrast, the reduction of M_s and Dzyaloshinckii-Moria interactions with temperature can explain the observed size change.

DE-10. Observation of zero-field skyrmion arrays in Pt/Co/Ni/Ir-based multi-layers. *M.P. Li*[1], M. De Graef[1] and V. Sokalski[1] *1. Materials Science & Engineering, Carnegie Mellon University, Pittsburgh, PA, United States*

Magnetic skyrmions have drawn a great deal of attention due to the efficiency by which they can be manipulated with electric current for use in spintronic devices. The spin structure of skyrmions results from the Dzyaloshinskii-Moriya interaction (DMI), but skyrmion arrays also often require a perpendicular field to become the ground state. Here we observe skyrmion arrays that are stable in the absence of a perpendicular field in Pt/Co/Ni/Ir-based thin films with a range of DMI strengths using Lorentz transmission electron microscopy (LTEM). Multi-layers of $[Pt/(Co/Ni)_M/Ir]_N$ were deposited onto Si_3N_4 TEM membranes via magnetron sputtering. The ferromagnetic thickness, M, can be varied to effectively tune interfacial DMI without loss of perpendicular magnetic anisotropy. We have previously shown interfacial DMI is sufficient to support chiral Néel domain walls and isolated Néel skyrmions in this system.[1] Fresnel-mode LTEM was performed on an aberration-corrected FEI Titan G2 80-300 in Lorentz-mode. In the demagnetized state, the magnetic domain pattern is irregular (Fig 1) where contrast is only visible with the application of sample tilt confirming Néel DWs. *Ex situ* application of a sufficiently large in-plane magnetic field produces a skyrmion array in the remnant state (Fig 1). Although the precise mechanism for this observation remains under investigation, the in-plane field will significantly reduce the DW energy, thereby, enabling a much finer initial domain size as the in-plane field is reduced below the saturation field, H_k. In these relatively thin samples dipolar interactions do not immediately drive the system to a labyrinth or stripe pattern as in conventional bubble materials. Rather, the combination of pinning and topological stability of 360° Néel transitions between skyrmions preserves a refined size distribution. This method, coupled with our tunable materials system, provides a means to investigate skyrmions out of equilibrium for the development of future spintronic devices.[2]

DE-11. High-Frequency Domain Wall Oscillations in Ferromagnetic Nanowire with a Nanoscale Dzyaloshinskii–Moriya Interaction (DMI) Region. *D. Kumar*[1], R. Sbiaa[2], P. Sengupta[1] and S. Piramanayagam[1]
1. School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore; 2. Department of Physics, Sultan Qaboos University, Muscat, Oman

It has been almost fifty years since Dzyaloshinskii and Moriya have observed and explained the non-collinear interaction between spins. However, only recently, the Dzyaloshinskii–Moriya Interaction (DMI) has picked up the interest of researchers [1]. Domain wall (DW) devices with interfacial DMI, exhibiting Chiral DW motion with high speed and Skyrmions are some examples [2, 3]. On the fundamental front, DMI has attracted interest because of its role in stabilizing several magnetic phases with non-collinear and non-coplanar spin orderings. Many of these phases exhibit exotic low energy excitations obeying fractional statistics and drive unconventional electronic transport phenomena such as linear magneto-resistance and topological Hall effect. In most of the studies involving DMI so far, the investigations were focussed on a ferromagnetic layer which is entirely under DMI. In this study, we have investigated a distinctive scenario, where DMI acts only in a narrow region of a ferromagnetic nanowire. Through micromagnetic simulations, we have observed that the DW oscillates with the microwave frequency for a limited range of geometrical and magnetic parameters (as shown in Fig. 1). Fig. 1 (c) shows the discrete phase diagram for DW pinning (smaller DMI) and oscillation (higher DMI). When an electrical current flows along the nanowire, STT pushes the DW. However, the DW also experiences an additional restoring force in this DMI modified region. As a result, DW was found to oscillate. The oscillation frequency (*f*) linearly increases with the current density while it does not depend on d. A good tunability of "*f*" was observed with the magnetic parameters as shown in Fig. 2. We have developed an analytical model, which explains our findings of the simulations. The details will be presented during the conference.

The Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan*

Recently, spintronics devices have been applied to artificial neural networks. In particular, reservoir computing (RC) based on spin torque oscillators (STOs) is an interesting research target, which enables us to classify and calculate a time sequence of input data such as spoken languages and movies [1]. Several functionalities of STOs, such as small size and nonlinearity, are preferable to the RC. The smallness of the device size, however, causes serious problems such as a large noise in the STO. Thermal fluctuation disturbs the magnetization oscillation, and gives randomness in its amplitude and phase [2]. The reduction of the noise from STO is highly required to improve the performance of RC. Synchronization phenomena such as forced synchronization have been known to be useful to reduce the noise from STO [3]. However, the performance of RC with synchronized STO has not been studied yet. In this work, we investigated the oscillation properties of a vortex-type STO synchronized to microwave field from the viewpoint of physical RC. As a figure of merit, we measured the short-term memory and parity-check capacities [4,5] by using the phase modulation of the microwave as a binary input. Figure 1 shows schematics of experimental. The modulated microwave field was applied to the STO, and causes transient dynamics of the vortex core. Since the transition dynamics depends on the sequence of the input data, the dynamics has the functionality of short-term memory. Optimizing the microwave amplitude, the short-time memory capacity was maximized to be 3.6 as shown in Fig. 2. Note that this value is two times larger than that without synchronization [6,7]. The parity-check capacity was also evaluated for the first time, which was 3.1 at maximum. The results demonstrated that the synchronized STO has a great potential to be applied in RC. This work was based on the results obtained from a project commissioned by NEDO.

DF-02. Oxygen-Migration-Based Magnetic Device Emulating a Biological Synapse. *R. Mishra*[1], D. Kumar[1] and H. Yang[1] *1. Electical and Computers Engineering, National University of Singapore, Singapore*

Electronic emulation of the biological synapse, which is the memory and learning element of the brain, is an important step towards the realization of brain-inspired computing systems. However, a complementary metal-oxide-semiconductor–based implementation of a synapse is not scalable due to the power and area inefficiency[1]. It is therefore essential to develop alternative material and device concepts that can mimic the synaptic functionalities in an energy-efficient way[2-3]. We demonstrate a nanosized energy-efficient three-terminal artificial synapse, with a separate read and write path, based on a magnetic material (Co) that could generate both positive and negative synaptic outputs. Devices from the structure MgO/Pt/Co were covered with gate oxide, GdO_x. The Co layer acts as the main functional layer of the

synapse. The weight of the magnetic synapse is defined using the measure of net Co magnetization and it is quantified with the anomalous Hall resistance (R_{AHE}). The synaptic weight is modulated by applying an electric field on the GdO_x gate which results in the movement of oxygen ions[4] in and out of the Co layer as shown in Fig. 1. Synaptic potentiation and depression is shown in Fig. 2(a). When V_g pulses of +10 V and 50 ms duration are applied on the magnetic synapse, an increase in R_{AHE} is observed. Spike time dependent plasticity (STDP) of the magnetic synapse as shown in Fig. 2(b) results in weight modulation whose magnitude depends on the relative arrival of pre and postsynaptic spikes similar to that observed in the biological brain. The magnetic synapse can emulated other synaptic functions as well such as spike magnitude and rate-dependent plasticity, and the transition from short-term to long-term plasticity. Our results[5] suggest the viability of a spintronic synapse in neuromorphic computing.

DF-03. Hardwired MTJ Circuits for Stochastic Computing. *B. Parks*[1] and S. Majetich[1] *1. Physics, Carnegie Mellon University, Pittsburgh, PA, United States*

Magnetic tunnel junctions (MTJs) have been proposed as components of logic gates for stochastic computing [1]. The two resistance states of an MTJ, parallel and antiparallel, are used as logical 1 and 0. When the energy barrier to magnetization reversal is low compared to the thermal energy, the MTJ switches between 1 and 0 stochastically. The average dwell time before another switch can be tuned, using spin transfer torque (STT), such that the resistance is instantaneously digital yet analog in time average. When these STT-controlled stochastic MTJs are electronically coupled, the same circuit may be used to multiply and factor numbers. In-plane magnetized films were deposited consisting of SiO_2/Ta(5)/CoFeB(2.5)/MgO(1)/CoFeB(2.5)/Ru(0.85)/CoFe(2.5)/IrMn(8)/Ru(10), where the numbers in parentheses are the thicknesses in nanometers. The IrMn layer pins the CoFe layer, which in turn pins the CoFeB reference layer. We patterned these films into MTJ pillars with platinum leads and wire bond pads (Figure 1a). As shown in Figure 1b, the feedback between devices is regulated using resistance in series with transimpedance amplifiers to modulate the input current. We set the probability of the 1 state for each device using independent input currents and then allow the feedback mechanism to fluctuate about that set probability. Figure 2 shows binarized experimental measurements of the resistance of an MTJ for two different STT currents. The mean of the product of the two measurements agrees with the product of the two means to within 3% with an averaging time of 300 μs. This approach is extended to demonstrate invertible logic operations.

Camsari, Kerem Yunus, et al. “Stochastic p-bits for invertible logic.” *Physical Review X* 7.3 (2017): 031014.

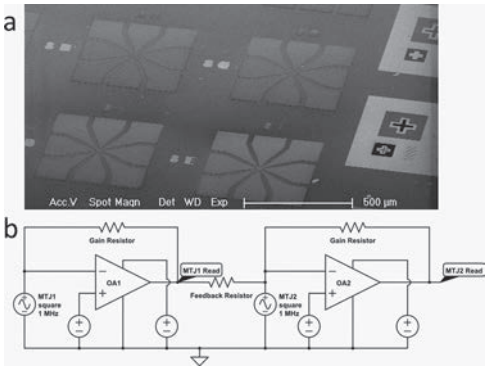

Figure 1: a) MTJ pillars lay at the center of each of the star-shaped bond pad structures. b) Transimpedance amplifiers are used to read the state of each MTJ and to provide feedback between devices such that the state of one device can influence the state of another.

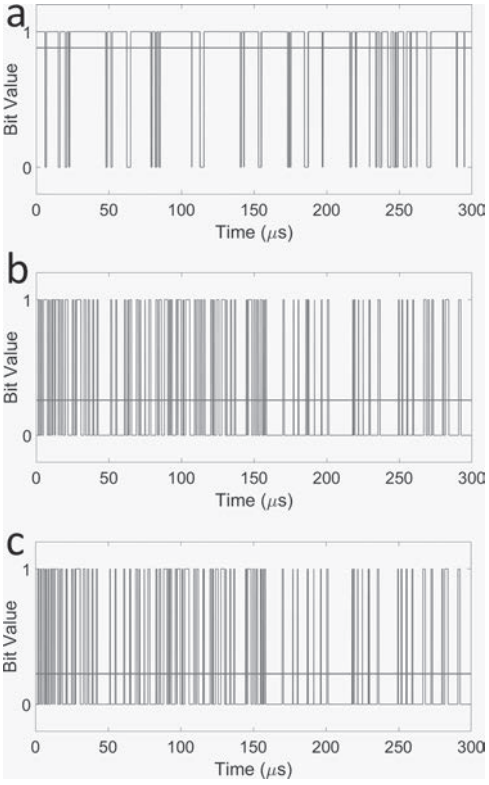

Figure 2: Measured bit values are shown in blue with mean values in red. A current of 52.5 μA results in a mean of 0.89 (a) while a current of 142 μA gives a mean of 0.26 (b). The product of the two measurements (c) gives a mean of 0.23, the same as the product of the means.

DF-04. Advantage of domain wall synapse over RRAM synapse for "on-chip" learning in hardware Fully Connected Neural Network. *D. Kaushik*[1], U. Singh[2], U. Sahu[1] and D. Bhowmik[1] *1. Electrical Engineering, Indian Institute of Technology Delhi, New Delhi, India; 2. Electronics and Communication Engineering, Delhi Technological University, New Delhi, India*

Resistive RAM (RRAM) has been widely used as synapse in hardware Neural Network (NN) [1,2,3]. Here we demonstrate advantage of recently proposed spin orbit torque driven Domain Wall (DW) device (Fig1a) [4,5] as synapse compared to RRAM for "on-chip" learning (training in hardware) in NN. RRAM synapse is simulated using VerilogA module in SPICE circuit simulator, benchmarked on HfOx device (Fig1c) [1]. Though conductance and hence weight increases gradually with increasing gate voltage pulses of short duration (200 ns), a RESET pulse (6 μs) that consumes large amount of time and energy is needed to decrease conductance [1,2,3]. Still conductance drops abruptly (Fig1d). This affects accuracy in "on-chip" learning because weights need to change gradually. Similar issue occurs in Phase Change Memory (PCM) synapse [3]. Using 2-RRAM or PCM devices per synapse overcomes accuracy issue to a degree [2,3,6] but occasional RESET pulses increase time and energy for "on-chip" learning, e.g, when we train a Fully Connected NN (FCNN) made of RRAM synapses on popular Fisher's Iris dataset [7] 6 RESET pulses were needed within 50 epochs for a particular synapse (Fig2c). However in DW synapse conductance varies symmetrically and linearly with current pulse of opposite polarities because of the nature of DW motion as observed in our micromagnetic simulations, benchmarked against experimental data on Pt/CoFe/MgO structure [4,5,8] (Fig1a,b). Hence when we design FCNN on SPICE simulator with micromagnetic model of DW synapse present in it as VerilogA module (Fig2a), the same 3 ns long current pulse of Fig1b increases and decreases the weight of the synapses (Fig2b) as needed during training on same dataset. No RESET pulse is needed. Hence total energy in synaptic weight update during "on-chip" learning on DW synapse NN is 9 orders lower than that in RRAM NN and time for learning is also much less (Fig2d).

DF-05. Artificial Synapse and Neuron Based on the Dynamics of Spintronic Devices. *A. Kurenkov*[1,2], S. DuttaGupta[1,2], C. Zhang[1], S. Fukami[1,2], Y. Horio[1] and H. Ohno[1,2] *1. RIEC, Tohoku University, Sendai, Japan; 2. CSIS, Tohoku University, Sendai, Japan*

The human brain can perform complex cognitive tasks with amazing efficiency which is far superior to von Neumann machines. While there has been considerable progress in software-based artificial intelligence dedicated to specific tasks, building neural networks of the efficiency and complexity of the brain will require reproducing its architecture in hardware. A major obstacle here is that functionalities of the unit elements—synapses and

neurons—are complex and very different. This either forces their implementation in different material systems or requires a large number of CMOS elements to build a single neuron/synapse. Here we will show how spintronics can help to reconcile the contradictory requirements of synapses and neurons and realize them in a lean and biologically plausible way by considering an antiferromagnet/ferromagnet heterostructure with field-free spin-orbit torque switching[1,2]. First, control of its switching mode from binary to analog-like[3] will be discussed. This is an essential requirement to realize binary firing/nonfiring states of the neuron and analogue weight memorization of the synapse in the same material stack. Next, we will show that a uniform mechanism of "local time" can drive the functionalities of synapses and neurons despite their differences. To realize such mechanism in the considered spintronic devices, their dynamical properties under current pulses down to 1 ns will be analyzed. After identifying a suitable dynamical process, it will be used as a timer and thereby as a basis for artificial synapses and neurons. Finally, all the discussed physical properties will be combined to demonstrate units with inherent synapse- and neuron-like properties, made from the same material and driven by a uniform principle[4]. We will show that the devices respond like their biological counterparts, which makes them promising candidates for future artificial spiking neural networks, and discuss their operation. DF-06. The recognition accuracy and power consumption of weightless neural network adopting spin-torque MRAM with a high write error rate. *H. Arai*[1] and H. Imamura[1] *1. AIST, Tsukuba, Japan*

The weightless neural network (NN) is a memory-based NN that has the benefit of simple and quick learning [1]. The weightless-NN is basically a pattern recognition system, but can recognize subjects having noise. Though it is an old technology, its performance is as good as that of conventional machine learning methods for classification tasks. Spin-torque magnetic random access memory (ST-MRAM) has attracted much attention as a fast and low-power non-volatile memory. The use of ST-MRAM instead of conventional volatile memories can reduce the power consumption of a weightless-NN because it consumes much less leakage power. In addition, the write error rate (WER) of ST-MRAM increases with decrease of the current density [2]. Therefore the power consumption for writing bits can be reduced if one accepts a high WER. However, little attention has been paid to the effects of the use of memories with a high WER on the accuracy as well as the power consumption of the weightless-NN. We investigated the recognition accuracy and power consumption of the weightless-NN consisting of ST-MRAM with a high WER. We numerically performed multi-class classification for binary images of hand-written digits in MNIST database [3]. We found that the weightless-NN works well even if the write error appears in the RAMs. As shown in Fig.1, the curve for the case with WER=10^{-3} corresponds to that for the case without the write error. In addition, the maximum accuracy is comparable for that for the case without the write error, and retained up to 10^{-3} of WER for 10 trials, shown in Fig.2(a). We also evaluated the power consumption until reaching the maximum accuracy and found that it can be reduced owing to the trade-off relation of ST-MRAM between WER and power consumption, shown in Fig.2(b).

DF-07. Implementation of Spike Time Dependent Plasticity (STDP) enabled supervised learning in a Spiking Neural Network (SNN) using Domain Wall (DW) motion based neurons and synapses. *U. Sahu*[1], A. Pandey[2], K. Goyal[3] and D. Bhowmik[1] *1. Electrical Engineering, Indian Institute of Technology Delhi, New Delhi, India; 2. Electrical and Computer Engineering, Georgia Institute of Technology, Atlanta, GA, United States; 3. Mechanical Engineering, Indian Institute of Technology Delhi, New Delhi, India*

Spin orbit torque driven Domain Wall (DW) and skyrmionic devices have been proposed as Leaky Integrate Fire (LIF) neurons [1,2] and Spike Time Dependent Plasticity (STDP) exhibiting synapses [3,4,5] in Spiking Neural Network (SNN). Only testing has been shown in [1], using spintronic devices only for neurons. Training has been shown in [3,4]. But only the synapses are spintronic in [3,4] and not neurons. Here we have shown training, for the first time to the best of our knowledge, on SNN designed with both spintronic (DW based) synapses and neurons (Fig. 1(a)). Also in [3,4] STDP enabled unsupervised learning scheme is followed for training [6], But here we follow a STDP enabled supervised scheme [7,8]. DW synapse,

proposed in [4,9], is simulated using micromagnetics on "mumax3", benchmarked against experimental data on Neel DW motion in Pt (heavy metal) /CoFe(ferromagnet)/MgO heterostructures due to in-plane current (write current or I_{write}) reported in [10] and used in the designed SNN (Fig. 1(b)). To incorporate STDP property we design transistor based circuit operating in sub-threshold regime [4] on SPICE circuit simulator that applies 3ns long I_{write} pulse on the synapse. Magnitude of I_{write}, and hence DW position and hence conductance and weight of DW synapse, show exponential dependence on time difference between spikes of pre and post-neuron with time constant (τ_{STDP} = 1.5 μs)- characteristic of STDP (Fig. 1(c),1(d)). DW neuron (Fig. 2(a)) is designed next with LIF characteristic such that time difference between two consecutive spikes is in the order of τ_{STDP} and hence three orders higher than time duration of I_{write} pulse for DW synapse (Fig. 2(b)). High classification accuracy is obtained for designed SNN on the popular Fisher's Iris dataset of flowers [11] and MNIST database of handwritten digits [12] (Fig. 2(c),(d)). Such high accuracy (85%) for MNIST is obtained for first time in the case of this STDP enabled supervised learning algorithm [7,8]. Synaptic weights form impression of the digits just like in [6] showing successful training (Fig.2(e)).

DF-08. Neuromorphic computing using two-dimensional arrays of spin Hall nano-oscillators. *J. Åkerman*[1] *1. Department of Physics, University of Gothenburg, Gothenburg, Sweden*

Mutually synchronized spin torque nano-oscillators (STNOs) are one of the promising platforms for bioinspired computing and microwave signal generation [1,2]. Using STNOs one can achieve 90% recognition rate in spoken vowels [3]. However, in order to do more complex tasks, larger scale synchronized oscillators are needed, something that is not easily done with the STNOs demonstrated so far. In my talk, I will describe a different type of spin current driven device called spin Hall nano-oscillators (SHNOs), which can generate microwave frequencies over a very wide frequency range [4]. The SHNOs are based on 50 – 120 nm wide nano-constrictions in Pt(5)/Hf(0.5)/NiFe(3) trilayers (all numbers in nm). When multiple nano-constrictions are fabricated close to each other (300 – 1200 nm separation) they can mutually synchronize and chains of up to nine nano-constrictions have been demonstrated to exhibit complete synchronization [5]. For the first time, we can now also synchronize two-dimensional SHNO arrays with as many as 8 x 8 = 64 SHNOs [6]. The mutual synchronization is observed both electrically and using scanning micro-BLS microscopy. Both the output power and linewidth of the microwave signal improves substantially with increasing number of mutually synchronized SHNOs, such that quality factors of about 170,000 can be reached. Following the approach of Romera et al [3], we also demonstrate neuromorphic computing using a 4 x 4 SHNO array with two injected microwave signals as inputs. Given their high operating frequency (~10 GHz), ease of fabrication, and highly robust synchronization properties, nano-constriction SHNO arrays are the most promising candidates for neuromorphic computing based on large oscillator networks.

Magnetic nanoparticles have proven useful for contactless heating in biological applications, such as hyperthermia in cancer therapy. A relatively new application, nanowarming cryopreserved organs [1-3], requires uniform heating that is much faster than 50°C/min to avoid crystallization of vitrified cryoprotective agents (CPA), which act as antifreeze buffers. Unlike iron oxide nanoparticles, magnetic nanowires (MNWs) have high saturation magnetizations (M_s) and high magnetic anisotropies, which are ideal for magnetic heating in an alternating magnetic field (AMF).[4] Here, Au-tipped MNWs were coated with polyethylene glycol (PEG) and specific absorption rates (SAR) were measured in glycerol to mimic the viscosity of a typical CPA. SAR increased when using metals with increasing M_s ($Co_{35}Fe_{65}$ > Fe > Co > Ni), reaching 1610 ± 20 W/g metal at 1 mg metal/ml glycerol for $Co_{35}Fe_{65}$ nanowires using 190 kHz and 20 kA/m. Aligning these nanowires parallel to the AMF increased SAR up to 2010 W/g $Co_{35}Fe_{65}$. Next, $Co_{35}Fe_{65}$ nanowires were used to nanowarm vitrified VS55, a common CPA. Nanowarming rates up to 1000 °C/min (5 mg $Co_{35}Fe_{65}$/ml VS55) were achieved, Fig. 1a, which is 20x faster than the critical warming rate for VS55 and other common CPAs. In this talk, magnetic measurments such as the area of minor loops, Fig. 1b, and design rules for optimized MNWs will be presented. To check for cytotoxicity, human dermal fibroblast cells exposed to VS55, and $Co_{35}Fe_{65}$ nanowire concentrations of 0, 1 and 2.5 mg Fe/ml, and all cases showed similar (high) cell viability. With the ability to provide rapid and uniform heating, MNWs have excellent potential for nanowarming cryopreserved tissues, in addition to enrichment [5] and MRI contrast [6] as shown previously.

Precise and programmable magnetic fields at the microscale can improve the resolution of magnetic cell sorting to a single-cell level for personalized cell therapy applications. Current technologies comprising soft and hard magnetic materials enable bulk cell separation but are currently unable to be actuated for programmable magnetic capture/release of target single-cells from a larger cell population [1]. These previous materials lack programmability to release cells while electromagnets are programmable but lack localization of a sufficient force to capture single-cells. This work demonstrates a new generation of programmable multiferroic devices that promises precise and tunable capture/release of cells across massive arrays [2]. Magnetoelastic Terfenold-D microstructures ($Tb_{0.3}$ $Dy_{0.7}$ $Fe_{1.92}$) microstructures (diameter 5-100 μm) were fabricated using photolithography and dry etching methods on a (011)-cut PMN-PT piezoelectric substrate (Fig.1A). Single-domain structures are established in Terfenol-D microdisks (20 μm) after the application and removal of a 0.5 T saturating magnetic field. Magnetic beads and magnetically-labeled cells were introduced in the device via microfluidic channels with a steady flow rate of 5 μL/min, where single-cells were captured and arrayed on Terfenol-D microdisks (Fig.1B), then subsequently released with an applied electric field (Fig.1C). An electric field of 0.8 MV m^{-1} induces compressive strain of 900 ppm along [100] direction and tensile strain of 300 ppm along [0-11] direction (Fig.1D). The resulting total strain of 1200 ppm, perturbs the single domain state due to magnetic anisotropy variation following which magnetic beads were released from the Terfenol-D micromagnets to the outlet of the microchannel. This programmable

strain-coupled multiferroic device provides an array-addressable element that can serve as the basis for massively parallel single-cell sorting via electronic actuation of magnetoelastic Terfenol-D microstructures.

DG-03. *In-Situ* Visualization of Iron Oxide Nanoparticle Growth Within a Hydrogel Network Using Magnetic Resonance Imaging (MRI). *S. Oberdick*[1,2], G. Zabow[2], K.E. Kennan[2], M.E. Poorman[1,2] and S.E. Russek[2] *1. Physics, University of Colorado Boulder, Boulder, CO, United States; 2. Applied Physics Division, NIST, Boulder, CO, United States*

It is challenging to monitor the growth of nanoparticles over the course of synthesis without perturbing the system or arresting the synthesis at successive times for analysis. Magnetic resonance imaging (MRI) is a powerful tool for non-invasive characterization of magnetic nanoparticles due to its inherent sensitivity to magnetic materials. Here, we describe a series of *in-situ* characterization experiments, measuring iron oxide nanoparticles as they grow within size-constraining hydrogels. Polyethylene glycol-based hydrogels were loaded into a custom, temperature-controlled MRI-compatible reaction chamber. Within the reactor, magnetic nanoparticles were grown within the crosslinked hydrogel via coprecipitation of iron chloride salt solutions. The diffusion of reactants through the hydrogel was monitored and visualized using T_2^* maps throughout the course of the reaction, which is particularly sensitive to the presence of magnetic nanoparticles. Quantitative T_1, T_2, and susceptibility maps of the hydrogel were also acquired at multiple time points during the reaction. The dynamic measurements in the MRI can be compared against SQUID magnetometry to correlate the DC magnetic properties, such as saturation magnetization and susceptibility, to relaxation times. Moreover, we have developed a SQUID compatible reaction vessel to directly connect datasets from magnetometry to MRI as a function of time. We describe how to engineer the magnetic properties of the hydrogel/nanoparticle composite by changing size, density and composition of particles, and explore how they impact MRI. Finally, we discuss applications of the hydrogel/nanoparticle system for developing bio-iron mimics and "living reference objects" for MR characterization of the transition from healthy iron types to pathological types within a tissue mimicking environment.

Cell tracking by magnetic resonance imaging (MRI) is a key tool in cell therapy that enables achieving the therapeutic potential of cells after implantation into a host.[1] MRI is a non-invasive imaging technique for cell monitoring, and requires labelling the cells with contrast agents.[2] Iron nanowires with their strong magnetic properties and biocompatibility are excellent materials for MRI applications.[3, 4] In this work, the capability of iron nanowires to perform as contrast agents for cell detection through MRI was investigated. Using a 1.5 T system, iron nanowires were first evaluated as longitudinal (T1) and transversal (T2) contrast agents, revealing a great potential to enhance the T2 contrast with transversal relaxivity (r_2) values of ~40 $s^{-1}mM^{-1}$. The effects of the different variables such as oxidation level and surface coating of the nanowires on the T2 contrast were further studied by measuring their r_2 values at 7 T with values higher than 200 $s^{-1}mM^{-1}$, from which two of the tested formulations were selected. The suitability of iron nanowires to label cells for detection through MRI was first demonstrated in T2-weighted images of the labeled cells implanted in vitro in a tissue-like environment. Cellular internalization of the nanowires was assessed by iron quantification and confocal microcopy. We found a high sensitivity with the possibility to detect a minimum of 25 cells/μL with a concentration of nanowires as low as 0.8 μg of Fe/mL, thus preventing toxic effects. Finally, a selected formulation of nanowires was used to label cells prior to their implantation in the parenchyma of mice brain at two different concentrations. A high sensitivity was achieved allowing almost single cell detection after in vivo implantation persisting for at least 40 days. The nanowires-based cellular detection opens a window for studies in cancer treatment, regenerative medicine and cellular migration where nanowires could be also magnetically guided to the target area.

There is a new drive for personalized cancer prevention and treatment, but there are still unmet medical needs, such as more effective biomarkers. In order to survive and metastasize, cancer cells use exosomes, microvesicles that contain materials unique to each cell. Therefore, these exosomes present as potential biomarkers.[1] We found that cancer cells can internalize magnetic nanowires (MNWs)[2] and package them into exosomes, enabling their magnetic isolation. Here, we employed Fe/Au and Ni MNWs, and also used more conventional iron oxide-based nanoparticles: magnetosomes synthesized by magnetotactic bacteria.[3] Osteosarcoma (OSCA-8) cells were incubated with Fe/Au and Ni MNWs for 48 hours before imaging with fluorescence and transmission electron microscope (TEM). The OSCA-8 cells internalized PEG-coated MNWs better than bare MNWs, and these MNWs were fragmented into small pieces in lysosomes inside the cells. Magnetosomes were also located inside the lysosomes, but they remained nearly intact. In addition, we repeated the experiments with human cancer cells, e.g. bone (U2OS), lung (a549), and breast (mcf7), and obtained similar results, Fig. 1. Next, exosomes were isolated using both magnetic and non-magnetic methods. TEM images show that exosomes indeed packaged small pieces of MNWs or individual magnetosomes. We analyzed the exosome size distribution using a nanoparticle tracking analyzer (NanoSight) and found that exosomes isolated magnetically had similar size distributions to those isolated non-magnetically. Importantly, the magnetic isolation takes about 10 minutes compared to two days for non-magnetic isolation. Our data show that MNWs are potential candidates for fast, inexpensive magnetic exosome isolation, and our goal is to use these MNWs for RF identification of exosomes. The methodology developed in this study should be transferable to identify exosomes from virtually any type of cancer cells.

DG-06. Can Magnetic Nanoparticles Operate as Temperature Sensitive MRI Contrast Agents in the Motional-Narrowing Regime? *J.H. Hankiewicz*[1,2], J. Stroud[1], J. Stoll[1], Y. Garbovskiy[1], S.E. Russek[2], S. Jurga[3], M. Kempka[3], T. Zalewski[3] and Z. Celinski[1] *1. Biofrontiers, University Colorado Colorado Springs, Colorado Springs, CO, United States; 2. National Institute of Standards and Technology, Boulder, CO, United States; 3. NanoBioMedical Center, Adam Mickiewicz University, Poznan, Poland*

Our earlier study [1] confirmed usefulness of micrometer size magnetic particles as novel exogenous temperature sensitive contrast agents for MRI thermometry. These particles, suspended in hydrogels, produce temperature dependent dipolar magnetic fields and provide images with temperature dependent intensities using T2* weighted gradient echo sequences. Although such large particles can be delivered to the tissue of interest by injection, they cannot diffuse beyond the area of injection. Additionally, safety concerns prevent such large particles from being used for *in vivo* studies. Here, we investigate using smaller $Co_{0.3}Zn_{0.7}Fe_2O_4$ ferrite particles, which solves the problem of retention in tissue. Their magnetic properties, specifically transition temperature and magnetization vs temperature, were determined with a SQUID magnetometer while crystallographic structure was studied with XRD [2]. Batches of different sized nanoparticles were obtained using sonication and sedimentation. Particles were tested in aqueous solution by DLS. Two groups of nanoparticles were selected with hydrodynamic sizes of 150 and 50 nm. Particles were suspended in 1 % agar water gels with a concentration of 0.3 mM and tested using a 9.4 T preclinical MRI scanner in temperature from 5 to 50 ^{o}C. The apparent diffusion coefficient (ADC) of water was measured at 3 T. Relative image intensities (the ratio of image intensities of pure agar to agar doped with particles), presented in Fig. 1, showed strong temperature dependence for larger particles (150 nm) and longer echo time (TE). We attribute weak temperature dependence of image intensities observed in samples doped with 50 nm particles to the averaging effect of local dipolar field due to fast diffusion of water molecules (Fig. 2). With such small particles present protons are no longer in the static dephasing regime but rather in the motional-narrowing regime, where motion of water molecules cannot be neglected [3, 4, 5]. In the future, we will study smaller particles in higher concentrations to obtain a stronger temperature dependence images and optimize TE.

DG-07. Oleic acid functionalized Fe_3O_4 magnetic nanoparticles and its adsorption capability of oil for potential biomedical applications. *G.C. Hermosa*[1], K. Chen[1], C. Liao[1], S. Wang[2], Y. Chen[3,4], C. Koh[4] and A. Sun[1] *1. Department of Chemical Engineering and Materials Science, Yuan Ze University, Taoyuan, Taiwan; 2. Department of Materials and Mineral Resources Engineering, National Taipei University of Technology, Taipei, Taiwan; 3. Chemical Engineering and Materials Science, Yuan Ze University, Taoyuan, Taiwan; 4. Surgery, Far Eastern Memorial Hospital, New Taipei, Taiwan*

Hypertension is caused by excessive oils present in the blood vessels and is a global epidemic at present. Though the conventional method such as different drug blockers are available, they still face challenges regarding adverse effects which can greatly limit their efficacies. Oleic acid (OA) is a good lipophilic material, which already widely used in nanoparticle synthesis since it can form a protective layer and can strongly be bonded to the nanoparticles. In recent years, Fe_3O_4 (commonly known as magnetite) is the choice of researchers because of their, high moment at low magnetic field, superparamagnetic property, stability at physiological conditions, biocompatibility and excellent adsorption capacity. In order for the OA suitable to be controlled *in vivo* applications and for an easy recovery from aqueous solutions, they are coated with magnetite nanoparticles. Henceforth, in this work, magnetite was synthesized via co-precipitation method and modified with different amounts for oleic acid (x=0.5, 1, 2 mL) with the evaluation of the synthesis process parameters (temperature, H_2O amount and pH), in seeking to understand the adsorption capability of oil for potential biomedical usage. The morphology and chemical structure of the OA coated Fe_3O_4 nanoadsorbents were characterized by FT-IR, XRD, SEM, VSM and MTT assay for the cytotoxicity test. Successful coating was confirmed by FTIR and showed COO- groups within the spectra. The results indicated that the adsorption capacity was 588, 833 and 1000 mg/g for x= 0.5, 1 and 2 mL respectively. An increase in the amount of OA leads to the decrease in magnetization but still demonstrated a superparamagnetic property for an easy recovery. Grain size was evaluated, and was found out to be in the range of 8nm-10nm. The adsorbent is well fitted on the Langmuir model suggesting a monolayer adsorption. Regarding the adsorption kinetics, the adsorbent follows the pseudo second order with high $R^2 = 0.98$. The nanoadsorbent exhibited a high cell viability rate signifying low toxicity. Therefore, the synthesized nanoparticle is a good candidate for biomedical applications as such for hypertension treatment, as shown in this study.

DG-08. New MnO-based Nanoparticle Contrast Agents for Magentic Resonance Imaging. *S. Trudel*[1], A. Banerjee[1] and B. Tomanek[2] *1. Chemistry, University of Calgary, Calgary, AB, Canada; 2. Clinical Neurosciences, University of Calgary, Calgary, AB, Canada*

Multimodal probes are an asset for simplified, improved medical imaging. In particular, fluorescence and magnetic resonance imaging (MRI) are sought-after combined capabilities. Here, we show that pyrrolidin-2-one capped manganese oxide nanoparticles (MnO^{pyrr} NPs) combine MRI with fluorescence microscopy to function as efficient bifunctional bionanoprobes. We employ a one-pot synthesis for ca. 10 nm MnO NPs, wherein manganese(II) 2,4-pentadionate is thermally decomposed using pyrrolidin-2-one as a solvent and capping ligand. The MnO^{pyrr} NPs are soluble in water without any further post-synthetic modifications. The r_1 relaxivity and r_2/r_1 ratio indicate these NPs are potential T_1 MRI contrast agents at clinical (3 T) and ultra-high (9.4 T) magnetic fields. Serendipitously, the as-prepared NPs are photoluminescent. The unexpected luminescence is ascribed to the modification of the pyrrolidin-2-one during the thermal treatment. MnO^{pyrr} NPs are successfully used to enable fluorescence microscopy of HeLa cells, demonstrating bifunctional imaging capabilities. A low cytotoxic response in two distinct cell types (HeLa, HepG2) supports the suitability of MnO^{pyrr} NPs for biological imaging applications. Additionaly, we have investigate the shape-dependent MRI capabilities of MnO-based contrast agents. A variety of shapes (spheres, cubes, octapods, agglomerated particles) are obtained by modifying the synthetic protocol, and their MRI capabilities evaluated through relxivity and relaxation dispersion measurements.

DG-09. 2D and 3D magnetic nanoparticles for biomedical applications.
P. Tiberto[1], F. Celegato[1], G. Barrera[1], M. Coisson[1] and M. Cialone[2]
1. Advanced Materials and life sciences, INRIM, Torino, Italy;
2. Chemistry, Università di Torino, Torino, Italy

Magnetic nanoparticles of controlled size have raised a broad technological interest in different areas such as catalysis, photonics, and biomagnetism. Fe-Pd alloys possess outstanding magnetic and mechanical properties making them suitable for different applications and due to their high magnetic saturation and metallic nature they are here studied for biomedical applications depending on nanostructures shape. In this work, 2D and 3D nanostructures have been obtained by exploiting two bottom-up processes starting from a continuous layer and their magnetic properties have been compared and discussed. $Fe_{70}Pd_{30}$ films have been deposited on Si substrates (previously coated with a MgO sacrificial layer) by rf-sputtering (film thickness 30 nm). Fabrication of 2D FePd nanodisks (NDs) is performed by nanolithography exploiting self-assembling of polystyrene nanospheres (starting diameter 500 nm) [1]. NDs with controlled diameter (≈300 nm, see Fig. 1a) have been obtained. The room-temperature magnetization process of detached NDs is characterized by a vortex core, (see hysteresis curve in Fig. 1c). This feature is very promising for magnetic hyperthermia being marked by high saturation magnetisation and zero remanence to prevent aggregation. As an alternative route to synthesize 3D nanoparticles (NPs), solid-state dewetting has been performed [2]. Here, to promote dewetting, the as-deposited thin films are subsequently submitted to a furnace annealing in vacuum atmosphere at 834 °C for 1000 s and spherical nanoparticles are obtained (≈300 nm diameter and height, see Fig. 1b). The NPs room-temperature hysteresis loop (see Fig.1 d) indicates a magnetisation process typical of a soft magnetic alloy, but still with a considerable hysteresis loop area. The specific loss power (SLP) at 100 kHz (field amplitude 30 – 60 mT) of both NDs and NPs dispersed in water have been measured through a calibrated non-adiabatic setup [3]. SLP values much larger than those achieved with conventional magnetite or ferrite nanoparticles are achieved in both nanostructures.

DG-10. Laser Monitoring of Dynamic Behavior of Magnetic Nanoparticles in Magnetic Field Gradient.
K. Tsunashima[1], K. Jinno[1], B. Hiramatsu[1], K. Fujimoto[1], K. Sakai[1], T. Kiwa[1], M. Saari[2] and K. Tsukada[1] *1. Graduate School of Interdisciplinary Science and Engineering in Health Systems, Okayama University, Okayama, Japan; 2. Faculty of Electrical and electronic Engineering, Universiti Malaysia Pahang, Pekan, Malaysia*

Magnetic nanoparticles (MNPs) have been extensively studied in the field of biotechnology and medicine. The MNPs for bio- or medical purpose are generally used for magnetic correction of antibodies in a conventional immunoassay and drug delivery. Additionally, we have studied magnetic immunoassays to detect bio-based materials in solutions with high sensitivity. Manipulation of MNPs by a magnetic gradient in solutions is an excellent option to promote reactions of MNPs with bio-materials. However, the dynamic behavior of MNPs generally depends on various properties of MNPs and solutions. In this study, a laser transmission system (LTS) has been developed to evaluate dynamic movement of MNPs in a solution with changing gradient fields. Figure 1 shows the schematic of the LTS. A laser (with a wavelength of λ~635 nm) was focused in the glass cell, which was filled with the MNPs solution. The transmitted laser beam was pass through a pin-hole and a polarizer to cut off the scattered laser beam, and subsequently focused on a Si photodiode. The detector's output increased by decreasing the concentration of MNPs (in the region where the laser was focused), and the localized concentration of MNPs was measured. Here, a permanent magnet was mounted on a linear stage to change the distance from the cell, and the gradient field change was monotonically. Figure 2 shows the output signal of the Si photodiode while the distance between the cell and the magnet changed from 4 mm to 49 mm. The speed was at ~10 mm/s. We used Resovist of 50 mg/mL as the MNPs, and the serum was mixed in the solution. The result indicates that the MNPs were first localized near the magnet and diffused over the cell, and the diffusion speed decreased with increasing serum concentration. Our series of measurements on the same solutions using dynamic light scattering (DLS) method, zeta-potential measurement, and magnetic susceptibility measurement suggest that the difference in the diffusion speed can not only be attributed to viscosity of the solution but also to the aggregation of the MNPs.

DG-11. Towards Development of a Temperature Contrast Agent for MRI Guided Laser Ablations. J.H. Hankiewicz[1], N. Alghamdi[1], K. Gorny[2], D. Woodrum[2], A. Anderson[3,2], A. Cruz Hernandez[4], J. Brown[4] and *Z. Celinski*[1] *1. Biofrontiers, University Colorado Colorado Springs, Colorado Springs, CO, United States; 2. Radiology, Mayo Clinic College of Medicine, Rochester, MN, United States; 3. Philips Healthcare, Best, Netherlands; 4. Colorado Center for Nanomedicine and Nanosafety, University of Colorado Anschutz Medical Campus, Aurora, CO, United States*

Current MRI-guided laser ablations use proton resonance frequency (PRF) shift for real-time monitoring of tissue heating [1]. PRF thermometry, however, is easily inhibited by the presence of adipose tissue, tissue movement and/or phase drift caused by magnetic field instablility or inhomogeneity [2]. Recently, we developed a new method of MRI thermometry (tMRI), using magnetic particles, which circumvents these problems [3]. These particles embedded in tissue create a temperature dependent local dipolar magnetic field that modulate the field homogeneity of the MRI scanner. Resulting intensities in T2* weighted gradient echo MR images allow us to obtain spatial temperature maps. $MgFe_2O_4$ ferrite is nontoxic at low concentrations [4]. $Mg_{1-x}Zn_xFe_2O_4$ 2 μm particles, in $0.5 \leq x \leq 0.75$ range, were tested. Magnetic properties, using SQUID, were studied between 5 to 350 K. Cell viability and reactive oxygen species production was studied following exposure to ferrite particles at concentrations of 30-240 mg/mL. Adding Zn to $MgFe_2O_4$ reduces the Curie temperature and provides biocompatible compounds. Water proton NMR linewidth, in agar gel with embedded particles, was measured between 278 to 323 K. Preliminary MRI results were obtained with a laser ablation system shown in Fig. 1. Fig. 2 shows mass magnetization vs. temperature for all compositions. Magnetization of ferrites decreases with increasing Zn content and temperature. Between 278 and 323 K, a 30% reduction of proton NMR linewidth, correlated with decreasing magnetization, was found. In laser heating experiments, 1.5 T MRI images taken at 313 and 338 K, show a 20% change of intensity, indicating that our tMRI method can provide real-time temperature maps during MRI-guided laser ablation procedure [5].

Achieving to determine the local temperature of nano-objects would suppose a major breakthrough in many technological and scientific fields. In biomedicine, magnetic and photo-induced hyperthermia therapies [1-3] employ nanoparticles as heating sources for therapeutic purposes, whose protocols are based on global temperature measurements. However, local heating effects produced at the nanoparticle surface are a key issue to evaluate the onset of thermal doses and quantify possible side effects derived from achieving high local temperatures (i.e. destroying healthy cells in the tissue, degradation of proteins and enzymes in the extracellular medium, etc). In this work, we explore the use of the extended X-ray absorption fine structure (EXAFS) analysis as an universal and accurate *in situ* probe to determine the local temperature at the nanoscale.[4] We will compare the temperatures measured in magneto-photothermal nanoparticles subjected to hyperthermia conditions by means of EXAFS spectroscopy and by infrared thermographic imaging as macroscopic temperature methods in different biological environments.

Magnetic particle hyperthermia has been proposed as a promising, minimally invasive and targeted cancer therapy [1]. So far, the majority of published works have focused on superparamagnetic (SPM) and ferromagnetic (FM) materials [1,2]. SPM materials have an intrinsic low response to alternating-current (a.c.) magnetic field and yield a low specific absorption rate (SAR). FM materials, on the other hand, even though they have high SAR values, they have the tendency to agglomerate and form large particle aggregates, even in zero applied field, which could potentially lead to occlusion of blood vessels. A possible approach utilizing the high magnetization of the FM state for SAR while preventing the agglomeration effect is to use a metamagnetic transition where the FM state is induced by a bias field. In this proof of concept study, we employed MnCoSi (MnCoSi) [3], where a first-order magnetic transition is known to take place. A CoMnSi ingot was prepared by arc melting under a purified Ar atmosphere. The ingot was annealed at 1123 K for 216 ks and ground to particles which were < 30 mm. The SAR was measured at 212.0 kHz and 31.0 kA/m. The room-temperature magnetization curve was found to show little remanent magnetization and no tendency of agglomeration for the CoMnSi powders was observed via optical microscopy. The magnetization curve showed an abrupt increase in magnetization to 67.7 Am^2/kg at $m_0H = 1$ T, reflecting the metamagnetism of this compound. The SAR measured under a direct-current (d.c.) bias field of 1.0 T was 10.7 W/g, indicating a moderate heating effect in the ferromagnetic state. Moreover, MnCoSi showed an anisotropic SAR that depended on the direction of the applied d.c. bias field. These results indicate that the heating power of metamagnetic materials can be controlled by the applied d.c. bias field, opening a new direction in the search for controlled hyperthermia cancer therapy.

DH-01. $LaTiO_3$/ $SrTiO_3$ Interfaces: From Giant Rashba Spin Splitting to Edge State Conduction. M. Veit[1,2], R. Arras[3], B. Ramshaw[4,5], M. Chan[4], D. Yi[2], R. Pentcheva[6] and *Y. Suzuki*[1,2] *1. Applied Physics, Stanford University, Stanford, CA, United States; 2. Geballe Laboratory for Advanced Materials, Stanford University, Stanford, CA, United States; 3. Department of Physics and Center for Nanointegration, University of Duisburg-Essen, Duisburg, Germany*

The Mott insulator/ band insulator interface of $LaTiO_3$/ $SrTiO_3$ was first shown to exhibit metallicity due to electronic reconstruction by Ohtomo and Hwang many years ago. Since then there has been little subsequent study of this system in comparison to the $LaAlO_3$/$SrTiO_3$ interface. We have recently found that the low dimensional metallic behavior at the $LaTiO_3$/ $SrTiO_3$ interface is accompanied by giant Rashba spin-orbit coupling. Evidence for giant Rashba spin splitting is manifest in two sets of Shubnikov-de Haas oscillations associated with an inner and outer Fermi surface, Berry phase of π, substantial anisotropic magnetoresistance and a weak anti-localization correction to the magnetoconductivity. Together these results indicate a giant Rashba coupling which is an order of magnitude larger than other complex oxide interfaces. By gating the samples with an electric field, we observe (i) quantized resistance peaks which are independent of sample dimensions in a conventional 6-terminal Hall bar geometry, (ii) a strong negative magneto-conductance near the quantized peaks in resistance, and (iii) nonlocal transport in a 4-terminal geometry. All of these observations are consistent with edge state conduction and the quantum spin Hall effect. †This work was funded by the Vannevar Bush Faculty Fellowship of the Department of Defense under Contract No. N00014-15-1-0045.

DH-02. Current-induced effective magnetic field in $La_{0.67}Sr_{0.33}MnO_3$/ $LaAlO_3$/$SrTiO_3$. *M. Yamanouchi*[1,2], T. Oyamada[2] and H. Ohta[1,2] *1. Research Institute for Electronic Science, Hokkaido University, Sapporo, Japan; 2. Graduate School of Information Science and Technology, Hokkaido University, Sapporo, Japan*

Recently, we have reported that the sign of the planar Hall effect (PHE), which originates from the spin-orbit interaction (SOI), for $La_{0.67}Sr_{0.33}MnO_3$/ $LaAlO_3$/$SrTiO_3$ (LSMO/LAO/STO) is opposite to that for LSMO/STO at low temperature [1]. This observation suggests that the SOI in LSMO is modified by LAO/STO and generation of current-induced effective magnetic field H_{eff} originating from the SOI is expected in LSMO/LAO/STO. In this work, we investigated H_{eff} in LSMO/LAO/STO structures. LSMO(18)/LAO(0,2,6)/STO structures were grown on STO (001) substrates by pulsed laser deposition, where numbers in parentheses are nominal film thicknesses in unit cells (u.c.). The LAO(6)/STO is conductive, whereas the LAO(2)/STO is insulating, which is consistent with the formation of a two-dimensional electron system (2DES) at the LAO/STO interface with a thicker LAO (>= 4 u.c) layer [2,3]. The structures were processed into a Hall bar structure having a 10-mm wide channel along [100] and two pairs of Hall probes. The magnetic field angle dependence of transverse resistance R_{yx}, which is dominated by the PHE, shows that all the structures have an in-plane biaxial magnetic anisotropy with the easy axes almost along <110> and the sign of the PHE coefficient for LSMO(18)/LAO(6)/STO is opposite to that for LSMO(18)/LAO(0,2)/STO at low temperature. After aligning magnetization direction along [-110], we measured variation of R_{yx} reflecting the switching of magnetization direction from [-110] to [-1-10] by sweeping H in [0-10] under various currents. The switching magnetic field is larger for negative current than that for positive current in LSMO(18)/LAO(6)/STO, which shows that H_{eff} is exerted on magnetization. Similar H_{eff} is observed in LSMO(18)/LAO(0,2)/STO, however the direction is opposite. The sign of the PHE coefficient and H_{eff} depend on the presence of a 2DES, suggesting that H_{eff} observed in LSMO/LAO/STO is related to the SOI modulation caused by formation of a 2DES at LAO/STO.

DH-03. Spin susceptibility of topological Kondo insulator. *P. Goswami*[1] *1. Physics, University of Delhi, D.B. College, New Delhi, India*

A topological insulator is a material with topologically protected metallic boundaries and an insulating bulk. The strongly-correlated Kondo variety [1-4], such as SmB_6, has recently been widely investigated owing to its promise of being the first realized topological Kondo insulator (TKI). We study here a generic TKI system by performing a mean-field theoretic (MFT) calculation within the frame-work of slave-boson protocol. We assume infinite Hubbard-type interaction among the quasi-localized electrons (QLE). We also investigate the consequences of break-down of the time-reversal symmetry (TRS) due to bulk substitutional magnetic impurities (MIs), such as Co atoms. These impurities couple with itinerant electrons of the system. One of the note-worthy outcome is the impurities change the single-particle excitation spectrum in a fundamental way. We obtain the grand canonical potential of the system and self-consistent equations for MFT parameters minimizing the potential with relative to these parameters. The parameters enforce constraints on the pseudo-particles due to the infinite Coulomb repulsion and the need of the formation of singlet states between an itinerant electron and a localized fermion at each lattice site in order to have a Kondo insulator. A fundamental quantity describing the magnetic response of a system is the spin susceptibility. The Kondo screening mechanisms are mostly characterized by this quantity. We have calculated the bulk spin susceptibility of the generic TKI system in the metallic and insulating phases of the system at a fixed chemical potential and found them behaving

differently with relative to change in the field corresponding to the localized moments. The difference between the metallic and insulating phase is in the sign of nearest neighbor hopping of QLE : It is positive for the metallic and negative for the insulating phase.

DH-04. Epitaxial growth of RVO_3 by ozone assisted MBE towards multiferroism in $(LaVO_3)_n/(PrVO_3)_m$ superlattices. *G. Masset*[1], O. Copie[1], K. Dumesnil[1], J. Ghanbaja[1] and S. Andrieu[1] *1. Institut Jean Lamour, Nancy, France*

Transition metal oxides with perovskite structure (ABO_3) attract an increasing interest driven by their wide range of physical properties and the opportunity to functionalize them in nanometric heterostructures for new electronic devices. The current study focuses on rare-earth (RE) vanadates ($REVO_3$). In decreasing temperature, these materials undergo first a V *3d-t_{2g}* orbitals ordering accompanied by a structural transition (symmetry lowering), followed by a spin ordering at lower temperature [1]. *Ab initio* calculations predict that (i) a shift of RE atoms (X_5^- displacements) could induce hybrid improper ferroelectricity in layered structures combining different cations, and that (ii) the coupling of polarization to Jahn-Teller distortions could let envision a direct and strong coupling between polarization and magnetism [2]. Our objective is thus to synthetize a multiferroic material in combining strains and interfaces engineering in $AVO_3/A'VO_3$ superlattices. The systems are grown in a Molecular Beam Epitaxy chamber with controlled ozone pressure. Single films of $LaVO_3$ and $PrVO_3$ have been first synthesized on $SrTiO_3$ (001) substrates. RHEED and X-ray diffraction analysis permit the optimization of the growth window (deposition temperature and ozone pressure) to obtain highly controlled 2D growth and stoichiometry. Electronic microscopy (TEM and STEM) experiments highlight the orthorhombic structure and the three growth domains on the square symmetry surface of $SrTiO_3$. The accurate determination of the atomic positions [3] enabled us to observe the X_5^- displacements of rare-earth atoms required for the appearance of ferroelectricity. Magnetic measurements confirm ordering temperatures ($T_{Néel}$) in agreement with stoichiometric bulk compounds. $(LaVO_3)_n/(PrVO_3)_m$ superlattices of high quality have then been grown, even for thinnest individual layers (one unit cell). Electrical transport measurements are planned very soon to explore the ferroelectricity in $(LaVO_3)_n/(PrVO_3)_m$ superlattices. These results will constitute a significant advance in the understanding of the electronic properties of oxide-based heterostructures, in particular for the emergence of their ferroelectric and multiferroic characters.

DH-05. Transverse resistivity anomalies in the ferromagnetic oxide $SrRuO_3$ and their interpretation: Topological or Traditional? *D. Kan*[1] *1. Kyoto University, Uji, Japan*

Transport phenomena yielding voltages transverse to electric currents, such as anomalous and topological Hall effects have been a subject of intensive investigations in recent years. Here, we show that epitaxial thin films of the ferromagnetic oxide $SrRuO_3$ exhibit transverse resistivity anomalies associated with magnetization reversal [1], which is quite similar to what have been claimed to be the emergence of the topological Hall effect (THE) due to formations of topologically non-trivial magnetic textures, such as skyrmions. Our thorough investigations revealed that the anomalies are enhanced at a certain temperature at which the sign of the anomalous Hall effect reverses. Based on our experimental observations, we proposed a model considering inhomogeneous magnetoelectric properties (such as the anomalous Hall coefficient and coercive field) in the material [2]. Our analyses fully explain every feature of the transverse resistivity anomalies without resorting to the THE. In this presentation, I will also present time and field sweep rate dependence of the transverse resistivity anomalies in $SrRuO_3$ and discuss their origin.

DH-06. Unusual Magnetic and Electric Properties of $SrRuO_3$(111) Thin Films. *J. Flores*[1], K. Meng[1], A.S. Ahmed[1] and F. Yang[1] *1. Physics, The Ohio State University, Columbus, OH, United States*

Oxide thin films offer a wide platform for investigating the effects of lattice strain due to the variety of substrates with similar lattice parameters. Lattice distortions have been known to cause significant changes to the magnetic and electrical properties. $SrRuO_3$ has been shown to have enhanced magnetization when grown on $SrTiO_3$(111) as opposed to the conventional (001)-orientation. Here we explore the structural, magnetic, and electric properties of epitaxial $SrRuO_3$ films grown on $SrTiO_3$(111). $SrRuO_3$ films were grown by off-axis dc magnetron sputtering on treated $SrTiO_3$(111) substrates. Crystalline quality of the films was verified by X-ray diffractometry and atomic force microscopy showing epitaxial growth and sub-nanometer roughness. In Fig. 1, SQUID magnetometry measurements show a magnetization of 2 μ_B/Ru and ~1μ_B/Ru for 5nm and 35nm films respectively. The difference in magnetic moment suggest a different spin configuration in the 5nm films in comparison to the 35nm films. In the ultra-thin regime we expect the $SrRuO_3$ to be completely strained to the substrate whereas in 35nm the film has partially relaxed resulting in a lower net moment due to contributions from the unstrained system. Resistivity measurements indicate metallic behavior in films down to 5nm, smaller than previously reported. Hall measurements showed a nonlinear response not seen in $SrRuO_3$ grown on STO(001). Fig. 2 shows a nonlinearity that exists in thicknesses ranging from 5-15nm showing up near the coercive field. The effect is not seen in 35nm $SrRuO_3$ where the film has relaxed. We will explore the possible origin of the unusual behavior by a thickness dependence study of the structural, magnetic, and electric properties.

$LaCoO_3$ (LCO) has been extensively studied due to its thermally-assisted spin-state crossover, deriving from the small difference between crystal field and Hund's exchange energies. Bulk LCO is thus a diamagnetic insulator below ~30 K, above which the spin-state crossover is initiated. Relatively recently, ferromagnetic (FM) order in epitaxial LCO thin films [1], in stark contrast to the bulk, has gathered attention. While stabilization of a finite spin-state and FM interactions under tensile strain are known to play a role, no consensus has emerged as to the origin of the FM. Additionally, due to the insulating nature, little attention has been paid to transport. Here, we present a study of epitaxial LCO (8-22 nm thick) grown under both tensile (on $SrTiO_3$, LSAT) and compressive strain (on $LaAlO_3$, $SrLaAlO_4$), emphasizing magnetism and transport. Based on X-ray diffraction, atomic force microscopy, and scanning transmission electron microscopy (STEM), the films are phase-pure, smooth, epitaxial, and fully strained, from -1.5 to 2.5% mismatch. STEM reveals oxygen vacancy ordering, with orientation controlled by strain-state, similar to Sr-doped LCO [2,3]. Tensile films exhibit ferromagnetism with saturation magnetization 1-1.5 μ_B/Co and Curie temperature ~80 K, consistent with prior work (Fig. 1a). Polarized neutron reflectometry reveals relatively uniform magnetization depth profiles. Most notably, transport, which is semiconducting, reveals an unanticipated correlation between strain-state and majority carrier type (Fig. 1b & c). FM is found to be associated with inversion to *n*-type, supported by density functional theory calculations indicating significant changes in conduction band effective mass under strain. We have thus revealed an important additional clue to the origin of the controversial FM in this system. Work supported by DOE Center for Quantum Materials under DOE-SC0016371.

DH-08. La_2CoMnO_6 Ordered Double Perovskite Epitaxial Thin Films Grown by Polymer Assisted Deposition. H. Wang[1], J. Gazquez[1], C. Frontera[1], M. Chisholm[2], A. Pomar[1], N. Mestres[1] and *B. Martinez*[1]
1. Magnetic Materials and Complex Oxides, ICMAB-CSIC, Bellaterra, Spain; 2. Materials Science and Technology Division, Oak Ridge National Laboratory, Oak Ridge, Oak Ridge, TN, United States

Double perovskite La_2CoMnO_6 (LCMO) thin films are highly attractive due to their insulating ferromagnetic behavior and magnetodielectric effect near room temperature, making it a promising material for applications into new devices and spintronics.[1] However these properties are strongly dependent on the ordered arrangement of cations in the double perovskite $A_2BB'O_6$structure.[2] Therefore, many efforts have been made to improve the level of cationic ordering to obtain optimal properties while suppressing antisite defect formation. In this work, high quality epitaxial LCMO films were grown on (001) $SrTiO_3$ substrates by polymer assisted deposition (PAD).[3] This technique allows an easy control of stoichiometry by mixing different metal-polymer precursor solutions with the corresponding metal molar ratios. The precursor solutions were spin coated on (001)-STO substrates and the resultant coatings were thermally treated at 900 °C in flowing oxygen. We show that the particular crystallization and growth process conditions of PAD (very slow rate, close to thermodynamic equilibrium conditions) promote high crystallinity and quality of the films, as well as B-site cationic ordering. The LCMO films show saturation magnetization values of about 6 μ_B/f.u. and a Tc≈230K, thus indicating full cationic ordering of Co^{2+}/Mn^{4+} in a double perovskite structure Confirmation of the achievement of full Co/Mn

cationic ordering was found by scanning transmission electron microscopy (STEM) measurements; EELS maps indicated the ordered occupancy of B-B' sites by Co/Mn cations.

Argonne National Laboratory, Argonne, IL, United States*

One of the most intriguing outcomes of symmetry breaking and spin-obit interactions in magnetic systems is the possibility to create non-collinear and chiral spin textures. The Dzyaloshinskii-Moriya interaction (DMI) results from strong spin-orbit coupling and broken inversion symmetry to generate magnetization rotations with fixed chirality. The discovery of magnetic skyrmions originating from strong DMI in metal thin films has led to an explosion of efforts to manipulate magnetic phases originating from interfaces. I will describe our progress to understand interface-induced magnetism in epitaxial 3*d*/5*d* iridate/manganite superlattices. Our previous work on high-quality epitaxially stabilized $SrMnO_3/SrIrO_3$ superlattices revealed charge-transfer induced interfacial collinear ferromagnetism and an anomalous Hall effect [1,2]. In $LaMnO_3/SrIrO_3$ superlattices, we find a large additional topological Hall effect arising from the interaction of charge carriers with a noncoplanar chiral spin texture induced by interfacial DMI [3]. I will describe how the interfacial atomic layer stacking and symmetry enabled by the nonmagnetic A-sites determine the competition between collinear and chiral magnetic interactions originating from the oxide interface. These results will be compared with magnetometry measurements, soft and hard x-ray experiments, which provide a comparison of the bulk and interface electronic and magnetic properties. Our findings provide insight to the manipulation of chiral magnetism from atomic-scale control of DMI at oxide interfaces.

DH-10. Size evolution of magnetostructural transitions in spin and orbital-frustrated $NiCr_2O_4$: A possible magnetic multiferroic. *A. Rathi*[1], P. Babu[2], A. Awasthi[3], P. Rout[4], R. Pant[1] and G. Basheed[1] *1. AcSIR, CSIR-National Physical Laboratory (NPL) Campus, New Delhi, India; 2. UGC-DAE Consortium for Scientific Research, R-5 Shed, B. A. R. C., Mumbai, India; 3. UGC-DAE Consortium for Scientific Research, D. A. University Campus, Indore, India; 4. CSIR-National Physical Laboratory (NPL), New Delhi, India*

Frustrated magnetism has been at the forefront of modern condensed matter physics [1]; alongside its fundamental importance, spin frustration stabilize complex spin textures like in type-II multiferroics, generally antiferromagnets (AFM) [2] etc. Meanwhile, spinel ferrimagnet (FiM) chromite, ACr_2O_4 with Cr^{3+} ions on frustrated pyrochlore lattice have provided a great platform to study "spiral" multiferroicity with low-filed electric polarization reversal, as in cubic $CoCr_2O_4$ [3]. Here, we dare to undertake another spinel FiM chromite $NiCr_2O_4$ with Jahn-Teller (JT) active Ni^{2+} ions, which are expected to suppress the geometrical frustration via structural distortions. We study in detail the magneto-structural transitions in spin and orbital-frustrated $NiCr_2O_4$ from bulk to nanoscale by neutron diffraction (ND), magnetization, specific heat and magneto-dielectric measurements. The Jahn-Teller (JT) distortion temperature is reduced down to $T_{JT} \approx 268$ K on nanoscale (from its bulk value of 310 K) [4]; the nanoscale confinement further induces a significant enhancement in the magnetic collinearity, leading to (longitudinal) FiM ordering at higher Tc ≈ 100 K than in bulk $NiCr_2O_4$ at 70 K. Moreover, the ordering of frustrated (transverse) AFM interactions (at $T_S \approx 30$ K with frustration index, $f = |\theta_{CW}|/T_N \approx 18$ in bulk) is not observed on nanoscale down to 3 K; this suggests the possible co-existence of magnetic ordering and a spin-liquid state in nanochromite $NiCr_2O_4$. More importantly, another low-temperature transition is observed for bulk $NiCr_2O_4$ at $T_f \approx 8$ K in high magnetic fields in both magnetization and magneto-dielectric measurements, suggesting a field-induced type-II multiferroicity in $NiCr_2O_4$. The study concludes that structural transitions/distortions in $NiCr_2O_4$ are stabilized by magneto-elastic effects, spin and orbital frustration.

DH-11. Spin Reorientation, Metamagnetism and Spin-Phonon Coupling in Polycrystalline $EuFe_{0.5}Mn_{0.5}O_3$. *K. Chandran*[1], P. Lekshmi[1] and s. P N[1] *1. Physics, Indian Institute of technology Madras, Chennai, India*

Rare earth orthoferrites ($RFeO_3$) are receiving attention these days owing to their interesting applications in sensors, magneto-optic properties, multi-ferroics, spin switching, optical control of spins and domain wall physics, etc. $EuFeO_3$ exhibits similar properties like all other orthoferrites and have high octahedral rotations due to the smaller size of the Eu^{3+} ion. In many $RFeO_3$ the substitution of different magnetic at the Fe site is found to tune the magnetic transitions and change the nature of spin reorientation due to modified crystallographic and magnetic features. In the present work, 50% of Mn ion is substituted at the Fe site in order to create an equal distribution of Mn ions in the Fe matrix. Polycrystalline samples of $EuFe_{0.5}Mn_{0.5}O_3$ were synthesized by a sol-gel route. Rietveld refinement of Synchrotron XRD patterns taken at different temperatures down to 15 K were fitted with orthorhombic unit cell having *Pbnm* space group without any structural change in the measured temperature range. Thermomagnetic measurements indicate the presence of a magnetic transition around 280 K, due to the AFM ordering of Fe^{3+}/Mn^{3+} sublattice, followed by a sharp drop in the magnetization at 220 K, due to the spin reorientation (SR) of Fe/Mn spins. The presence of weak ferromagnetism is reflected by the increase in bulk magnetization below the transition and a minor hysteresis loop observed in M(H) isotherms. The modified magnetic interactions coupled with the co-existence of multiple magnetic ions (Er/Fe/Mn) further establish metamagnetic transition and Griffith like features in $EuFe_{0.5}Mn_{0.5}O_3$. Additionally, in order to investigate the phonon behavior across the magnetic transitions, Raman spectrum was taken at several temperatures ranging from 170 K to 300 K. Spin phonon coupling is observed at both antiferromagnetic transition and SR transition. The presence of high T_N, sharp spin reorientation transition, Griffith like behavior, metamagnetic transitions and spin-phonon coupling makes this material suitable candidate for practical applications.

DI-01. Emergent Phenomena in the Shastry-Sutherland Model System as Function of Magnetic Field, Pressure and Chemical Doping.
S. Haravifard[1] *1. Physics, Duke University, Durham, NC, United States*

The physics of Mott insulators holds the key that might unlock some of the most pressing problems in condensed matter physics, such as the long-sought Resonating Valence Bond (RVB) superconductivity [1]. A particularly important proposal involves the doping-induced superconductivity in spin-1/2 orthogonal dimers on a square lattice, the so-called Shastry-Sutherland (SS) model as realized physically in the Mott insulator SrCu2(BO3)2 (SCBO) [2,3]. Furthermore, SCBO has been studied vigorously for its extremely rich phase diagram and exotic properties at high magnetic fields [4], while recently it has been attracting additional attention as a bosonic topological insulator candidate which is suggested to host chiral edge modes of triplon bound states at low magnetic field regime, and for the proposals of novel states emerging as function of pressure. [5] Therefore, it is of great interest to shed light on the roles magnetic field, pressure, and chemical doping play in tuning the underlying interactions in SCBO. Additionally, understanding the interplay between pressure, chemical doping, and magnetic field in SCBO (at both high and low fields regimes) provides critical information and reveals a fresh prospective, illuminating the path to advancing our knowledge of topological phenomena and emergent quantum states in SCBO and similar systems of interest. In this talk, I present a comprehensive study of the field- [6], pressure- [7] and chemical doping-induced [8] novel emergent states in SCBO. We use multiple complementary measurement techniques to probe static and dynamic magnetic structure, magnetization, and magnetic susceptibility at fields up to 65 T, pressures up to 5 GPa, and cryogenic temperatures, conducted for several doping concentrations. Our numerical simulations performed using DMRG and iPEPS techniques complement these results, providing firsthand description of the intriguing experimental observations.

DI-02. Ferromagnetic order in a cuprate superconductor.
R.l. Greene[1], T. Sarkar[1], N.R. Poniatowski[1] and P. Mandal[1] *1. Physics, University of Maryland, College Park, MD, United States*

Conventional wisdom dictates that the mysterious and extraordinary properties of the cuprates arise from doping an antiferromagnetic (AFM) Mott Insulator. Such a picture can account for the increase of the superconducting (SC) transition temperature (Tc) with increasing doping as a consequence of the competition between the AFM and SC orders, but not for the decrease of Tc beyond optimal doping. In fact, there is no satisfactory theoretical explanation for this decline of Tc. In this work, we report the emergence of a ferromagnetic (FM) phase beyond the superconducting dome in the electron-doped cuprate $La_{2-x}Ce_xCuO_4$ (LCCO) as evidenced by resistivity, magneto- thermopower and magnetization experiments. This unexpected discovery suggests that a quantum phase transition occurs at the end of the SC dome and that a competition between superconductivity and FM could provide an explanation for the decrease in Tc in the overdoped cuprates. Our findings show that the physics of the overdoped cuprates is much richer than previously thought, and pose a challenge to most proposed models of the cuprates.

DI-03. Vortex state study of superconducting Fe(Te, Se) thin films deposited on $SrTiO_3$ substrate by pulsed laser deposition technique.
R. Kumar[1], D. Mitra[1] and G.D. Varma[1] *1. Physics, I.I.T. Roorkee, Roorkee, India*

Superconducting thin films of two thicknesses have been fabricated on (*100*) oriented $SrTiO_3$ (STO) substrates using the target of composition $Fe_{1.05}Te_{0.50}Se_{0.50}$ by pulsed laser deposition technique. The structural and transport properties of the fabricated thin films have been investigated and the results indicate the enhancement in the superconducting properties with increasing thickness of the thin films. The onset of the superconducting transition temperature of the grown thin films of thicknesses ~82 nm and ~179 nm are ~12.10 and 12.62 K at 0 T magnetic field, respectively. To estimate the upper critical fields $H_{C2}(0)$, thermally activated energy (TAE) and vortex phase diagram, the magnetoresistance measurements have been performed in the magnetic field range of 0 - 8 T. $H_{C2}(0)$ has been calculated by Ginzburg Landau (GL) theory as well as by Werthamer-Helfand-Hohenberg (WHH) model by taking the criterion of 90%, 50% and 10% of normal state resistivity and the corresponding GL coherence lengths have also been calculated. In the present work, the TAE has been estimated by conventional Arrhenius relation and modified thermally activated flux flow (TAFF) theory [Fig. 1]. The power law dependence of TAE, shows prominently the possible planer defects in the system. From the modified TAFF model, the values of fitting parameter 'q' suggests the 3 dimensional behaviour of the vortices for both the grown thin films. The detail correlations among the structural and superconducting properties of both the thin films have been discussed in this paper.

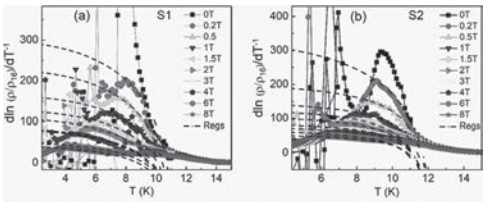

Figure 1: $d\ln(\rho/\rho_{16})/dT^{-1}$ versus T (K) plots at different magnetic fields for the calculation of TAE using modified TAFF model for both the thin films.

DI-04. Magnetic Screening Effects in Superconductor/Ferromagnet Heterostructures. *P. Quarterman*[1], N. Satchell[2], B.J. Kirby[1], R. Loloee[2], N. Birge[2] and J. Borchers[1] *1. NIST, Gaithersburg, MD, United States; 2. Michigan State University, East Lansing, MI, United States*

Ferromagnetic Josephson junctions are a viable candidate for low power cryogenic memory alternative compared to traditional CMOS technologies. Magnetic screening properties of superconductors in proximity to ferromagnetic materials are of interest due to recent predictions of a long-range magnetic field in the superconductor induced by proximity effect [1]. These additional screening currents may account for several experimental observations, most notably in Co/Nb/Cu stacks where an anomalous Meissner effect has been reported [2]. Prior to this work, we characterized analogous Nb films with polarized neutron reflectivity (PNR), modelled the Meissner effect, and extracted the London penetration depth which matches the known value. In this work, we report on our progress characterizing samples which are expected to exhibit the predicted 'electromagnetic proximity effect.' Specifically, we have carried out PNR measurements on Ni(2.8)/Nb(200) bilayers and Ni(2.8)/AlO_x(3)/Nb(200) samples to probe screening-effect distortions in Nb when in proximity of a ferromagnet. Figure 1 shows the spin asymmetry, as determined from the polarized neutron reflectometry for both samples at 3 K, and the sample with an oxide interlayer at 12 K. In the Ni/AlO_x/Nb sample, the spin asymmetry is understood by modeling the Meissner effect in conjunction with the ferromagnetic Ni layer at 3 K, and just the ferromagnetic component at 12 K. When the Ni and Nb are in direct contact, PNR shows that the Meissner effect is suppressed, and the data cannot be described by the same Meissner and ferromagnetic model. The data analysis we discuss in this work highlights the sensitivity of the spin asymmetry to anomalous suppression of field screening in Ni/Nb heterostructures.

DI-05. Spin Hall Current Dependence of Superconducting Transition Temperature in Superconductor/Spin-Valve Nanowires. *A. Jara*[1], I. Krivorotov[1], E. Moen[2] and O. Valls[2] *1. Physics and Astronomy, University of California - Irvine, Irvine, CA, United States; 2. School of Physics and Astronomy, University of Minnesota, Minneapolis, MN, United States*

Superconductor/ferromagnetic (S/F) heterostructures have been a focus of intensive research over the past two decades. Apart from their importance for the understanding of fundamental physics of the superconducting proximity effect, S/F nanostructures may find applications in low-power cryogenic computing [1]. Competition between superconducting and ferromagnetic ordering in S/F heterostructures can lead to unusual types of magneto-transport effects emerging from the proximity effect at the S/F interfaces such as odd-triplet superconductivity and spin-polarized supercurrents. A prominent example of an S/F proximity effect is the spin switch effect (SSE) observed in S/F/F superconducting spin valve multilayers, in which the superconducting transition temperature T_c is controlled by the angle Φ between the magnetic moments of the F layers [2]. Here we present an experimental study of SSE in Nb/Co/Cu/Co/CoO nanowires measured as a function of bias current flowing in the plane of the layers. In this structure, the magnetization of the top Co layer is pinned by a strong exchange bias from the antiferromagnetic CoO layer, while the magnetization of the bottom (free) Co layer can be easily rotated in the plane of the sample by a relatively small magnetic field. These measurements reveal an unexpected dependence of $T_c(\Phi)$ on the bias current: $T_c(\pi) - T_c(0)$ changes sign with increasing current bias (Fig. 1). We attribute the origin of this bias dependence of the SSE to a spin Hall current, induced by the bias current and perpendicular to the plane of the multilayer, which suppresses the critical temperature of the multilayer. We rule out other possible explanations on either qualitative or quantitative grounds. The bias dependence of SSE can be important for hybrid F/S devices such as those used in cryogenic memory for superconducting computers as device dimensions are scaled down to the nanometer length scale. We will present detailed measurements of the magnitude of this effect as a function of bias current and the thickness of the free magnetic layer.

DI-06. Unprecedented Electronic Structure, Magnetic Anisotropy and Orbital Moment in Rare Earth (RE) - Cobalt Systems. *D. Paudyal*[1], R. Choudhary[1] and R. Skomski[2] *1. Ames Laboratory, Ames, IA, United States; 2. University of Nebraska, Lincoln, NE, United States*

We have used theory and computation to investigate the magnetic properties of Fe substituted RE-Co systems. Many features of these systems are consistent with past research. Figure 1 examplifies the theoretically calculated magnetocrystalline anisotropies and formation energies of SmCo5-xFex as a function of Fe content. Some of the electronic structure findings are seemingly contradictory to past research. The disagreement is not caused by numerical errors or accidental mistakes but reflects how the many-electron nature of the rare-earth 4f electrons is interpreted by crystal-field and local spin density approximation with Hubbard model and spin orbit coupling (LSDA+U+SOC) theories. The two-sublattice crystal-field theory is known to describe a broad variety of RE-Co properties, such as the temperature dependence of magnetization and anisotropy, but it is not a first-principle approach. By contrast, our first-principle approach, LSDA+U, yields a substantial orbital-moment quenching, which violates Hund's rules and is contradictory to conventional knowledge accumulated over several decades of rare-earth research. Rationalizing the orbital-moment quenching in terms of the dependence of the charge distribution (Fig. 2) on the magnetization angle, we argue that medium- and long-run future research will be necessary to reconcile experiment, sublattice models, and first-principle calculations for RE-Co materials. This work is supported by the Critical Materials Institute, an Energy Innovation Hub funded by the U.S. Department of Energy, Office of Energy Efficiency and Renewable Energy, Advanced Manufacturing Office. The work in Nebraska was supported by the US Department of Energy (Grant No. DE-FG02-04ER46152) and performed in part in the Nebraska Nanoscale Facility and the Nebraska Center for Materials and Nanoscience which are supported by NSF NNCI #1542182, and the Nebraska Research Initiative.

3:06

DI-07. Exchange interaction and Curie temperature in R_2Co_2Al. *X. Liu*[1], Z. Altounian[2] and C.I. Nlebedim[1] *1. Ames Lab, Ames, IA, United States; 2. Physics, McGill University, Montreal, QC, Canada*

We present the magnetization, exchange interaction and Curie temperature of R_2Co_2Al (R=Nd, Sm, Gd, Tb, Dy, Ho, Er, Tm) and also the effects of Fe-substitution for Co. R_2Co_2Al with R = Nd, Sm, Gd, Tb, Dy, Ho, Er, and Tm crystallizes in the W_2CoB_2-type orthorhombic structure[1]. These compounds display complex magnetoresistance and magneto-caloric effects around the magnetic transition temperature,[2–4] which is intimately related to their magnetic exchange interaction. Our study is based on a first principles DFT calculation and a linear response method with the Heisenberg model. The crystallographic parameters are fully relaxed with the PAW (projector augmented wave) method, implemented in the QuantumEspresso package. The optimized crystal parameters are in good agreement with the experimental values[1]. The calculated magnetic moments are mainly contributed by the R-atom's 4*f* electrons. The Co atoms display a small induced magnetic moment of about 0.2-0.3 μ_B, and are antiferromagnetically coupled with the spin magnetic moment of the R-atoms, in agreement with neutron diffraction results[4]. The exchange interaction parameters were derived from the calculated band structures using a linear response method. We found that the values of the nearest R-R inter-site exchange coupling constants are comparable to those of R-Co and Co-Co pairs. These results imply that the small magnetic moments, induced at the Co sites, are important for stabilizing the magnetic structure in R_2Co_2Al compounds. Based on the Heisenberg model, the estimated trends in the mean field Curie temperatures are in good agreement with the experimental results (Fig. 1). Further, the calculations for $Gd_2(Co,Fe)_2Al$ with the W_2CoB_2-type structure indicate that Fe has a magnetic moment of 1.2 μ_B, which enhances the R-Co(Fe) inter-site exchange interaction, confirming the important role of the magnetic moment of Co(Fe) in this system. The calculated mean field Curie temperatures are 113 K and 366 K for Gd_2Co_2Al and virtual Gd_2Fe_2Al compounds, respectively.

DI-08. Spin Current: a Probe for Quantum Materials. *W. Han*[1]
1. Peking University, Beijing, China

Spin current generally means the electron-mediated current with spin polarization after the discovery of giant and tunneling magnetoresistances in 1980s. Recently, new types of spin current in quantum materials have been found, which are mediated by magnons, superconducting (SC) quasiparticles, spinons etc. These quantum materials have exhibited fascinating spin-dependent properties, which are attractive for future spintronics applications [1]. In this talk, I will discuss some primary experimental results to illustrate how spin current could be a powerful probe for new quantum materials. I will discuss the SC quasiparticle-mediated spin current as a probe for spin dynamics of an s-wave superconducting film [2], which might be useful to probe the spin dynamics for unconventional superconducting thin films. I will also discuss the spin superfluid-mediated spin current for the probe of novel quantum phase of spin superfluidity/superconductor ground states. The spin current in canted antiferromagnet Cr_2O_3 is investigated, which provides important experimental signatures of the spin superfluid ground states [3]. At the end, I will present the current status and the outlook of this exciting direction of using spin current as a probe for quantum materials [4].

DI-09. Lattice and magnetic excitations in CrAs: A Raman spectroscopy study. *K. Sen*[1], Y. Yao[1], R. Heid[1], A. Omoumi[1], F. Hardy[1], K. Willa[1], M. Merz[1], A. Haghighirad[1] and M. Le Tacon[1] *1. Institute for Solid State Physics, Karlsruhe Institute of Technology, Eggenstein-Leopoldshafen, Germany*

Following the discovery of high-temperature superconductivity in Fe-based compounds, several transition-metal pnictides have been investigated [1–4]. CrAs is a representative of this family of compounds, which undergoes a first-order transition from a high-temperature paramagnetic state to a low-temperature non-collinear double-helical magnetic state below T_N= 265 K [5]. Concomitantly, it exhibits a giant structural anomaly which involves the abrupt expansions of the crystallographic b-axis by 4 % and the unit cell volume by 2.2 % below T_N [6]. This helical magnetic ground state gets suppressed upon chemical doping or hydrostatic pressure. In the latter case, bulk superconductivity with a maximum T_c of 2 K has been reported [7], making this system the first Cr-based superconductor to date. Moreover, recently observed quantum critical behavior in CrAs suggests that this is an unconventional superconductor [8]. Despite the evident interplay between the lattice and magnetic degrees of freedom in CrAs, only a few studies of the spin and lattice dynamics of this system have been reported to date. We have addressed this issue using polarized Raman scattering. Large renormalizations of the phonon energies and linewidths are observed across T_N, which along with the results of first-principle calculations suggest the presence of a sizeable spin-phonon coupling in this compound. Furthermore, we observe two broad modes around 350 and 1700 cm^{-1} in the magnetic phase, which we associate with two-magnon Raman scattering, providing one of the few examples of magnetic Raman scattering from a non-collinear magnet.

DI-10. Origin of Itinerant Carriers in an Antiferromagnetic $LaFe_{1-x}Mo_xO_3$ Studied by X-ray Spectroscopies. *D. Phuyal*[1], S. Mukherjee[1], S. Jana[1,2], C.U. Segre[3], L. Simonelli[4], S.M. Butorin[1], H. Rensmo[1] and O. Karis[1] *1. Department of Physics and Astronomy, Uppsala University, Uppsala, Sweden; 2. Methods and Instrumentation for Synchrotron Radiation, Helmholtz-Zentrum Berlin, Berlin, Germany; 3. CSRRI & Department of Physics, Illinois Institute of Technology, Chicago, IL, United States; 4. BL22 CLÆSS, CELLS-ALBA Synchrotron, Barcelona, Spain*

We report on the electronic structure of a Mo-doped $LaFeO_3$ at the crossover from insulating to metallic phase transition. Comprehensive x-ray spectroscopic methodologies are used to understand core and valence electronic structure as well as crystal structure distortions associated with the electronic transition. Despite the antiferromagnetic (AFM) ordering at room temperature[1], we show direct evidence of itinerant carriers at the Fermi level revealed by resonant photoemission spectroscopy (RPES) at the Mo L_3 edge. RPES data taken at the Fe L_3 edge show spectral weight near the valence band edge and significant hybridization with O 2*p* states necessary to account for AFM ordering. Resonant inelastic x-ray scattering (RIXS) spectra taken across Fe $L_{2,3}$ edges show electron correlation effects (U) driven by Coulomb interactions of *d* electrons as well as broad charge-transfer excitations for $x \geq 0.2$ where the compound crossovers to a metallic state. Site substitution of Fe by Mo ions in the Fe-O_6 octahedra enhances the separation of the two Fe-O bonds and Fe-O-Fe bonding angles relative to the orthorhombic $LaFeO_3$, but no considerable distortions are present to the overall structure. Mo ions appear to be homogeneously doped, with average valency of both metal sites monotonically decreasing with increasing Mo concentration. This insulator-to-metal phase transition with AFM stability is primarily understood through interaction strengths between correlation (U) and bandwidth (W). These results highlight the important role of extrinsic carriers in stabilizing a unique phase transition that can guide future efforts in antiferromagnetic-metal spintronics.

DI-11. Fine Tuning of Canted Magnetization in Stepped Fe Films Through Thickness Variation, Au Capping and Quantum Confinement. M. Dabrowski[1], M. Cinal[2] and *M. Przybylski*[3] *1. Department of Physics and Astronomy, University of Exeter, Exeter, United Kingdom; 2. Institute of Physical Chemistry of the Polish Academy of Sciences, Warszawa, Poland; 3. Academic Centre for Materials and Nanotechnology, AGH University of Science and Technology, Kraków, Poland*

Our results demonstrate that well defined canted magnetization can be achieved without application of an external field. By taking advantage of broken symmetry of a vicinal substrate, we show that magnetic anisotropy of Fe films grown on the Ag-stepped surface results in the canted magnetization with its azimuthal orientation locked within the plane perpendicular to the step edges. The value of the tilting angle can be precisely tuned by changing the thickness of Fe film and Au overlayer. This is possible thanks to continuous rotation of magnetization from out-of-plane to in-plane direction with increasing thickness of Fe and the fact that the direction of magnetization rotation can be reversed by covering Fe films with Au layers. At low temperatures, QWS formed within Fe films come into play and contribute to the magnetocrystalline anisotropy, resulting in periodic modulations of the tilting angle, which substantially affects the magnetization rotation associated with the SRT. The analysis of the proposed theoretical model reveals that the ferromagnetic system grown on vicinal surface can only be fully described if two additional, step-induced, anisotropy constants are included in the magnetic anisotropy energy of the film. The model reproduces the experimental findings and predicts that the tilting of magnetization results from the superposition of the three uniaxial magnetic anisotropies acting within the vertical plane perpendicular to the step edges. The step-induced anisotropy term with the easy axis oriented at 45^o or –45^o to the terrace plane affects the tilting angle significantly. The presence of this term is crucial for explaining the reversed rotation of magnetization upon covering the stepped Fe films by Au. The presented methods allow for fine engineering of canted magnetization state and can be beneficial for control of the magnetization direction via voltage or optical pulses since tilted magnetization provides an additional torque and reduces the external energy required to switch the magnetization.

DP-01. Controlling the Magnetic Properties of $MoSe_2$ Monolayer by Mn and Cr Substitutional Doping and Vacancy Clustering: A First-Principles Study. *M.B. Kanoun*[1] and S. Goumri-Said[1] *1. Physics, Alfaisal University, Riyadh, Saudi Arabia*

The search for spintronic materials remains a continuous priority [1,2] due to promising new functionalities for future information technologies. The recent discovery of two-dimensional (2D) materials [4] provides a way to overcome these difficulties and new research area for materials science and technology. These 2D materials have revealed large potential for the new generation low-dimensional transistors, photo-emitting devices and spintronics devices due to their distinct crystal structures and electronic properties [3,4]. Here, we report the effect of Mn and Cr doping on electronic and magnetic properties of $MoSe_2$ monolayer using first principles calculations based on density functional theory within generalized gradient approximation [5], as implemented in the Vienna Ab initio Simulation (VASP) code [6]. The interactions between electrons and ions were described by the projector-augmented wave (PAW) method [7]. The layered structures of $MoSe_2$ have a sandwich structure which is composed of three atomic layers with one Mo layer between two Se, as shown in Fig. 1. A 4 × 4 × 1 $MoSe_2$ monolayer supercell structures containing 32 Se and 16 Mo atoms is built. To explain the role of the Mn -doping on the electronic structure, we calculated the density of states (DOSs) as shown in Figures 2 (a and b). The DOSs showed that the substitution of Mn at Mo site can induce spin polarized state and introduces highly localized orbitals within the energy band gap region of the un-doped compounds. Indeed, the polarized charges mainly rise from the localized Mn 3d states with weak contribution of the delocalized 4d states of the Mo atom and p states of Se atom (Fig. 2b). For Cr doping, it is known that the Cr atom is isoelectronic to Mo which shows an identical behavior of valence band and conduction band maximum between doped system and pristine monolayer. Then, we aim to study and control the magnetic properties of $MoSe_2$ monolayer by including single or double Se vacancies cluster near Cr/Mn atoms to enhance magnetism in doped system.

DP-02. Magnetotransport properties of Ni-nanoparticle-decorated graphene. E. Argüello[1], P. Ducos[1], Z. Gao[2], A.T. Johnson[2] and *D. Niebieskikwiat[1] 1. Departamento de Física, Universidad San Francisco de Quito, Quito, Ecuador; 2. Department of Physics and Astronomy, University of Pennsylvania, Philadelphia, PA, United States*

In this work, we characterize the effect of Ni magnetic nanoparticles on the magnetotransport properties of chemical vapor deposition (CVD) graphene. The magnetoresistance of a Ni-nanoparticle-decorated Graphene Resistor (Ni-GR, nanoparticles diameter ~ 7 nm) is measured while sweeping the magnetic field at different temperatures and compared with measurements done on the unmodified Graphene Resistor (GR), with no nanoparticles, as a control sample. Our results show that, in the presence of Ni nanoparticles, the commonly observed zero-field peak of the resistivity is widely suppressed, while the high field magnetoresistance shows a fourfold enhancement as compared to the GR sample. These results are discussed in terms of electron-electron-interaction corrections to the Drude conductivity, as well as weak localization effects arising from quantum interference phenomena at low magnetic fields. On one hand, the magnetic interaction of graphene with the Ni nanoparticles frustrates quantum interference, suppressing weak localization. On the other hand, a possible charge transfer between Ni and graphene may reduce the carrier density, increasing the carrier's mean free time and affecting both, weak localization and electron-electron interaction contributions to the conductivity of graphene.

DP-03. Topological spin-Hall effect in 2D Cr-halogenated materials. *Y. Dahnovsky*[1] and A. Zadorozhniy[1] *1. Physics and Astronomy, University of Wyoming, Laramie, WY, United States*

We study the THE in various systems on 2D magnetic materials. The focus will be on the spin textures in the atomic thin 2D materials (CrI<s_3, $CrCl_3$, and $CrBr_3$). The system consists of two layers: one is a CrI_3 layer while the other is $CrCl_3$. We have selected such a system such a system because it provides an interesting spin texture: a CrI_3 layer is a ferromagnet with an out-of-plane magnetic moment while a $CrCl_3$ layer is also a ferromagnet with an in-plane magnetization. The calculations of a topological Hall current will help us to understand how a spin texture affects the transport and magnetic properties of the system. From the estimations a skyrmion size is about 30-40 nm. The computations of a spin Hall effect and magnetoresistance require the calculations of the nonequilibrium distribution function, which we will determine from the kinetic Boltzmann equation. The distribution function describes by a 4 × 4 matrix because of different spin projections and the spin-dependent momenta of conducting electrons. However, if we consider two layers, there are two types of electrons: (1) the electrons are from CrI_3 layer and (2) the electrons are from $CrCl_3$ layer. Thus, the matrix

becomes 8 × 8. The matrix elements contain various parameters such as effective masses, exchange constants, etc., that will be found from the first principle calculations. The reason why such system exhibit topological Hall effect is because the scattering transition probability matrix has an antisymmetric part with respect to the scattering angle. The scattering asymmetry acts as an effective magnetic field, which sign can be either the same for both spin projections of an incident electron, hence leading to a *topological charge Hall effect*, or opposite for different electron spin projections, *leading to the topological spin Hall effect*.

DP-04. Demonstration of low Schottky barrier height in monolayer MoS_2 field effect transistor with ferromagnetic metal contacts. *S. Gupta*[1], F. Rortais[1], R. Ohshima[1], Y. Ando[1], T. Endo[2], Y. Miyata[2] and M. Shiraishi[1] *1. Kyoto University, Japan, Kyoto, Japan; 2. Tokyo Metropolitan University, Tokyo, Japan*

Molybdenum disulfide (MoS_2) is a semiconductor with a sizable band gap, which makes it promising for semiconducting electronics.1 A high on/off ratio (~10^8) and high carrier mobility at room temperature have been demonstrated in MoS_2-based field effect transistor (FET).[2] However, the large electrical potential drop due to high Schottky barrier at the metal/ semiconductor-MoS_2 junction may strongly limit the performance of MoS_2-based devices, which remains an open challenge for the integration of MoS_2 in future technology. We report electronic properties of monolayer MoS_2 based FET devices using permalloy (Py) as ferromagnetic (FM) metal contact. Monolayer MoS_2 channels were directly grown on SiO_2/Si substrate via chemical vapor deposition technique. To determine the Schottky barrier height (SBH), two-probe source-drain current-voltage (I_{DS}-V_{DS}) curve measurements (Fig. 1) were carried out as a function of temperature and gate voltage (V_g). Figure 2(a) shows that I_{DS}-V_{DS} curves are almost linear at 300 K. As temperature decreases to 10 K, I_{DS}-V_{DS} curves show strong deviation from linearity and significant reduction in I_{DS} (Fig. 2b). This suggests that the device goes in the off state at low temperatures. The increase in I_{DS} with V_g shows the tunability of FET characteristics (Fig. 2). SBH was estimated using an activation energy method by employing the 2D thermionic emission equation.3 SBH for Py/MoS_2 contacts was found to be +28.4 meV for V_g = 0 V, which is the smallest value reported so-far for any direct metal / monolayer MoS_2 contact. With the application of gate voltage (+10 V), SBH reduces to a negative value of -6.8 meV, revealing ohmic behavior of Py/MoS_2 contacts. Low SBH with the control of the ohmic nature of FM contacts is a primary requirement for MoS_2 based spintronics and therefore using directly grown MoS_2 channels in the present study can pave a path towards high performance devices for large scale applications.

DP-05. Electrical detection of current generated spin in topological insulator surface states: Role of interface resistance. *C.H. Li*[1], O. Van't Erve[1], C. Yan[2], L. Li[2] and B. Jonker[1] *1. Naval Research Lab, Washington, DC, United States; 2. Physics and Astronomy, West Virginia University, Morgantown, WV, United States*

Current generated spin polarization in topological insulator (TI, e.g., Bi2Se3) surface states due to spin-momentum locking has been detected recently using FM/tunnel barrier contacts, where the projection of the TI spin onto the magnetization of the FM is measured as a voltage [1]. However, opposing signs of the spin voltage have been reported [e.g., 1-4], which had been tentatively attributed to the coexistence of trivial 2DEG states on the TI surface which may exhibit opposite current-induced polarization [4,5]. Models based on electrochemical potential have been developed to derive the sign of the spin voltage expected for the TI surface states [3]. However, these models only consider the spin-dependent electrochemical potential for the spin-up and spin-down electrons in the TI channel, and do not take into account key experimental parameters such as the interface resistance. Specifically, in most studies, a blanket layer of tunnel barrier material such as Al_2O_3that is often deposited on the TI as the first step (for capping and/ or to simplify fabrication). It is therefore also present at the interfaces of the current injecting contacts, which can be nonlinear and/or asymmetric [6,7]. Here we present a Mott two-spin current resistor model which takes into account these parameters, and show that such inclusions can lead to a crossing of the voltage potential profiles for the spin-up and spin-down electrons within the channel (Fig. 1), which can lead to measured spin voltages of either sign [6,7]. These findings offer a resolution of the ongoing controversy regarding opposite signs of spin signal reported in the literature, and further highlight the intricate nature of the seemingly straightforward electrical measurement of current generated spin in TI surface states, where experimental parameters such as spin dependent resistances in both the channel and at current injecting interfaces must be considered to accurately account for the sign of spin voltage measured.

DP-06. Giant Spin-Orbit Torque in Sputtered Perpendicular Bi_2Te_3/FM Films. *H. Yang*[1] and X. Qiu[1] *1. School of Physics Science and Engineering, Tongji University, Shanghai, China*

The large charge-to-spin conversion efficiency of topological insulator (TI) has attracted great attention for ultra-low power consumption magnetic storage and logic applications [1, 2]. It has been demonstrated that the TI such as Bi_2Se_3 can be used to switch the magnetization of ferromagnetic Co-Tb alloy with perpendicular anisotropy at low current densities [3]. Recently, extremely efficient spin-orbit torque in sputtered Bi_xSe_{1-x} has been reported. However, the presence of intercalated Ta may decrease the device efficiency and complicates the transmission of spin current [4]. Direct exertion of spin-orbit torque from TI to a directly contacted ferromagnet with perpendicular anisotropy is still much awaited to explore. In this work, we study the spin-orbit torque in a perpendicular magnetized Ta/Cu/[CoNi]/Bi_2Te_3/TaO_x by magnetron sputtering shown in Fig. 1. By characterizing spin-orbit torque by second harmonic measurements, a giant spin-orbit toque is found at low temperature and the spin Hall angle increases with decreasing the temperature shown in Fig. 2a and b. More remarkably, we found the current density required for the magnetization switching is extremely low,~1.3×10^6 Acm^{-2} at 5 K, which is one order of magnitude smaller than Ta. In addition, comparing to Ta sputtered Bi_2Te_3 show much lower power consumption as shown in Fig. 2d. The giant spin-orbit torque found in Ta/Cu/[CoNi]/Bi_2Te_3/TaO_x at low temperature can be ascribed to the strengthened topological surface state. The giant spin-orbit torque, efficient perpendicular magnetization switching and the ultra-low power consumption with sputtered Bi_2Te_3 show great prospects for topological spintronics applications.

DP-07. Helicity-dependent photo-induced magnetoresistance in topological insulator/semiconductor heterostructures. *T. Guillet*[1], C. Zucchetti[2], A. Marchionni[2], F. Bottegoni[2], A. Marty[1] and M. Jamet[1] *1. Univ. Grenoble Alpes, CEA, CNRS, Grenoble INP, IRIG-Spintec, Grenoble, France; 2. LNESS-Dipartimento di Fisica, Politecnico di Milano, Milan, Italy*

We report the observation of a new kind of magnetoresistance effect, which is the result of the interplay between two spin accumulations at the topological insulator/semiconductor interface. For this purpose, we grow single crystalline Bi_2Se_3 thin films on Ge (111) by molecular beam epitaxy and make microdevices shown in Fig. 1a and 1b where pure spin currents with in-plane spin polarization are generated by optical spin orientation in Ge. The scattering of circularly polarized light on the right (left) edge of a Pt stripe creates a pure spin current in germanium with in-plane orientation pointing to the right (left) respectively [1,2]. The spin accumulation generated in Ge by the laser spot diffuses to the spin detector (Bi_2Se_3 here). The distance between the Pt bars and the spin detector can be as large as 10 μm thanks to the long spin diffusion length of low-doped Ge. When passing a DC current in the Bi_2Se_3 spin detector, a second spin accumulation is induced by the Edelstein effect at the Bi_2Se_3/Ge interface. Experimentally the light circular polarization is modulated ω=50 kHz and we apply DC current in the detector. We observe an helicity-dependent photovoltage (HDP) at ω, which changes sign when the current direction or the spin orientation in Ge are reversed. The HDP scales linearly with the DC current, laser power and degree of circular polarisation [3]. We interpret these results by analogy with the uniaxial spin Hall magnetoresistance (USMR) in heavy metal/ferromagnet bilayer, where the ferromagnet is replaced by an out-of-equilibrium spin accumulation. This type of experiments enables to explore new physics and test our best understanding of spin-dependent phenomena.

While classical spintronics has traditionally relied on ferromagnetic metals as spin generators and spin detectors, spin-orbitronics exploits the interplay between charge and spin currents enabled by the spin-orbit coupling (SOC) in non-magnetic systems. An efficient spin-charge interconversion can be obtained through Spin Hall Effect and Inverse Spin Hall Effect in heavy metals such as Pt or Ta. Yet a more efficient conversion can be obtained by exploiting the direct and inverse Edelstein effects at interfaces where broken inversion symmetry induces a Rashba SOC. Although the simple Rashba picture of split parabolic bands is usually used to interpret such experiments, it fails to explain the largest conversion effects and their relation to the actual band-structure. Here, we demonstrate a giant spin-to-charge conversion effect by means of Spin Pumping FMR in an interface-engineered high-carrier-density SrTiO3 two-dimensional electron gas. We use angle-resolved photoemission and Boltzmann calculations to map its peculiar gate dependence. We show that the conversion process is amplified by enhanced Rashba-like splitting due to orbital mixing, and in the vicinity of avoided band crossings with topologically non-trivial order. Our results indicate that oxide 2DEGs are strong candidates for spin-based information readout in novel memory and transistor designs. In parallel, they confirm the promise of topology as a new ingredient to expand the scope of complex oxides for spintronics.

DP-09. Higher-Order Topological Insulator Taking into Consideration Uniaxially Anisotropic Hopping. *S. Komori*[1] and K. Kondo[1] *1. Research Institute for Electronic Science, Hokkaido University, Sapporo, Japan*

Topological materials have attracted enormous attention in the field of condensed matter physics from about a decade ago. Recently, it is found that there exist new types of topological insulators (TIs) having topologically protected gapless hinge states. They are called "higher-order topological insulators (HOTIs)". Then, HOTIs have been investigated intensively by theoretical and experimental researchers. Generally, the systems with gapless boundaries of codimension n are called "nth-order TIs". Conventional TIs are classified as 1st-order TIs in this sense. Schindler *et al*. constructed the model of 2nd-order chiral TIs based on Wilson-Dirac type 1st-order TIs. It is known that the model is distinguished by Z_2 topological invariant termed mirror Chern number (C_m). However, in the case of anisotropic systems, both the electron structure and the topological phase have not yet been investigated to our knowledge. In this study, we are going to investigate the model with uniaxially anisotropic hopping strength in the z-direction. Fig. 1 shows the electron density of the anisotropic model. We can confirm most electrons exist at the hinges. The Wilson loop method is utilized for calculating the mirror Chern number C_m of our model. Fig. 2 shows the trajectory of the Wilson loop. The trajectory wraps once around the cylinder, which corresponds to $C_m = 1$ and means that the gapless hinge states exist. Using the above C_m, we have obtained the topological phase diagram of the model with changing the hopping strengths. It is found that the phase diagram suggests that the Z_2 invariant of 2nd-order TIs reflects the Z_2 index of 1st-order strong TIs. This result is expected to serve as a criterion to realize a new kind of HOTI. At the conference, we are going to talk about the differences from the isotropic model. Moreover, we are going to compare the topological phase diagram of 1st-order TIs with that of 2nd-order TIs and discuss the features of their phases in detail.

DP-10. Strong Spin-textures Anisotropy of Ultra-Thin 3*d* Transition Metals Induced by Topological Surface States. *S. Laref*[1] and A. Manchon[1] *1. Physical Science and Engineering Division, King Abdullah University of Science and Technology (KAUST), Thuwal, Saudi Arabia*

Topological insulators (TIs) such as Bi_2Se_3, Bi_2Te_3, and Sb_2Te_3 have attracted remarkable consideration because of their strong surface states, which are introduced by strong spin-orbit coupling (SOC) and protected by time-reversal symmetry (TRS). In particular, there is tremendous interest in heterostructures composed of transition metal magnetic layers deposited on TI surfaces as such system can display quantized anomalous Hall effect, as well as extremely large spin-charge conversion efficiency. Based on density functional theory calculations, we rigorously study the spin-momentum locking performance of a wide range of transition metals (3*d*-TM) adsorbed on Bi_2Se_3. Our results show that monolayer anisotropy is initiated by the hybridization of spin-polarized states on 3*d*-TM with spin-momentum locked surface states conducting electrons on the TI. Additionally, we demonstrate that the spin texture on the 3*d*-TM monolayer becomes momentum dependent, enabling the emergence of large spin-charge conversion processes. The bottom surface of the slab, interfaced with vacuum, shows delocalized Bi and Se *p*-orbitals forming an unperturbed Dirac cone, while the top surface of the slab, interfaced with the 3*d*-TM overlayer, displays localized *p*-states with strong spin texture. Indeed, the excess of 3*d*-TM electronic charge pushes down the top layer Dirac cone towards lower energy, and the distortion on the point of Dirac comes from the hybridization of 3*d*-TM and TI. Finally, the 3*d*-TM absorbed on the hollow adsorption site at the top surface display localized *d*-states that acquire a spin texture through proximity effect with the TI. The strength of the spin texture on the TI and 3*d*-TM orbitals are reported for the whole range of 3*d* transition metal series.

DP-11. Characterization of Traps in Sputtered Topological Insulator FET (TI-FET). *P. Sahu*[1], J. Chen[2] and J. Wang[2,1] *1. School of Physics and Astronomy, University of Minnesota, Minneapolis, MN, United States; 2. Department of Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States*

Topological insulators have captured the attention of condensed matter physicists for their highly spin-polarized conducting surface states. Such materials allow us to make dissipation less spin channels for spintronic applications. Recently, high charge-to-spin conversion and vice-versa was reported in sputtered topological insulators [1-3]. Non-stoichiometric 2D materials often have open bonds at the surface, which can be a source of ionic traps [4]. Topological insulators are especially susceptible to this, since a small change in surface conduction can produce a substantial change in the overall transport property. In order to understand this mechanism, we start by chemically characterizing the depth profile of the film using X-ray photoelectron spectroscopy at different sputter etch times. Going deeper into the film, a change in the shape and position of Bi4f peaks can be seen. This change is attributed to the oxidation of Bismuth near the top interface. We also observe Mg^{2+} impurities through the film, which is a strong candidate for mobile ion traps. The atomic force microscopy shows a relatively rough surface, which is due to the formation of crystal twins [5]. These films are then fabricated into FET structures with SiO_2 dielectric (t ~ 70 nm) deposited by CVD. We measure the resistivity of the film as a function of gate voltage. The transport measurements depict a very clear and strong hysteretic behavior. Negative to positive gate sweep shows a maximum and vice versa. Such strong long-delay hysteresis can be attributed to the movement and trapping of ions across the interface. We further develop a detailed semi-empirical model to explain the effects of ionic traps on transport properties (carrier density, mobility and conductivity). This allows us to calculate the effective trap density due to gate voltage. We fit the model into our experiment to get the important parameters relating the trap density with gate voltage.

DP-12. Highly Efficient Spin-to-Charge Current Conversion at Room Temperature in Strained HgTe Surface States. P. Noel[1], *M. Cosset-Chéneau*[1], C. Thomas[2], P. Ballet[3], L. Vila[1], T. Meunier[2] and J. Attané[1] *1. Univ. Grenoble Alpes, CEA, CNRS, Grenoble INP, INAC, SPINTEC, Grenoble, France; 2. Institut Néel, C.N.R.S. and Université Joseph Fourier, Grenoble, France; 3. Univ. Grenoble Alpes, CEA, LETI, MINATEC Campus, Grenoble, France*

Spin current manipulation in spintronic requires finding an efficient way to transform charge currents into spin currents, and vice-versa. If classical spintronics generally relies on magnetic materials, the spin manipulation can also be achieved by harnessing the Spin Orbit Coupling (SOC) in non-magnetic materials such as topological insulators. The main interest of topological insulators lies in their surface states, which possess a linear Dirac-like dispersion, and a spin momentum locking. A flow of electric current in the 2DEG leads to a spin accumulation. The direction of the accumulated spins is parallel to the surface, and perpendicular to the electron motion direction. This effect is known as the Edelstein Effect, while the reverse spin-to charge-conversion effect is known as the Inverse Edelstein Effect (IEE). Recent results suggest that surfaces of topological insulators have a strong potential for spintronics, both for the generation or detection of spin currents through direct or inverse Edelstein effects. Among these newly discovered class of materials, strained HgTe is a promising one, as it is an archetypal topological insulator, compatible with electronic and optoelectronic applications. Gap opening and Topological insulator properties can be induced in HgTe by applying a tensile strain that can be achieved by epitaxy of HgTe on a substrate with a larger lattice constant, such as CdTe. We present the study of spin to charge interconversion in strained HgTe thin films by ferromagnetic resonance spin pumping in cavity. The spin to charge current conversion rate, the inverse Edelstein length, was measured to be up to 2 nm, one to two orders of magnitude larger than in Bi-based topological insulators. Moreover, the non-conventional thickness dependence of the conversion rate allows to ascribe this conversion to the topological surface states [1].

DP-13. Bulk and Layered Magnetic Properties of Two-Dimensional van der Waals ferromagnetic VI_3. *E.E. Gordon*[1] and L. Ke[1] *1. Division of Materials Science & Engineering, Ames Laboratory, Ames, IA, United States*

Two-dimensional (2-D) magnetic materials have recently gained significant focus due to potential film and device applications. VI_3, a new ferromagnetic material, has gained recent interest due to experimental evidence suggesting VI_3 is easily cleavable down to a few layers, and being the first know hard 2-D van der Waals magnetic material. We investigate VI_3's bulk, bilayer, and monolayer intrinsic magnetic properties via density functional theory (DFT) within VASP. Our DFT + *U* calculations agree well with the experimentally determined ferromagnetic insulating ground state, experimental bulk band gap, experimental bulk Curie temperature (T_c), predicts a small change in the T_c as a function of the number of layers (similar to what is found in CrI_3), and predicts a similar spin-wave spectra to CrI_3 along high-symmetry hexagonal paths. A change in the spin-wave spectra along high-symmetry hexagonal paths is seen as interlayer exchange interactions are included as xy-components are present within some extracted interlayer exchanges. Layer-dependent magnetization experiments are suggested to explore T_c as a function of the number of layers and inelastic neutron scattering experiments are suggested to explore the possibility of a spin-wave gap, as present in CrI_3, due to Dzyaloshinkii-Moriya (DM) interactions along the second nearest neighbor intralayer interaction.

Blue spheres represent V within 1 plane and red spheres represent V in the plane below. J_1, J_2, and J_3 spin exchanges represents the nearest-neighbor, 2nd nearest-neighbor, and 3rd nearest-neighbor interactions within the V hexagonal ab-plane. J_{c1}, J_{c2}, and J_{c3} spin exchanges represents the nearest-neighbor, 2nd nearest-neighbor, and 3rd nearest-neighbor interactions between V planes. Curved arrows represent interactions of the blue plane V with the red plane V. V(1) spin exchanges along the +c (-c) direction is the same as V(2) spin exchanges along the -c (+c) direction.

Spin-wave spectra plots of VI_3 using extracted spin exchange interactions along hexagonal high symmetry paths, i.e., Γ -> K, Γ -> M, Γ -> A. Black (red) lines represent the spin-wave spectra excluding (including) interlayer spin exchanges. Plots were created using the SpinW program.

DP-14. Experimental evidence of the valley Nernst effect in WSe_2. M. Dau[1], C. Vergnaud[1], *T. Guillet*[1], A. Marty[1], C. Beigné[1], S. Gambarelli[2], V. Maurel[2], H. Okuno[3] and M. Jamet[1] *1. Univ. Grenoble Alpes, CEA, CNRS, Grenoble INP, IRIG-Spintec, Grenoble, France; 2. Univ. Grenoble Alpes, CEA, CNRS, IRIG-SYMMES, Grenoble, France; 3. Univ. Grenoble Alpes, CEA, IRIG-MEM, 38000 Grenoble, France, Grenoble, France*

We study the interplay between thermoelectricity and the valley degree of freedom in monolayers of WSe_2. By using van der Waals epitaxy, high quality WSe_2 mono and multilayers are grown on epitaxial graphene on SiC over large areas (Fig. 1a and 1b). Using such millimeter-sized sample, we are able to apply well-defined temperature gradients and demonstrate the very strong Seebeck response of this material. In a second step, we use the ferromagnetic resonance-spin pumping technique to (i) apply the temperature gradient by off centering the sample in the RF cavity and (ii) address a single valley using the spin pumping through spin-valley coupling (Fig. 1c). The combination of a temperature gradient and the valley polarization leads to the valley Nernst effect in WSe_2 that we detect electrically in the RF cavity (Fig. 1d). The Nernst coefficient we measure is in very good agreement with the predicted value. This effect can be exploited to generate large transverse valley currents for valleytronics applications.

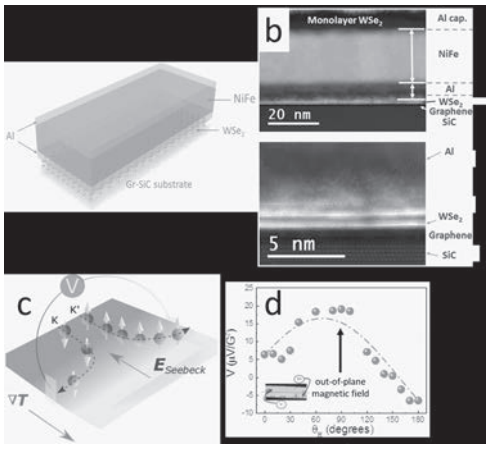

Fig.1 : (a) Sketch of the WSe2/metallic stack to study the Valley Nernst effect. (b) Cross sectional transmission electron microscopy images of the full stack. (c) Illustration of the valley Nernst effect when a temperature gradient is applied and a single valley is addressed. (d) Valley Nernts effect voltage measured by the FMR-spin pumping technique.

DP-15. Spin and Valley Transport in Strained Silicene Heterojunctions: Zigzag versus Armchair Interface. *Z. Siu*[1] and M.B. Jalil[1] *1. Electrical and Computer Engineering, National University of Singapore, Singapore*

In this work, we study the spin and valley transport across silicene[1] heterojunctions consisting of a strained[2] central segment sandwiched between two semi-infinite unstrained leads. We employ a tight-binding Hamiltonian obtained by generalizing the procedure in Ref. 3 to account for arbitrarily distorted lattices. The strain displaces the Dirac points and introduces angular anisotropies into the Fermi surfaces (FS). Fig. 1a shows a schematic diagram of a heterojunction with zigzag interfaces. Fig 1b shows that due to the anisotropy of the strained central segment FS for a given value of incidence angle φ_j, the corresponding conserved value of k_x cuts across different portions of the central segment FS. This results in differing transmission between the two valleys, and hence spin and valley polarizations (Fig 1c) of the resultant transmitted current. Fig 2 shows a schematic diagram of a heterojunction with armchair interfaces. In contrast to the zigzag interface in Fig 1b where the halves of the central FS propagating from the source to drain in the two valleys are symmetrical to each other, in the armchair interface the halves of the central FS propagating in the correct direction are asymmetrical in the two valleys (Fig 2b). This induces an asymmetrical spin and valley polarization of the transmitted current with respect to the incidence angle, in contrast to the zigzag interface where the polarizations are symmetrical (Fig 2c).

DP-16. Spin reorientation in quasi-2D ferromagnet Cr_5Te_8. *Y. Chen*[1], J.G. Lin[1,2], C. Kuo[3] and C. Lue[3] *1. Center for Condensed Matter Science, National Taiwan University, Taipei, Taiwan; 2. Center for Atomic Initials for New Materials, National Taiwan University, Taipei, Taiwan; 3. Department of Physics, National Cheng Kung University, Tainan, Taiwan*

$Cr_{1-\delta}Te$ is a family of metal-deficient hexagonal half-metal with strong spin-orbit coupling and crystalline anisotropy, which could be a good candidate for the spintronics applications. Recently, a critical analysis on magnetization revealed a unique 2D to quasi-2D type of ferromagnetic transition near 230 K in trigonal Cr_5Te_8,[1] leading to a prominent question of how this dimensional transition affects magnetic properties. In this work, the

temperature-dependent magnetic anisotropy in a Cr_5Te_8 single-crystal slab was studied by means of ferromagnetic resonance (FMR) across the dimensional transition. The temperature dependence of in-plane and out-of-plane magnetization shows a switch of easy-axis near the transition. The results of angular-dependent FMR field (Fig. 1) confirms a spin reorientation transiting the easy axis from *a*-*b* plane to the direction title by ~π/4 as cooling from 260 to 200 K. A numerical simulation indicates this spin reorientation involving with the sign reversal of 2nd-order magnetic anisotropy from negative to positive and a substantial enhancement of 4th-order crystal magnetic anisotropy for T < 240 K. In summary, our results suggest a strong enhancement of crystal anisotropy below the temperature of 2D to quasi-2D transition, corresponding to a structure anomaly through the strong spin-orbital coupling in Cr_5Te_8.

DP-17. The application of machine learning on the optical identification of two-dimensional nanostructures. X. Lin[1], Z. Si[1], W. Fu[1], *X. Wang*[1], G. Wei[1] and W. Zhao[1] *1. Microelectronics, Beihang University, Beijing, China*

Two-dimensional (2D) materials and their heterostructures, with wafer-scale synthesis methods and fascinating properties, have attracted significant interest and triggered revolutions in corresponding device applications. However, facile methods to realize accurate, intelligent, and large-area characterizations of these 2D nanostructures are still highly desired. Herein, we report the successful application of machine-learning strategy in the optical identification of 2D nanostructures. The machine-learning optical identification (MOI) method endows optical microscopy with intelligent insight into the characteristic color information of 2D nanostructures in the optical photograph. The experimental results indicate that the MOI method enables accurate, intelligent, and large-area characterizations of graphene, molybdenum disulfide, and their heterostructures, including identifications of the thickness, existence of impurities, and even stacking order. With the convergence of artificial intelligence and nanoscience, this intelligent identification method can certainly promote fundamental research and wafer-scale device applications of 2D nanostructures.

DP-18. Controllable growth of 2D magnetic and non-magnetic van der Waals crystals via temperature-oscillating chemical vapor transport. *Z. Li*[1,2], X. Xi[1] and W. Wang[1] *1. State Key Laboratory for Magnetism, Beijing National Laboratory for Condensed Matter Physics, Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2. University of Chinese Academy of Sciences, Beijing, China*

Dimensionality effect exhibited by two-dimensional (2D) van der Waals (vdW) materials has recently attracted considerable interest due to their convenience for mechanically exfoliating, transferring and stacking to fabricate novel heterojunction devices [1]. Thus growing highly crystalline single crystals is of vital importance for studying intrinsic physical property. However, comparing bottom-up with top-down synthetic strategies for obtaining low dimensional layers, it is found that physical and chemical vapor deposition methods are lacking in defect control. As for $NbSe_2$, disorder-induced localization of Cooper pairs appears to strongly suppress the superconductivity [2]. As a result, the superconducting transition temperature of these bottom-up grown samples [3-5] are 2 kelvin degrees lower than samples exfoliated from bulk form [6, 7]. Therefore, chemical vapor transport (CVT) and mechanical exfoliation should be the most reliable and low-priced method for obtaining high-quality 2D vdW single crystals. Herein, we developed an innovative design for growing 2H-NbSe2 single crystals with controlled morphology and quality via temperature-oscillating CVT process. In combination of a thermodynamics calculation, we grew crystals under different degrees of supersaturation, and obtained various shapes of crystals from screw-dislocated types to homogeneously hexagon types. The formation mechanisms of morphology was quantitative explained with the Burton-Cabrera-Frank (BCF) model. And the quality of obtained single crystals was characterized by XRD, HRTEM and electrical resistance measurements. It should be noted that the growth at higher temperature tended to decompose and generate more selenium vacancy [8]. Our designed temperature-oscillating method could reduce the growth temperature to the lowest value ever reported in the same reaction, and the best grown samples had the exceptional RRR≈61 and Tc≈7.4K. Furthermore,

this temperature-oscillating technique could be universally applicable among other CVT reactions. We also succeeded in growing 2D magnetic crystals Fe_3GeTe_2, CrI_3, and so on.

DP-19. A New Method for Probing the Light-controlled Ferromagnetism in a Two-dimensional van der Waals Heterostructure System.
V. Ortiz-Jimenez[1], V. Kalappattil[1] and M. Phan[1] *1. Physics, University of South Florida, Tampa, FL, United States*

Van der Waals heterostructures of transition metal dichalcogenides (TMDs) have been a subject of great interest in recent years due to their outstanding electrical, magnetic, and optical properties [1,2]. A plethora of potential applications have emerged as a result, such as spintronics, valleytronics, and quantum computing technology among many others. It has been shown that as a consequence of the magnetic proximity effect, magneto-optical properties of non-magnetic TMDs may be induced or enhanced by stacking them with other magnetic TMDs [3]. In this work, we show a van der Waals heterostructure composed of VSe_2 monolayer/MoS_2 bilayer grown on SiO_2, in which the presence of the VSe_2 layer enhances the magnetization of the MoS_2 layer. Interestingly, the presence of VSe_2 enables us to use light to control the magnetization of the heterostructure. This phenomenon has been probed using the magnetic LC-resonance principle. This technique employs a soft ferromagnetic Co-based microwire coil driven near resonance with an RF signal. The microwire shows an excellent giant magneto-impedance (GMI) effect, so it is very sensitive to small magnetic fields. When driven near resonance, the coil becomes highly sensitive to changes in magnetic flux through its core. By placing the van der Waals structure at the core of the coil and exciting the material with a laser, we were able to measure the changes in magnetization of the heterostructure. We observed how the magnetization is dependent on the laser power, which would allow us to tune it within a certain range. The tunability of the magnetization is associated with the excellent photon absorption of the MoS_2 bilayer which creates electron-hole pairs that mediate the magnetization. These findings may inspire novel two-dimensional spintronic devices that exploit light-controlled ferromagnetism.

DP-20. Lateral non-local black phosphorus spin valve.
C. Li[1], X. Xu[1], Y. Wu[1], K. Meng[1], J. Miao[1] and Y. Jiang[1] *1. University of Science and Technology Beijing, Beijing, China*

Two dimensional materials(2D materials), such as graphene,MoS_2,-MoS_2,BN, due to long spin diffusion length etc., have been widely applied in spintronics. Nowadays, black phosphorus(BP) is a promising material in this field [1]. The black phosphorus(BP), which is a new kind 2D material, has a direct bandgap and the electron mobility and the spin relaxation length of bP are comparable with graphene [2]. With increasing the thickness of BP, the size of bandgap changes from 2 eV to 0.35 eV. In this work, we discuss the influence of BP, as a spin channel, on spin injection and spin transport. The schematic of the lateral non-local spin valve is showed in Fig.1(a). Firstly, we purchased bP layers with the Scotch tap by the means of mechanical exfoliation. Then, BP was transferred onto Si/SiO2 substrate. Fig.1(b) shows the Raman spectra of BP with different thicknesses which can detect the layer of BP. To form a non-local spin valve, we deposited 4 electrodes with different widths on a certain bP stripe with 1.5 nm Al_2O_3 followed by 40nm Co [3]. The Al_2O_3 layer is a tunnel layer to filter current and get pure spin current. Fig.1(c) and Fig.1(d) shows non-local spin valve signals of a same sample in 300K and 50K. Both in 300 K and 50 K, signals are obvious which means efficient spin injection and spin transport. Of course, the curve in 50 K seems more smooth without thermal effect. We also estimated the spin diffusion length λ is 594 nm by an equation[4,5]. Although the spin diffusion length of BP is not comparable with graphene, there still many works to do to achieve more excellent feature.

Theoretical studies on manganese-rich Mn_2FeGe Heusler alloy through first principle calculations have found that this material is nearly half-metallic, a ferrimagnetic and stabilizes in the inverse Heusler-type crystal structure [1, 2]. In this work we present structural, magnetic, and magnetocaloric properties of Mn_2FeGe of nominal composition synthesized in bulk form by arc melting and as rapidly solidified melt-spun ribbons. X-ray diffraction results show that the alloy crystallizes into the hexagonal DO_{19} crystal structure at room temperature with a small trace of a secondary phase. Mn_2FeGe was found to be ferro/ferrimagnetic at low temperatures undergoing a well-defined magnetic transition of second order at a Curie temperature (T_C) of ~ 202 K for bulk and 192 K for melt-spun ribbons. A ground state magnetization values of ~ 1.6 μ_B/f.u. (in bulk) and 1.7 μ_B/f.u. (ribbons) were found. These magnetization values obtained for the polycrystalline Mn_2FeGe are in good agreement with the value 2.0 μ_B/f.u. predicted by the Slater-Pauling rule. Further theoretical investigations are necessary to understand the properties of the hexagonal structure. Maximum absolute values of magnetic entropy change at T_C were found to be 1.6 $Jkg^{-1}K^{-1}$ ($\mu_0\Delta H$ = 5 T) and 0.9 $Jkg^{-1}K^{-1}$ ($\mu_0\Delta H$ = 2 T) for bulk and ribbons, respectively. Corresponding values of refrigerant capacity for bulk and melt-spun ribbons were found to be 128 Jkg^{-1} ($\mu_0\Delta H$ = 5 T) JKg^{-1} and 40 Jkg^{-1} ($\mu_0\Delta H$ = 2 T). Acknowledgments. DQ-02. Phase transitions and magnetic properties in $Mn_{1-x}La_xCoGe$ system. *P. Zhang*[1], H. Zhang[2], H. Imam[2] and B. Song[2] *1. Shaanxi University of Science & Technology, Xi'an, China; 2. Beijing University of Technology, Beijing, China*

MnCoGe is the most intensively studied compound among the newly discovered MM′X system with so-called Curie temperature window (CTW) behavior [1]. Many efforts have been made to build and enlarge the CTW. The most successive way so far is substitutions on the transition metal sites (Mn or Co) with elements such as Fe, V, Ti, Cu, Ni and Zn, or substitutions on the main group element site (Ge) with Ga or Al. In this work, we use rare-earth element La to replace Mn and address the phase stability as well as the martensitic transformation of the system. The $Mn_{1-x}La_xCoGe$ compounds with x = 0, 0.01, 0.02, 0.03, and 0.05 were prepared by arc melting under a high purity argon atmosphere. From Fig. (a), we can see that the increase in La content will increase the percent of hexagonal phase, and there is also the sign of secondary phase. This indicates that the martensitic transition temperature (T_M) gradually decreases and eventually below room temperature. However, the subsequent annealing process causes the increase of T_M because the hexagonal phase almost disappears in Fig. (b). Temperature dependence of the magnetization of the $Mn_{1-x}La_xCoGe$ compounds before and after annealing process are shown in Fig. (c, d). The as-casted samples show abrupt transitions with obvious thermal hysteresis along the increase of La content, which is a sign of magnetostructural transition. On the other hand, the annealed samples only show simple transition from ferromagnetism to paramagnetism, confirming the increase of T_M. Further investigations reveal that the substitution on transition metal site with La can help to establish the magnetostructural coupling and thus CTW by causing Ge deficiency beside Mn defficiency in the MnCoGe system.

XRD patterns of the (a) as-casted and (b) annealed $Mn_{1-x}La_xCoGe$ series. M-T curves measured under a magnetic field of 0.01T in both heating and cooling modes for the (a) as-casted and (b) annealed $Mn_{1-x}La_xCoGe$ series. The three photos shows the appearance of the as-casted $Mn_{0.99}La_{0.01}CoGe$, $Mn_{0.95}La_{0.05}CoGe$ and the annealed $Mn_{0.95}La_{0.05}CoGe$.

DQ-03. Influence of A-site Cation Size-Disorder on the Magnetocaloric Response of $La_{0.6}Ca_xSr_{0.4-x}MnO_3$ Nanoparticles. *C.S. Hunt*[1], R. Barua[2] and E. Carpenter[2] *1. Chemistry, Virginia Commonwealth University, Richmond, VA, United States; 2. Nuclear and Mechanical Engineering, Virginia Commonwealth University, Richmond, VA, United States*

Magnetic refrigeration is an energy-efficient and environmentally-friendly alternative to the conventional vapor-compression refrigeration systems. The key component of a magnetic cooling device is a working magnetocaloric material that demonstrates significant magnetocaloric effect (MCE) - large magnetic entropy and temperature change (ΔS and ΔT, respectively)

upon application and removal of a magnetic field - in the proximity of a room temperature magnetic phase transition [1]. To this end, manganites having the general formula $La_{1-x}M_xMnO_3$ (M=Ca, Sr, Ba etc.) have attracted considerable attention in the last decade. In particular, $La_{0.6}Ca_{0.4}MnO_3$ compounds exhibit the largest MCEs among the existing manganites (ΔS= 5 J/kgK at μH=3T) [2]. We have recently observed an enhanced MCE in $La_{0.6}Ca_{0.4}MnO_3$ nanoparticles (NPs) – a feature attributed to alteration of free energy terms dependent upon the surface area and volume of finite systems [3]. Building on this work, $La_{0.60}Ca_x\ Sr_{0.40-x}MnO_3$ ($0<x<0.4$) nanoparticles were synthesized via a modified Pechini sol-gel method, as verified by powder x-ray diffraction and laser ablation-inductively coupled plasma-mass spectrometry. The temperature-dependence of the magnetic entropy change between 200K and 300K in a magnetic field of μH=3T was evaluated by means of Maxwell's relations and isothermal MH curves. The reported values of ΔS_{max} increase from 1.5 J $kg^{-1}K^{-1}$ to 4.7 J $kg^{-1}K^{-1}$ as x increases from 0 to 0.4, Figure 1. The results show a clear positive correlation between calcium concentrations and the value of -ΔS, suggesting that a larger atom at the calcium site negatively impacts the magnetocaloric effect, thereby decreasing magnetic refrigeration viability.

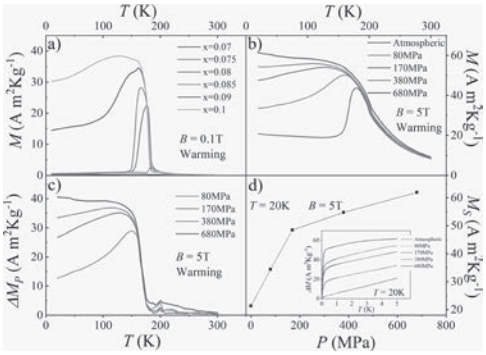
DQ-04. Geometrically designed Gd-alloy microwire arrays with enhanced magnetocaloric properties for energy-efficient magnetic refrigeration. *C. Hung*[1], H. Srikanth[1] and M. Phan[1] *1. Physics, University of South Florida, Tampa, FL, United States*



Magnetic refrigeration (MR) based on the magnetocaloric effect (MCE) with its high efficiency, tunable device, and environmental friendliness is a promising alternative to the vapor compression based cooling technology. In an actual cooling device, however, the geometry of a magnetic refrigerant is crucial as it strongly affects the operating frequency, the heat exchange rate and consequently the cooling power of the device. Magnetocaloric wire-shaped materials have been theoretically and experimentally shown to have improved mechanical strength, lower viscosity, and greater MCE performance as compared to their bulk counterparts or the particle and ribbon forms [1,2]. Our recent findings of the large MCEs in melt-extracted Gd-alloy microwires have opened the door for realizing this technology [2,3]. In the present study, we propose a new geometrical design method for enhancing the cooling power of a magnetic refrigerant by arranging magnetocaloric wires (e.g. soft ferromagnetic $Gd_{55}Al_{20}Co_{25}$ microwires) into laminate-like structures. In multilayer systems, layers are orthogonally arranged to each other, forming a grid-like structure. Magnetocaloric experiments showed larger values of magnetic entropy change (ΔS_M) over wider temperature ranges in the laminated microwires relative to a single microwire or a bundle of microwires, as a result of the enhanced wire-wire and layer-layer interactions. Both the magnetic interactions between wire-layers and geometric effect arising from the wires' arrangement play important roles in determining the MCE performance. The even-layer systems show significantly enhanced ΔS_M values (~9.8 J/kg.K) compared to the odd-layer ones (~8.5 J/kg.K). Among the systems investigated, the highest relative cooling power (RCP ~ 918 J/kg at 5T), which is the product of the maximum ΔS_M and the temperature span, is achieved for the four-layer system. The newly designed Gd alloy wire-based structures are promising for energy-efficient MR technology.

DQ-05. Giant baromagnetic effect in Sn-doped MnNiGe. *F. Shen*[1], F. Liang[1], J. Hao[1], F. Hu[1], J. Wang[1], J. Chen[2], L. He[1], T. Liang[2], J. Sun[1] and B. Shen[1] *1. Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2. Spallation Neutron Source Science Center, Dongguan, China*

Pressure sensor (PS) has important application in artificial intelligence and modern industries. Baromagnetic effect (BME), i.e. pressure-induced magnetic moment change, is regarded as the candidate technology for new PS. The reported large BME in $Mn_3Ga_{0.95}N_{0.94}$ [1] has gained great attention. The origin comes from the pressure-induced spin re-orientation from Γ^{5g} antiferromagnetic (AFM) to M-1 ferrimagnetic phase. Recently, the ternary metallic compounds MM'X (M, M' = transition metals, X = main elements) have attracted renewed attention due to their barocaloric effect [2], and giant negative thermal expansion [3]. In the MM'X family, the MnNiGe alloy possesses a martensitic structural transiton from austenite (with ferromagnetic (FM) ground state) to martensite (with AFM ground state) [4]. By doping the Sn into the Ge site, the martensite become unstable and can be easily converted to austenite by pressure. A giant BME is therefore achieved. $MnNiGe_{1-x}Sn_x$ ($0.07\leq x\leq 0.1$) compounds were prepared by arc-melting technique (Fig. 1a). Here, the critical composition (x = 0.085) is chosen to study the BME. The results show that an application of hydrostatic pressure is able to increase the magnetization significantly (Fig. 1b). Neutron powder diffraction reveal that the origin is closely relative to collapse of AFM structure enforced by pressure and establishment of FM structure. We quantify the BME by ΔM_P ($\Delta M_P = M(T, P) - M(T, P_0)$), where M(T, P) is the magnetization under different temperature and pressure, and P_0 stands for the atmospheric pressure (Fig. 1c). The maximal ΔM_P reaches 40.5 A m^2Kg^{-1} at 20K under 680MPa, which is three times larger than the maximum ΔM_P (13.0 A m^2Kg^{-1} under 1000MPa) of the well-known material $Mn_3Ga_{0.95}N_{0.94}$ [1], and the ΔM_P can maintain above 30 A m^2Kg^{-1} below 160K. The pressure dependent spontaneous magnetization (M_S) is also measured (Fig. 1d), and intrinsic mechanism of the giant BME relative to the evolution of magnetic structure is discussed. Fig.1. a) M-T under 0.1 T for $MnNiGe_{1-x}Sn_x$ ($0.07\leq x\leq 0.1$). b) M-T and c) ΔM_P–T under 5 T and different pressures, and d) M_S–P at 20K for $MnNiGe_{1-x}Sn_x$ (x=0.085). The inset shows the corresponding M–H curves for the M_S–P.

DQ-06. Fe-Ni-Al-Zr Amorphous Thin Films for Magnetic Refrigerants near Room Temperature. *R. P*[1], P. Svedlindh[1] and G. Andersson[1] *1. Uppsala University, Sweden, Uppsala, Sweden*

Amorphous Fe-Zr-based thin films are suitable candidates for magnetic refrigeration due to the relationship between their magnetic and microstructural properties. These systems have the advantage of low cost, due to that they are free of rare-earth elements, and they can exhibit large changes in magnetic entropy close to room temperature at relatively low applied fields (< 2 tesla), while being free from magneto-structural phase transitions. Furthermore, they exhibit higher electrical resistivity, relatively larger values of refrigerant capacity (RC) and tunable Curie temperature in the amorphous phase compared to that of rare-earth based films at room temperature. Fe-Zr based amorphous films $(Fe_{1-x}Ni_x)_{90}Zr_{10}$ and $(Fe_{0.95}M_{0.05})_{90}Zr_{10}$, with M being one of Al, Si, Ga, Ge and Sn, have been studied as candidate materials for room temperature magnetic refrigeration with larger values in RC [1, 2]. In the present studies, Fe-Ni-Al-Zr (FNAZ) amorphous thin films were prepared at room temperature, using DC magnetron sputtering by co-deposition of individual elemental targets. The presence of Ni and Al improves the magnetic moment and minimizes the eddy currents respectively in these films. An order-disorder transition temperature of 289 K for a specific FNAZ amorphous film was determined using SQUID magnetometry at an applied field of 100 Oe. A magnetic entropy change (ΔS_M) of 3.58 J/kgK at an applied of 2 T was observed close to the order-disorder temperature. The magnitude of this value makes the material a possible candidate for future room temperature magnetic refrigeration applications.

DQ-07. Rotating Magnetocaloric Effect in the Region of Spin-Reorientation Transition in the Fe_7Se_8 Single Crystal. *I. Radelytskyi*[1,2] and Y. Konopelnyk[2] *1. Jülich Centre for Neutron Science at MLZ, Garching, Germany; 2. Institute of Physics PAS, Warsaw, Poland*

Trigonal Fe_7Se_8 (3c type) shows in constant magnetic fields a spin-reorientation transition from the easy *c*-axis to the easy *c*-plane near the temperature $T_R \approx 125$ K, as a first-order phase transition. This transition is induced by temperature and/or by an applied magnetic field. We investigated a Fe_7Se_8 single crystal by magnetization measurements above and below T_R and observed first order metamagnetic field induced transitions. The maximum rotating entropy change was evaluated from magnetization data using the Maxwell equation to be about $\Delta S_{rot} \approx 0.566$ J /(kg K) for H = 2T. The calculated refrigeration capacity is equal $RC_{rot} \approx 35.71$ J/kg for H=2 T, which is twice time bigger that conventional magnetocaloric effect at the same magnetic field magnitude. A one-ion model of the rotating magnetocaloric effect has been developed and its predictions have been compared with experimental data.

DQ-08. Near Room Temperature Magnetocaloric Effect in CrTe1-xSbx Alloys. M.K. Hamad[1], E. Martinez-Teran[2], Y. Maswadeh[3], R. Hamad[1], E.G. Alnahari[1], *A.A. El-Gendy*[2] and K.A. Ziq[1] *1. Physics, King Fahd University of Petroleum & Minerals, El Damam, Saudi Arabia; 2. Physics, University of Texas at El Paso, El Paso, TX, United States; 3. Department of Physics and Science of Advanced Materials Program, Central Michigan University, Mt. Pleasant, MI, United States*

We investigated the structural, magnetic properties and magnetocaloric effect in CrTe1-xSbx with different Sb concentration ($0 \le x \le 0.2$). Rietveld refinement of the XRD patterns revealed that the Sb substituted samples are pure phase hexagonal structure with P63/mmc (194) space group. However, the Sb-free sample (CrTe) contains a non-reacted minority phase. Moreover, a small concentration of Sb (~5%) was enough to produce samples with pure hexagonal structure. The magnetic properties of CrTe1-xSbx have also been investigated. The magnetic susceptibility revealed that ferromagnetic transition temperature decreases gradually in the range (330-285K) with Sb substitutions. Moreover, the molecular field coefficient γm obtained from the susceptibility also showed a gradual reduction with increasing Sb concentration, indicative of a weakening of the ferromagnetic interaction. Magnetization isotherms have been used to investigate the magnetocaloric effect in CrTe1-xSbx polycrystalline with $0 \le x \le 0.2$. We observed a significant enhancement in the maximum entropy change (deltaS max) and the rate of cooling power (RCP) upon Sb substitutions in a maximum cycling field at 3 Tesla. These results indicated that CrTe1-xSbx is a potential candidate as a room temperature magnetocaloric material.

DQ-09. Tuning of structural transition and phase stability in MnCo(Ge, V) system. H. Imam[1], *H. Zhang*[1], B. Song[1], Q. Lu[1], W. Liu[1], Y. Li[1], Z. Altounian[2] and M. Yue[1] *1. College of Materials Science and Engineering, Beijing University of Technology, Beijing, China; 2. Center for the Physics of Materials, Department of Physics, McGill University, Montreal, QC, Canada*

MnCoGe compound possesses a highly tunable martensitic transformation from low temperature TiNiSi-type structure to high temperature Ni_2In-type structure, which makes it a prototype for the investigation of magnetostructural coupling of the well-known MM'X systems [1]. Recently, all-d-metal Heusler system Ni-Mn-Ti-Co has been reported, in which low-valence-electron-element Ti can play the role as main-group element in traditional Heusler compounds by means of d-d hybridization. Base on this idea, a substitution of V for Ge in MnCoGe compound has been investigated in this work to understand the structure transition, phase stability and magnetic behavior of the system. Fig.(a) shows the patterns of the $MnCoGe_{1-x}V_x$ (x=0.005, 0.01, 0.015, 0.02, 0.03 and 0.04) compounds. They can be indexed as TiNiSi-type orthorhombic phase, mixed with a growing amount of Ni_2In-type hexagonal phase. This indicates that the martensitic transformation temperatures are decreased by V doping. Fig.(c) shows the BSEM and EDS results of the x = 0.04 samples. One can see that there are two different contrasts, dark one and grey one, corresponding to the $Mn_{0.91}CoGe_{0.96}V_{0.04}$ and $Mn_{0.91}CoGe_{0.70}V_{0.03}$ phases, respectively. The temperature dependence of the magnetization of the $MnCoGe_{1-x}V_x$ samples were studied in both the cooling and heating processes, as seen in Fig.(b). The increase of thermal hysteresis between the cooling and heating processes along V doping indicates that the phase transition temperature is decreased and eventually the magnetostructural coupling is established. The isothermal entropy change -ΔS was derived using the Maxwell relation and shown in Fig.(d), in which the largest $-\Delta S_{Max}$ is 10 J/kgK for x = 0.015. The values of the refrigerant capacity were also calculated and the largest one is 129.5 J/kg for x = 0.015. These results prove that d-d hybridization in MM'X systems can also help to achieve the magnetostructural coupling and thus realize magnetocaloric effect.

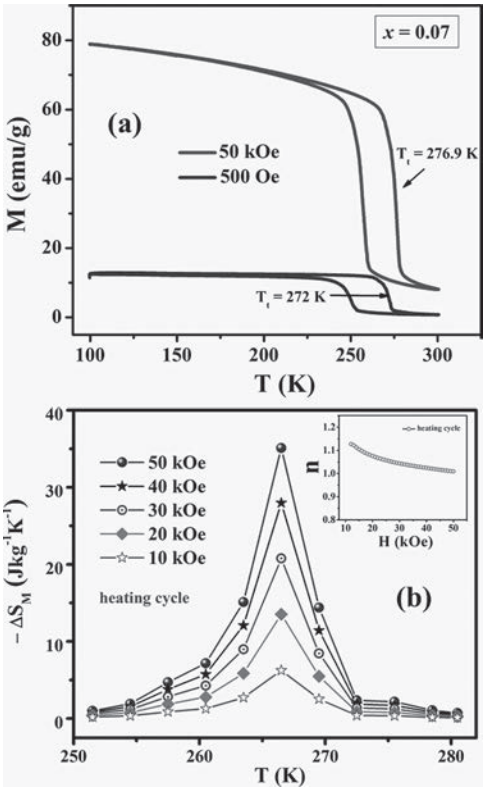
DQ-10. Quadrupolar ordering effect on magnetocaloric effect in rare-earth tetraborides. *M. Song*[1], K. Cho[1], J. Lee[1] and B. Cho[1] *1. Gwangju institute science and technology, Gwangju, The Republic of Korea*

The interplay of charge, spin, orbital and lattice degrees of freedom has recently received much attention due to its potential to improve the magnetocaloriceffect (MCE) for the purpose of magnetic cooling applications. The exotic inverse MCE is observed in rare-earth tetraborides, $Ho_{1-x}Dy_xB_4$ (x = 0.0, 0.5, and 1.0), and the strong coupling of magnetic dipole moments with quadrupole moments is found to induce the MCE in the presence of geometric frustration of 4*f* moments. It is remarkable that the maximum entropy change is realized in the critical fields below H = 5 T, which depends on the x values. So, it enables to induce a field-tuned entropy change and to bring about a significant advantage for several applications. On the other hand, ErB_4 and TmB_4 show the maximum entropy changes of 11.4 J/kgK, and 12.6 J/kgK with the critical field of » 40 kOe, respectively, which are significantly smaller than those of $Ho_{1-x}Dy_xB_4$. Although ErB_4 and TmB_4 have a similar structural and magnetic properties to those of $Ho_{1-x}Dy_xB_4$, i.e, the consecutive magnetic transitions, magnetization plateau, and strong anisotropy, those compounds are found to have strong competition between Zeeman effects and magnetic frustration, instead of the quadrupolar interaction. Thus, it supports the fact that the strong coupling between quadrupolar and magnetic dipolar moments plays important role in the exotic giant MCE in rare-earth tetraborides system.

DQ-11. Magnetostructural Transition and Giant Magnetocaloric Effect near Room Temperature in Al doped $(Mn_{0.6}Fe_{0.4})NiSi$ Alloys. *S. Ghosh*[1], P. Sen[2] and K. Mandal[1] *1. Condensed Matter Physics & Material, S. N. Bose National Centre for Basic Sciences, Kolkata, India; 2. Physics group, Variable Energy Cyclotron Centre, Kolkata, India*

MnNiSi [1] compound exhibits a first order structural transition, beyond a magnetic transition at T_C = 622 K, from orthorhombic TiNiSi-type structure to a hexagonal Ni_2In-type structure at a high temperature about ~1210 K in the paramagnetic region which is not suitable for room temperature magnetic refrigeration and it is desired to lower the structural transition to room temperature in the magnetically ordered ferromagnetic (FM) state. Magnetoresponsive properties of the above system are related to change in magnetization across its phase transitions. Therefore it is crucial to couple both magnetic and structural transition to achieve giant magnetocaloric effects in this alloy [2]. Here, first order magnetostructural transition (MST) between ferromagnetic orthorhombic and paramagnetic hexagonal structure and giant magnetocaloric effect near room temperature are observed in transition metal based low cost Al doped $(Mn_{0.6}Fe_{0.4})NiSi_{1-x}Al_x$ (x = 0.06, 0.07 and 0.08) alloys. Isothermal magnetic entropy change (ΔS_M) as large as ~ 35.1 and 6.52 $Jkg^{-1}K^{-1}$ is found for the alloy with x = 0.07 due to a change of 50 and 10 kOe magnetic field respectively. Interestingly, no noticeable field induced metamagnetic behavior is observed during heating cycle for these alloys which is very advantageous in respect of efficiency of these materials as refrigerant [3]. Moreover field dependence of ΔS_M data during heating cycle show universal behavior and are fitted well with a Lorentz function. Giant value of ΔS_M associated with large relative cooling power (RCP = 182.5 J/kg, for ΔH = 50 kOe) observed for the alloy of x = 0.07 enable the alloy as a potential candidate for magnetic refrigerant.

McCandless, J. Y. Chan, P. W. Adams, D. P. Young, N. Ali, and S. Stadler, Phys. Rev. B 91, 020401 (2015) [3] S. Ghosh, P. Sen, and K. Mandal, IEEE Trans. Magn. 54, 1 (2018)



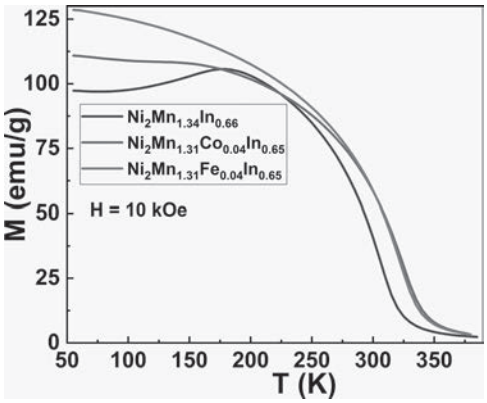


Fig.1: (a) M-T curves for the alloy x = 0.07 in presence of 500 Oe and 50 kOe magnetic field (b) Magnetic entropy change estimated from isothermal M-H curve as a function of temperature for the different field variation of x = 0.07 alloy in heating cycle [Inset: the exponent n as a function of magnetic field in heating cycle]

DQ-12. Magnetocaloric effect in Ni_2MnIn-based Heusler alloys with second-order phase transition. *B.R. Dahal*[1], Z. Lehmann[1], Y. Huh[1] and P.R. Kharel[1] *1. Department of Physics, South Dakota State University, Brookings, SD, United States*

Magnetic materials with second-order phase transition near room temperature exhibiting strong magnetocaloric effect (MCE) are preferred for room temperature magnetic refrigeration technology because these materials are free from magnetic and thermal hysteresis.[1] The MCE in Ni-Mn-In-based Heusler alloys have been widely investigated for their application in magnetic refrigeration but the main focus is in the MCE near their magnetostructural (first-order) phase transitions due to the observed large value of entropy change. We are interested to investigate the MCE of Ni-Mn-In-based alloys with elemental composition close to the critical composition between the first and second order phase transitions. We have investigated the structural, magnetic, and magnetocaloric properties of $Ni_2Mn_{1+x}In_{1-x}$ alloys prepared using arc-melting and vacuum annealing. We have found that the $Ni_2Mn_{1.34}In_{0.66}$ alloy shows a clear second-order phase transition near room temperature (Tc = 305K) with substantial MCE, but it also shows a first order phase transition(FOPT) when cooled below room temperature, Fig. 1. However, the first-order phase transition in $Ni_2Mn_{1.34}In_{0.66}$ can be completely suppressed with partial substitution of Mn with Fe or Co. We have found that the FOPT is highly suppressed in $Ni_2Mn_{1.31}Co_{0.04}In_{0.65}$ and completely suppressed in $Ni_2Mn_{1.31}Fe_{0.04}In_{0.65}$ alloys with a slight increase in saturation magnetization and Curie temperature, Fig. 1. The magnetic entropy change calculated from the isothermal magnetization *M(H)* curves measured at 30 kOe fields indicate that the maximum entropy change in $Ni_2MN_{1.31}Co_{0.04}In_{0.65}$ and $NI_2Mn_{1.31}Fe_{0.04}In_{0.65}$ alloys are 3.95 $Jkg^{-1}K^{-1}$ and 4.30 $Jkg^{-1}K^{-1}$, respectively. The corresponding relative cooling power near their Curie temperatures are 205 Jkg^{-1} and 211 Jkg^{-1}, respectively. These values are relatively high for rare-earth-free magnetocaloric materials showing second-order phase transitions near room temperature. We will also discuss the effect of annealing on the crystal structure and MCE of these alloys.

DQ-13. Magneto-elastic coupling in $AlFe_2B_2$-based compounds. *R. Barua*[1,2], B. Lejeune[2], Y. Mudryk[3], B.A. Jensen[3], M. Kramer[3], V.K. Pecharsky[3] and L. Lewis[2,4] *1. Department of Mechanical & Nuclear Engineering, Virginia Commonwealth University, Richmond, VA, VA, United States; 2. Department of Chemical Engineering, Northeastern University, Boston, MA, United States; 3. Division of Materials Sciences and Engineering, Ames Laboratory, Ames, IA, United States; 4. Department of Mechanical and Industrial Engineering, Northeastern University, Boston, MA, United States*

Understanding structure-magnetic property correlations provides insight into the fundamental drivers underlying the magnetocaloric effect (MCE) in $AlFe_2B_2$-based compounds, thus enabling fine-tuning of their functional response for potential magnetic cooling applications. To this end, samples of nominal composition $Al_{1.2}Fe_2B_2$ and $Al_{1.1}Ga_{0.1}Fe_2B_2$ were synthesized via casting, followed by annealing at 1040 °C for 3 days. Both single-phase samples adopt the expected orthorhombic (space group *Cmmm*) crystal structure wherein the Fe and B atoms form Fe_2B_2 layers that are separated by Al monolayers along the *b*-axis, Fig 1. Energy dispersive spectroscopy indicates that the solid solubility of Ga in the $AlFe_2B_2$ lattice is limited; hence the addition of Ga appears to favor non-stoichiometric enrichment by Fe.[1] Intriguingly, a 16 K increase in Curie temperature and 60% improvement in the magnetic entropy change was observed in the $Al_{1.1}Ga_{0.1}Fe_2B_2$ specimen (T_C=290 K; ΔS=4.4 J/kgK at μ_0H=2T), relative to $Al_{1.2}Fe_2B_2$ (T_C=274 K; ΔS=2.6 J/kgK at μ_0H=2T).[1] The noted changes in the magnetic character of the samples motivated examination of the temperature dependence of the lattice parameters and three significant interatomic distances within the coordination polyhedron of B (shaded in Fig. 1) - $d_{Al\text{-}Fe}$, $d_{(Fe\text{-}Fe)c}$ and $d_{(Fe\text{-}Fe)ab}$ - by X-ray Diffraction. In both samples, the *a*- and *b*-parameters increase upon heating while the *c*-parameter decreases, confirming a small volumetric thermal expansion of ~0.2 % in the temperature range 100 K - 325 K. In $Al_{1.1}Ga_{0.1}Fe_2B_2$, a broad discontinuity in $d_{Al\text{-}Fe}$ and an abrupt change in $d_{(Fe\text{-}Fe)ab}$ is noted through the magnetic transition, Fig. 2. These two structural features are largely absent in $Al_{1.2}Fe_2B_2$. It is surmised that magnetostructural coupling is stronger in $Al_{1.1}Ga_{0.1}Fe_2B_2$ than in $Al_{1.2}Fe_2B_2$ and is likely the underlying basis of the enhanced MCE in this sample. Magnetic materials undergo temperature variation when exposed to an external magnetic field, this is said to be the magnetocaloric effect [1]. In the past two decades, the interest in magnetocaloric effect has grown by the scientific community mainly due to the application for eco-friendly magnetic refrigeration. Moreover, it is interesting that magnetocaloric materials can also be used for magnetic hyperthermia treatments [2]. Among the magnetocaloric materials, gadolinium was one of the first and most important elements investigated so far due to its remarkable magnetic properties at close to room temperature [1]. In this work, we studied the intermetallic alloys of gadolinium and neodymium with different compositions to understand the magnetocaloric effect and magnetic properties using experimental and computational methods. A set of five samples were prepared by arc-melting method with the following compositions: $Gd_{90}Nd_{10}$, $Gd_{80}Nd_{20}$, $Gd_{70}Nd_{30}$, $Gd_{60}Nd_{40}$, $Gd_{50}Nd_{50}$. The samples were characterized using two commercial magnetometers and X-ray diffraction (XRD) analyses. The results indicate that both magnetic transition temperature and saturation magnetization can be modified by changing the composition of Gd and Nd as shown in Fig. 1 and Fig. 2. It is reasonable to infer that the addition of Nd atoms changed the magnetic interaction between the magnetic atoms of alloys and thereby the magnetic properties [3]. Our perspectives are to investigate the magnetic ordering of our samples using X-ray magnetic circular dichroism (XMCD) measurements, specifically, we expect to obtain information about the local magnetism of the chemical elements in our samples, distinguishing the contributions of the magnetic orbital and spin moments of each element and compare the experimental and theoretical results.

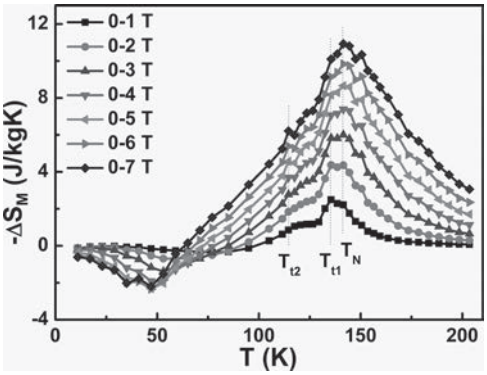
DQ-15. Magnetic properties and large magnetocaloric effect in R_3NiSi_2 (R=Tb, Dy) compounds. *J. Liu*[4,3], W. Liang[4,3], L. Wang[2], J. Xu[1], X. Zheng[1], T. Zhao[4], F. Hu[4,3], J. Sun[4,3] and B. Shen[4,3] *1. University of Science & Technology Beijing, Beijing, China; 2. Capital Normal University, Beijing, China; 3. University of Chinese Academy of Sciences, Beijing, China; 4. Institute of Physics, Chinese Academy of Sciences, Beijing, China*



Gd_3NiSi_2 compound present a reasonable magnetocaloric effect (MCE) than other recently reported R-Ni-Si systems [1] and the crystal structure had extensively been investigated [1-4]. In this work, orthorhombic polycrystalline R_3NiSi_2 (Tb, Dy) compounds were prepared using arc-melting method and the magnetic properties and magnetocaloric effect were investigated in detail. Magnetic measurements on R_3NiSi_2 indicated that there were several

magnetic phase transitions in both compounds. As temperature decreases, Tb_3NiSi_2 compound experienced a paramagnetic (PM) to antiferromagnetic (AFM) transition at T_N and an AFM to ferromagnetic (FM) transition at T_{t1}. When the temperature continue to reduce, Tb_3NiSi_2 compound underwent a FM to FM transition T_{t2} and an FM to AFM transition at T_{t3}. Not only normal MCE, but also inverse MCE can be found in Tb_3NiSi_2 compound. Under a field change of 0–7 T, the maximal value of inverse and normal MCE were about 2.3 J/kgK and 11.1 J/kgK for Tb_3NiSi_2 compound, respectively. As for Dy_3NiSi_2 compound, transition temperature T_{t3} cannot been observed compared with Tb_3NiSi_2 compound. And only normal MCE was verified with the maximal value at about 10.8 J/kgK for a field change of 0-7 T. Considering of normal and inverse MCE, Tb_3NiSi_2 shows considerable refrigerant capacity among the R_3NiSi_2 (Tb, Dy) compounds, indicating its potential applications in middle temperature magnetic refrigeration.

Magnetic refrigeration has drawn much attention during the last decades because of the advantages on energy efficiency and environment friendliness compared with conventional refrigeration. [1-3] Magnetic refrigeration is based on magnetocaloric effect (MCE) and the MCE materials with low transition temperatures can be used for low temperature refrigeration such as gas liquefaction. A lot of low temperature MCE materials have been reported, including TmGa and HoGa compounds. [4-5] In this work, the influence of Tm-substitution for Ho atoms on the magnetic property and MCE of HoGa compound was studied in detail. According to powder X-ray diffraction (XRD) measurements, $Ho_{1-x}Tm_xGa$ (x=0.2, 0.3, 0.4) compounds are all pure phases. Magnetic measurements (Fig.1a) show that $Ho_{1-x}Tm_xGa$ (x=0.2, 0.3, 0.4) compounds exhibit three successive magnetic transitions: ferromagnetic (FM)-I to FM-II, FM-II to antiferromagnetic (AFM), and AFM to paramagnetic (PM) transition. The FM-I to FM-II transition comes from spin reorientation (SR) which has been studied already.[4] The other two transitions have been reported in TmGa compound.[5] As the content of Tm increases, the T_{FA} and T_N decreases monotonically from 54.5 K to 42.0 K and 55.5 K to 44.0 K, respectively. T_{SR} changes little and almost keeps at about 20.0 K, in good accordance with the results of $Gd_xEr_{1-x}Ga$ compounds. [6] It is found that two peaks can be observed on the ΔS_M curves for all $Ho_{1-x}Tm_xGa$ (x=0.2, 0.3, 0.4) compounds (Fig.1b). The two peaks get closer in temperature with the content of Tm increasing. More specially, the maximal magnetic entropy change $(-\Delta S_M)_{max}$ at T_{SR} increases from 5.9 J/kg K with x=0.2 to 15.6 J/kg K with x=0.4, indicating a larger magnetic order change around T_{SR}. As for refrigerant capacity (RC), it increases monotonously from 393.9 J/kg to 553.8 J/kg with increasing Tm. Therefore, Tm-substitution for Ho atoms has a positive influence on the performance of HoGa compound.

The validity of entropy change (ΔS) calculated by Maxwell relation from magnetization isotherms has been widely discussed in the first-order magnetostructural transition during the last decades[1-5]. Here, by both standard and loop modes, we investigate the entropy change ΔS of $Ni_{50}Mn_{35}In_{15}$ alloy, which exhibits first-order magnetostructural transition from high temperature cubic phase to low temperature tetragonal phase. Considering the thermodynamics of the first-order phase transition process, the rationality of the entropy change calculated by Maxwell relation is discussed in $Ni_{50}Mn_{35}In_{15}$. The *M-T* curves under 0.01 T, 5 T, and *M-H* curves in the phase transition region on cooling is shown in Fig. 1 (a) and (b), respectively. In the two-phase region, the initial increase of magnetization indicates the magnetization process of ferromagnetic (FM) martensite phase. At higher field, the structural transition from non-magnetic tetragonal phase to ferromagnetic cubic phase is responsible for the further increase of magnetization. As shown in Fig. 1 (c), during cooling process, there exists obvious difference between the standard and loop mode in the branch of ascending magnetic field. The isothermal entropy change calculated from both standard and loop process under magnetic field of 1 T, 2 T and 5 T is shown in Fig. 1 (e) (ascending process) and Fig. 1 (f) (descending process). Compared with the standard process, the peak value of is lowered from 30 J $kg^{-1}K^{-1}$ to 25 J $kg^{-1}K^{-1}$ under field change of 0-5 T in loop process. However, the magnetization of standard and loop modes keep consistent in the branch of descending magnetic field, as shown in Fig. 1 (d). This can be explained that the driven direction of the phase transition by temperature and magnetic field is converse in cooling and ascending process but consistent in cooling and descending process. Mechanism related to coexistence of multiphase is discussed.

Recently, the great scientific interest has focused on the design of smart materials, which exhibit large caloric effects (CE) combined with strong magnetoelectric (ME) coupling, for biomedicine and energy efficient technologies. As known, caloric materials are observed adiabatic temperature (isothermal entropy) changes, when the applied external field (magnetic, electric, mechanic) changes. Depending on type of external field stimulus, these caloric effects deals to magnetocaloric, electrocaloric and mechanocaloric effects. The phenomena relates with observation of two or more caloric effect, called as multicaloric effects and the materials, which demonstrate these effects-multicalorics. Multiferroics are advanced materials for multicaloric studies and the ME composites were proposed for it, due to their strong ME coupling. In this connection, recent studies conducted a search for multicalorics with high caloric effects and ME coupling around room temperature. The new multiferroic polymer composites with large magnetocaloric and ME effects around room temperature were fabricated, their structure, magnetic and ME properties were studied. Polymeric 0-3 type composites FeRh / PVDF and GdGeSi / PVDF, consisting of magnetocaloric microparticles $Fe_{50}Rh_{50}$ and $Gd_5Ge_{1.6}Si_{2.4}$ embedded into a piezopolymer matrix of polyfilidendenedluoride (PVDF) in mass ratios from 2 to 40%. The methodics for fabrication of flexible polymer ME composites based on magnetocaloric microparticles (Fe-Rh and Gd-Ge-Si) were developed, their structure and basic physical characteristics were studied in detail. Preliminary experiments on samples with mass fractions of the magnetic phase of 2 and 12% observed the presence of a ME interaction in the vicinity of the magnetic phase transition temperature of the magnetocaloric component of the composite, which can be used for applications in smart composites. In was experimentally demonstrated that the introduction of Gd-Ge-Si

microparticles into an electroactive PVDF with a volume fraction of 2 and 12%, gives rise to a ME coupling and, consequently, a multicaloric effect. *The work was supported by Russian Science Foundation (project #18-79-10176).*

DQ-19. Ising Model Simulations of the Magnetocaloric Material $Gd_5(Si_xGe_{1-x})_4$. *A. Evans*[1], M. Gao[2] and D. Read[1] *1. Physics & Astronomy, Cardiff University, Cardiff, United Kingdom; 2. Engineering, Cardiff University, Cardiff, United Kingdom*

The magnetocaloric effect (MCE) is characterized by an adiabatic change of temperature resulting from a varying external magnetic field. Recently, the giant MCE (GMCE) has become of greater interest due to its enhancement of the temperature response[1,2] achieved by coupling the effect with a crystallographic phase transition. New materials discoveries have allowed for MCE use at or close to room temperature[2]. An MCE based refrigeration system would allow for less environmentally harmful materials to be used with a higher efficiency and lower energy consumption[3]. The Ising model has previously been used to study MCE materials[4], based on modeling a set of localized sites in a 3D system each with an associated spin value. Here we employ the RKKY interaction, commonly used to describe the coupling in rare earth materials, in order to model the coupling strength as a function of bond length. We have investigated the effects of a changing inter-site distance, corresponding coupling and the associated energy for the crystal phases of GdSiGe. Our simulations show that a transition from an orthorhombic to monoclinic GdSiGe phase is energetically favourable over a temperature range of 96K to 300K, dependent upon a term introduced into the Hamiltonian to represent the bond energy (E) between interstitial slabs. Calculations show that a ferromagnetic orthorhombic phase exists as a lower energy state of the system than a ferromagnetic monoclinic phase (see figure 1). Increasing the bond energy (E) shows an increasing transition temperature up to 300K where the monoclinic phase is no longer favoured. Figure 2 shows that the peak value of the entropy change decreases as higher temperature transitions are achieved with increasing bond energy (E), calculations are shown for zero field and for magnetic fields of 5T.

At least three temperature induced phase transitions at $T=T_1$, T_M/T_A and, T_C related to ferromagnetic order of martensitic phase (FMMP), martensitic transitions (MT) and, ferromagnetic order of austenitic phase (FMAP), respectively, have been detected in the result of magnetic studies of off-stoichiometric Heusler alloys of $Ni_{50-x}Co_xMn_{35}In_{15}$ (x=1, 2.5) and $Ni_{45}Co_5Mn_{37}In_{13}$. The phase transition temperatures are found to be depended on alloy composition. The ground state (T=4.2 K and external field H=0) of the alloys was found to be characterized by three main lines; two, partially overlapping, in the higher frequency, (300-450) MHz, (most likely corresponding of manganese resonance lines) and one at lower frequency of about 200 MHz. Significant shift the spectrum of $Ni_{45}Co_5Mn_{37}In_{13}$ of about 100 MHz to higher frequencies was observed. This effect indicates approximately one third of the increased magnetic moment in the $Ni_{45}Co_5Mn_{37}In_{13}$. The correlation of magnetizations obtained from magnetic moment and NMR studies is discussed. We report on defects in C-doped ZnO powders and their role as a source of ferromagnetism in these compounds. The samples were prepared by standard solid-state reaction and sintering in either reducing (95 % Ar + 5 % H) or nitrogen atmosphere. For the samples sintered in a reducing atmosphere X-ray diffraction and X-ray photoelectron spectroscopy data gave evidence for C substitution at Zn sites (C_{Zn}) and for carbon in interstitial sites (C_i). X-ray photoelectron and Auger spectroscopy studies also demonstrated the presence of oxygen vacancies, zinc interstitials (Zn_i) and defect complexes involving C-C bonds. Magnetization studies showed room temperature ferromagnetism in these powders, with the saturation magnetization being largest for compositions with high concentration of carbon defect complexes with (C-C) bonds and with high Zn_i concentration. We relate the Zn_i and the defect complexes with C-C bonds to the formation and stabilization of Zn vacancies and thus support the prediction that ferromagnetism in ZnO type oxides is associated with cation (zinc) vacancies. Samples sintered in nitrogen, an atmosphere which favours hole doping, showed instead diamagnetic behaviour.

DR-03. Vacancy and doping modulated magnetic properties of InN monolayer. *R. Chaurasiya*[1], N. Kumar[1] and A. Dixit[1] *1. Physics, Indian Institute of Technology Jodhpur, Jodhpur, India*

The monolayers are widely explored because of their nteresting electronic properties with potential in next generation the optoelectronic devices [1-3]. InN monolayer is one of the most interesting materials in semiconductor. Bulk InN is a narrow band gap material with very high electronic mobility [4-6]. Thermoelectric devices, solar cells and high speed electronic devices are realized with InN and nanostructuring may lead to further enhancement in these properties. InN monolayer may be a promising material with desired physical properties for such applications [7-8]. In nitride semiconductors, the experimental and theoretical work is focused on understanding the properties of bulk materials and their potential in electronic devices such as light emitting diodes (LEDs), field effect transistors (FET) [9]. There are efforts to understand nanostructured systems and researchers have explored III-Nitride monolayers for their optoelectronic properties. However, there are limited studies available on magnetic properties of InN monolayer. We investigated the onset of magnetization in thermodynamically stable InN monolayer, Fig 1. by modulating the vacancy defects such as In, N, both In/N and the antisite defects such as In↔N sites. The light elemental dopants such as B, Be, C, F, Li, and O at N site are investigated to understand the change in magnetic properties of InN monolayer. In, N and In/N vacancy defects showed 3.00 μ_B, 0.00 μ_B and 2.00 μ_B magnetic moment, respectively, whereas antisite vacancies do not exhibit any mangetization in InN monolayer. Further, we observed 0.04 μ_B, 0.91 μ_B and 1.09 μ_B magnetic moment with the extrinsic B, Be, and C dopants, respectively while other dopants do not exhibit any magnetization. Thus, we showed the onset of magnetic ordering by manipulating the vacancy and dopant defects. The microscopic origin of magnetic behaviour will be discussed in terms of computed charge density, electronic band structure and density of states.

DR-04. Spin wave resonance study in a series of etched ferromagnetic semiconductor films. *X. Liu*[1], Y. Zhou[1], S. Bac[2,1], S. Lee[2], M. Dobrowolska[1] and J.K. Furdyna[1] *1. Physics, University of Notre Dame, Notre Dame, IN, United States; 2. Physics, Korea University, Seoul, The Republic of Korea*

Although ferromagnetic semiconductor films have already been investigated for the last two decades, some fundamental issues still puzzle the researchers in this field. One of these issues is how the magnetic anisotropy field is distributed along the growth direction. Two models, the volume inhomogeneity model and surface inhomogeneity model, are proposed to address the inconsistent features observed in spin wave resonance (SWR) studies.[1] To solve such inconsistencies, a series of etched samples formed by wet-etching a 158-nm GaMnAs film for 2min, 4min, 7min and 10min were studied by XRD, SQUID and FMR. The thicknesses of the etched GaMnAs films were determined by XRD measurements, using the oscillations observed in ω-2θ scans around the GaAs (004) plane, as shown in Fig. 1. It should be mentioned that the XRD peaks from GaMnAs films are constant for all etched samples, indicating the Mn content to be the same along the growth direction. Magnetizations of the films are measured by SQUID as a function of field and temperature, and are the same for all etched samples. However, SWR measurements obtained with dc field perpendicular to the sample plane at 4K (Fig. 2) reveal a series of modes which vary linearly as a function of field, indicating a parabolic magnetic anisotropy field along the growth direction. However, such a magnetic anisotropy profile is inconsistent with the position of the main FMR peak as a function of film thickness in etched samples. In order to reconcile such inconsistencies, we conducted angular dependent SWR measurements in all etched samples to map the surface anisotropy using the newly reported spherical surface pinning model.[2] These results suggest the approach to reconcile the inconsistencies between the two inhomogeneity models. For completeness, we also plan to carry out similar measurements on GaMnAsP films to further expand our understanding to magnetic systems with perpendicular anisotropy.

DR-05. Effect of annealing on magnetic properties of graded GaMnAsP film. *S. Bac*[1,2], K. Lee[1], S. Lee[1], X. Liu[2], M. Dobrowolska[2] and J.K. Furdyna[2] *1. Department of Physics, Korea University, Seoul, The Republic of Korea; 2. Department of Physics, University of Notre Dame, Notre Dame, IN, United States*

Ferromagnetic films with out-of-plane (OP) magnetic anisotropy have been extensively studied because of the wide applications in magnetic devices with perpendicular magnetization[1,2]. Magnetic easy axes of ferromagnetic semiconductor GaMnAs, which is normally in the film plane when it is grown on GaAs substrate[3], can be changed to OP by alloying GaMnAs with phosphorus. Here we investigate magnetic properties of GaMnAsP thin film with graded phosphorus composition. The phosphorus content was varied from 0 % to 30 % along the vertical direction in the film. Hall measurement of as-grown graded GaMnAsP film showed the presence of both in-plane (IP) and OP magnetization in the film. Transitions involving these magnetization are distinguished in the figure: the sharp transitions at very low fields represent the reversal of the OP magnetization characteristic of the phosphorus-rich part of the graded sample; and the transitions at higher fields correspond to rotation of IP magnetization between IP easy axes. Both types of transitions are accompanied by their own hystereses. From the analysis of anomalous and planar Hall effects, the portion of magnetic components with OP and IP easy axes was obtained to about 20 % and 80 %, respectively, in the graded film. After low temperature annealing of the sample, the Curie temperature increases in both components, and the coercive field is enhanced in the film, especially for the component with vertical magnetic easy axis. The most prominent feature of the annealing effect for our graded GaMnAsP film is the significant change in the ratio of magnetic components with OP and IP easy axes. Specifically, the ratio of the OP magnetization in the annealed GaMnAsP film increased to nearly 60 % of the entire film, while the IP component reduced to 40 %, thus showing that the relative portions of the graded GaMnAsP film with magnetization having OP and IP easy axes can be selectively controlled by the annealing process.

DR-06. Muon-Spin-Relaxation Study of Ferromagnetic Insulator (Ga,Mn)N. *K. Gas*[1], T. Prokscha[2] and M. Sawicki[1] *1. Institute of Physics, Polish Academy of Sciences, Warsaw, Poland; 2. Laboratory for Muon Spin Spectroscopy, Paul Scherrer Institute, Villigen PSI, Switzerland*

$Ga_{1-x}Mn_xN$ belongs to the well-known family of dilute ferromagnetic semiconductors which exhibits low-temperature ferromagnetism driven by ferromagnetic superexchange among the Mn^{3+} ions. However, in this material systematic information about the uniformity and of the volume fraction of the ferromagnetic phase and on the distribution of internal fields is generally lacking. We report here on the results of the very first studies of spatial homogeneity of ferromagnetic phase in the $Ga_{1-x}Mn_xN$ using muon-spin-relaxation (μSR) spectroscopy applied to a single phase and high quality molecular beam epitaxy grown $Ga_{1-x}Mn_xN$ layer with x = 10% and Curie temperature T_C = 10 K [1]. Our μSR measurements revealed that the magnitude of the asymmetry parameter A started to saturate (or the magnetic volume fraction rolled off to zero) at temperatures being about 5 and 10 K above the value of the T_C established beforehand for this sample by SQUID magnetometry [1]. These temperature scans were obtained for 50 and 1500 Oe in transverse field (TF) configuration, respectively, and are indicative that the magnetic configurations of Mn species are strongly affected by the external field, at least on a time scale relevant to μSR. Another rather unexpected finding of our μSR measurements is the observation that the temperature dependence of the TF μSR depolarization rate λ has truly a λ-like shape, when plotted in a log-log scale, peaking strongly at T = 20 K, that is where A starts to saturate. Above this temperature λ obeys a clear power law dependence on T, $\lambda \sim T^{-\alpha}$, where $\alpha > 0.2$ μs^{-1}, corresponding to a previously observed similar dependence of magnetic susceptibility in $Ga_{1-x}Mn_xN$ [2]. We assign this nonstandard dependence to a gradual formation of coupled neighbor spin clusters (spin pairs, triplets, etc.) on lowering temperature. Importantly, these clearly non-zero values of λ are seen well above T_C in a very well characterized single phase material [1]. This work has been supported by the National Science Centre, Poland through grants DEC-2014/12/S/ST3/00549 and DEC-2018/31/B/ST3/03438.

DR-07. Investigating Surface-Induced Ferromagnetism in Pristine SnO_2 Film. *J. Kim*[1], S. Song[1], Y. Choi[1], D. Lee[1], H. Kim[2], H. Lee[2], J. Bae[3] and S. Park[1,3] *1. Physics, Pusan National University, Busan, The Republic of Korea; 2. Core Research Facilities, Pusan National University, Busan, The Republic of Korea; 3. Busan Center, Korea Basic Science Institute, Busan, The Republic of Korea*

The understanding ferromagnetic origin in semiconducting oxides, known as d^0-ferromagnetism, is an important subject not only for the fundamental interests but also for the potential applications in modern spin-based semiconductor devices. For example, SnO_2 film exhibits reproducible ferromagnetism well above room temperature even without magnetic cation doping. Since conventional super-exchange or double-exchange interactions cannot explain a long-range ordering in this system, defects have been considered as the source of the room temperature ferromagnetism. However, the main reason for the ferromagnetic order in SnO_2 is still unclear due to the lack of experimental evidence. We investigated the film thickness-dependent magnetic property of pristine SnO_2 films to understand the role of defects (either tin or oxygen vacancies) on the ferromagnetism. We found that the magnetization in the unit of surface area was consistent with respect to the film thickness, deducing a magnetic moment resides at the film surface or interface. Based on X-ray photoelectron spectroscopy, the amount of oxygen vacancy at the surface was consistent as well as the magnetization, supporting a magnetic ground state is induced at the surface of SnO_2 film by the oxygen vacancy. These works are supported in part by NRF-Korea (NRF-2017K1A3A7A09016305 and NRF-2018R1D1A1B07045663) and Korea Basic Science Institute (KBSI) grant (C38529) to Sungkyun Park.

DR-08. Large Tunable Magnetoresistance in Half-Heusler Compound RPtBi (R=rear earth). *J. Chen*[1,2], H. Li[1,2], B. Ding[1,2], Z. Li[1,2], Z. Hou[3], E. Liu[1,4], H. Zhang[1], X. Xi[1], G. Wu[1] and W. Wang[1,4] *1. Institute of Physics, Chinese Academy of Sciences, BeiJing, China; 2. University of Chinese Academy of Sciences, BeiJing, China; 3. South China Normal University, Guangzhou, China; 4. Songshan Lake Materials Laboratory, Dongguan, China*

Heusler is multifunctional platform to study the physical properties for their large amounts of compounds and the high tunableness. Recently, large amounts of half-Heusler compounds were predicted to be topological semimetals, which host diversity novel physical properties. The one of physical properties is large magnetoresistance, which has potential applications in future high-performance magnetoelectric devices. As the previous literature report, the large nonsaturating positive MR were observed in YPtBi[1] and LuPtBi[2]. But the haf-Heusler RPtBi (R=heavy rear earth) has not been systematic study. Here, we will present the results of (Tb, Ho, Er, Tm)PtBi. The carrier type of compounds change from single carrier to two type of carriers with the atomic number Z increasing. And the electron-hole-compensated play an important role in getting large MR. The compounds ErPtBi and TmPtBi with two kinds of carriers host a large MR, which is up to 1400% and 1800%, respectively. And comparing the values of MR, we can find the fact that the MR can be tune effectively by rear earth R.

Synchrotron Radiation Research Organization, The University of Tokyo, Sayo-cho, Japan*

Since half-metallic ferro- or ferrimagnets have been theoretically predicted in many kinds of Heusler alloys [1,2], a large number of investigations have been carried out from the interest in the field of spintronics. When electrons around the Fermi energy (E_F) are completely spin-polarized, a system must be very useful as a ferromagnetic electrode for the tunnel magnetoresistance and spin injection as well as various spin utilizable devices. In the present study, bulk sensitive resonant inelastic soft x-ray scattering (RIXS) was performed under an external magnetic field in order to verify the half-metallic electronic states of V and Mn 3*d* electrons in the ferrimagnet Mn_2VAl Heusler alloy. RIXS for V and Mn 2*p* core excitation was measured at room temperature using the ultrahigh resolution soft X-ray emission spectroscopy in BL07LSU of SPring-8, Japan, with using a single crystal of Mn_2VAl. For the measurement, external magnetic field of 0.25 T was applied by a permanent magnet [3,4]. The *d*-*d* excitation due to the t_{2g}-e_g splitting is clearly observed for V in Mn_2VAl under the L_3-edge excitation, and the loss energy is comparable to the splitting energy between the theoretically predicted e_g and t_{2g} states. The delayed branching off in the V 3*d*-2*p* fluorescence peak from the elastic peak demonstrates the nearly absent V 3*d* partial density of states (PDOS) around E_F. Figures show RIXS spectra measured at incoming photon energy, $h\nu_{in}$ of 512.5 eV (a) and 638.6 eV (b) at the V and Mn L_3-edges for Mn_2VAl alloy, respectively, together with the difference between them (MCD). The RIXS-MCD of the fluorescence peaks of Mn 3*d*-2*p* transition under the L_3-edge indicates negative two peak's behavior with clear hn_{in} dependence. Such an MCD behavior is reproduced in consistence with the calculated spectra, suggesting the half-metallicity of Mn_2VAl Heusler alloy [5].

DR-10. Disorder and the Spin Gapless Semiconductor, Mn_2CoAl. R.G. Buckley[1,2], T. Butler[1], C. Pot[1], N.M. Strickland[1] and *S. Granville*[1,2] *1. Robinson Research Institute, Victoria University of Wellington, Lower Hutt, New Zealand; 2. MacDiarmid Institute for Advanced Materials and Nanotechnology, Wellington, New Zealand*

Band structure calculations of Heusler alloy Mn_2CoAl have identified it as a potential spin-gapless semiconductor [1]. However, more recent calculations indicate significant sensitivity of the band structure to deviations from the ideal stoichiometry and inter-site disorder [2,3]. Experimental reports to date [4-7] have generally not invoked disorder to understand the physical properties of Mn_2CoAl. We present a study of DC sputtered Mn_2CoAl films on MgO using temperature and field-dependent resistance, magnetisation, and anomalous Hall measurements. We also report reflection spectroscopy from the far infrared to the UV. Interestingly, in general the temperature-dependent resistivities reported in the literature, including ours, show the same behaviour, notably the same magnitude and a small, negative temperature coefficient of resistivity (100-700 μΩcm and -2 x 10-4 ppm/K respectively). This behaviour is often seen in highly disordered metals rather than semiconductors. We have successfully employed a weak localisation model to describe this behaviour emphasising the role of disorder (Fig. 1). This conclusion is supported by the infrared reflection study where the response at energies below the inter-band absorption can be understood largely by a single Drude term with a relatively large scattering-rate similar to that calculated from the DC resistivity data (Fig. 2). Moreover, we observe that the magnetic behaviour is also consistent with significant compositional and anti-site disorder. We conclude that the characteristics of our Mn_2CoAl thin films result from disorder rather than intrinsic properties. These characteristics are common to most published reports on this material to date, indicating that significantly more care needs to be taken to isolate the role of disorder and correctly identify the behaviour of potential spin-gapless semiconductor materials.

DR-11. Magnetic properties and tunnel magnetoresistance effect of fully compensated ferrimagnetic Mn-Co-V-Al Heusler alloy. *T. Tsuchiya*[1] and S. Mizukami[2,1] *1. Center for Science and Innovation in Spintronics (Core Research Center) and Center for Spintronics Research Network, Tohoku University, Sendai, Japan; 2. WPI Advanced Institute for Materials Research, Tohoku University, Sendai, Japan*

Mn-Co-V-Al Heusler alloy is one of candidate for a fully compensated ferrimagnet(FCF). $(Mn\text{-}Co)_2VAl$ was predicted to be a FCF, however, the Curie temperature was lower than room temperature (RT) [1]. Recently, the magnetization compensation was experimentally observed in a Mn_2(Co-V)Al alloy [2-3]. Furthermore, the Curie temperature was estimated to be 695 K, which was higher than RT. The half-metallicity of Mn_2(Co-V)Al was demonstrated by first principles calculation [3]. However, there are no reports to fabricate the Mn_2(Co-V)Al film. In this study, we investigated the magnetic properties of the Mn_2(Co-V)Al films and the tunnel magnetoresistance (TMR) effect for the magnetic tunnel junctions with its electrode to gain insight into its half-metallicity. Samples were prepared by the magnetron sputtering. The stacking structures of the single layer samples and MTJs were MgO(001) sub./ Mn-Co-V-Al (30)/ MgO (2)/ Ru (2) and MgO(001) sub./ Mn-Co-V-Al (30)/ Mg (0.4)/ MgO (2)/ CoFe (5)/ IrMn (10)/ Ru (8) (thickness is in nm), respectively. The Mn-Co-V-Al layer was deposited at 700°C and the other layers were deposited at the room temperature (RT). The crystalline structures were characterized by x-ray diffraction (XRD). The magnetic properties were measured by a vibrating sample magnetometer (VSM). The microfabrication of the MTJs were performed using a standard photo-lithography technique. The TMR effect was measured by a four-probe method. The XRD measurements indicated that Mn_2VAl and $Mn_2Co_{0.5}V_{0.5}Al$ samples have the $L2_1$ or XA ordering. The magnetization for Mn-Co-V-Al films were smaller than the bulk value. However, its composition dependence was similar to that for bulk experiments, and the magnetization compensation was confirmed for $Mn_2Co_{0.5}V_{0.5}Al$. The TMR effects were observed for Mn-Co-V-Al films and the TMR ratios were -0.5%, 0.12% and 0.05% for Mn_2VAl, Mn_2CoAl and $Mn_2Co_{0.5}V_{0.5}Al$, respectively. These signs of TMR effects for Mn-Co-V-Al were consistent with the spin polarization for those alloys predicted from the first principles calculation. The origin of the small TMR ratio will be discussed. This work was partially supported by KAKENHI(No. 18H05948) and CREST(No. JPMJCR17J5).

DR-12. Experimental and theoretical investigations of half-metallic $Co_{2-x}Fe_xCrAl$ (x = 0.25, 0.50 and 0.75) Heusler alloys. *A.K. Patel*[1], L. Bainsla[2], V. Yenugonda[1], K. Suresh[1] and A. Alam[1] *1. Physics, IIT Bombay, Mumbai, India; 2. WPI Advanced Institute for Materials Research, Tohoku University, Sendai, Japan*

Heusler alloys gained renewed interest for the last three decades due to the discovery of half-metallic property in some of the alloys [1]. Recent studies have shown that equiatomic Heusler alloy CoFeCrAl is interesting due to the halt metallic nature [2]. In this work, we have explored the structural and the magnetic properties of $Co_{2-x}Fe_xCrAl$ (x = 0.25, 0.50 and 0.75) using experimental and theoretical tools. All the arc melted alloys crystalize in $L2_1$ structure. Rietveld refined room temperature XRD for $Co_{1.50}Fe_{0.50}CrAl$ is shown in fig. 1(a). The absence of (111) reflection indicates the B2 type of disorder, possibly resulting from the nearly equal electronegativities of Al and Cr. Fig. 1(b)-(d) show the field dependent magnetization of $Co_{2-x}Fe_{x}$-CrAl. The moments for x = 0.50 and 0.75 are close to the estimated moments using the Slater-Pauling rule and hints at the half-metallic nature. T_C of $Co_{2-x}Fe_xCrAl$ (x = 0.25, 0.50 and 0.75) are found to be 540, 696 and 530 K respectively. Hence, these compositions are suitable for room temperature spintronic applications. Electronic structure calculations show that half-metallic nature is present for x = 0.50 and 0.75. Fig 2(a) shows the spin-resolved DOS for x = 0.50 and fig. 2(b) shows the unit cell used for it. Other possible disorders for x= 0.50 were also considered and calculations carried out. Half-metallic nature is found to be robust irrespective of the disorder. All the three compositions of $Co_{2-x}Fe_xCrAl$ are found to crystallize in $L2_1$ structure. The compositions for x= 0.50 and 0.75 follow the Slater-Pauling rule, which hints the possibility of half-metallic nature. Maximum anomalous Hall effect is found to be 1.81 μΩ-cm and decreases with increasing temperature, which is following the magnetization. Theoretical simulation confirms the half-metallic nature irrespective of antisite disorder for x=0.50 and 0.75 compositions. Hence it can be concluded that these two compositions are potential candidates for spintronic applications.

Transition metal dichalcogenides (TMDCs) have received a lot of attention due to a plethora of exciting physical phenomena and their excellent electronic, optical, thermal and mechanical properties [1-3]. TMDCs can exist in several different phases displaying a variety of electronic properties including semiconducting, metallic, superconducting, topological insulators and Weyl Fermionic states. TMDCs also possess high spin-orbit coupling (SOC), which gives rise to spin polarized surface states in topological insulators and Weyl semimetals. Here, we present our investigations on Weyl semi-metal candidate $MoTe_2$ by both electronic transport experiments and density functional theory (DFT) calculations. The basic material properties were investigated by electron, thermal and magneto-transport measurements. We observed the structural phase transition from 1T' to T_d in both resistivity and Seebeck coefficient measurements, and significant spin-orbit coupling as evident from weak anti-localization signatures (Figure 1). The samples exhibit a very large and strongly anisotropic resistivity anomaly in the T_d phase of $MoTe_2$ that occurs between 25 and 50 K. This is up to 13% in the temperature window between 25 and 50 K, which is found to be strongly anisotropic. Based on the experimental data in conjunction with density functional theory calculations, we conjecture that the anomaly can be related to the presence of defects in the system. These findings open opportunities for further investigations and understanding of the transport behavior in these newly discovered semi-metallic layered systems.

National Nanofab Center, Daejeon, The Republic of Korea; 5. Mainz University, Mainz, Germany*

Mn-based Heusler compounds have been received of great interest due to the tetragonally distorted structure showing half-metallic ferrimagnetism, which has an advantage of low saturation magnetization requisite for spin-transfer-torque based spin devices. The magnetization of tetragonal Mn_3Ga vanishes over a wide range of temperature because the magnetic moments of two Mn sublattices are antiferromagnetically aligned with different magnitude [1,2]. However, the tetragonal distortion tends to destroy the compensated ferrimagnetism as well as the half-metallic behavior [1,3]. In theory, Mn_3Ga can crystallize in an ordered $D0_3$ cubic phase, which is predicted to display half-metallicity with collinear antiferromagnetic order, anticipating both complete spin polarization and zero net magnetic moment [4,5]. However, the ordered phase of cubic Mn_3Ga has not been experimentally verified yet in a bulk or film form. In the present work, we have successfully fabricated hetero-epitaxial Mn_3Ga films with stable cubic phase by using RF magnetron sputtering method. We report the structural, magnetic, and electrical properties of the cubic Mn_3Ga (C-Mn_3Ga), in comparison with the tetragonal phase (T-Mn_3Ga). The structural analyses reveal that C-Mn_3Ga deposited with low RF power crystallizes in the disordered Cu_3Au-type fcc structure, and it transforms to T-Mn_3Ga as the power increases. Compared to theoretical calculations for ordered cubic phase, Ga atoms exchange their positions with MnI and MnII atoms to have an equal number of MnI and MnII atoms, and the spin moments are aligned ferromagnetically in layers which are stacked antiferromagnetically. We find the antiferromagnetic transition at T_N = 400 K for C-Mn_3Ga, while the ferrimagnetic transition at T_C = 800 K for T-Mn_3Ga. Furthermore, the electrical resistivity is higher in the antiferromagnetic phase of C-Mn_3Ga than that in the ferrimagnetic phase of T-Mn_3Ga.

Department of Physics & Astronomy, Louisiana State University, Baton Rouge, LA, United States

Two metamagnetic Heusler alloys based on $Ni_{45}Cr_5Mn_{37}In_{13}$ with differing Mn concentrations (by 0.2 at. %) were studied using magnetization, resistivity, and Hall resistivity measurements. It is shown that this small variation in composition leads to fundamental changes in magnetic properties. Near the martensitic phase transitions, the anomalous Hall coefficient (R_S) was found to increase with temperature while the resistivity (ρ) decreases. Thus, in the case of $Ni_{45}Cr_5Mn_{37}In_{13}$, the general correlation between R_S and ρ, considered as applicable for all crystalline and amorphous ferromagnetic alloys, breaks down completely. We explain this behavior in the framework of an s-d model where it is assumed that the resistivity and anomalous Hall effect (AHE) are determined by different groups of current carriers. The obtained results on the AHE can shed light on the long-standing discussion regarding the mechanism of the martensitic transition in Heusler alloys. DR-16. Effect of stoichiometry on crystal structure and magnetism in $Mn_{3-x}Cr_xGa$ ($0 \le x \le 2$) Heusler alloy.
S. Perween[1,2], A. Rathi[1,2], B. Gahtori[1,2] and *G. Basheed*[1,2] *1. National Physical Laboratory, Delhi, India; 2. NPL -Campus, Academy of Scientific and Innovative Research (AcSIR), Delhi, India*

The Cr doped tetragonal $D0_{22}$ Mn_3Ga Heusler alloy has been emerged as an potential candidate for spintronics applications after observation of Mn_2CrGa [1] as a half metallic ferrimagnet with high Curie temperature (T_c ~ 800 K) but interestingly in cubic structure (B2-type). In order to obtain high magneto crystalline anisotropy, many groups [2, 3] have done theoretical and experimental studies to search for the possibility of phase transformation from a cubic to tetragonal phase. Here, we have synthesized the full series of Cr-doping, $Mn_{3-x}Cr_xGa$ (x = 0, 0.5, 1, 1.5, 2) alloys synthesized by arc melting method. The $D0_{22}$ symmetry holds upto x = 0.5, after which the disordering of tetragonal symmetry is observed, which leads to an observation of a mixed phase (~ 85% $D0_{22}$ & ~15% B2-type) and (~ 40% $D0_{22}$ & 60 % B2-type) for x = 1 (Mn_2CrGa) & 1.5, respectively, and finally, single phase B2-type cubic phase for x = 2 ($MnCr_2Ga$). In initial magnetization study with Vibrating sample magnetometer (VSM, 2T), the magnetization for x = 0.5 increases with spontaneous magnetization, M_s ~ 24 emu/g, remanent M_r ~ 18 emu/g (only at 2T field) and minimal decrease of H_c from parent Mn_3Ga. In end members from Mn_3Ga (x = 0) to $MnCr_2Ga$ (x = 1), the magnetic nature changes from hard magnet (Hc = 3.71 kOe for x =0) to soft magnet (Hc = 1.53 kOe for x = 2), as seen in Fig.1. The coercivity mechanism of $Mn_{3-x}Cr_xGa$ (x = 0.5, 1) is evaluated from field dependence Ms and Hc through hysteresis loops up to 2T [see Fig. 2] where the alloys confirm the movement of domain wall with low impedance through nucleation mechanism. The more detailed structural and magnetic measurements are going on to understand the effect of Cr-doping on destabilization of tetragonal $D0_{22}$ phase and adoption of B2-type cubic symmetry and its role on magnetization in these alloys. *Key words: Heusler alloy, spintronics, magneto crystalline anisotropy*

DS-01. Exploring magnetic resonance with a compass. *D. Nelson*[1], E. Cookson[1], M. Anderson[1], D. McKinney[2] and I. Barsukov[1] *1. Physics and Astronomy, UC Riverside, Riverside, CA, United States; 2. Santa Rosa Academy, Menifee, CA, United States*

Magnetic resonance plays an important role in today's science, engineering, and medical diagnostics. Learning and teaching magnetic resonance is challenging since it requires advanced knowledge of condensed matter physics and quantum mechanics. Driven by the need to popularize this technologically impactful phenomenon, we develop an inexpensive table-top demonstration experiment. It unveils the magnetic resonance of a hand-held compass in the magnetic fields of a permanent magnet. The setup provides an immediate visualization of the underlying physical concepts and allows for their translation to broad student audiences. This work was supported by the National Science Foundation under Grant No. ECCS-1810541.

DS-02. Magnetic Fields Web Series: Engaging Middle School Students in STEM. *P. Pena Martin*[1], J. Isberg[1], E. Ertekin[1,3], V. Lorenz[1,2] and N. Mason[1,2] *1. Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 2. Department of Physics, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 3. Department of Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, United States*

Web based media can make scientific content accessible to audiences far beyond the scientific community. We created a web series called "Magnetic Fields" that aims to introduce materials science, particularly concepts related to magnetism, and promote themes more general to STEM fields, such as persistence and the scientific process, through use of characters and a story geared towards a middle school audience. The goal is to build and maintain interest in science at an age where this tends to drop off. The four-episode arc follows a group of high school characters as they encounter a strange new material during a class field trip to a laboratory. The series is directed by John Isberg, with professional actors making up most of the cast. The series was initiated by scientists in the Illinois MRSEC, and the storyline was developed in collaboration with MRSEC students and faculty. The episodes were released in May 2019 through Youtube. We report on the process of creating this series, response to it upon release, and discussion of its use as an educational tool. The authors acknowledge primary support of the NSF through the University of Illinois at Urbana-Champaign Materials Research Science and Engineering Center DMR-1720633.

DS-03. In-class experiments with smart phones for teaching upper-level electricity and magnetism. A. Davidson[1], A. Ranjan[2] and *X. Fan*[1] *1. Physics and Astronomy, University of Denver, Denver, CO, United States; 2. Cherry Creek High School, Greenwood Village, CO, United States*

Interactive-engagement method such as studio physics [1, 2], has demonstrated higher learning gains than traditional lecturing in intro-level physics classes. However, there have been limited applications in upper-level classes, such as Electricity and Magnetism (E&M), possibly because experiments on E&M topics can be too costly and sophisticated to be carried out in the classroom. Smart phone, which is equipped with magnetic field sensors, radio signal detectors and light sensors, provides a convenient platform for carrying out E&M-related experiments. In this poster, we will present three examples of the implementation of smart-phone-based studio physics in an E&M class for Physics majors: (1) Detection of earth magnetic field inclination; (2) quantifying skin depth of aluminum foil with cellphone tower signals; and (3) Measurement of Brewster's angle. Besides sensitive sensors, smart phone also has computational power, which can be explored to further expand the breadth and depth of the smart-phone-based studio physics. Due to the wide accessibility of smart phones and the simplicity of experimental setup, we expect this teaching technique can be easily transferred to other institutes in the world.

DS-04. The Use of Virtue Modules in Physics Lab Teaching. *W. Zhang*[1], R. Bidthanapally[1], T. Sebastian[2], Y. Xiong[1,3], H. Qu[3] and J. Sklenar[4] *1. Physics Department, Oakland University, Rochester, MI, United States; 2. THATec Innovation GmbH, Mannheim, Germany; 3. Electronic and Computer Engineering, Oakland University, Rochester, MI, United States; 4. Physics Department, Wayne State University, Detroit, MI, United States*

Lab sessions in physics education connect the fundamental concepts to practical examples and are effective measures of the students' understanding and reasoning through ultimate real-world tests. Many topics in condensed

matter physics are known to be challenging to convey in both lectures and labs. In addition, these topics are usually resource demanding, which has been one of the challenging issues. Here, we introduce and demonstrate the use of virtue lab modules for teaching physics labs and for effectively integrating research and education. Experiments that are relevant to magnetism and spintronics include, but not limited to, spin current detecting, microwave energy harvesting, and spin-based thermoelectric effects. An important highlight of these modules is the highly-interactive laboratory learning platform. In the class, each piece of experimental hardware (e.g. electrometers, oscilloscopes, etc) will be paired with a computer-based virtual module. The individual modules mimic the hardware, which the students can use to become familiar with the hardware, acquire real-time feedback, and visualize the data acquisition dynamics, on-demand and risk-free. The virtual component is also helpful for demonstrating delicate, shared hardware in class, without risk of damaging the actual instrumentation. These individual components are connected to a central operating system and the experiment can be re-programmed by simple coding and user-interfaced commands [1]. Work at Oakland University is supported by NSF DMR-1808892.

Session DT
MAGNETIC CHARACTERIZATION IV: PHOTON, ELECTRON AND NEUTRON BASED TECHNIQUES (Poster Session)

Hendrik Ohldag, Chair
Lawrence Berkeley National Laboratory, Berkeley, CA, United States

DT-01. Super-Resolution Magnetic Microscopy using Nitrogen-Vacancy Centers in Diamond. *N. Mosavian*[1], B.A. Richards[1], P. Kehayias[2] and V.M. Acosta[1] *1. Center for High Technology Materials and Department of Physics and Astronomy, University of New Mexico, Albuquerque, NM, United States; 2. Sandia National Labs, Albuquerque, NM, United States*

Nitrogen-vacancy (NV) centers are point defects in diamond whose fluorescence is sensitive to magnetic fields. They are among the most sensitive magnetic field sensors and are now routinely used for quantitative magnetic imaging [1]. Typically the imaging resolution is limited by optical diffraction to a few hundred nanometers. We are developing a new tool that uses 2-D optical lattices (Fig. 1) and the nonlinear optical properties of NV centers to realize parallel magnetic microscopy with a resolution that may approach 10 nanometers. We intend to use the microscope to study the nanoscale magnetic properties of superparamagnetic nanoparticles and correlated electron materials, such as superconductors.

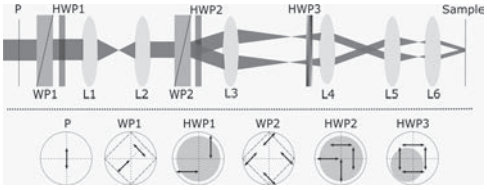

Figure 1: 2D optical lattices. Top: Optical setup to obtain a 2-D optical lattice. An unpolarized 637 nm laser beam passes through the polarizer P before entering the first Wollaston prism WP1. The relay lenses L1 and L2 project the two beams onto a second Wollaston prism WP2, resulting in four symmetric beams with equal power. Lenses L3, L4, and L5 project the beams onto the back aperture of the objective (L6). The end result is a 2D square optical lattice with a pitch of ~0.5-1 micrometers (depending on the choice of objective). Bottom: Polarization of beams after each optical element. Three half wave plates (HWP) are placed in different locations to generate the desired polarization for interference. The gray area indicates the region covered by each HWP.

DT-02. Ultrafast Magnetic Spectroscopy, Scattering and Full-Field Imaging Using Tabletop High Harmonic Sources. *P.C. Johnsen*[1], R. Karl[1], J. Thurston[1], J. Knobloch[1], C. Gentry[1], H. Kapteyn[1] and M. Murnane[1] *1. JILA / CU Boulder, Boulder, CO, United States*

We present scattering and full field imaging of magnetic nanostructures and dynamics using EUV high harmonic sources. By harnessing the high spatial and temporal coherence, as well as the ability to shape the polarization and orbital and spin angular momentum, we can uniquely spectroscopically probe and image very fast spin dynamics, on few-femtosecond timescales on up.

DT-03. Polarization analysis on the small-angle neutron scattering diffractometer KWS-1: A faster, more versatile instrument. *L. Barnsley*[1], A. Feoktystov[1], E. Babcock[1], Z. Salhi[1] and H. Frielinghaus[1] *1. Jülich Centre for Neutron Science (JCNS) at Heinz Maier-Leibnitz Zentrum (MLZ), Forschungszentrum Jülich GmbH, Garching, Germany*

A number of upgrades have been made to the KWS-1 small-angle neutron scattering (SANS) instrument, operated by the Jülich Centre for Neutron Science (JCNS) and located at the research reactor FRM II of the Heinz Maier-Leibnitz Zentrum (MLZ) in Garching, Germany. A neutron flux on the sample of 1×10^8 cm^{-2} s^{-1} makes it one of the most intense SANS instruments in the world, while an optional double-disc chopper can reduce wavelength spread down to $\Delta\lambda/\lambda = 1\%$ [1], allowing for high resolution measurements. In this presentation, we will describe two recent upgrades, aimed towards optimization of studies of nanoscale magnetic correlations. The first is the installation of an upgraded detector. In September 2018, we were able to achieve commissioning of a new detector consisting of an array of ^{3}He tubes interfaced with fast electronics (supplied by GE Reuter Stokes, OH, USA) to minimize dead-time for high-intensity measurements. An increase in the total detected area resulted in a new maximum Q-range of 0.7 Å^{-1}, a 60% improvement over the previous geometry. ^{3}He provides improved discrimination from background events, increasing signal-to-noise, while a faster detector response allows us to increase the source aperture for even shorter measurement times. In-line with our development of KWS-1, particularly for the magnetic SANS community, we report on recent developments for the option of measuring with polarization analysis. An analyser cell with polarized ^{3}He allows detection of all four scattering cross-sections with a Q_{max} exceeding 0.06 Å^{-1}. The ^{3}He cell is contained inside a μ-metal chamber, designed in-house by our JCNS ^{3}He group, to ensure a high degree of uniformity of the magnetic field at the cell position. In recent experiments, a cell lifetime of more than 90 hours was achieved. A new option for in-situ polarization of a ^{3}He cell, allowing for time-independent analyzing efficiency of post-scattered neutrons, will be discussed.

DT-04. Second harmonic response of magnetic nanoparticles enhanced by a static bias magnetic field perpendicular to an alternating excitation field for magnetic particle imaging. S. Ota[1], K. Nishimoto[2], T. Yamada[2] and *Y. Takemura*[2] *1. Department of Electrical and Electronic Engineering, Shizuoka University, Hamamatsu, Japan; 2. Department of Electrical and Computer Engineering, Yokohama National University, Yokohama, Japan*

Magnetic particle imaging (MPI) has attracted attention as a medical imaging technique using magnetic nanoparticles (MNPs) as tracers [1]. The harmonic signals of MNPs generated on applying an alternating-current (AC) magnetic field are detected for MPI. In a previous research, we studied the effects of a particle structure on the harmonics [2]. In this study, we reveal a large second harmonic on the application of an AC field with a direct-current (DC) bias magnetic field instead of the third harmonic shown in conventional research works. We prepared the Fe_3O_4 nanoparticles commercially distributed as M-300 by Sigma Hi-Chemical Inc., which were bonded with epoxy to form the measured sample. Two types of directions were set for the

AC field, H_{AC}, DC bias field, H_{DC}, and signal detection. In set A and B, H_{AC} was respectively perpendicular and parallel to H_{DC}, which in turn was parallel to the signal detection (Fig. 1(a)). The intensity and frequency of H_{AC} were 4 kA/m and 10 kHz, respectively. The gradient of H_{DC} was 1 T/m. The second harmonic, M_2, measured in set A and B is denoted as $M_{2,A}$ and $M_{2,B}$, respectively. The third harmonic, M_3, was measured in set B without H_{DC}. Figure 1(b) shows the AC magnetization curve measured in set A with an H_{DC} of 2.4 kA/m. Figure 2 shows the dependence of $M_{2,A}$, $M_{2,B}$, and M_3 on the distance from the point of zero H_{DC} as the field-free point (FFP). M_2 increases with the increase in the intensity of H_{DC} up to 8 kA/m. Tanaka *et al.* also showed that $M_{2,B}$ was larger than M_3 [3]. In this study, it was shown that $M_{2,A}$ was larger than $M_{2,B}$, and both of which were larger than M_3 depending on the directions of H_{AC}, H_{DC}, and the signal detection. M_2 was not associated with a non-linear response of the magnetization to H_{AC}. In conclusion, H_{DC} perpendicular to H_{AC} increased M_2, which was larger than M_3. M_2 was significantly affected by the relationship between the directions of H_{AC}, H_{DC}, and the signal detection. The dependence of M_2 on the frequency and intensity of H_{AC} was also presented.

DT-05. Automated visualization of the origin of the coercivity by using persistent homology. *M. Kotsugi*[1,2], T. Yamada[1,2], C. Mitsumata[2], T. Ueno[3], I. Obayashi[4,5], K. Akagi[5,2] and Y. Hiraoka[6,2] *1. Tokyo University of Science, Katsushika, Japan; 2. NIMS-MI2I, Tsukuba, Japan; 3. QST, Sayo, Japan; 4. RIKEN-AIP, Tokyo, Japan; 5. Tohoku Univ., Sendai, Japan; 6. Kyoto Univ., Kyoto, Japan*

Coercivity is one of the most important magnetic property in ferromagnetic materials for use in widespread applications, i.e. the core loss of soft magnets or the maximum energy product of hard magnets. It is the intensity of the external magnetic field to reduce the magnetization from saturation to zero. However, the detailed mechanism, how the macroscopic coercivity correlates to the microscopic magnetic domain structure, has not been perfectly understood yet. Here, we used "persistent homology", and developed an automated visualization technique of the origin of coercivity in the magnetic domain structure (Fig. 1)[1]. Persistent homology is an algebraic tool for measuring the topological features of shape, and it can offer the feature extraction of the spatial fluctuation in the magnetic domain. Moreover, the combination with machine learning offers us to establish a correlation between microscopic structure and macroscopic property [2]. In the experiment, we applied persistent homology to the magnetic domain of Bi-substituted rare-earth iron garnet. (1) We examine the availability of persistent homology for the feature extraction of the magnetic domain. (2) We investigate the systematic change of the feature respect to the external magnetic field. (3) We visualized pinning center on the original magnetic domain in combination with principal component analysis. As a result, we confirmed that persistent homology can accurately extract the feature of labyrinth magnetic domain, especially striped structure, blanched structure and terminated structure. The extracted feature synchronizes to the magnetic domain reversal process, and sensitive to the change of the external magnetic field. We automatically visualized the pinning center in the original magnetic domain structure that contributes to coercivity. Moreover, the projected points are corresponding to the topological defects, and it offers us to describe the non-equilibrium state in the microstructure. We could demonstrate that persistent homology is a useful approach to data-driven magnetic domain analysis for the first time.

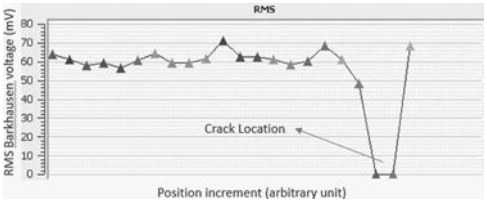
Visualization of the origin of the coercivity in the magnetic domain structure by using persistent homology and machine learning.

DT-06. Precision Magneto-optical Measurements of Magnetically Doped Mn-PbSnSe. *L. Riney*[1], B. Assaf[1], G. Krizman[2], X. Liu[1], J. Wang[1] and L. de Vaulchier[2] *1. University of Notre Dame, South Bend, IN, United States; 2. Ecole Normale Supérieure, Paris, France*

Recently, the topological crystalline insulator $Pb_{1-x}Sn_xSe$ has been of interest due to its ability to exhibit tunable trival and non-trivial topological phase transitions with varying Sn content. In this work, we explore magnetically doped Mn-$Pb_{1-x}Sn_xSe$ using magneto-optical techniques with a magnetic field that varies from 0 to 17T to perform Landau-level spectroscopy. We measure the exchange parameters of Mn-$Pb_{1-x}Sn_xSe$ in various fields and temperatures ranging from 1.6K to 200K. With a high enough mobility (>3000cm^2/Vs), we are able to probe the Landau-levels of our samples at 3T and above. We find that our measurements agree well with our k.p theory model that includes magnetization terms to account for the Mn doping. Magnetic topological insulators are of particular interest because they exhibit naturally gapped surface states which have the potential to exhibit a topologically protected quantum anomalous Hall conductive state.



DT-07. Use of AC Faraday Rotation as a Complementary Technique in Material Characterization. *M. Syed*[1], J. Monarch[1], W.J. Li[1] and N. Fried[1] *1. Physics & Optical Engineering, Rose-Hulman Institute of Technology, Terre Haute, IN, United States*

Magnetic measurements like Hall Effect, etc. have a long history of providing useful information related to material characterization. Here, we study glasses using a very sensitive AC Faraday rotation (FR) setup to show that magneto-optic techniques can also be utilized to study types of samples that are not necessarily known for their magnetic response. Samples included in this study are widely used in technological and research applications ranging from microscopy to solar cell applications. The experimental setup employs a stabilized He-Ne lase (633 nm) along with AC magnetic field that enables lock-in detection. We investigate a series of glass samples that include borosilicate glass and quartz subjected to UV treatment and glass with transparent conducting oxide films (TCO). The TCO samples include the more widely used Indium Tin Oxide (ITO) and the relatively newer Fluorine doped ITO. Various other measurements like absorbance, four-point probe, and ellipsometry have been conducted on these samples as well. We plan to discuss the results of these measurements in conjunction with FR measurements to show how a standard magneto-optic measurement can work in concert with these other measurements to provide characterization outcomes that are more consistent than the ones obtained from a single measurement. We will discuss the role played by sample thickness (substrate and TCO films), carrier concentration, and resistivity and how they relate to the framework of a FR measurement.

DT-08. C-scan imaging with magnetic Barkhausen emission measurements for the detection of shallow surface micro-cracks. N. Prabhu Gaunkar[2], *G. Prabhu Gaunkar*[1] and D.C. Jiles[2] *1. Mechanical Engg, IIT Goa, Farmagudi, India; 2. Electrical and Computer Engineering, Iowa State University, Ames, IA, United States*

Surface cracks can develop in components due to residual stresses, fatigue, stress corrosion cracking, corrosion fatigue, etc., Different NDT methods are employed to detect and monitor such cracks. Magnetic Barkhausen Noise (MBN) analysis is one such technique that is used for in-situ examination of microstructural anomalies or stress patterns. In the present work, we study the applicability of MBN for the detection of surface cracks. A part through surface crack was created by controlled fatigue loading of a martensitic stainless steel plate. The surface of the sample was scanned for BN emissions in incremental steps parallel and perpendicular to the crack. Measurements of MBN signal strength were recorded and assessed. Typical values for scans across the crack at its mid-length and in the vicinity of the crack tip are shown in Fig.1. It is observed that the number of MBN events drop significantly as the test spot location approaches the crack. Minimum MBN is thus observed whilst traversing the crack. Two distinct minima in the MBN peak amplitude are seen for scans just ahead of the crack tip. The estimated magnetic permeability also shows a similar pattern. The drop in the MBN signal is attributed to the localized deformation that accompanies the crack growth forming a plastic zone of much wider thickness than the crack itself. During the scan, the plastic zone gets detected along with the crack. The pinning sites in the form of dislocations along with the void within the crack are responsible for the drop in the recorded MBN. The detection sensitivity thus gets enhanced since material adjacent to the crack that is plastically deformed contributes to the signal detected thus revealing the presence of a crack. The double minima seen ahead of the crack tip are attributed to the characteristic residual stress pattern inherited from the typical butterfly shaped stress field ahead of a growing crack. C-scan mapping of component surfaces with miniature Barhausen Emission probes can thus provide a cost-effective and sensitive non-destructive examination tool for ferromagnetic materials.

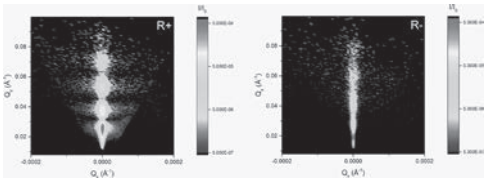
DT-09. Crystal & Magnetic Structure Studies of Li-ion Battery Materials with Neutron Powder Diffraction. *S. Lee*[1] *1. Kaeri, Daejeon, The Republic of Korea*

Neutron powder diffraction experiment is the most powerful experimental tool to give unique information for study of an electrochemical reaction mechanism. For examples, the microscopic structural deformation of a light element such as Lithium-ion and oxygen-ion in unit cell could be distinguished by only neutron diffraction. The information about the distribution of Li-ion is strongly correlated in the conduction mechanism. Also, the stability of structure in Li-ion battery materials depends on the change of site occupancy of Li-ion. Another merit of neutron diffraction for Li-ion battery is the strong penetration property of neutron. This property of neutron can be studied the conduction process using Li-ion battery full system. We have been developing protocols that allow for analysis of electrochemical cell reactions "in-situ," that is, methods for monitoring a battery while it is undergoing charging and discharging. But there are still many problems to be overcome such as a large neutron diffraction background of battery system and the inappropriate analysis of overlapped diffraction pattern based on very complicated multi-phase. In this talk, we will introduce the crystal and magnetic structure studies of battery materials using high resolution neuron powder diffraction (HRPD) in HANARO. For examples, we have investigated the magnetic and crystal structure of $Na_xFe_3(PO_4)_2(P_2O_7)$ ($1 \le x \le 4$) with a mixed polyanion framework using neutron powder diffraction. The new compounds contained three-dimensional (3D)-sodium paths supported by P2O7 pillars in the crystal. The de/sodiation of the $Na_xFe_3(PO_4)_2(P_2O_7)$ electrode occurs via a one-phase reaction with a reversible Fe2+/Fe3+ redox reaction and accompanies an exceptionally small volumetric change of less than 4%. Very interestingly, we have observed a very strong spin-lattice coupling behavior in this compound. Even though, the spin ordering of this material is happened at a low temperature, the trials to understand a strong correlation between spin and lattice within electrode materials are valuable to open an opportunity which realizes the new concept's second battery to be controlled the conduction property of electrode by the spin ordering.

DT-10. Kerr Effect Microscope with Rotating Analyzer for Exact Spatial Determination of Kerr Angle of Magnetic Domains. *J. Zázvorka*[1], A. Papackova[1], L. Beran[1], L. Nowak[1], V. Kletečka[1], T. Maleček[1] and M. Veis[1] *1. Charles University, Prague, Czechia*

Magneto-optical (MO) methods are used as highly sensitive non-destructive techniques to probe physical properties of various magnetic materials down to the nanometre scale. Spatially resolved MO experiments are suited for visualization of magnetic domains larger than 150 nanometres [1]. There are many advantages of magneto-optical microscopy, such as non-destructiveness, possible high time resolution, low requirements on samples and easy manipulation with them. MO microscopy posses a way to analyse large variety of nanostructured magnetic materials [2]. As disadvantage of the MO microscopy, the obtained results represent only optical contrast and for advanced



investigation a comparison with additional methods, e.g. magnetometry or anisotropy measurements, needs be used. We report on the development of a magneto-optical Kerr effect (MOKE) microscope that employs the rotating analyser method. This technique is usually used in spectroscopic measurements and allows for obtaining the exact value of the Kerr rotation of the studied system directly form the captured pictures with the accuracy of several millidegrees resolution. Spatial imaging of the Kerr rotation, combined with sub-pixel domain wall detection and image post-processing techniques, is useful for detailed characterization of magnetic properties. e.g. nucleation and stability of magnetic domains, pinning, magnetic transport, etc. Combined in a setup with a high-speed camera, capable of capturing 100 fps, dynamics of magnetic domains can be captured as well. To demonstrate the setup capabilities, we present exemplary measurements and characterization of several samples, such as NiFe permalloy gratings, domain structures of Bi:YIG garnets and investigation of domains in magnetic shape memory material Ni_2MnGa.

DT-11. POLREF: Time of flight Polarised Reflectometer for Magnetism. *C. Kinane*[1] and A. Caruana[1] *1. STFC, Rutherford Appleton Laboratory, Oxford, United Kingdom*

Polarised Neutron Reflectometry (PNR) measures surfaces, buried interfaces and layers, yielding information about layer thicknesses, densities, surface/interface roughness and interdiffusion. Uniquely it can provide the magnetic equivalents of these quantities, including the total in-plane magnetisation [1,2]. A large variety of thin film phenomena can be investigated using the POLREF beamline, including topological insulators, proximity-induced and fundamental magnetism, superconductivity and spintronic devices. Furthermore, POLREF has the capability to perform off-specular PNR and specular Polarisation Analysis (PA) measurements. If the problem can be made flat and is in the right length scales (~1 nm – 200 nm) then it can be probed by PNR. The POLREF time of flight PNR beamline is located in the second target station at the ISIS neutron and Muon source [3,4]. With a polarised wavelength band of 2-15Å (PEff~96%), low instrument backgrounds of I/I0 < 10-7 and a resolution of dQ/Q better than 1%, QMAX = 0.25-0.3 Å-1 is routinely accessible for small (10x10 mm) samples within reasonable count times. The POLREF beamline has gone through a number of recent upgrades. Upgrades of the spin flippers and analyser system have improved the capability of the beamline to measure samples with larger moments or weaker spin flip signals when using the PNR and PA modes. The 1D linear detector efficiency has also been upgraded and now is fully commissioned into the user program providing full off-specular capability in the NR and PNR (see Figure 1) modes and some off-specular PA capability (the maximum Qx being restricted by the analysing mirror). Here, we will present the current capabilities of the POLREF beamline, including science highlights and how to get access to the ISIS neutron facility and POLREF beamline.

DT-12. Control and observation of ferromagnetic domains in resistive random access memory conducting filament nanostructures formed in epitaxial NiO thin films. *E. Lee*[1] and J. Son[1] *1. Kyung Hee University, Yong-in, The Republic of Korea*

We investigated resistive random access memory (RRAM) characteristics of epitaxial NiO thin films and using microcapacitor in micrometer scale and conducting atomic force microscope (CAFM) in nanometer scale. CAFM and magnetic force microscope were used to form and observe RRAM filament nanostructures of nanodots, nanorads, and nanorings. Depending on the size of the CAFM tip, the size of the nanodots was determined and nanodots with diameters of about 5 nm could be formed. Since the CF nanostructures have ferromagnetic properties, It was possible to control the magnetization directions of the nano-rad and nano-rings by the magnetic field formed by applying voltage to the CAFM tip.

DT-13. Magnetic Bubble States and Their Current-Driven Motion in C-Added MnNiGa. *S. Zuo*[1,2], J. Liu[1,2], K. Qiao[1,2], T. Zhao[1], F. Hu[1,2], J. Sun[1,2] and B. Shen[1,2] *1. Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2. University of Chinese Academy of Sciences, Beijing, China*

Topological magnetic domains have received intensive attention due to their potential applications in the magnetic recording and memory devices [1]. Previous research reveals that biskyrmions can be observed in MnNiGa alloy with a wide temperature range [2], which would change into magnetic bubbles after the substitution of Y, but the bubble density is low similar to biskyrmions in MnNiGa [3]. Magnetic domains in C-added MnNiGa have been directly observed in the present work by means of Lorentz TEM. Magnetic bubbles with high density were obtained after the addition of C without changing the crystal structure. Furthermore, the bubble density and diversified spin configurations are systematically manipulated via combining the electric current with perpendicular magnetic fields. The magnetic bubble lattice at zero field were achieved and magnetic bubble states with uniform type-I or –II bubbles were observed after the optimized manipulation. Physics related to the magnetic domain evolution is discussed for present alloy, which probably stimulate further exploration of the universal phenomenon and mechanism.

DT-14. Scanning laser magneto-optical microscopy for the study of magnetization dynamics of magnetic nanoparticles. R. Soucaille[1], M.E. Sharifabad[2], N. Telling[2] and *R. Hicken*[1] *1. University of Exeter, Exeter, United Kingdom; 2. Keele University, Stoke-on-Trent, United Kingdom*

Detailed characterization of magnetic nanoparticle (MNP) dynamics is needed to improve the efficiency of magnetic hyperthermia as a cancer therapy. It is necessary to investigate the MNPs within the cellular environment since the specific absorption rate of energy depends upon the spacing between the MNP and their agglomeration state. We have developed a scanning laser magneto-optical microscope to probe the magneto-optical response of the MNPs. The polarization rotation induced by the Faraday effect is small (typically less than 100 mdeg) and other sources of polarization or intensity change can cloud the characterization of the MNPs so that it is important to optimize all elements of the microscope design. Since the magneto-optical response depends upon the wavelength of the light, we have studied both the low-field AC susceptibility (ACS) and high field AC response of MNPs in solvent at different wavelengths. We report the wavelength dependence of the magneto-optical response in the 400 to 900nm range. For magnetite nanoparticles the magneto-optical response changes sign around 560 nm, while we also find that the optical ACS shows a response different to that expected from linear response theory. We have related this response to a change in the MNP configuration in the magnetic fluid. Another important aspect of the measurement system is the electromagnet that has been designed to optimize high frequency magnetic field generation with minimum loss. The magnet delivers a polar magnetic field while also providing an optical path for Faraday measurements. We finally developed a beam scanning Faraday microscope, that employs galvo mirrors and exploits the same electromagnet, to explore the dynamics of MNPs. The beam scanning microscope provides a fast and versatile means of mapping the magnetization dynamics and other processes that can affect the light polarization. Different schemes for the detection of the polarization change have been compared, including modulation of polarization and use of a balanced bridge detector. Measurements of the domain structure within a Co/Pt multilayer deposited on a glass substrate confirm that the microscope is well suited to the study of thin transparent magnetic structures.

DT-15. Element Specific Magnetometry of Buried Layers by HAXPES. *A. Gloskovskii*[1], G. Fecher[2], K. Ederer[1], C. Schlueter[1], G. Schönhense[3] and W. Drube[1] *1. Photon Science / Deutsches Elektronen-Synchrotron DESY, Hamburg, Germany; 2. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 3. Institut für Physik, Johannes Gutenberg-Universität, Mainz, Germany*

The intensity and shape of photoelectron lines of magnetic materials depend on the relative orientation of the sample magnetization, the photon helicity vector and the electron emission direction. In the hard X-ray regime, the photon polarization can be conveniently modified utilizing the phase shift produced by a diamond phase plate in the vicinity of a Laue or Bragg reflection. A single-stage in-vacuum diamond phase retarder has been built for the HAXPES beamline P22 at PETRA III (Hamburg, Germany) [1]. The electronic and magnetic properties of buried CoFe and Co_2MnSi nano-layers were studied using the linear and circular magnetic dichroism in the angular distribution of photoelectrons [2, 3]. The layers were remanently magnetized *in-situ* and probed using HAXPES at PETRA III (beamline P09). It is demonstrated that magnetic dichroism in HAXPES is an effective and powerful technique to perform element specific magnetometry of deeply buried (~10 nm) ferromagnetic and antiferromagnetic materials, which are inaccessible with conventional soft X-ray photoelectron spectroscopy. The data analysis allows the determination of the relative orientation of magnetization in the different layers of these complex nano-structured samples. We are operating a time-of-flight HAXPES setup with spinfilter option at P22 [4]. The instrument is providing momentum and spin-resolved HAXPES with unmatched efficiency for the user community. It takes advantage of the unique time structure of the reduced bunch filling modes of PETRA III, offering rather large bunch separation of up to 192 ns (with 40 bunches) owing to the large circumference of the storage ring (2.3 km).

DU-01. Immuno-magnetic sorting of circulating tumor cells using microstructured NdFeB-PDMS composites. *D. Le Roy*[4], L. Descamps[1], S. Mekkaoui[1], E. Laurenceau[2], M. Audry[1], A. Deman[1], J. Garcia[3] and L. Payen[3] *1. Univ. Lyon 1, INL, Villeurbanne, France; 2. Ecole Centrale Lyon, INL, Lyon, France; 3. Hospices Civils Lyon, Lyon, France; 4. Univ. Lyon 1, ILM, Villeurbanne, France*

Circulating tumor cells (CTCs) are found to be valuable indicators of cancer stage [1]. Monitoring CTCs can serve to analyze treatment response and carry out personalized therapy [2]. However, recovering CTCs is challenging due to their scarcity in blood: few ppm at most. Microfluidic devices are interesting tools for cellular handling as they offer precise spatial and temporal control. Moreover, these devices can be easily made in low cost polymers such as polydimethylsiloxane (PDMS). In view to isolate CTCs, immuno-magnetic based micro-devices offer high selectivity and the possibility to recover living cells for subsequent analysis [3]. An external magnet is often used to create a magnetic flux pattern, but larger gradients, so reachable forces, are obtained when integrating micrometer-sized magnetic flux sources in the close region of the fluidic channel. Microstructured composites, made of magnetic particles and a polymer, is an efficient way to integrate micro-flux sources, and breakswith standard approaches [4]. Here we investigate mixtures of NdFeB particles with PDMS. During the PDMS reticulation, a magnetic field pattern serves to create arrays of NdFeB particle agglomerates, used as magnetic traps. Depending on the NdFeB concentration, one can vary the traps size and density. Figure 1(a-b) shows reconstructed 3D views from X-ray tomography, and a schematic of the microfluidic device. We first used model magnetic beads (12 µm) to assess trapping performances of the composites under varying fluidic conditions. We then performed preliminary experiments to specifically immuno-capture WBCs. To do so, WBCs were magnetically labelled with nanoparticles. We observed efficient WBC trapping using NdFeB-PDMS composites in microfluidic devices (Figure 1 (c-d)). These results demonstrate the potential of this approach for the immuno-magnetic sorting ofCTCs, either by positive selection, or by any negative selection through the capture of WBCs in pre-filtered blood sample.

DU-02. Flexibility of Undulating Magnetic Microbead Swimmers. *Y. Li*[1] and S. Chen[1] *1. Department of Mechanical and Aerospace Engineering, Chung Cheng Institute of Technology, National Defense University, Taoyuan, Taiwan*

The effect of curvature on the propulsive efficiency of the magnetic microswimmer subjected to an external field is investigated experimentally. The overall field is composed of a homogeneous static field H_d and a dynamical sinusoidal field H_y with a maximum amplitude H_p and an adjustable frequency f, that is, $H_y = H_p \sin(2\pi ft)$. The swimmer is obtained by combining the self-assembling ability of microsized superparamagnetic particles composed the iron oxide magnetite embedded in polystyrene microspheres suspended in distilled water. The flexibility of the swimmer can be determined by the value of C_{max}, a dimensionless ratio of the diameter of the magnetic particle to the swimmer's radius of curvature. Fig. 1(a) shows the sequential images of L2S2 swimmer (comprising two large and two small particles) and L1S3 swimmer (comprising one large and three small particles) swimming in an identical external field. It is noted that the undulating pattern of L2S2 is quite different from that of L1S3. Additionally, L2S2 has higher propulsive efficiency than that of L1S3. Fig. 2 shows the comparison of the swimming velocity for the L2S2 and L1S3 swimmers steered in different field conditions with various C_{max}. The velocities of both swimmers nearly linearly increase with the flexibility and reach the highest values at their corresponding C_{max}. The velocity of L2S2 is more sensitive to the flexibility than the counterpart of L1S3. In addition, L2S2 longer than the L1S3 obtains the maximum velocity of 3.16 µm/s when C_{max} =0.35, while the L1S3 possesses a maximum velocity of 1.5 µm/s at the flexibility of C_{max} =0.48. Our experimental results indicate that not only the flexibility is an essential controlling parameter for the propulsive efficiency, the length (or wetted area) of the swimmer which determines the friction for pulling the swimmer perpendicular to its long axis is a dominated factor for the propulsion generation as well.

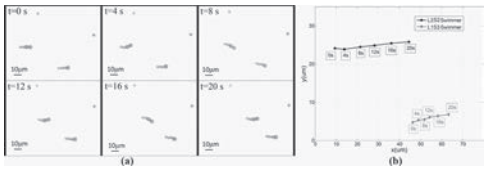

Fig.1 (a) Sequential images of L2S2 and L1S3 swimmers waggling in field strength of H_p=2000 A/m, H_d=1930 A/m, and frequency of f=10Hz. (b)Moving trajectories of the swimmers shown in Fig. 1(a).

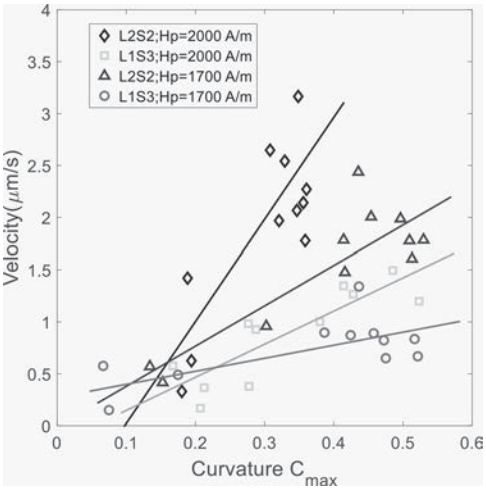

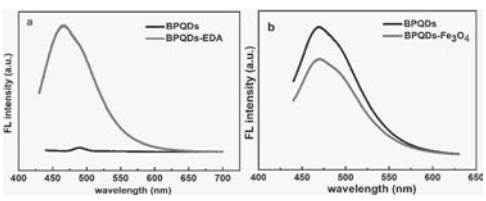

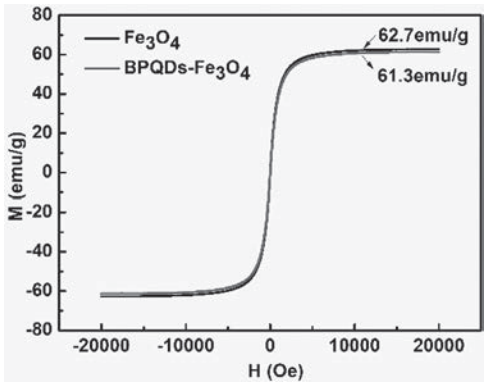

Fig.2 Comparison of the maximum velocities for different types of microswimmers with various flexibility.

DU-03. Fe_3O_4-BPQDs Nanoplatforms as Dual Mode Detection Probe. *Y. Ma*[1], X. Xu[1] and Y. Jiang[1] *1. School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China*

The magnetic nanoplatforms involving black phosphorus quantum dots (BPQDs) and Fe_3O_4 nanoparticles will become a novel dual mode detection probe to improve accuracy of medical diagnosis and detection. Black phosphorus quantum dots (BPQDs) has unique optical properties and biocompatibility [1,2], while they have groups on surface and therefore can be decorated to avoid oxidation and weak emission [3-4]. The passivated BPQDs can bonded to superparamagnetic Fe_3O_4 nanoparticles, which are widely used as T_2 magnetic resonance imaging (MRI) contrast agent. Here, high fluorescent BPQDs are synthesized by thermal-pyrolysis and then effectively surface passivated by reaction with ethylenediamine (EDA). As shown in Figure. 1a, the fluorescent intensity of passivated BPQDs-EDA is much higher than pure BPQDs. The enhanced PL is contributed to high yield of BPQDs and P-N bond on the surface introduced by passivation. As shown in Figure. 1b, Fe_3O_4 nanoparticles are coated with chitosan, which can prevent the fluorescence quenching of BPQDs due to Fe_3O_4 NPs effectively. The magnetic nanoplatforms have a saturation magnetization (Ms) of 61.3 emu/g, while the Ms of Fe_3O_4 NPs is 62.7 emu/g in Figure. 2. It means that the magnetic nanoplatform can used as novel MRI contrast agent. According to our experiments, by successfully assembling the passivated BPQDs and Fe_3O_4 NPs, the dual-mode detection of MRI and fluoresce imaging can be effectively achieved in vivo.

DU-04. Investigating the Role of Pulsed Magnetic Field Intensity on the Growth and Proliferation of N27 Dopaminergic Neuronal Cells. *J. Boldrey*[1], L. Que[1], I. Schneider[2], R.L. Hadimani[3] and D.C. Jiles[1] *1. Electrical and Computer Engineering, Iowa State University, Ames, IA, United States; 2. Chemical and Biological Engineering, Iowa State University, Ames, IA, United States; 3. Mechanical and Nuclear Engineering, Virginia Commonwealth University, Richmond, VA, United States*

Much of the biomedical research to find the causes of and treatments for Parkinson's Disease (PD) and Alzheimer's Disease (AD) is performed using cell lines from animals that model the behavior of cells in the human brain that are linked to PD and AD. The N27 dopaminergic cell line is well-established in neurodegenerative disease research. [1] [2]. Transcranial Magnetic Stimulation (TMS) has been approved by the US Food and Drug Administration (FDA) as a method for treating major depressive disorder (MDD), obsessive-compulsive disorder (OCD) and certain types of migraine headaches [3]. However, the effect of TMS type fields at the cellular level are not fully understood. Recent studies have shown that monophasic pulsed magnetic fields generated by a TMS stimulator increases growth and proliferation of N27 cells in vitro [4] [5] [6]. In TMS therapy, each session is tailored to the specific patient by establishing a base threshold level of magnetic field strength (H). This is performed by aiming the stimulation coil at the patient's motor cortex and finding the minimum intensity level to make the patients thumb visibly twitch. This H field intensity baseline, called the motor threshold (MT), is then multiplied by a specified percentage set by the therapy protocol established by the FDA. Different patients have different MTs. Therefore, the intensity of the H field delivered to the brain cells of different patients should also vary. Recent studies have shown that monophasic pulsed magnetic fields generated by a TMS stimulator increases growth and proliferation of N27 cells in vitro [4] [5] [6]. The goal of our research is to investigate the effects of different H field intensities on N27 cells. By modulating the H field, an exploration was made into the role of variable H field intensity experienced during TMS therapy due to different MT between patients. The results of our research will increase our understanding of the effects of magnetic fields at the cellular level, increase the knowledge of the underlying mechanisms behind TMS, and contribute the ongoing research into treatments for PD and AD.

DU-05. Selective Separating and Retrieving Mechanism of Untethered Magnetic Robot for the Application of Human Vascular Disease.
J. Park[1], W. Lee[1], J. Kim[1], E. Jung[1], N. Kim[1] and G. Jang[1] *1. Hanyang University, Seoul, The Republic of Korea*

Because untethered magnetic robot (UMR) can be controlled remotely and precisely utilizing external magnetic field (EMF) generated by magnetic navigation system, UMR has been actively investigated to be applied to various biomedical fields such as vascular disease treatment [1]. However, propulsive force of UMR is not enough to move forward to target lesion against the high blood flow velocity up to 70 cm/s. Also, it is difficult to effectively deliver and retrieve UMR in blood vessels. In this paper, we proposed an integrated magnetic robot (IMR) and selective separating and retrieving (SSR) mechanism to overcome these limitations of UMR. The proposed IMR is consisted of a flexible-legged UMR(FLUMR) [2] and a tethered delivery catheter as shown in Fig. 1(a). Assembled magnet (AM) which is composed of two axially magnetized half-ring type magnets, is equipped at distal tip of the catheter and at \rear part of the FLUMR. SSR mechanism separates the FLUMR from the catheter by generating a repulsive force in coupling part and attaches the FLUMR with the catheter by generating an attractive force in coupling part as shown in Fig. 1(b). The magnetic moment of AMs is designed to be zero in such a way that the FLUMR does not move even though magnetic field is applied during the navigation of IMR. To verify the SSR mechanism, we prototyped IMR and conducted an experiment as shown in Fig. 2(a) and (b). FLUMR was selectively separated by applying more than 10 mT at 7.4 Hz which generates sufficient external magnetic torque when the spacer thickness between the magnets of AMs is 0.5 mm. Finally, we verified the navigation and SSR mechanism of IMR by *in vitro* experiment with the pseudo blood vessel (Y-shaped glass tube filled with water) as shown in Fig. 2(c). This study can contribute to expanding the application field of UMR by proposing safe and effective navigation and retrieval methods of UMR.

DU-06. Effect of Microstructure on r_2 Relaxivity for T_2 Weighted Magnetic Resonance Imaging in Magnetite Nanoparticles.
B. Park[2,1], M. Ko[2] and Y. Kim[2] *1. Research Institute of Engineering and Technology, Korea University, Seoul, The Republic of Korea; 2. Department of Materials Science and Engineering, Korea University, Seoul, The Republic of Korea*

Magnetite (Fe_3O_4) nanoparticles (NPs) have been considered as reagents for T_2 weighted magnetic resonance imaging (MRI) because they can accelerate spin-spin relaxation of adjacent protons by appearing a magnetic field [1]. In particular, since r_2 relaxivity, an indicator of T_2 contrast, is directly related to the magnetic moment and size of the NPs, control of diameter and surface are key factors to achieve high relaxivity [2]. Recently, it was reported that clustered Fe_3O_4 NPs (c-Fe_3O_4 NPs) composed of assemblies of several crystallites can exhibit high r_2 values [1]. However, it was difficult to precisely control the crystallite size of NPs smaller than 100 nm in a chemical route. In this study, we present a synthetic method by which we can control the diameter (D) and crystallite size (C) separately. The relevant c-Fe_3O_4 NPs were prepared by hydrothermal polyol process in the presence of iron(Fe^{3+}) chloride, sodium acetate, water, and ethylene glycol. We were able to control the crystallite size by changing the ratio of sodium acetate and water, which act as sources of OH^- ion during forming Fe_3O_4 phase. Figure 1 shows TEM images of two groups with different crystallite sizes. S1 (D: 30 nm) and S2 (D: 42 nm) consist of crystallites with a size of 15 nm and L1 (D: 25 nm), L2 (D: 34 nm), and L3 (42 nm) consist of crystallites with a size of 26 nm. As shown in Fig. 2, the c-Fe_3O_4 NPs with larger granule size has high saturation magnetization (M_s) and coercivity (H_c) resulting in high r_2 relaxivity. The r_2 values increased as the number of crystallites constituting the NP decreased in both groups. It should be noted that the microstructural changes play critical roles in magnetic NP design for T_2 weighted MRI.

DU-07. Experimental Validation of an Analytical Model for Diametrically Magnetized Permanent Magnets.
N. Riahi[1] and A. Komaee[1] *1. ECE, Southern Illinois University, Carbondale, IL, United States*

Our team is devoted to development of noncontact permanent magnet manipulators for a variety of biomedical applications. The ultimate goal is to replace the existing electromagnet manipulators with more compact, more effective, and less expensive devices by employing permanent magnets that offer superior strength-to-size-ratio and energy efficiency. A key component toward this goal is the availability of reliable models for the magnetic fields generated by the permanent magnets of various geometries. Finite-Element Method is usually the most accurate approach to use. However, the undeniable need for analytical methods in design and dimension optimization for several applications including micro-actuators, have led to some analytical models for various types of permanent magnets. In particular, we are interested in an analytical 2-D model proposed in [1] for diametrically magnetized cylindrical magnets, a simplified and modified version of 3-D model presented in [2]. Before using this model in our design, the accuracy of model is verified experimentally, as reported below. Employing a SENIS MMS-1-RS 3-axis magnetic field mapper with accuracy of 0.5%, we measured the magnetic field around a diametrically magnetized magnet RX04X0DIA from KJ-Magnets. The magnetization factor was estimated from empirical data by LS method to be incorporated into the analytical model. The magnet dimensions appearing in the model were directly measured. Fig.1. compares the calculated and measured fields along the north pole direction of the magnet. The graphs indicate reasonably close match in particular as moving further from the magnet. For the entire area

around the magnet, the relative error between the analytic and empirical magnetic fields is illustrated in Fig.2. Since the magnet is not necessarily perfectly manufactured, it is not fully symmetric and asymmetry in the relative error is observed. Overall, the relative error over the area around the magnet does not exceed 11%. This relatively small error confirms that the analytical model in [1] can be safely used in our future work.

DU-08. Development of a procedure for experimental mapping of electric field induced by TMS in an anatomically accurate brain phantom. *H. Magsood*[1] and R.L. Hadimani[1] *1. Virginia Commonwealth University, Richmond, VA, United States*

Transcranial magnetic stimulation (TMS) is therapeutic and diagnostic technique for various neurological and psychiatric disorders [1], [2]. There are extensive modeling and simulation studies to understand the effect of TMS coils on the brain [3], [4]. However, there is a lack of experimental and physical models for examining the brain stimulation. Previous experiments attempted to measure e-field on a conducting material that mimic the electrical conductivity of the brain but lacked the geometric/anatomical accuracy. We previously reported a newly developed brain phantom that is geometrically/anatomically accurate and has an averaged conductivity closely matching the human brain [5]. This work is an attempt to establish a methodology to map the e-field from the magnetic field applied on material like the brain. Previous work was based on the measurement of the electric field and characterization of the TMS coils but on highly conductive probes in air [6][7]. Our analogy of mapping the e-field on the brain phantom is divided in three part. The first is the mapping of the e-field induced on an oscilloscope probe to help characterizing TMS coils and establish a reference for measurements. The second part is the mapping of e-field from the voltage measurement on electrically conductive sheet (a composite of polydimethylsiloxane, PDMS and multi-walled carbon nanotubes, MWCNT) made with the same material composition of the brain phantom in order to simplify the geometry. The third part is to map the e-field from the brain phantom which is in progress. The upper half of Fig. 1 shows the e-field constructed from the voltage reading on the reference oscilloscope probe. The result trend is consistent with the previous modeling and computational studies[8]. The lower half of Fig. 1 shows the results of constructing the e-field from the electrically conductive sheet. The high electric field can be attributed to the polarization effect of the conductive polymer.

DU-09. Detailed Analysis of Specific Absorption Rate of Magnetic Nanowires for Biomedical Applications. *M. Zamani Kouhpanji*[1,2], A. Ghoreyshi[1], D. Bilardello[4], P.B. Visscher[3] and B. Stadler[1] *1. Electrical and Computer Engineering, University of Minnesota Twin Cities, Minneapolis, MN, United States; 2. Biomedical Engineering, University of Minnesota Twin Cities, Minneapolis, MN, United States; 3. Physics and Astronomy, University of Alabama, Tuscaloosa, AL, United States; 4. Institute for Rock Magnetism, University of Minnesota Twin Cities, Minneapolis, MN, United States*

Magnetic nanowires have found applications in electronic and spintronic devices, in green technologies, such as water purification agents, and in biomedical applications, such as thermal therapies and RNA/DNA extraction agents [1-3]. To truly design properties optimized for each application, quantification of the intrinsic reversible and irreversible magnetization mechanisms is important, but so far elusive [4]. Here, a novel mathematical approach is proposed to quantitatively distinguish the intrinsic irreversible versus reversible magnetization mechanisms of the nickel nanowire arrays using first order reversal curves (FORC). The energy barrier, domain wall length, effective anisotropy constant, switching field, and coercivity were calculated to identify the reversal mechanism and calculate the specific absorption rate (SAR) of the nanowires, Figure 1. Furthermore, the angular-dependent coercivity (ADC) was measured to validate the FORC results. The FORC data show that the energy barrier of the nickel nanowires (Figure 1a) increased as their diameter increased which could lead to larger energy generation, suitable for thermal therapeutic applications. However, since the larger nanowires have larger volumes, their SAR values decreased resulting in lower efficiency per volume (and per mass) for thermal therapeutic applications, Figure 1b. A good agreement was found between the results of the ADC and FORC techniques, Figure 1d. However, ADC predicted the effective anisotropy slightly larger than FORC, Figure 1c, which is closer to what reported in previous literature [5].

DU-10. Study on the Blood Flow in Stenosed Microvascular Model under Pulsed Magnetic Field. S. Han[1], J. Mok[1] and *H. Lee*[1] *1. Sangji University, Wonju, The Republic of Korea*

The use of pulsed magnetic field (PMF) was proposed as an alternative non-invasive medical treatment for influencing human physiology, via inducing electric current in deep tissue with the rapidly changing field of the magnetic impulses and has been reported to be effective in improvement of blood circulation.[1] It is widely known that abnormal peripheral blood circulation due to intravascular stenosis causes ischemic diseases and blood circulatory disorders. Since the stenosis occur due to hemodynamic and geometric characteristics of blood vessels, as well as pathological and physiological factors, therefore, present study has tried to investigate the influence of PMF on hemodynamic characteristics in blood vessel with stenosis. Stenosed microvascular channels were fabricated using polydimethysiloxane (PDMS). Red Blood Cell (RBC) suspension with hematocrit (Ht) of 5~20% was prepared using phosphate buffer saline (PBS) and it was injected into micro-channel with the blood flow rate of 1 μl/h using syringe pump. The changes in blood flow and deformation of RBCs were examined before and after PMF stimulus. These hemodynamic information on RBC passing through the stenotic region might provide the treatment of blood circulatory disorders.[2] Our PMF stimulator has the maximum intensity of 0.27T at a transition time of 102 μs with pulse intervals of 1Hz. The blood flow velocities of RBC in the micro-channel having a diameter of 15μm and stenosis rate of 30% increased by 32% and 89% after PMF stimulus with intensities of 0.1T and 0.27 T, respectively.(Fig.1) And the RBC deformability near the stenosis increased by an average of 30% after PMF stimulus. Our study shows that PMF plays an important role in hemorheologic and hemodynamic properties. In order to extend our results to clinical applications, we need develop more indicators for hemorheologic characteristics such as viscosity and resistance, and need further experiment with diverse PMF condition such as pulse shape, pulse duration, or repetition rate.

DU-11. Cavity-shaped magnet for highly sensitive magnetic detection of magnetic nanoparticles in breast cancer patients. *A. Kuwahata*[1], M. Kusakabe[2,1], S. Chikaki[1], I. Saito[3] and M. Sekino[1] *1. The University of Tokyo, Tokyo, Japan; 2. Matrix Cell Research Institute Inc., Ibaraki, Japan; 3. iMed Japan Inc., Tokyo, Japan*

Recent clinical studies demonstrated the feasibility of a magnetic sentinel lymph node biopsy using magnetic nanoparticles (MNPs) and a dedicated magnetic probe [1-3] to diagnosis cancer metastasis in breast cancer patients. Our handheld magnetic probe with a conventional column-shaped permanent magnet and a Hall sensor [3] can effectively generate larger magnetic fields (B) to magnetize MNPs compared with the magnetic probe with a coil. However, a large gradient of magnetic fields (∇Bz ~ 160 mT/mm) around

the magnet has been an obstacle to employ high-sensitive magnetic sensors (e.g., a magneto-impedance sensor) for detecting the MNPs at a further distance. This study presents a novel configuration of a permanent magnet to overcome the above issue. We proposed the cavity-shaped magnet with zero gradient of the magnetic field at the magnetic null area where $B \sim 0$. Figure 1 shows the two-dimensional distribution of magnetic fields calculated by the finite element method. The narrow magnetic null area of the conventional magnet is shown in Fig. 1(a). By contrast, the proposed cavity-shaped magnet produces the wider magnetic null (Fig. 1(b)). Although the cavity area of the magnet produces the zero gradient, the strength magnetic fields are still large. The small ring magnet located at the tip of the magnet plays an important role to eliminate the large magnetic field under keeping the zero gradient, resulting in the novel configuration magnet with $\nabla Bz \sim Bz \sim 0$. In addition, at the further distance ($Z > 11$ mm), the magnetic sensitivity of the cavity-shaped magnet shows the larger value compared with that of the conventional magnet, as shown in Fig. 2. These results indicate the proposed magnet is useful for the enhancement of the detection performance of the magnetic probe. We will present the detailed characteristics of the cavity-shaped magnet and the application of highly sensitive magnetic sensors.

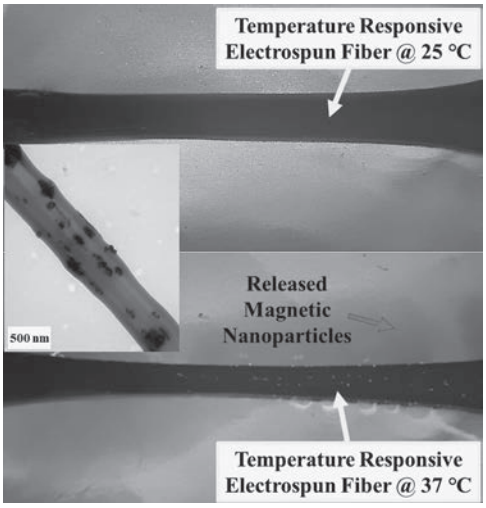
DU-12. Exploring exchange-coupled cobalt ferrite/iron oxide and iron oxide/cobalt ferrite core/shell nanoparticles for advanced magnetic hyperthermia. *J. Robles-Garcia*[1], E. Fuller[2], R. Das[3], M. Phan[1] and H. Srikanth[1] *1. Physics, University of South Florida, Tampa, FL, United States; 2. Physics, Ohio State University, Columbus, OH, United States; 3. Phenikaa Unversity, Hanoi, Vietnam*



Iron/iron oxide core/shell nanoparticles have recently been exploited as a promising candidate for magnetic hyperthermia, owing to their biocompatible and expectedly enhanced magnetic properties. However, atomic diffusion between the core (Fe) and shell (Fe_3O_4 or γ-Fe_2O_3) hindered the heating capacity of these nanoparticles, making them impractical for application in magnetic hyperthermia [1]. To overcome this, we propose the design and synthesis of exchange-coupled cores/hell nanoparticles with exchange coupling between soft (Fe_3O_4) and hard ($CoFe_2O_4$) magnetic phases. We have systematically studied the effects of the core and shell composition/thickness on the heating efficiency in both $Fe_3O_4/CoFe_2O_4$ and $CoFe_2O_4/Fe_3O_4$ core/shell nanoparticles. The nanoparticles were synthesized using thermal decomposition of organometallic precursors. Transmission electron microscopy (TEM) showed formation of spherically shaped $CoFe_2O_4/Fe_3O_4$ and $Fe_3O_4/CoFe_2O_4$ nanoparticles. Magnetic measurements showed high saturation magnetization (MS~70 emu/g) and a superparamagnetic behavior for the nanoparticles at room temperature. Magnetic hyperthermia measurements indicated a large increase in specific absorption rate (SAR) for $Fe_3O_4/CoFe_2O_4$ compared to $CoFe_2O_4/Fe_3O_4$ nanoparticles of same size (~10 nm). The heating efficiency of $CoFe_2O_4/Fe_3O_4$ increased to ~200 W/g as compared to $Fe_3O_4/CoFe_2O_4$ (~159 W/g). The increase in SAR is attributed to the increases in both the saturation magnetization and the effective magnetic anisotropy field.

DU-13. Development of Temperature Responsive Electrospun Fiber for Magnetic Nanoparticles Releasing. *T. Chen*[1], C. Huang[1], C. Tsou[1] and T. Ger[1] *1. Biomedical Engineering, Chung Yuan Christian University, Taoyuan City, Taiwan*

In this study, we present a temperature responsive magnetic nanoparticle embedded fiber which was fabricated through the electrospun process. The electrospun fibers could be temperature increasing by the alternating magnetic field (AMF) because of the magnetic nanoparticles in fibers. Temperature responsive material of PNIPAAm changed the compound structure at the low critical solution temperature which was 32 °C and expressed the morphology variation between shrunken and swollen state. With this behavior, we observed that the magnetic nanoparticles with the fiber release out during the temperature variation, made it got the potential to be applied in the magnetic particles releasing platform and could be further used in the field of hyperthermia treatment. The surface morphology of the electrospun fibers were characterized by the transmission electron microscope and the magnetic property was measured by superconducting quantum interference device. High frequency alternative magnetic field machine was use to triggered the temperature response behavior and recorded by the thermal infrared image system. The fibers morphology variation under the AMF was recorded by the CCD camera system. The results showed that the temperature responsive fibers were successfully fabricated by the electrospun process with the magnetic nanoparticles and the captured image showed the releasing of magnetic nanoparticles behavior under the AMF trigged.

DU-14. Image-based feedback control of a distal part of magnetic catheter to enhance a path-following capability of its position and orientation. *N. Kim*[1], W. Lee[1], J. Kim[1], E. Jung[1], J. Park[1] and G. Jang[1] *1. Convergence Mechanical Engineering, Hanyang University, Seoul, The Republic of Korea*

Various methods to control a magnetic catheter (MC) have been widely investigated to follow the path precisely. Some of the prior researchers have controlled a distal tip position of MC by utilizing various beam models [1], [2], [3]. They did not include the effect of external forces, such as pulsatile flow and heartbeat, which continuously change in real time. These methods have a potential problem to move the distal part of MC with large tilting angle which may damage blood vessel during navigation. We propose an image-based feedback control method to reduce the position error and tilting angle of the distal part of MC with respect to the pre-defined path. This method does not utilize a beam model but determines the required magnetic field from the positions of 2 markers. Fig. 1(a) shows 2 markers on MC and normal distances (d_1, d_2) of each marker from the pre-defined path. We classified the states of MC into 17 cases as shown in Fig.1(b) and decided the required magnetic field by comparing d_1 with d_2 as shown in Fig.1(c). The proposed method controls the magnetic field to minimize, and the middle point between 2 markers indicates how precisely the MC follows the path. To verify the proposed control method, we conducted *in vitro* experiment following a pre-defined path with commercial MC and traced the trajectories of 2 markers as shown in Fig.2. The trajectories are the area in which the distal part between d_1 and d_2 sweeps during navigation. As shown in Fig.2, the proposed method contains the pre-defined path around the central part of the trajectory. The results show that the proposed method reduces position error and tilting angle of the distal part in comparison with the method to control only a distal tip position. This research can contribute to improving a safe control of MC and can be utilized to automatic control of MC using deep learning by big data classification of various states of the catheter.

DU-15. Enhanced Steering Capability of the Distal End of a Magnetic Catheter by Utilizing Magnets with Optimized Magnetization Direction. *E. Jung*[1], W. Lee[1], J. Kim[1], N. Kim[1], J. Park[1] and G. Jang[1] *1. Mechanical Engineering, Hanyang University, Seoul, The Republic of Korea*

Conventional catheters can only be controlled from outside of a patient's body by a medical doctor which makes it difficult to precisely control the distal end of catheter. Magnetic navigation system (MNS) and magnetic catheter (MC) have been developed to overcome this limitation of conventional catheters [1,2]. Magnets in a MC make it possible to control the MC's distal end by applying an external magnetic field (EMF) generated by MNS to the magnets [3]. Conventional MCs are made of multi-magnets with same magnetization direction which tend to align along the direction of EMF. However, these MCs cannot deform only the distal end of the MC but whole MC. It does not provide precise navigating ability and it also damages blood vessel when navigating through a steeply bifurcated branch of complex blood vessel. In this paper, we propose a MC that can generate large curvature to precisely navigate through complex blood vessel. The proposed MC is composed of a flexible tube, three magnets as shown in Fig. 1(a). To design the magnetization direction of magnet1 (Φ_1) and magnet2 (Φ_2), we defined two parameters *k* (the curvature of the MC's distal end) and *D* (the vertical displacement of MC's proximal end) as shown in Fig. 1(b). We optimized *k* and *D* by utilizing Euler-Bernoulli beam theory with the application of EMF for 6 cases that satisfies $0°\leq\Phi_2\leq\Phi_1\leq180°$ (Φ_1, Φ_2=0°, 90°, 180°). We prototyped the optimized MC with enhanced steering capability in case of Φ_1=180° and Φ_2=90°. We verified its performance by comparing the curvature of the conventional MC (30.1 m^{-1}) with that of the proposed MC (77.5 m^{-1}) under same EMF (100 mT) as shown in Fig.2(a), (b). Finally, we confirmed that the proposed MC can precisely and successfully navigate through a bifurcated glass tube with -140° *in vitro* experiment as shown in Fig. 2(c).

DV-01. Structue and Output Voltage Model Optimization of Magnetostrictive Force Sensor. *B. Wang*[1,2], X. Cui[1,2], W. Huang[1,2] and L. Weng[1,2] *1. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Tianjin, China; 2. Key Laboratory of Electromagnetic Field and Electrical Apparatus Reliability of Hebei Province, Tianjin, China*

A force sensor plays an increasingly important role. It is complementary to visual perception and can be widely used in robotic grasping of objects and daily life. Since most of the existing magnetostrictive force sensor output voltage models do not consider the influence of magnetostriction on the output voltage, the model calculations are deviated from the experimental results. It is essential to establish a output voltage model that can accurately reflect the material mechanism for the magnetostrictive force sensor. A novel output voltage model is proposed considering the external forces, the bias magnetic field, and the magnetostriction. In order to prove the accuracy of the sensor output voltage model,a magnetostriction sensor for precise sensing of small external forces is designed. It consists of a sheet cantilever beam, a coil, a hard contact, a Hall element, a skeleton, and a silicone casing (Fig.1). The cantilever beam is magnetostrictive material Fe-Ga or Fe-Co sheet, which has a favorable magnetostriction combined with mechanical strength, and fast response speed. The sensor output voltage designed in this paper is studied through experiments,The output voltage of the design force sensor are measured and analyzed. It is found that the results of the theoretical calculation are consistent with the experimental ones (Fig.2). We can see that the output voltage of the sensor gradually increases as the external force increases when the magnetostriction and bias magnetic fields are constant. The results show that the proposed output voltage model of the force sensor has high accuracy and the designed force sensor has good practicability.

DV-02. A Highly Sensitive Coplanar Line Thin Film Sensor for Magnetocardiographic Measurement. H. Kudo[1], H. Uetake[3], H. Onodera[2], *L. Ton That*[1,2], S. Yabukami[1,2], J. Hayasaka[3] and K. Arai[3] *1. Tohoku University, Sendai, Japan; 2. Tohoku Gakuin University, Tagajo, Japan; 3. Research Institute for Electromagnetic Materials, Tomiya, Japan*

Highly sensitivity thin film sensors operating at room temperature are gaining more attention for use in biomagnetic measurement because they are much cheaper and easier to operate than SQUID, and can be easily integrated into sensor arrays compared to large-scale induction coils and fluxgate sensors. In previous studies, we successfully detected magnetocardiogram signals without magnetic shielding [1]. To enhance the sensitivity, this study developed a new coplanar line thin film sensor composed of CoNbZr,

SrTiO and Cu/Cr films mounted by flip chip bonding, then examined the phase change to the film thickness and the signal and noise level under a low-frequency magnetic field. As shown in Fig. 1, the sensor element was fabricated by depositing an amorphous CoNbZr film on a glass substrate by RF sputtering and processing coplanar lines of Cu film by liftoff through SrTiO film. CoNbZr film was annealed in a rotating magnetic field, then in a static magnetic field to induce transverse magnetic anisotropy. Cr film used to improve the contact between SrTiO film and Cu film. To evaluate the sensor, dc magnetic field of 0–10 Oe was changed slowly in the longitudinal direction of the coplanar by a Helmholtz coil, and the phase change of the carrier was detected by a network analyzer. The carrier frequency was 0.3 MHz–4 GHz. Fig. 2(a) shows the relationship between the thickness of CoNbZr film and the slope of phase change with respect to external magnetic field. The sensor had good characteristics with a maximum phase change of 295.8 deg/Oe and a gain of over –40 dB for CoNbZr film thickness of 1 μm under the carrier frequency of 1670 MHz and external magnetic field of 4.5 Oe. We considered that the magnetization is easily aligned in the plane, thereby magnetization rotation with less dispersion can be obtained. Next, we measured the output spectrum of the carrier under a weak magnetic field of 20 Hz and 2.7×10^{-9} T using a laboratory-made setup [2]. As shown in Fig. 2(b), the noise level achieved was approximately 100 pT/√Hz around 20 Hz.

DV-03. Design and Output Characteristics of Magnetostrictive Flexible Tactile Sensor Array. *L. Weng*[1], S. Gao[1], B. Zhang[1], S. Liu[1], B. Wang[1] and W. Huang[1] *1. Hebei University of Technology, Tianjin, China*

Tactile information is essential in determining physical properties of objects[1]. Various types of tactile sensors have been proposed, which can be categorized as piezoresistive[2], piezoelectric, capacitive, and optical sensors[3]In practical applications, the tactile sensor is required to detect multi-contact information and achieve flexible[4]. A magnetostrictive tactile sensing unit based on the Villari effect of iron-gallium alloys (Galfenol) line was designed and integrated into an flexibly array. The output characteristics of the flexible magnetostrictive tactile sensor array were tested. The magnetostrictive tactile sensing unit is composed of Galfenol wires, Hall sensor, contact, permanent magnets, and shell, as shown in Fig.1 (a). When the contact of tactile sensing unit touches an object, the Galfenol wires are deformed and the magnetic induction changes, which further cause the change of output voltage in Hall sensor. The sensing unit is consisted of three Galfenol wires with length of 10 mm and a diameter of 0.5 mm as the transducing component. Two permanent magnets are installed in the side wall of the shell to provide bias magnetic field. The Hall sensor is placed on the back side of shell. The contact is used to transfer force to bend the wires. The size of the sensing unit is 7.5 mm × 4.4 mm × 4.5 mm, and the weight is 0.56 g. The flexible array integrated with a 2 × 3 matrix magnetostrictive tactile sensing unit is fabricated on a flexible printed circuit (FPC), as shown in Fig.1 (b). Two adjacent sensing units share permanent magnets. Fig. 2 shows the relationship between the output voltage of magnetostrictive tactile sensing unit and the applied force F in the bias magnetic field of 2.5 kA / m. The results show that the output voltage increases with the increase of force applied to the unit. When the force increases to 3 N, the output voltage reaches 183.9mV. The sensitivity is 61.3 mV/ N in the range of 0 - 3 N.

DV-04. Controlling domain configuration for the sensing layer of magnetic tunneling junction by using exchange bias. *S. Ranjbar*[1], M. Al-Mahdawi[2], M. Oogane[1,2] and Y. Ando[1,2] *1. Applied Physics, Tohoku University, Sendai, Japan; 2. Center for Science and Innovation in Spintronics (Core Research Cluster), Organization for Advanced Studies, Tohoku University, Sendai, Japan*

Magnetic tunnel junctions (MTJs) are becoming important for magnetic field sensing applications, like the bio-magnetic sensing. However, the low-frequency noise is still a major challenge for low-field sensing. We expect that the main origin of magnetic noise of MTJs is the fluctuating domain walls at the center of MTJ device. The purpose of this study is controlling the multidomain structure in the sensing layer by using an exchange bias from an antiferromagnetic (AFM) layer. In this study, we used PtMn as an AFM layer because it shows higher blocking temperature (410 C) than other AFMs such as IrMn [1]. Additionally, PtMn has a large unidirectional anisotropy constant (J_k = 0.24 erg/cm^2) which is comparable with IrMn [2, 3]. We studied the effect of exchange bias on the micro-patterned Permalloy (Py: $Ni_{80}Fe_{20}$) sensing layer. We deposited (A) single Py (70 nm) layer, and (B) $Pt_{48}Mn_{52}$ (15nm)/Py (60 nm) exchange-biased films on thermally-oxidized silicon substrates. After annealing at 370 C, sample B showed a small coercivity and exchange bias (7 Oe). After micro-fabrication into 50 μm × 50 μm square pillars, we measured the domain structure by Magneto Optical Kerr Effect (MOKE) microscopy. Figures 1 (a,b) show the domain configurations of samples A and B at zero field, respectively. Sample A has a simple closure domain at the center, whereas sample B exhibits a more complicated structure but with a single domain at the center region due to exchange bias overcoming the magnetostatic energy. The dashed rectangle shown in the MOKE images is the area of pinned layer for MTJ devices. Therefore, sample B is promising for decreasing the magnetic noise due to single domain at the center of PtMn/Py sensing layer. This work was supported by the S-Innovation program, Japan Science and Technology Agency (JST) and by JSPS KAKENHI Grant Number JP19K15429.

DV-05. Improving Filmed Planar Inductor by Grooved Gratings for Sensor Applications. *X. Zhou*[1], Y. Wen[1], Y. Mu[1] and P. Li[1] *1. Shanghai Jiao Tong University, Shanghai, China*

Soft magnetic materials have relative permeabilities that are extremely sensitive to an applied magnetic field and they are always made into a specific structure such as a film structure for miniaturization and circuit integration. A filmed inductor, which consists of a planar coil sandwiched by two soft magnetic films, can show different inductances under various external magnetic fields[1]~[2]. When sensing an applied field, the films are magnetized so that the film permeability changes. Ideally, the inductance will change dramatically as much as the permeability's variation, which suggests a great potential for magnetic sensor applications[3]. However, as no closed-up magnetic circuit is formed in the film, demagnetization and flux leakage are inevitable. Hence, the inductance variation cannot perform so high as the ideal condition and the performances of the device is constrained accordingly. In this paper, we propose an approach of improving the filmed inductor's performances by producing grooved gratings on the film surfaces. First, the relationship between demagnetization and film structure is studied. The results reveal that grooved gratings not only reduce demagnetization by thinning the film, but also generate stray field whose component has the same direction as the applied field. Thus, as shown in Fig.1, the internal field (effective field) is enhanced and the variation of effective permeability is improved. On the other hand, as the filmed coil is a device that converts electrical energy into magnetic energy and stores it, the more field induced by the coil current concentrated in the film, the larger inductance the device obtains. We precisely calculate the flux in the film and the coil inductance through Maxwell's equations. In Fig.2, compared with the coil sandwiched by smooth films, the current-induced field is enhanced in the film, and both the inductance and its variation rate with different permeabilities are improved significantly. Finite-element simulations also indicate a good agreement with our analysis which suggests a more sensitive inductor in magnetic sensor applications.

DV-07. Analysis of Output Characteristic Model of 3D Tactile Sensor Based on Cantilever Beams. *L. Wan*[1] and B. Wang[1] *1. Hebei University of Technology, Tianjin, China*

Tactile sensing and recognition are indispensable for new generation intelligent robot. Along with the development of the intelligent robotic hand, tactile sensing and recognition technologies have increasingly attracted a wide attention. In this paper, a novel tactile sensor of three-axis detection is developed, which based on the material of Fe-Ga alloy. The relationship between the output voltage of the tactile sensor and the force signal of texture surface has been analyzed and the structure of tactile sensor has been designed. The 3D tactile sensor mainly composed of four Fe-Ga cantilever beams, the permanent magnet, four Hall elements, four probes and an elastomer shaped as fingertips, as shown in Fig.1. In order to increase the flexibility of the tactile sensor, the four probes at the free end are wrapped together in elastomer, while the other end is installed at a cylindrical base, 90 degrees apart from each other. The maximum magnetostrictive coefficient of the cantilever beam exceeds 280ppm along the rolling direction. The cylindrical base has the radius of 11mm and the fingertip-like the elastomer has the height of 5mm. The 3D tactile sensor is mounted on the support bracket and can touch the surface texture of the object from different angles. The contact between the elastomer and the surface of the object moving at a certain speed forms a contact surface, whose normal stress and shear stress can be analyzed according to the three-dimensional stress state. After the elastomer of 3D tactile sensor is deformed by external object, the positions of the four probes fixed at the free end of the cantilever beam are changed, and drive the Fe-Ga sheet to move up and down. According to Fig.1, the results of the analysis and simulation show that the normal stress on the four probes is the same in the same direction; one shear stress acts on the cantilever beams in the x-axis direction is equal in the magnitude but opposite in direction; the same is true for the cantilever beams in the y-axis direction. Therefore, the four output voltages of the 3D tactile sensor, related with the stress can reflect the texture information of the object surface from three dimensions.

DV-08. The output characteristic of texture tactile sensor based on the inverse-magnetostrictive effect and the surface texture detection. *L. Wan*[1] and B. Wang[1] *1. Hebei University of Technology, Tianjin, China*

Humans rely on sense of touch for perception and control of the body, grasping, manipulating, and identifying objects via their physical properties, such as texture, shape, and stiffness. The perception of the textural properties of object is one the most challenging task in robotics. In order to extract robust features from the generated raw tactile signals during tactile object exploration, the key is to design a set of novel tactile sensor. However, research work on the tactile sensor, based on the inverse-magnetostrictive effect, is rare. Therefore, it is necessary to investigate the output characteristic of the texture tactile sensor based on the inverse -magnetostrictive effect. The output voltage model for the texture tactile sensor has been developed, according to the inverse-magnetostrictive effect, the Jiles-Atherton model, the hall effect and the strain theory of the beam. The output voltage detected by the Hall element is mainly related to the bias magnetic field, the contact depth, the contact pressure angle, the width of the ridge and the groove of the object surface. The contact depth is determined by the normal force applied to the texture tactile sensor. The prototype of the texture tactile sensor is manufactured, based on $Fe_{83}Ga_{17}$ alloy sheet, which has the length of 10mm, the width of 3mm, and the thickness of 0.1mm. Fig.1 shows the relationship between output voltage of texture tactile sensor and normal force under different magnetic induction. The experimental result shows that output voltage increases with increasing normal force (in the range 0-1.15N). From the data in Fig.1, the ratio of output voltage to normal force is 16mv/N, 27mv/N, 28mv/N,24.5mv/N, while the magnetic induction changes from 0.1T to 0.4T. Therefore, the normal force and the magnetic induction from the permanent magnet provide the basis for the design of the tactile sensor. In addition, the texture tactile sensor mounted on an artificial fingertip has been designed to detect surface textures of different dimensions. The output signal generated during the exploratory movement of the finger reliably correlates to all the widths of grooves and ridges of the surface textures under investigation.

DV-09. Dependence of the noise of an orthogonal fluxgate on the composition of its amorphous wire-core. *M. Butta*[1,2], M. Vázquez[2], R. Pérez del Real[2] and E. Calle[2] *1. Faculty of Electrical Engineering, Czech Technical University in Prague, Prague, Czechia; 2. Consejo Superior de Investigaciones Científicas - CSIC, Instituto de Ciencia de Materiales de Madrid, Madrid, Spain*

Amorphous magnetic wires have been used for long time as cores of orthogonal fluxgate sensors as well as for other sensors such as GMI. Despite the good results in terms of the noise [1] of the fluxgates based on such wires we still have limited information about the origin of this noise. In this paper we study the dependance of the noise on the composition of the wires. We casted amorphous wires changing the composition $(Co_{100-x}Fe_x)_{72.5}Si_{12.5}B_{15}$ for different values of x: 5, 5.5, 6, 6.2, 6.5, 7 and 8. We changed the relative amount of iron and cobalt keeping the total amount of these two elements unchanged to the respect of silicon and boron. By doing so we changed the magnetostriction of the alloy, because of the different compensation between positive and negative contribution to magnetostriction brought by iron and cobalt [2]. The wires were produced by water quenching and they all had diameter between 120 and 130 μm. We manufactured three sensors for each composition using wires produced with three different master alloys and three casting processes to avoid the effect of the random defects due to the manufacturing process. There wires were cut in 8 cm long pieces and used as cores for orthogonal fluxgate. Each core had 2 wires connected in series and soldered on a fiberglass substrate at 3 mm distance. Finally a 2500 turns pick up coil was wound around the cores. All sensors showed resonance at a value of frequency around 40 kHz. We then measured the noise using 50 mA DC current in the wires added to an AC component at 40 kHz with different values of amplitude. The lowest noise was obtained for all sensors around 40 mA. Fig. 1 shows the dependence of the noise at 1 Hz vs. the percentage of iron in the wire. We clearly see that the minimum noise (about 2.5 pT/√Hz) is achieved between 6 and 6.2 % of iron, which should give the minimum magnetostriction [2]. This indicates that a component of the noise in orthogonal fluxgates is caused by the magnetostriction connected to the stress introduced to the wires during casting and during the assembling of the sensor.

DV-10. Elastomer Based Force Sensor Fabricated by 3D Additive Manufacturing. *M.G. Kisic*[1], N.V. Blaz[1], L.D. Zivanov[1] and M.S. Damnjanovic[1] *1. Department of Power, Electronic and Telecommunication Engineering, University of Novi Sad, Faculty of Technical Sciences, Novi Sad, Serbia*

Numerous sensors with ferrite materials are fabricated for specific sensing applications [1, 2]. A large number of innovative sensors demonstrated very good performances of silicone rubber Ecoflex for realization of various sensors [3]. In this paper a new simple soft inductive magnetic sensor for force measurement is presented. The working principle of the sensor is based on the variation of the inductance caused by distance changes of ferrite in close proximity to the inductor. The sensor consists of a casing, an inductor, a piece of ferrite and a layer of elastomer (Fig. 1.). For the fabrication of inductor are used 3D printer and silver. The rectangular spiral inductor has outer dimensions of 21x25mm^2, 8 windings, and lines of width and spacing of 600 μm. At comparison of various fabrication technologies additive technology is one of the more reliable which enables the realization of cost-effective sensors with enhanced features. The dimensions of the used ferrite are 21x25x3.7mm^3. Two liquid parts of Ecoflex (vol. 1+1 ml) are mixed, poured into the 3D printed mold (in the shape of a matrix with outer dimensions of 21x25x1.5mm^3), cured under room temperature for 4 hours after which it is demolded from the mold. Sensor's elastic layer is in the form of a matrix in order to achieve a better elasticity of Ecoflex and sensitivity of the sensor. Ecoflex rubbers open new opportunities for designs of the sensor simultaneously with good performances due to their good properties. The casing of the sensor is 3D printed, with 4 pins in the corners in order to hold all the components together. All fabricated parts of the sensor are placed in the casing and the characterization of developed sensor is done by employing Impedance Analyser4194A and in house developed forcer. The Ecoflex deforms under the applied force which decreases distance between the inductor and the ferrite and causes the increase in the inductance of the sensor (Fig. 2.). The measurements are done for the forces up to 2N and the obtained sensitivity is 2nH/N.

DV-11. High-Performance Magneto-Resistive Cytometer of Filtered Magnetically Labeled Cells. *S. Amara*[1], M. Alawein[1] and H. Fariborzi[1] *1. CEMSE, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia*

Flow cytometers provide rapid and reliable analytical capabilities, making them an important tool for biological and biomedical analyses. We propose a compact magnetic biosensor cytometer with Tunneling Magneto-Resistive (TMR) sensors suitable for the detection of cells labeled with superparamagnetic beads. This concept has a number of distinct advantages. Firstly, biological samples hardly contain any magnetic material; therefore the detection background is intrinsically low. Secondly, TMR sensors for label detection can be integrated on-chip [1-6]. A spiral microfluidic device with a trapping magnet is implemented to filter free beads and separate them from labeled cells. The curvilinear micro-channels under continuous flow presents an inherent Dean Vortex which focus larger labeled cells against the inner wall, with inertial lift forces. The trapping magnet is added to further improve the separation of free beads from labeled cells. The labeled cells are directed to pass by the TMR sensor, where their passage is detected. The cytometer consists of TMR sensor with a high sensitivity of 12%/Oe (Fig.1.a) and a curvilinear polydimethylsiloxane micro-channel (Fig.1.b). The beads, magnetized by 15 Oe external field, are used to label the human embryonic kidney cells 293. The stray fields of the bead can be sensed by the MTJ, if the magnetic bead is within the sensing region. The sensor is first tested using free beads in a simple linear PDMS micro-channel. When magnetic beads pass over the TMR sensor, the resistance of the sensor changes, causing a variation of the sensor output voltage (Fig. 2). When free beads are filtered by the micro-fluidic channel, no significant peak is detected. When injecting cell-bead compounds (after 24h of incubation), signals are observed even after filtering, indicative of labeled cells passing by the sensor. The results prove the efficiency of the implemented filter and sensor system for detection of magnetically labeled cells.

DV-12. Magneto-mechano-electric devices operating in torque mode without magnetic bias field. *J. Wu*[1], Z. Hu[1], Z. Wang[1], Z. Zhou[1] and M. Liu[1] *1. Xi'an Jiaotong University, Xi'an, China*

Giant magnetoelectric coefficient is discovered in laminated composites consisting of piezoelectric and magnetostrictive layers, where the magneto-mechano-electric coupling effect is mediated by strain.[1-3] To obtain the highest ME coefficients under a small AC magnetic field, magnetostrictive layer in ME composites must be DC biased to the point of maximum slope in the strain-magnetic field curve, inducing an ME voltage via piezoelectric effect.[4-6] Here, we propose a stress-mediated magneto-mechano-electric structure operating in torque mode without DC bias, which can be designed as a magnetic field sensor, a magnetic energy harvester, or a magnetic compass. NdFeB permanent magnets combined with elastic layers are employed to induce compressive stress on piezoelectric layer via torque effect under an external magnetic field, thus the structure is suitable for magnetic field sensing and energy harvesting. The proposed ME sensor detects both DC and AC magnetic fields, of which the sensitivities are ~0.01 Oe and ~0.001 Oe, respectively. A barbell-shaped magneto-mechano-electric device that mediated by stress reveals excellent performance for harvesting low-frequency magnetic field energy, presenting a low resonate frequency (<50 Hz), a ME coefficient higher than 1 V/cm Oe, a high output voltage (>10 V @ 10 Oe), and a maximum output power of ~10.5 μW. A magnetoelectric compass is designed for detecting the direction of an in-plane AC magnetic field. The intensity sensitivity and angle sensitivity of the proposed ME compass are 0.01 Oe and 0.2°, respectively. The multiple

functionalities realized in the magneto-mechano-electric devices without DC bias field show great potential for low power applications.

DV-13. Investigation of low-frequency noise dependent on serial MTJs with various junction areas. *Z. Jin*[1], Y. Wang[1], M. Oogane[1,2] and Y. Ando[1,2] *1. Applied of Physics, Tohoku University, Sendai, Japan; 2. Center for Science and Innovation in Spintronics, Tohoku university, Sendai, Japan*

Magnetic tunnel junctions (MTJ) have received much attention due to their ultra-high tunnel magnetoresistance (TMR) [1], which can be used as high-sensitivity magnetic sensors to detect small variations in magnetic fields. To date, many studies focus on enhancement in TMR to improve sensitivity. However, the reduction of low-frequency noise is a noticeable issue for improvement of MTJ performance. Previous studies indicated that an integrated MTJ sensor could suppress low-frequency noise [2], and the electrical 1/*f* noise is related to junction area [3]. Since the choice of MTJ area has an important effect on low-frequency noise, this study investigated the low-frequency noise properties in serial MTJs with various junction areas. The stacking structure of films was SiO2 sub./Ta(5)/Ru(10)/Ta(5)/$Ni_{80}Fe_{20}$(70)/Ru(0.9)/$Co_{40}Fe_{40}B_{20}$(3)/MgO(1.6)/$Co_{40}Fe_{40}B_{20}$(3)/Ru(0.9)/$Co_{75}Fe_{25}$(5)/$Ir_{22}Mn_{78}$(10)/Ta(8)(in nm). Three types of 20 serial-MTJs sensor were fabricated with junction areas of 598 μm^2, 1520 μm^2, and 4488 μm^2, respectively. In addition, their transfer curves, noise power spectral densities, and Signal/Noise (S/N) ratio were measured. Figure 1(a) shows noise power spectral densities of serial MTJs with junction areas at a bias voltage of 100 mV and zero magnetic field. The dominant 1/*f* can be determined at the low-frequency region. The result indicated that the low-frequency noise can be decreased by increasing junction area. Figure 2(a) shows the output signals from the sensors when a 23 Hz AC magnetic field was applied from Helmholtz coils which shows clear voltage peaks. Fig. 2(b) shows the dependence of S/N ratio ($V_{peak}/V_{background}$) on the junction area at a bias voltage of 100 mV. Owing to small low-frequency noise, the high S/N ratio was obtained in the serial MTJs with a large junction area (4488 μm^2). This study indicated the choice of junction area is very important to reduce noise power and enhance the detectivity of the MTJ sensor.

Electrical steel sheets are widely used in electromagnetic devices as core material. During the manufacturing of these devices the core undergoes plastic and elastic deformations. These deformations affect the magnetic properties of the material which in return affects the performance of the electromagnetic devices [1-3]. In addition, it is important to understand the effect of elastic stresses imposed in plastically deformed materials in order to develop magnetic methods for nondestructive evaluation. This paper studies for the first time the effect of simultaneous plastic and elastic deformations on the magnetic properties and iron losses of M400-50A electrical steel. The dog-bone shaped steel specimens were prepared by pre-straining the samples to various plastic strain levels ranging from 0.2% to 10% using a universal testing machine. A custom made uniaxial single sheet tester from [4] was then used to measure the magnetic characteristics of the samples under alternating field and various additional tensile and compressive elastic stresses. The magnetic flux density (*B*) and magnetic field strength (*H*) were measured by *B*-coil and tunneling magneto resistive sensor at the middle of the specimen, respectively. The supply voltage waveform of the magnetizing device was controlled to obtain sinusoidal flux density at the measurement area. *B-H* loops were measured at various flux density amplitudes and magnetizing frequencies. In Fig. 1 (a) and (b) the measured *B-H* loops for various pre-strained samples are shown. The plastic deformation increases the coercive field and decreases the permeability significantly compared to undeformed sample. These effects are attributed to change in dislocation density and pinning sites as a result of the plastic deformation. In Fig. 2 (a) and (b) the variation of the energy loss density of undeformed and 1% deformed sample at 10 Hz and 1.5 T peak flux density with respect to the applied elastic stress is shown. The detailed analysis of the effect of plastic deformation together with elastic stress on the magnetic properties and on different iron loss components in electrical steel sheets will be studied in the full paper.

DW-02. Soft Magnetic Properties of a FeCoNiGaNb High Entropy Alloy. *C. Bormio-Nunes*[1], F. Martins Cardoso[1] and P. Pereira[1] *1. Engenharia de Materiais, Universidade de São Paulo - Escola de Engenharia de Lorena, Lorena, Brazil*

Soft magnetic material (SMM) applications comprise diverse requirements that are frequently tough and challenging for their design and fabrication. The SMMs must have a maximum permeability, small coercive force, hysteresis loss and remanent magnetization, as well as high saturation magnetization. AC applications involve equipments as power supply transformers, DC-DC Converters, electric motors and the most important issue is the material energy loss. Here we report a class of SMM material based on high-entropy alloys (HEAs) [1]. The alloy is composed of Fe, Co, Ni, Ga and Nb. The alloy has two phases, where the majority phase has a fcc structure. The second phase occupies only 9% of the volume and is richer in Nb compared to the main phase. The FeCoNiGaNb microstructure is shown in Fig. 1. Although the material is not single phase, the soft magnetic properties of the material are favorable. Magnetization measurements as a function of applied magnetic field made on a PPMS/VSM system from QD at 300K are depicted in Fig. 2. The attained coercive field is H_c = 793 A/m, the remanent magnetization is14 mT and the saturation polarization 0.68 T. Extrapolation of the magnetization vs temperature data, measured in the interval between 4 and 310 K, by using second order polynomial and exponential decay curves resulted in Curie temperatures of 721K (448 C) and 851K (578 C) respectively. The elimination of the second phase should have a positive effect on magnetic properties causing a decrease of H_c value, because it can be acting as domain wall pinning centers. In addition, if the second phase is not ferromagnetic, which is expected since it is Nb rich, the increase of the saturation magnetization is probable. Complementary data of resistivity, plus new data on the single phase alloy will be presented.

DW-03. Effects of neutron irradiation on magnetic first-order reversal curves in reactor pressure vessel steels. *S. Kobayashi*[1], H. Murakami[1], A. Horvath[2], L. Almasy[2], F. Gillemot[2] and A. Feoktystov[3] *1. Iwate University, Morioka, Japan; 2. Hungarian Academy of Science, Budapest, Hungary; 3. Forschungszentrum Julich GmbH, Garching, Germany*

Magnetic method is one of useful non-destructive evaluation techniques for irradiation hardening in reactor pressure vessel (RPV) steels. Recent magnetic measurements revealed the competing mechanism due to recovery and formation of nanoscale features, which contribute to magnetic softening and hardening, respectively [1]. While neutron-irradiated materials have been investigated by measuring a major loop, first-order reversal curves (FORCs), which are one type of minor loops, have been rarely measured, primarily due to a difficulty of installing large FORC measurement system in hot cell laboratory. Here, we report results of the first attempt of measuring FORCs for neutron-irradiated RPV steels. Russian-type VVER440 and high-Ni VVER1000 steels [2], were neutron-irradiated at 290^{O}C up to a fluence of 4.3 x 10^{19} n/cm^2. FORC distribution as a function of switching field Hc and interaction field Hu, was obtained by analyzing FORCs [2]. Figs. 1(a) and 1(b) show a FORC diagram for VVER440 before and after neutron irradiation. The FORC diagram has a single FORC distribution peak on the Hc axis, which slightly shifts towards a lower Hc after irradiation. Figs. 1(c) and 1(d) show a change in the peak position $H_{c,p}$ and width parameter s of the FORC distribution peak along the Hc axis, obtained by least-squares fits assuming lognormal distribution function. For VVER440, both $H_{c,p}$ and s decrease with neutron fluence, while those for VVER1000 are almost constant. A decrease of $H_{c,p}$ reflects a magnetic softening due to recovery. On the other hand, a decrease of s indicates that magnetic inhomogeneity originating from a mixture of magnetically hard (bainite) and soft (ferrite) phases, is reduced for VVER440, while matrix microstructure is rather stable for VVER1000. The present investigations demonstrate that FORCs provide useful microstructural information for irradiated materials, which was not revealed by conventional hysteresis measurements.

DW-04. FeSiAl Thin Films with Low Magnetic Anisotropy for the Free Layer of Magnetic Tunnel Junction Based Sensors. *S. Akamatsu*[1], M. Oogane[1,3], M. Tsunoda[2,3] and Y. Ando[1,3] *1. Applied Physics, Graduate School of Engineering, Tohoku University, Sendai, Japan; 2. Electronic Engineering, Graduate School of Engineering, Tohoku University, Sendai, Japan; 3. Center for Spintronics Research Network, Tohoku University, Sendai, Japan*

Soft magnetic materials such as NiFe, CoFeSiB have been used for a free layer in magnetic tunnel junctions (MTJs) for bio-magnetic field sensor because of their soft magnetic properties [1, 2]. However, these materials need to form a complicated stacking structure with CoFeB, facing to MgO barrier, to obtain high tunnel magnetoresistance (TMR) ratio. In this work, we focus on $Fe_{85}Al_{9.6}Si_{5.4}$ (Sendust) alloy which has $D0_3$-ordered structure and shows very low anisotropy associated with the $D0_3$ structure in bulk. By using Sendust film as a free layer of MTJs, both low magnetic anisotropy and high TMR ratio might be realized because of the coherent tunneling due to its good epitaxial relationship with MgO barrier and structural similarity to bcc-Fe[3]. However, FeSiAl thin films with nm-order thickness have never been fabricated, so we didn't know whether FeSiAl thin film could be fabricated, have $D0_3$-ordered structure and show soft magnetic property. We optimized post-annealing temperature to obtain FeSiAl thin film with such structural and magnetic property. All films with the stacking structure of MgO(20)/FeAlSi(30)/Ta(5) (in nm) were deposited on MgO (001) substrates using magnetron sputtering. After the deposition, the films were annealed at = 300-500 degrees for 1 hour. Their crystal structure, surface roughness, and magnetic properties were measured by X-ray diffraction (XRD), atomic force microscope (AFM) and vibrating sample magnetometer, respectively. Fig. 1 shows the XRD patterns for prepared FeAlSi films. For f-scan measurements, four-fold symmetric (111) peaks from $D0_3$-ordered structure were observed at = 400 and 500 degrees. We firstly succeeded in the fabrication of $D0_3$-ordered FeAlSi epitaxial thin films grown on MgO substrates. Fig. 2 shows magnetization curves for FeAlSi films with various T_a. The film annealed at =500 degrees showed the lowest = 1.8 Oe because of the $D0_3$ ordering. The obtained small H_c is comparable to NiFe [1] and CoFeSiB [2] films. We also confirmed by AFM measurement that $D0_3$-ordered FeAlSi films possess a low surface roughness of R_a~0.3 nm. The fabricated $D0_3$-ordered FeAlSi thin film with soft magnetic property is a promising candidate for a free layer of MTJ based sensors.

DW-05. Magnetization Process and Loss Decomposition in Fiber-Laser-Irradiated Grain-Oriented Steel Sheets. *S. Dobak*[1], J. Fuzer[1], P. Kollar[1], I. Petryshynets[2] and F. Kovac[2] *1. Institute of Physics, Faculty of Science, P. J. Safarik University, Kosice, Slovakia; 2. Division of Metal Systems, Institute of Materials Research, Slovak Academy of Sciences, Kosice, Slovakia*

Progress in loss reduction of grain-oriented (GO) steels, the key material for large-scale power transformers, has been achieved by generating thermomechanical stress to induce the artificial domain refinement [1,2]. Its influence on the bulk DC behavior has recently been understood by advanced domain imaging [2]. Little, however, is concluded on the quantitative correlation between dynamic excess loss and domain formation, affected by post-processing, playing a chief role in loss prediction at working frequencies. In this study we discuss how selective laser-irradiation, particularly designed to improve the dynamic loss response (Fig. 1), stimulate homogenization of discrete magnetization process with the attention to its theoretical assessment encompassing hysteresis and excess loss counterparts. Electric-spark-cut 3.2% Si GO sheets were stress-relief annealed and exposed to fiber laser scribing of either solid (continuous) or dotted (pulse) lines. A matrix of line spacing L (4–10 mm) and beam irradiated power P (12–240 W) was imposed to instigate domain walls (d.w.s) rearrangement, due to the interaction with residual stress pattern, in a controlled fashion. The loss in continuously treated sheet at low L decreased by 40% at $f \geq 50$ Hz while in pulse one by 16% even at 10 times higher P. By resorting to the statistical considerations on activated d.w.s [3], the dynamic d.w.-generated loss $W_{exc,calc}$ can be calculated (Fig. 2). Excellent predictive capability allows for mapping the effect of L and P on the number n of d.w.s, involved in magnetization reversal at the same time, defining the f-evolving domain structure to quantifiable extent. Such analysis, supported by domain imaging, revealed that $n(f \rightarrow 0) \sim 10–50$ increases with lower L and higher P resulting in moving width of a distribution of local d.w. pinning fields $\Delta H_c \sim 5–23$ A/m. Higher f brings about the extra domain refinement and ensuing smoothing of underlying process with further increase of n up to ~ 100 at $f = 200$ Hz and $J_p = 1.5$ T. *Support by the Slovak Research and Development Agency [APVV-18-0207] is acknowledged.*

DW-06. Magnetoimpedance studies on electrodeposited NiFe composite wires. *S. Vasam*[1] and S. Veeturi[1] *1. Physics, Indian Institute of Technology Madras, Chennai, India*

The giant magnetoimpedance effect has been observed in composite wires that consist of a highly conductive non-magnetic inner core and soft magnetic shell [1]. Experimental and theoretical studies have demonstrated that the presence of highly conductive inner core in composite wires results in significant increase of GMI effect [2]. The GMI is proportional to the skin depth, which varies with permeability (μ), conductivity (σ) and frequency (ω). In this work, we present the effect of core-wire diameter and its conductivity on GMI effect is studied experimentally. The electrodeposition of NiFe on 0.1(*C1)*, 0.2(*C2)*, 0.4(*C3)*, 0.6(*C4)* and 1.17(*C5) mm* diameter wires was done. Further magnetoimpedance measurements were also carried out on NiFe deposited on Ag ($0.63*10^8(\Omega m)^{-1}$), Cu ($0.58*10^8(\Omega m)^{-1}$) and $Ni_{80}Cr_{20}$ ($0.66*10^6(\Omega m)^{-1}$) wires. The electrodeposition was carried by using, $NiSO_4.6H_2O$ (0.2M), $FeSO_4.7H_2O$ (0.025M), H_3BO_3 (0.4M), NH_4Cl (0.28M), and Sodium saccharin (1g/L) bath. Magneto-impedance (MI) was measured using a IM 3536 impedance analyser. As shown in Fig.1, a maximum GMI value (705%) was observed at 50 kHz for NiFe/Ag while for sample deposited on Cu-wire (611%) was observed at 80 kHz. This could be due to higher conductivity of Ag core-wire. on the other-hand a maximum GMI value of 96% was observed at 500 kHz for the sample deposition on $Ni_{80}Cr_{20}$ wire. These observations suggest that if the conductivity of the substrate is increased maximum GMI values are shifted to low frequency

region (500kHz to 20kHz). From Fig.2. we observe high magnetoimpedance (611%) in case of C1 while for C5 the maximum MI drops to 31%. From the present observations we conclude that the frequency at which maximum magnetoimpedance is observed can be controlled by varying the substrate conductivity. On the other-hand the GMI values and sensitivity can be enhanced by choosing highly conducting substrates. As the thickness of the Cu-wire is increased maximum GMI value is observed to decreaseThe detailed experimental data supported by theoretical simulations.

DW-07. A Statistical Method for Modeling the Magneto-elastic Coupling Behavior of Magnetic Materials. *X. Yuan*[1] and L. Li[1] *1. North China Electric Power University, Beijing, China*

In order to accurately model the magnetization and loss properties of magnetic materials, a physic based model is needed to describe the phenomenon of magneto-mechanical coupling [1]. Since these phenomena usually have relatively complex nonlinear relationships, few macroscopic constitutive equations can accurately describe the effects of stress on the magnetic susceptibility and magnetostriction of the magnetic materials [2]. At the microscopic scale, the magnetic susceptibility and the magnetostriction of the magnetic materials is related to the structure of magnetic domains [3], which affects the technical properties of magnetic materials. As the intensity of the external magnetic field increases, the domain walls move and results in an increase in the number of domains whose directions are closer to the direction of the external magnetic field and a decrease in the number of domains whose directions are far from the direction of the external magnetic field. In the case of the application of stress, the stress state will also have an influence of this process which leads to the macroscopical magnetic susceptibility and magnetostriction of the magnetic materials [4] [5]. The potential energy of a magnetic domain in the magnetic materials is divided into exchange energy, magneto-static energy, magneto-crystalline energy and elastic energy. For each possible magnetization direction, the higher potential energy leads to the lower existence probability. In this paper, the existence probability of each possible magnetization direction is calculated, and the statistical method is used to model the magnetization process of the magnetic material. The magnetostriction and magnetization of two magnetic materials, giant magnetostrictive material Terfenol-D and iron-cobalt alloy are modelled by using the statistical method. Fig.1 shows the calculated macroscopic magnetostrictions of the single crystal of Terfenol-D in different directions under the applied external magnetic field. Fig.2 shows the calculated magnetization of iron-cobalt alloy under the external magnetic field and different applied uniaxial mechanical stresses.

DW-08. Magnetic properties of Fe-Ni-system films prepared by electroless deposition. *R. Tanaka*[1], R. Ueno[1], K. Mieda[1], J. Kaji[1], A. Yamashita[1], T. Yanai[1], M. Nakano[1] and H. Fukunaga[1] *1. Nagasaki University, Nagasaki-Shi, Japan*

Fe-Ni alloys are well-known as soft magnetic materials with excellent soft-magnetic properties, and we have reported the good soft magnetic properties of Fe-Ni films prepared by an electrodeposition method [1-3]. An electroless deposition method is also chemical technic to obtain films, and the process has some advantages such as thickness uniformity, economic viability, and high selectivity of substrates. Although some researchers have reported Fe-Ni films with good magnetic properties prepared by an electroless deposition [4-6], deposition rates were not enough high (< 10 μm/h). In the present study, we developed an electroless deposition process with high deposition rate for Fe-Ni-system films. The plating bath was consisted

of $NiSO_4$-$6H_2O$:50 g/L, $FeSO_4$-$7H_2O$:70 g/L, $C_6H_5Na_7$-$2H_2O$ (Trisodium Citrate Dihydrate): 110 g/L, $(NH_4)_2SO_4$ (Ammonium Sulfate): 60 g/L, $NH_4OSO_2NH_2$ (Ammonium Amidosulfate):25 g/L, H_3BO_3: 25 g/L, $(CH_3)_2NH$-BH_3 (Dimethylamine-Borane): 5 g/L. A Cu plate was used as a substrate, and the pH of the bath was adjusted to 7.5 using KOH. The bath temperature was changed from 70 to 80°C. Figure 1 shows the thickness of the Fe-Ni films as a function of the plating time. As shown in Fig.1, the thickness tends to increase with increasing the bath temperature. The deposition rate estimated from liner fitting curves was approx. 15 μm/h, and this rate is higher than that for Ref. 4. Although we can obtain high deposition rate, the surface condition was inferior as shown in the inset. To improve the surface conditions, we investigated a replacement of Ni with Co in the Fe-Ni film. Figure 2 shows the coercivity as a function of the Co content. The coercivity shows almost the same value up to 25 at.%-Co followed by a dramatic increase. The surface conditions were improved by the Co substitution. From these results, we found that a small amount of Co is effective to improve the surface condition of the electroless-deposited-Fe-Ni films without deterioration of good soft magnetic properties.

DW-09. Magnetic Loss Reduction in FeGa/NiFe Laminates for Strain-Mediated Multiferroic Micro-Antenna Applications. *K. Fitzell*[1], A. Acosta[1], C. Rementer[1,2], J.D. Schneider[3], J. Hu[3], A. Sepulveda[3], G. Carman[3] and J.P. Chang[1] *1. Chemical & Biomolecular Engineering, University of California, Los Angeles, Los Angeles, CA, United States; 2. Lam Research, Fremont, CA, United States; 3. Mechanical & Aerospace Engineering, University of California, Los Angeles, Los Angeles, CA, United States*

The ability to reduce the size of antennae would enable a revolution in wearable and implantable electronic devices. Multiferroic antennae, composed of individual ferromagnetic and piezoelectric phases, could reduce antenna size by up to five orders of magnitude through the efficient coupling of magnetization and electric polarization via strain. This strategy requires a material with strong magnetoelastic coupling and acceptable magnetic losses at high frequency. In this work, nanoscale laminates containing alternating layers of FeGa (possessing large magnetostriction but poor loss properties) and NiFe (possessing excellent loss properties but virtually no magnetostriction) were fabricated via DC magnetron sputtering to combine the complementary properties of the two magnetic phases, resulting in a composite material with a small coercive field, narrow ferromagnetic resonance linewidth, and high permeability (Rementer et al., 2017). Optical magnetostriction measurements confirmed that these laminates retain the large saturation magnetostriction of FeGa (200 με) while enhancing the piezomagnetic coefficient (7 ppm/Oe), allowing for optimal piezomagnetic actuation at substantially reduced magnetic bias fields. To further enhance the magnetic loss properties at high frequency, ultrathin layers of Al_2O_3 were incorporated into the multilayer materials to reduce the conductivity and mitigate the generation of eddy currents. The effect of Al_2O_3 thickness, FeGa:NiFe volume ratio, and multilayer architecture on the soft magnetic properties was studied, resulting in a 50% reduction in the ferromagnetic resonance linewidth. Optimized magnetic laminates were shown to exhibit a small coercive field (<20 Oe), narrow ferromagnetic resonance linewidth (<50 Oe), and high relative permeability (>500) while maintaining excellent magnetoelastic coupling, showing great promise for the use of FeGa/NiFe/Al_2O_3 laminates in strain-mediated micro-scale communications systems.

DW-10. Development of Rapid Cooling Atomizing Method and Production of High-B_s Nanocrystalline Powder with Large Particle Sizes. *K. Uji*[1], T. Tomita[1], K. Yoshida[1], T. Takahashi[1] and h. kuwata[1] *1. Tohoku magnet institute Co., LTD., Sendai, Japan*

An expectation for a nanocrystalline soft magnetic powder is increasing for a purpose of miniaturization and enhancing an efficiency of electronic devices. It seems to be important to achieve both a high saturation magnetic density, B_s, and a low coercivity, H_c, of a soft magnetic powder. In order to produce a high-B_s nanocrystalline powder, it is strongly required to produce an amorphous precursor with a quite rapid quenching rate. Yoshida[1] reported a new atomizing machine named as "HPWA/YK" which is based on a water atomization, and production of a $Fe_{83.3}Si_4B_8P_4Cu_{0.7}$ nanocrystalline powder with 5μm in an average diameter. A frequency dependent of a permeability of a soft magnetic core depends on particle size distribution. Therefore, it is important to produce powder of various particle sizes. However, it was difficult to obtain an amorphous precursor with a relatively large particle size (>10μm) avoiding precipitation of undesirable crystal grain. In this work, nanocrystalline powder with various particle sizes were produced using "HPWA/YK" machine. A molten metal with a composition of $Fe_{83.3}Si_4B_8P_4Cu_{0.7}$ was atomized in two steps. The fluid of the primary atomization and the secondary atomization were high pressure nitrogen gas and high pressure water, respectively. As a result, it was found that the cooling rate increased as the ratio of the gas pressure and water pressure increased, and amorphous precursor powder with particle size in the range of 5μm to 10μm were obtained. Finally, the amorphous powder having an average particle size of 18μm was obtained by removing the fine particles using an air flow classifier. After nanocrystallization, the B_s was revealed

as 1.68 T. It was exceedingly higher than that of conventional atomized amorphous powder (B_s < 1.4 T). In addition, it showed the low coercivity (128 A/m). These results indicate the evolution of cooling capability of the "HPWA/YK" machine.

DW-11. Soft Magnetic Co-rich Nanocrystalline Alloys for GMI Applications at Elevated Temperatures. F. Andrejka[1], *J. Marcin*[1], P. Svec[2] and I. Skorvanek[1] *1. Institute of Experimental Physics SAS, Kosice, Slovakia; 2. Institute of Physics SAS, Bratislava, Slovakia*

Technological demand for soft magnetic materials, which offer a reasonably large magnetic induction and at the same time are capable of operation at elevated temperatures has led to an increased interest in HITPERM-type FeCo-based nanocrystalline alloys prepared by devitrification of melt-spun amorphous precursors [1]. These alloys usually show a strong response to the magnetic field annealing, which can be used for tailoring the shape of their hysteresis loops for desired applications [2,3]. Heat treatment in magnetic field was also found to be a powerful tool for tuning of giant magnetoimpedance (GMI) characteristics in HITPERM alloys [4]. In this work, a controllable field annealing induced magnetic anisotropy was produced in series of Co-rich $(Co_{1-x}Fe_x)_{81}Nb_7B_{12}$ (x=0, 0.14 and 0.25) nanocrystalline alloys. The amorphous precursors were nanocrystallized at 773 K for 1 hour in longitudinal (LF) or transversal (TF) magnetic field. Reference samples were annealed in zero (ZF) magnetic field. Special attention is focused on testing the high temperature stability of soft magnetic properties and GMI characteristics in temperature range from 293 K to 573 K. The magnetoimpedance measurements are performed over a frequency range 0.1 – 100 MHz. The GMI response of LF annealed samples exhibits a single-peak behavior in whole frequency range investigated. On the other hand, ZF and TF annealed samples are characterized by a double-peak behavior. Our results show that the samples with higher amount of Co exhibit a stronger GMI response. The highest values of ΔZ/Z ratio ≈ 310% and sensitivity η ≈ 23%/Oe were observed at frequency 90 MHz for $Co_{81}Nb_7B_{12}$ sample annealed in transverse magnetic field. Application potential of such materials for construction of GMI magnetic sensors capable of operation at high temperatures is briefly highlighted. *This work was supported by the projects APVV-15-0621, VEGA 2/0171/19 and JRP SAS-TUBITAK MAGSAT.*

DW-12. Oxygen dependence of transparent amorphous magnetic thin films Co-Fe-Ta-B-O magnetization: experiments and simulations. *C. Xiong*[1] and X. Zhang[1] *1. Material Science and Engineering, Tsinghua University, Beijing, China*

Quaternary alloy Co-Fe-Ta-B with very high Young's modulus and fracture strength has extraordinary soft magnetic properties and unusual magnetic behaviors like spin reorientation transition. Recently, researchers made the magnetic thin film transparent by oxygen doping. So that a lot of interesting electric, magnetic and optic properties are generated, which brings it a potential to fabricate magnetic semiconductor. These properties are very sensitive to the oxygen content in Co-Fe-Ta-B-O system. We fabricated the films $(Co_{20}Fe_{47}Ta_{20}B_{13})_{1-x}O_x$ of ~100 nm in thickness by using magneto sputtering method. The oxygen content x can be divided into 3 regions. First is the metallic region when x is less than 0.37, the magnetization behavior is like soft bulk metal material with a multi-domain structure and a coecivity less than 120 Oe. Second, when x increases to 0.37~0.48, the coecivity at low temperature will be largely increased (maximum ~1000 Oe at x=0.41) and the magnetization behavior is like magnetic granular films composed of single domain granules. This region is called hybrid region with magnetic granules in insulating matrix. When x is larger than 0.48, the magnetization gets weak. This region is called insulator region. The magnetic phase diagram (Fig. 2) shows three magnetic states ferromagnetic(FM), superparamagnetic(SPM) and paramagnetic (PM) at different temperature and composition. A magnetic granular model was also built to simulate the magnetization properties by using Monte Carlo method. The Hamiltonian of the system is composed of Zeeman energy, anisotropy energy, exchange interaction energy and magneto static interaction energy. The simulation result shows that the percolation effect in magnetic granule system causes the transition of metal and hybrid region and the missing of exchange interaction between adjacent granules in hybrid and insulator region causes the difference in temperature dependent magnetic properties.

DW-13. Strain Induced Anisotropy in Nanocomposite $Co_{74.6}Fe_{2.7}Mn_{2.7}Nb_4Si_2B_{14}$. *A. Srivastava*[1,2], K. Cole-Piepke[1,2], A. Koenig[3], T. Burton[3], C.K. Mewes[1,2], T. Mewes[1,2], G. Thompson[3], R. Noebe[4] and A. Leary[4] *1. Center for Materials for Information Technology, University of Alabama, Tuscaloosa, AL, United States; 2. Physics and Astronomy, University of Alabama, Tuscaloosa, AL, United States; 3. Department of Materials and Metallurgical Engineering, University of Alabama, Tuscaloosa, AL, United States; 4. Materials and Structures Division, NASA Glenn Research Center, Cleveland, OH, United States*

We report on broadband ferromagnetic resonance (FMR) characterization of strain induced magnetic anisotropy in nanocomposite $Co_{74.6}Fe_{2.7}Mn_{2.7}Nb_4Si_2B_{14}$ ribbons, about 22 mm wide and 22 microns thick, produced by a single roller melt spinning process[1]. The in-plane angular variation of resonance field shows a uniaxial anisotropy with the spin cast direction (also the direction of applied stress during annealing) as the hard axis (figure 1(a)), which is commonly observed in these type of ribbons[2]. A higher value of stress during the annealing process gives rise to an increased anisotropy value (H_u) as determined by both broadband FMR and in-plane angle dependent FMR measurements (figure 1(b)). The relative permeability (μ_r) calculated by using effective magnetization (M_{eff}) and uniaxial anisotropy (H_u) (obtained from FMR) is compared with relative permeability values obtained from measurements on bulk toroid samples and both are found to be in good agreement (figure 2). This indicates that FMR measurements on small samples could be used for determining the permeability of bulk cores wound from these ribbons. The effective magnetization and gyromagnetic ratio calculated from broadband FMR[3] show no significant dependence on degree of stress on the ribbon during annealing.

DW-14. Role of Jahn-Teller Distortions and Ferrimagnetic Transitions in $(Co_{1-x}Cu_x)Cr_2O_4$ (x = 0.5, 0.25) Nanoparticles. *P. Mohanty*[1], C. Sheppard[1], B. Doyle[1], E. Carleschi[1] and A. Prinsloo[1] *1. Department of Physics, University of Johannesburg, Johannesburg, South Africa*

The normal spinel ferrimagnet $CoCr_2O_4$ with T_C 93–97 K [1–3] demonstrates multiferroic properties due to a spiral ordering at 26 K [2–4]. In addition, a lock-in transition appears at 15 K [3]. Structurally, $CoCr_2O_4$ retains the cubic phase down to 11 K [4]. In contrary, the normal spinel $CuCr_2O_4$ only crystallizes into the cubic phase above 853 K [1]. The tetrahedral crystal field around Cu^{2+} in the cubic phase causes fully occupied low energy *e* levels and triply degenerate t_2 levels that leads to a cooperative lattice distortion from cubic to tetragonal symmetry below 853 K with a disputed ambient temperature structure [1]. Jahn-Teller (JT) activity of the Cu elevates the frustration in the Cr^{3+} sublattice [1]. Neutron diffraction studies confirm the magnetic structure of $CuCr_2O_4$ consisting of two canted Cr^{3+} sublattices with a net magnetic moment and a Cu^{2+} sublattice that couples antiferromagnetically to the net moment of the Cr^{3+} sublattices below 135 K [1]. Compression of CuO_4 tetrahedra towards a square planar configuration accounts for the tetragonal to orthorhombic phase transition at ~ 130 K [1]. Looking at such strong links between the distinct degrees of freedom motivates exploring new classes of multifunctional systems specifically at the nanoscale [5]. In this direction, current work focuses on the modification of structural and magnetic properties upon substituting Cu at the Co site in $CoCr_2O_4$. In order to do so, $(Co_{1-x}Cu_x)Cr_2O_4$ (x = 0.5, 0.25) nanoparticles were synthesized through sol-gel techniques. XRD reveals the cubic structure at ambient temperature for x = 0.25 and 0.5, with average crystallite sizes of ~21 nm and ~13 nm, respectively. JT distortion becomes prominent for x = 0.75. The temperature dependent magnetization studies reveal the T_C remains similar for both the samples: 101.6(4) K for x = 0.5 and 100.2(3) K for x= 0.25. However, the feature related to T_S has been enhanced for x = 0.25, where as it becomes suppressed for x = 0.5. Hysteresis loops measured at low temperature show enhanced constriction for x = 0.25 quite distinct from both chromites. Changes in the valence band and core level electronic structure from XPS support these observations.

In this present study, $Zn_xFe_{3-x}C$ ($0 \le x \le 1$) MNP_S were synthesized using the simple and cost-effective sol-gel technique. The carbide phase for these samples (size range = 12-45 nm) was obtained after calcination at 700 C in N_2 atmosphere which was confirmed by X-ray diffraction, electron diffraction, and Mössbauer spectroscopy. The samples contain Fe, Zn, and C which was indicated by X-ray photoelectron spectroscopy. The saturation magnetization (M_S) value for $x = 0.1$ sample was 58 Am^2/kg which has decreased minutely with increased Zn substitutions. In contrast, the M_S values were 68 Am^2/kg for pure Fe_3C and the value decreased continuously with Co substitution due to antiferromagnetic coupling [1-2]. The heating abilities of their ferrofluids prepared using F127 polymer exhibited comparable specific absorption rate (SAR) values as that of iron oxides [3]. The maximum, SAR as well as intrinsic loss power (ILP) values were 85 W/g and 1.9 nHm^2/kg for $x = 0.7$, at 25 mT external magnetic field. The cytotoxicity of these MNP_S was examined with human lung adenocarcinoma A549 cells using SRB assay and found to be compatible up to 1 mg/mL.

DW-16. Electroplated Fe-Co films prepared in citric-acid-based plating baths. *K. Mieda*[1], R. Tanaka[1], J. Kaji[1], A. Yamashita[1], T. Morimura[1], T. Yanai[1], M. Nakano[1] and H. Fukunaga[1] *1. Nagasaki University, Nagasaki-shi, Japan*

To reduce the coercivity of soft magnetic materials, a reduction in the grain size is one of the effective methods [1]. We found out that Fe-Ni films electroplated by citric-acid-based baths have nano-structure and show low coercivity due to the grain the refinement effect [2]. Although Fe-Co alloys have high saturation magnetization, coercivity of typical Fe-Co alloys is higher than that of Fe-Ni ones. In the present study, for reduction in coercivity of Fe-Co alloys, we employed a citric-acid-based plating bath for preparation of Fe-Co films and evaluated magnetic and strucural properties of the films. We plated Fe-Co films on Cu substrates using a direct current. The bath contains $225 - x$ [g/L] of $CoSO_4$, x [g/L] of $FeSO_4$, 10 g/L of $C_6H_8O_7$-H_2O, 10 g/L of NaCl, 5 g/L of $C_7H_4NNaO_3S$-$2H_2O$, 1 g/L of $C_{12}H_{25}OSO_3Na$. The current density, the plating time, and the bath temperature for the electroplating were set at 200 mA/cm^2, 2.5 min, and 50°C, respectively. Figure 1 shows the coercivity H_c and the saturation magnetization M_s as a function of the Fe content in the Fe-Co films. The change in M_s over the Fe content almost agreed with the expected change from the Slater-Pauling curve. The maximum M_s was 221 emu/g around $Fe_{70}Co_{30}$. In contrast, we obtained the minimum value of coercivity around $Fe_{70}Co_{30}$. These results indicate that we can obtain the Fe-Co films with high M_s and low H_c by adjusting Fe content around 70 at.%. To confirm reasons of low coercivity, we carried out structural analyses. Figure 2 shows XRD patterns of the films. As shown in Figure 2, the diffraction peaks of the $Fe_{70}Co_{30}$ film were very weak compared with those of other films. The result for the X-ray analysis implies that the grain size decreases with increasing Fe content, and the $Fe_{70}Co_{30}$ film has a very fine structure. To obtain direct evidence of the structure, a TEM observation was carried out and the result is shown in Fig.2 as an inset. Large grains were not observed, and we confirmed that the fine structure effectively works to reduce the coercivity. From these results, we concluded that the citric-acid-based bath is attractive for obtaining Fe-Co films with high M_s and low H_c.

DW-17. Iron Loss Separation Model Under DC Bias for Filter Inductors of Power Electronic Converters. H. Sun[1,2], *Y. Li*[1,2], S. Yue[1,2] and M. Yang[1,2] *1. State Key Lab of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China; 2. Key Lab of EFEAR of Hebei Province, Hebei University of Technology, Tianjin, China*

The calculation of iron losses in inductive components is difficult because of complex excitations and has not yet been entirely solved. In particular, it is impossible to predict the influence of dc bias and duty cycle on the iron losses simultaneously without extensive measurements [1]. In this paper, nanocrystalline ring FT-3KS is used as sample. A separation model for predicting iron losses under rectangular waveform considering dc bias, such as shown in Fig. 1(a) in filter inductors is introduced. The iron losses of filter inductors under rectangular waveform considering dc bias is evaluated, which shows that the proposed model not only accurately predicts the iron losses but also identifies the hysteresis loss part. For a given duty cycle D, the total hysteresis loss or total eddy current loss under a fundamental waveform [see Fig.1 (a)] is the sum of two loss quantities. The first one is calculated with a frequency f1=f/2D and the second one is calculated with a frequency f2=f/2(1-D) [2] [3]. Since the parameters of the separation model are frequency dependent and they are only valid for a limited frequency range, different parameters is used in order to fit with measurements under different duty cycles and increase the accuracy of the iron loss model in this paper. A more detailed description of the model will be presented in full paper. This result indicates that the proposed model can model the iron loss under rectangular waveform considering dc bias condition. The iron loss value calculated by using the proposed model is compared with the measurement results. The calculation error is within 3%. A well-known empirical characteristics of the hysteresis loss is explained. The hysteresis loss will be independent with exciting voltage waveforms. These results are useful not only for iron loss calculation, but also for the optimal design of electronics applications.

DW-18. Improvement in soft magnetic properties exchange-coupled Fe-Ni/$Fe_{22}Ni_{78}$ bilayer films. *J. Kaji*[1], R. Tanaka[1], K. Mieda[1], A. Yamashita[1], T. Yanai[1], M. Nakano[1] and F. Hirotoshi[1] *1. Nagasaki University, Nagasaki, Japan*

For typical soft magnetic materials, both high saturation magnetization and low coercivity are required. Although $Fe_{22}Ni_{78}$ alloys are one of hopeful soft magnetic materials due to their extremely low coercivity, the saturation magnetization is relatively low. To increase in the saturation magnetization of $Fe_{22}Ni_{78}$-based alloys, we recently proposed exchange-coupled Fe-Ni/$Fe_{22}Ni_{78}$ bilayer films and confirmed that the bilayer films enable us to increase the saturation magnetization keeping low coercivity [1]. It is well-known that annealing often improves soft magnetic properties due to relaxing residual stresses. In the present study, we employed annealing to improve the soft magnetic properties of our previously-proposed bilayer films. We carried out the electroplating to obtain the Fe-Ni films using a direct current. The plating bath and conditions were described elsewhere [1]. Ni and Cu plates were used as electrodes, and 75 mm^2 Fe-Ni/$Fe_{22}Ni_{78}$ films were electroplated on the Cu plate. The films were annealed at 250 - 410°C for 60 min in a vacuum. The strength of the exchange coupling strongly depends on grain sizes, and we need to keep the fine structure to obtain good soft magnetic properties [2]. Figure 1 shows the grain size of the $Fe_{22}Ni_{78}$ and $Fe_{58}Ni_{42}$ single layer films as a function of the annealing temperature. As shown in Fig.1, dramatic grain growth was observed at 360°C for the $Fe_{22}Ni_{78}$ films. As the exchange coupling becomes weak with the increase in the grain size, the result for Fig.1 suggests that we need to set the annealing temperature below 360°C to obtain strong coupling between $Fe_{22}Ni_{78}$ and $Fe_{58}Ni_{42}$ layers of the double-layer films. Figure 2 shows the coercivity of the $Fe_{58}Ni_{42}$/$Fe_{22}Ni_{78}$ bilayer film as a function of the annealing temperature. The coercivity decreased with increasing the annealing temperature up to 350°C which was expected value from Fig.1. The saturation magnetization of the bilayer film was 120 emu/g, and this value was much higher than that for Ref.1. From these results, we found that the annealing without the grain growth improves the soft magnetic properties of the exchange coupled Fe-Ni/$Fe_{22}Ni_{78}$ bilayer film.

XA-01. Spin-transport physics – a gift from John, a new field of science. *J. Sun*[1] *1. IBM T. J. Watson Research Center, Yorktown Heights, NY, United States*

John Slonczewski passed away in May this year. It is a great loss to the condensed matter physics community. With sadness and a fond memory, I will reflect on our journey with John over the last two decades or so together at IBM Research and beyond. As an example of the inspiration derived from working with John, I will give a brief review of my studies on the development of the scientific basis for spin-transfer torque and related device and materials physics, and share some fond memories of those good times we had together. I got to know John in the mid-1990s at IBM Research, when my studies transitioned from superconductivity to magnetics. John patiently mentored me through my early adventures in magnetism. He was even then, and indeed much earlier, already well-aware of the new physics spin-dependent transport could bring. He urged us to take a closer look at high current-density spin transport and angular momentum conservation. The rest is history in the making, to this day. We now have spin-transfer torque physics and devices, magnetic tunnel junctions, and spin-orbit and thermal magnonic sources for even more efficient generation and propagation of spin-current. These new concepts are deeply rooted in John's creative thinking and encyclopedic understanding of magnetism. Take the example of spin-transfer torque. Twenty-three years ago, John published his seminal work on spin-transfer torque and its resulting magnetic switching. This concept has now been widely accepted. New terms have been added to the Landau-Lifshitz-Gilbert equation, and development is well under way to utilize this effect for a new type of all-solid-state, CMOS-integrated magnetic random-access memory. John's impact to our field cannot be overstated. Thanks to John's vision and deep insight, today we have many new topics blossoming in spin-transport physics. John's solid, stoic approach to the search for a sound, lasting scientific understanding will continue to guide me in my future work. Thank you, John.

XA-02. J. C. Slonczewski: From Bubble to MRAM. *S. Maekawa*[1,2] *1. Center for Emergent Matter Science, Riken, Wako, Japan; 2. Kavli Institute for Theoretical Sciences, Beijing, China*

Dr. John C. Slonczewski passed away in May, 2019, at the age of 90. He was constantly a front runner in magnetism research for more than 60 years. His interest in magnetism was from basic physics to its applications. In 1975, I had an opportunity to join his group at IBM Watson Research Center in Yorktown Heights, New York, where the main subject of research was to develop magnetic bubble memory. At the time, to increase the memory density, magnetic bubbles with sub-micron size were expected. One of the problems, however, was how to detect such a small bubble. John, as the leader of the bubble project at IBM, proposed that we develop a magnetic tunnel junction as a sensor of the weak magnetic field of the bubbles. We worked on various aspects of magnetic bubbles and magnetic tunnel junctions. John's formalism was always expressed in beautiful mathematics. We can see examples of this beauty in his book entitled "Magnetic Domain Walls in Bubble Materials", published together with A. P. Malozemoff. He also extended his study on the spin dynamics in magnetic metals. He then discovered the spin transfer torque and thereby opened the door to STT-MRAM. John was a great teacher for me. He visited Japan several times and we enjoyed our collaboration. When phone-calls interrupted our discussion in my office, he warned me saying "you are not concentrating on physics!". My wife and I are proud that John and Esther called us "our Daughter and Son". He kept his interest in physics until the end of his life. He always encouraged me saying that you are still young. We miss John, but we are happy to have his physics with us.

INVITED PAPERS

8:30

EA-01. The fundamental properties and applications of synthetic antiferromagnetc systems. *E. Fullerton[1] 1. Center for Memory and Recording Research, University of California San Diego, La Jolla, CA, United States*

The discovery of indirect exchange coupling of ferromagnetic layers (FM) across thin transition-metal layers [1] allowed the ability to form thin-film heterostructures where the adjacent FM layers are antiferromagnetically (AF) coupled. These materials are referred to as synthetic antiferromagnets (SAFs) as they are magnetically isomorphic to many natural forming AF materials. Advantages of SAFs is that is possible to tune the moment of the FM layers, the anisotropy (both strength and orientation) and the interlayer coupling allowing the design of model systems to probe complex behavior in AF systems. SAFs are particularly attractive for studying field-induced phase transitions in AF films because the exchange interaction that couples adjacent ferromagnetic layers is comparable to the Zeeman energy in modest applied fields. In addition, finite size and surface effects are more pronounced in SAFs and can be well controlled by the individual thicknesses of their composing layers [2,3]. One example is the observation of the surface spin-flop transition that was theoretically predicted to occur in AF materials [4]. SAFs have also become important components in modern magnetic and spintronic devices. First used as reference magnetic layer in giant magnetoresistance read heads [5] they are also used as longitudinal recording media [5], soft underlayers in perpendicular recording media and both reference and free layers in MRAM cells [6]. SAFs also have unusual dynamic properties [1] making them suitable for novel nano spin-torque oscillators, materials for all-optical switching [7], and fast current induced domain wall motion [8]. I will review the fundamental properties of SAFs in both the in-plane and perpendicular orientations [3] and then describe how these properties make them well-suited for applications.

EA-02. Tuning magnetic phases in synthetic antiferromagnets with perpendicular anisotropy via control of micromagnetic energy balance. *N.S. Kiselev[1] 1. Peter Grünberg Institute and Institute for Advanced Simulation, Forschungszentrum Jülich, Jülich, Germany*

The term synthetic antiferromagnets (SAFs) is typically used for magnetic multilayer systems with antiferromagnetic interlayer exchange coupling. SAFs with strong perpendicular magnetic anisotropy (PMA) represent an exceptional class of systems characterized by a large variety of magnetic phase transitions [1]. Similar to natural magnetic crystals the phase transitions in SAF can be induced both by external stimuli (e.g. applied magnetic field) and by a change in the internal energy balance (e.g. due to competition between magnetocrystalline PMA and easy-plane shape anisotropy induced by demagnetizing fields) [2]. The uniqueness of SAFs lies in the possibility to control the balance between different energy terms in a very wide range independently [2], while in the most of natural magnetic crystals i) this range typically is quite limited, ii) it is hard to change of a particular energy term without impact on the others. In this presentation, I will discuss how the competition between different energy terms as anisotropy, interlayer exchange coupling between nearest layers, and the long-range magnetostatic coupling between all layers lead to the formation of complex three dimensional (3D) magnetic states, which may correspond to the ground state of the system or metastable phases. Besides that, I will discuss the role of surface-induced Dzyaloshinskii-Moriya interaction, responsible for the stabilization of chiral magnetic textures, in the formation of complex states in SAF. The accent in my talk will be made on the metamagnetic transitions and the stabilization of localized states such as magnetic bubble domains [3] and skyrmions [4] in multilayers with strong interlayer exchange coupling and PMA. I will also briefly discuss possible practical applications of metamagnetic bubble domains (or skyrmions) in SAF (Fig.1) for data encoding in new nonvolatile memory devices.

EA-03. Perspectives of Synthetic Antiferromagnetic Spintronics.
R. Duine[1,2] *1. Physics, Institute for Theoretical Physics, Utrecht, Netherlands; 2. Physics, Eindhoven University of Technology, Eindhoven, Netherlands*

Spintronic and nanomagnetic devices often derive their functionality from layers of different materials and the interfaces between them. This is especially true for synthetic antiferromagnets — two or more ferromagnetic layers that are separated by metallic spacers or tunnel barriers and which have antiparallel magnetizations. Here, we discuss the new opportunities that arise from synthetic antiferromagnets, as compared to crystal antiferromagnets or ferromagnets. In particular, I will discuss applications for magnonics, magnon spintronics, and skyrmionics [2] (see figure).

EA-04. Using Synthetic AntiFerromagnetic (SAF) Structures for Biomedical Applications. T. Vemulkar[1], J. Verheyen[1], S. Leulmi Pichot[1], E. Welbourne[1], M. Stanton[1], D. Petit[1] and *R. Cowburn*[1] *1. Cavendish Physics Laboratory, University of Cambridge, Cambridge, United Kingdom*

Magnetic materials are currently used in a number of biomedical applications such as therapy, diagnostics, separation and sorting, with hyperthermia therapy being the most well-known. To date, most biomedical magnetism uses very simple magnetic materials – typically superparamagnetic iron oxide nanoparticles (SPION). This talk will describe a new approach in which physical vapour deposition (sputtering) combined with lithography is used to form large numbers of nano- and micro-structures across a silicon wafer, which are then released into solution to form a highly functional magnetic liquid [1]. The advantage of this approach over SPION is that phenomena such as RKKY coupling, spin textures and interfacial anisotropy can all be used to make the magnetic properties of the liquid more advanced and therefore better suited to particular biomedical applications. Of particular importance is the creation of synthetic antiferromagnetic (SAF) layer structures with perpendicular magnetic anisotropy (PMA). These combine the key requirements of having low or zero remanence, moderate coercivity and high anisotropy. The low or zero remanence prevents agglomeration in liquid [2]; the moderate coercivity allows a high moment to be recreated once the particles are absorbed into the relevant biological species; the high anisotropy allows strong mechanical torques to be generated for mechano-biological therapies and detection. In this talk we show latest experimental results in using magnetic nanostructures to treat glioblastoma brain tumours in mice [3], including combining with radiotherapy for enhanced cell damage, and to detect early stage kidney cancer by performing ELISA-like assays on the surface of the magnetic nanostructures.

EA-05. Giant Tunneling Magnetoresistance in van der Waals Layered Antiferromagnet. *T. Song*[1], X. Cai[1], Z. Fei[1], M. Tu[4], X. Zhang[3], C. Carnahan[3], M. McGuire[2], D. Cobden[1], D. Xiao[3], W. Yao[4] and X. Xu[1] *1. University of Washington, Seattle, WA, United States; 2. Oak Ridge National Laboratory, Oak Ridge, TN, United States; 3. Carnegie Mellon University, Pittsburgh, PA, United States; 4. University of Hong Kong, Hong Kong, Hong Kong*

Synthetic antiferromagnets and magnetic multilayer devices that exploit magnetoresistance are the backbone of magnetic sensing and data storage technologies. Similar to synthetic antiferromagnets, few-layer chromium triiodide (CrI_3) is a recently discovered layered antiferromagnetic insulator in its natural crystal form even down to the atomically thin limit. In this talk, we will report giant tunneling magnetoresistance in the layered antiferromagnet based on van der Waals (vdW) heterostructures in which atomically thin CrI_3 acts as a spin-filter tunnel barrier sandwiched between graphene contacts. We demonstrate tunneling magnetoresistance which is drastically enhanced with increasing CrI_3 layer thickness, reaching a record 57,000% for magnetic multilayer structures using four-layer CrI_3 at low temperatures. In a dual-gated structure, a pair of bistable magnetic states in four-layer CrI_3 can be switched reversibly by electrostatic gating, demonstrating a new kind of voltage-controlled vdW spintronic devices. Moreover, we demonstrate the control of 2D magnetism by hydrostatic pressure. The antiferromagnetic interlayer coupling in CrI_3 can be more than doubled and even change the sign. In bilayer CrI_3, pressure can change the stacking arrangement which induces a transition from layered antiferromagnetic to ferromagnetic phases. In trilayer CrI_3, pressure can create coexisting domains of three phases, one ferromagnetic and two distinct antiferromagnetic. Our work provides ample opportunities to engineer novel spintronic devices using layered antiferromagnets based on vdW heterostructures with voltage and pressure tunabilities.

EB-01. Spin-to-charge conversion in topological insulator/ semiconductor heterostructures probed by optical spin orientation. *T. Guillet*[1], C. Zucchetti[2], A. Marchionni[2], F. Bottegoni[2], A. Marty[1] and M. Jamet[1] *1. Univ. Grenoble Alpes, CEA, CNRS, Grenoble INP, IRIG-Spintec, Grenoble, France; 2. LNESS-Dipartimento di Fisica, Politecnico di Milano, Milan, Italy*

Topological insulators (TIs) are predicted to host exotic properties like topologically protected surface states (TSS) showing Dirac-like band dispersion and strong spin-momentum locking. Such characteristics make this class of materials ideal for the generation and the detection of spin currents. In this work, we grow single crystalline Bi_2Se_3 thin films on low n-doped (10^{16} cm^{-3}) Ge (111) by molecular beam epitaxy. Germanium is an optically active material with a long spin diffusion length ($l_{sf} \approx 10$ µm at room temperature) and it is compatible with the current silicon technology platform. We propose an original method to probe the spin-to-charge conversion in TIs by taking advantage of the Ge optical properties. We design microdevices (Fig. 1a) where pure spin currents with in-plane spin polarization are generated by optical spin orientation in Ge when the laser beam hits the edge of Pt bars [1,2]. Spin currents are then detected in a non-local geometry by the inverse Rashba-Edelstein effect in a Bi_2Se_3 bar at room temperature. We modeled the spin-to-charge conversion to estimate the efficiency of the process and we find λ_{IREE} =30 pm. When multiplied by the Bi_2Se_3 spin diffusion length, this value is comparable to the one obtained in a Pt bar in place of the Bi_2Se_3 using the same experimental conditions. However, Pt and Bi_2Se_3 show opposite spin-charge conversion and the possible reason for this sign change will be discussed in this presentation [3]. Our results highlight the efficiency of Bi_2Se_3 as a spin detector and pave the way toward spintronic devices without using ferromagnetic compounds.

Since the discovery of graphene, there have been many reports on two-dimensional (2D) materials. Especially, 2D materials showing phase transitions have attracted much attention not only from the viewpoint of fundamental physics but also for potential applications to atomic-layers [1,2]. The motivation of the present study is to fabricate conductive 2D antiferromagnets (AFMs) and to investigate unique magnetic states through electrical transport. The triangular AFMs induce *magnetic frustration* because of the geometrical spin configurations and bring about rich magnetic properties unique to the geometrical frustrations. Ag_2CrO_2 is one of the layered triangular AFMs with electrical conductivity (see the inset of Fig. 1). This material exhibits a unique thermodynamic property, so-called *partially disordered (PD) state*, below the AFM transition temperature T_N [3-6]. However, the magnetic structure of the PD state is not still elucidated because the single crystal has not been synthesized yet. In this work, we have fabricated a micrometer-size Ag_2CrO_2 which is presumably a single crystal [7], and mesured magnetotransport in order to investigate the effect of PD spin fluctuations on the electrical transport property. A clear butterfly-shaped magnetoresistance was observed only when the magnetic field direction is out-of-plane. The amplitude of the MR takes a maximum at $T \sim T_N$ (Fig. 1). These results indicate that spin fluctuations near T_N strongly affects the butterfly-shaped MR. Next, we have measured the Hall resistivity as shown in the inset of Fig. 2. Apparently, the Hall slope changes with increasing temperatures. The derivative of ρ_{yx} is plotted as a function of T in Fig. 2. It has a cusp structure near T_N where the butterfly-shaped MR is strongly enhanced. The observed Hall effect can be explained by a recent theoretical model based on the extrinsic topological Hall effect where the fluctuation of spins produces a finite scalar chirality due to the interfacial Dzyaloshinskii-Moriya interaction [8].

EB-03. Study of surface-spin accumulation in topological insulators using scanning tunneling microscopy. *S. Tyagi*[1], M. Dreyer[2], D. Bowen[2], D. Hinkel[2], A.L. Friedman[2], P. Taylor[3], R.E. Butera[2], C. Krafft[2] and I. Mayergoyz[1] *1. University of Maryland, College Park, MD, United States; 2. Laboratory for Physical Sciences, College Park, MD, United States; 3. US Army Research Laboratory, Adelphi, MD, United States*

Topological insulators are currently a very active area of research in spintronics due to their unique physical properties as well as their promising applications. Among these properties is the ninety-degrees locking between the spin and momentum of electrons in the topologically protected surface mode. This property results in surface accumulations of spin-polarized electrons caused by bias current flow through the topological insulators. In our work, we report the experimental study of this surface spin-polarized electron accumulation for Bi_2Se_3 by using Scanning Tunneling Microscopy with tungsten as well as iron-coated tungsten tips. The central idea of this study is to explore the asymmetries in electron tunneling caused by such surface spin-accumulation due to bias currents through the samples. We have experimentally observed two types of the above asymmetries in the tunneling currents: (a) for different polarities of tunneling voltages, and (b) for different directions of bias currents through the Bi_2Se_3 sample. The first type of asymmetry was detected by using tungsten tips, and it manifests in appreciable difference between the tunneling currents when spin polarized electrons tunnel from the sample to the tip as compared to the other way around. In the case of tungsten tips, no asymmetry was observed in tunneling currents by changing the direction of bias current through the Bi_2Se_3 sample. However, in the case of Fe-coated tungsten tips, this asymmetry was clearly pronounced. This can be related to the phenomenon of spin-dependent tunneling between Fe-coated tungsten tip and the sample. Many experimental results revealing these asymmetries are obtained. Here, we present two sample results. Fig. 1 illustrates the asymmetry in the tunneling currents for opposite polarities of tunneling voltage and various bias current pulses through the sample observed by using tungsten tip. Fig. 2 reveals the asymmetry in the tunneling current from the sample to the Fe-coated tungsten tip caused by changing the direction of the bias current through the sample.

EB-04. Surface State Magnetoresistance in Proximity Magnetized Topological Insulators. *N. Mason*[1], J. Sklenar[1], J. Oh[1], Y. Zhang[2] and M. Gilbert[3] *1. Physics, University of Illinios at Urbana-Champaign, Urbana, IL, United States; 2. Materials Science, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 3. Electrical and Computer Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, United States*

Topological insulators (TIs) have a variety of unique transport properties, including strong spin-orbit coupling and symmetry-protected spin-momentum locked surface states. These properties have driven significant interest in understanding the science and device potential of systems that combine TIs with magnetism. In particular, proximity magnetization—i.e., placing a layer of magnetic material in direct contact with the TI—can be used to control the surface state symmetry, and thus the transport properties. In this talk, I will discuss transport measurements of TIs proximity magnetized by magnetic insulators and metals, where in both cases out-of-plane magnetic anisotropy leads to gapping of the TI surface state. For the TI Bi2Se3 on the magnetic insulator YIG, we experimentally observe a new MR effect, that is identified as anisotropic magnetoresistance consistent with a magnetized surface state. For Bi2Se3 coupled to a Co/Pt multilayer, which has a perpendicular magnetic anisotropy, resistance switching is observed for every magnetic field direction. These results are consistent with magnetic anisotropy out of the sample plane opening an energy gap between the surface states, and provide insights into the fundamental mechanisms of magnetic proximity and interface interactions in topological systems. This work is supported by DARPA under ONR 14-17-1-3012 and NSF DMR 17-20633 through the MRSEC program.

EB-05. Magnetoelectric Induced Topological Phases in Graphene on Chromia Interface. *H. Takenaka*[1], S. Sandhoefner[1], A. Kovalev[1] and E.Y. Tsymbal[1] *1. University of Nebraska-Lincoln, Lincoln, NE, United States*

Topological antiferromagnetic (AFM) spintronics is an emerging field of research, which involves the topological electronic states coupled to the AFM order parameter known as the Néel vector. Recently, the control of these states is successfully envisioned through manipulation of the Néel vector by spin-orbit torques driven by passing electric currents. Here, using interface of graphene on Cr_2O_3 (0001) surface, we propose a different approach favorable for low-power AFM spintronics, where the control of the topological states in a two-dimensional material, such as graphene, is performed via the proximity effect by the voltage induced switching of the Néel vector in an adjacent magnetoelectric AFM insulator, such as chromia. Using density functional theory and tight-binding Hamiltonian approaches, we model the graphene/Cr_2O_3 (0001) interface and demonstrate non-trivial band gaps, differently open in the graphene Dirac bands near the *K* and *K′* valleys. This gives rise to an unconventional quantum anomalous Hall effect with the onset of an additional quantized value or the emergence of the valley Hall effect. The electrically switchable AFM order parameter in Cr_2O_3 determines the sign of the quantum anomalous Hall conductance. Furthermore, the Chern numbers which depend on the Néel vector orientation across the 180° AFM domain wall in Cr_2O_3 indicate the appearance and transformation of the five different topological phases in graphene as shown in Figure and the emergence of the chiral edge states due to the discontinuous changes. These topological properties are controlled by voltage through magnetoelectric switching of the AFM insulator with no need for spin-orbit torques.

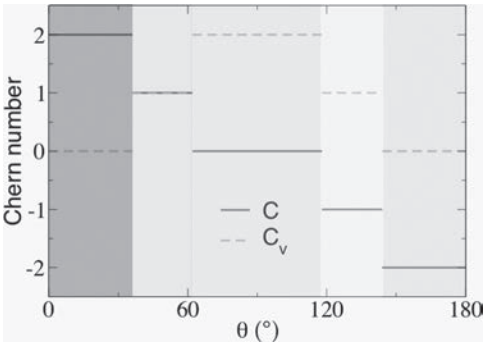

Fig.1 The phase diagram of Chern numbers for the graphene bands as a function of magnetization angle across 180° domain wall in chromia.

EB-06. Adiabatic and Resonant Spin Pumping in Two-dimensional Quantum Spin Hall Insulator. *Y. Araki*[1], T. Misawa[2] and K. Nomura[3] *1. Advanced Science Research Center, Japan Atomic Energy Agency, Tokai, Japan; 2. Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan; 3. Institute for Materials Research, Tohoku University, Sendai, Japan*

We present our theoretical work on spin pumping into a two-dimensional (2D) quantum spin Hall inslator (QSHI). QSHI is a topological insulator in 2D exhibiting gapless helical edge stats, which are responsible for the quantized spin Hall conductivity. Recent theories [1] and experiments [2] have demonstrated the QSHI phase in a monolayer of transition metal dichalcogenide 1T'-WTe_2, which can be easily engineered in contrast to traditionally-known HgTe/CdTe and InAs/GaSb quantum wells. While the theory of spin pumping is well established in normal metals by focusing on the spin-dependent electron scattering at the interface [3], it is unreliable for topologically nontrivial interfaces in such systems. In the present work, we consider a junction of a ferromagnet and a 2D QSHI at its 1D edge (Fig. 1), and demonstrate the pumping of angular momentum from the spin-precessing ferromagnet into the QSHI [4]. Using the Floquet theory for the electrons on the helical edge states, we analytically show that the time-periodic precession of the magnetization drives a charge current on the edge, for the whole range of precession frequency. This edge current can be regarded as a consequence of the inverse spin Hall effect intrinsic to the QSHI, which converts the injected spin current into a transverse charge current [5,6]. By varying the precession frequency of the magnetization and the coupling strength at the junction, we find a clear crossover between two regimes: the adiabatic regime, where the slow magnetization precession drives a quantized pumping, and the resonant regime, where the fast precession leads to a suppressed pumping. We also incorporate the effect of orbital dependence in the exchange coupling at the edge, and show numerically that it shifts the crossover point between the adiabatic and resonant regimes.

Institut für Theoretische Physik, Johannes Kepler Universität, Linz, Austria; 8. Institute of Strength Physics and Materials Science, Tomsk, Russian Federation*

Using state-of-the-art first-principles methods as well as Monte Carlo simulations, we have predicted the van der Waals block-layered compound $MnBi_2Te_4$ to be AFMTI [1,2]. An interlayer AFM ordering makes $MnBi_2Te_4$ invariant with respect to the combination of the time-reversal (Θ) and primitive-lattice translation ($T_{1/2}$) symmetries, $S = \Theta T_{1/2}$, which gives rise to the Z_2 classification of AFM insulators, $Z_2 = 1$ for this material. The *S*-breaking (0001) surface of $MnBi_2Te_4$ exhibits a giant band gap in the topological surface state thus representing an ideal platform for the observation of the quantized magnetoelectric coupling and intrinsic axion insulator state. Our prediction is confirmed experimentally by means of structural, transport, magnetic, angle- and spin-resolved photoemission spectroscopy measurements, with the first observation reported in Ref. [1]. In the 2D limit, we predict $MnBi_2Te_4$ to show a unique set of thickness-dependent magnetic and topological transitions, which drive it through FM and (un)compensated

AFM phases, as well as quantum anomalous Hall (QAH) and zero plateau QAH states [3]. Thus, $MnBi_2Te_4$ is the first stoichiometric material predicted to realize the zero plateau QAH state intrinsically. This state has been theoretically shown to host the exotic axion insulator phase. The discovery of the first AFMTI $MnBi_2Te_4$ opens new direction in the field of magnetic TIs that focuses on intrinsically magnetic stoichiometric compounds [4]. Apart from $MnBi_2Te_4$ itself, its FM building blocks can be utilized for the creation of topologically-nontrivial heterostructures [5,6]. Using the growth mechanism reported in [6], we theoretically propose a conceptually new type of interface between a trivial magnetic insulator and a nonmagnetic TI [7].

EB-08. Giant Spin Hall Angle in $Bi_{1-x}Sb_x$ Semimetals Driven by Thermally Excited Dirac-like Electrons. *Z. Chi*[1,2], Y. Lau[1,2] and M. Hayashi[1,2] *1. Department of Physics, The University of Tokyo, Tokyo, Japan; 2. National Institute for Materials Science, Tsukuba, Japan*

Charge-to-spin conversion induced spin-orbit torques in heavy metals (HM)/ ferromagnet (FM) heterostructures have attracted significant attention for its potential application in magnetic memory technologies. In order to obtain a high spin conversion efficiency, a variety of materials have been studied[1,2]. Due to its large spin orbit coupling, Bi has been predicted to possess a large spin Hall conductivity (SHC)[3,4]. However, up to date, the spin conversion efficiency of Bi has been reported to be extremely small compared to 5*d* transition metals[5,6]. In this presentation, we report experimental findings of large spin-orbit torque in $Bi_{1-x}Sb_x$/CoFeB bilayers prepared by magnetron sputtering. The Sb concentration dependence of the SHC is in good agreement with that calculated using a tight binding approach[4], indicating that the spin current has an intrinsic origin. Surprisingly, we find the strength of SHC in BiSb increases with increasing temperature, by nearly a factor of 3 when the measurement temperature is varied from 10 K to 300 K. We infer this temperature driven enhancement of the SHC is due to the increased number of thermally excited Dirac-like electrons located at the Bi *L*-valleys with large Berry curvature.

EB-09. Spin valve-like magnetoresistance of a topological insulator in proximity to a perpendicular magnet. *J. Oh*[1], V. Humbert[1], J. Sklenar[1] and N. Mason[1] *1. Physics, University of Illinois at Urbana-Champaign, Urbana, IL, United States*

Topological insulators (TIs) have a variety of unique transport properties, one of which is symmetry-protected surface states with spin-momentum locking. Efforts have been made to control the surface states by breaking time reversal symmetry via proximity magnetization, which is achieved by placing a magnetic layer in direct contact with the TI.[1,2] In parallel, other works demonstrated in similar TI/ferromagnetic systems that the magnetic layer's magnetization can be switched with electric current through TI due to the TIs' exceptional spin-to-charge conversion ratio.[3,4] We report an exotic spin valve-like magnetoresistance switching response observed at low temperatures in heterostructures of the TI, Bi_2Se_3, adjacent to a Co/Pt multilayer with perpendicular magnetic anisotropy. The magnetoresistance is hysteretic in magnetic field and nearly isotropic, as evidenced by the resistance state switching when either in-plane or out-of-plane magnetic fields are applied. In-plane angle dependence and temperature dependence of the field sweep imply that the effect does not arise from Co/Pt magnetization, but rather from the TI. The results indicate that ferromagnetism induced in a TI via proximity coupling can be probed through magnetoresistance measurements. *This work is supported by NSF under DMR 17-10437 and DMR 17-20633 through the MRSEC program, and DARPA under ONR 14-17-1-3012.

Abrupt magnetoresistance (MR) change observed for magnetic field swept along the current, H_x (left), and out-of-plane direction, H_z (right), in Bi_2Se_3/[Co/Pt] device at different temperatures. Sudden MR rise/drop occur at much lower fields (<7mT) than the switching field of Co/Pt multilayer (50mT). The square MR behavior becomes more suppressed as the temperature is raised before disappearing after 1K. Such result indicate that abrupt MR change arises from ferromagnetism induced in Bi_2Se_3.

Utilizing spin-orbit torque (SOT) to manipulate the magnetic order provides a promising route for low power-dissipation spintronic devices [1-4]. To date, the improvement of SOT efficiency is still a major challenge to further reduce the power dissipation of SOT-based devices, where topological insulators (TIs) with spin-momentum locked surface states promise a giant SOT compared to conventional heavy metals (HMs) with bulk spin-orbit coupling (SOC). Here, in the first part, we systematically study the SOT from topological insulators and heavy metals in a series of ferromagnet-based structures [TI(HM)/Ti/CoFeB/MgO] at room temperature. The effective spin Hall angle θ_{SH} of TIs is one order of magnitude larger than HMs, at the same time the resulted switching current density J_c is one order of magnitude smaller, indicating the high charge-spin conversion efficiency from topological surface states, as shown in Table 1. By tuning the Fermi level, we find the SOT is significantly enhanced near the Dirac point with the most insulating bulk contribution. In the second part, we change the ferromagnetic CoFeB to the ferrimagnetic GdFeCo. With tuning the magnetic moment of GdFeCo by its composition, we find that the SOT efficiency is enhanced

near the compensation point with the zero magnetic moment, as shown in Fig. 1. The switching current density J_c reaches as low as 1.2×10^5 A cm^{-2}, where the switching speed could be as fast as several picoseconds. This work demonstrates the ultrahigh SOT efficiency from topological surface states.

EB-11. Non-local electrical detection of helical surface states in three-dimensional topological insulators. *S. Jafarpisheh*[1,2], F. Volmer[1], Z. Wang[3], Y. Ando[3], C. Stampfer[1,2] and B. Beschoten[1] *1. 2nd Institute of Physics and JARA-FIT, RWTH Aachen University, Aachen, Germany; 2. Peter Grünberg Institute (PGI-9), Forschungszentrum Jülich, Jülich, Germany; 3. Physics Institute II, University Cologne, Cologne, Germany*

Spin-momentum locking on the surface of three-dimensional (3D) topological insulators (TIs) is a unique property that can be utilized in the future spintronic devices. A crucial step toward this goal is the direct detection of the surface states in transport measurements. A major problem, however, is the conductive bulk which acts as a parallel channel in transport and makes it extremely difficult to distinguish the contribution of the surface-states in conventional magneto-transport measurements. A solution is to perform non-local measurements where transport characteristics are investigated outside the region between the two current leads [1]. Due to the large spin-orbit coupling, the spin-diffusion length inside the bulk channel of TIs is very small and therefore, no bulk contribution is expected in the non-local signal. In contrast, the surface-states are expected to fully enclose the bulk of a strong 3D TI and therefore giving rise to a non-local spin-polarized current. Spin-sensitive studies of the non-local current thus allow to unambiguously probe the spin-momentum locking of the surface states. Here, we report on non-local spin transport measurements on exfoliated $BiSbTeSe_2$ flakes. We utilize potentiometric measurements by using ferromagnetic sensing electrodes to confirm the spin-momentum locking of the conducting surface states throughout the whole surface layer of the crystal. The spin signals in both local and non-local geometries are strongly temperature dependent and disappear at 50 K that excludes the dominance of magnetic fringe-fields from the ferromagnetic electrodes as origin of the spin signals. Furthermore, we identify thermally activated transport through bulk states at higher temperatures, which explains the disappearance of the surface states contribution by the loss of the non-local spin signal.

EB-12. Observation of opposite current-induced spin polarization in bulk-metallic Bi_2Se_3 and bulk-insulating Bi_2Te_2Se topological insulator thin flakes. *J. Tian*[1,2], C. Sahin[3], I. Miotkowski[1], M.E. Flatté[3] and Y.P. Chen[1] *1. Physics and Astronomy, Purdue University, West Lafayette, IN, United States; 2. Physics & Astronomy, University of Wyoming, Laramie, WY, United States; 3. Physics and Astronomy, University of Iowa, Iowa City, IA, United States*

One of the most fundamental and exotic properties of 3D topological insulators (TIs) is spin-momentum-locking (SML) of their topological surface states (TSSs), making 3D TI a promising candidate for future spintronics. [1-3] However, real 3D TI materials may also host other conductive channels, [4] such as a trivial two-dimensional electron gas (2DEG) with strong Rashba type spin-orbit interaction (SOI) and bulk spin Hall (SH) states. All the three states can possibly contribute to the current induced spin polarization (CISP), making the determination of the origin of the observed CISP in 3DTIs difficult. Here, we directly compare the CISPs in both bulk-insulating Bi_2Te_2Se (BTS221) and bulk-metallic Bi_2Se_3 thin flakes by spin potentiometry.[5] In bulk insulating BTS221 samples, the measured CISP can be unambiguously ascribed to the SML of TSS, whereas an opposite CISP is observed in bulk metallic Bi_2Se_3 samples, consistent with the expectations of Rashba SOI of the 2DEG due to band bending. We further calculated the intrinsic SH conductivity of the bulk Bi_2Se_3 and discussed its possible contribution to the measured CISP. Our results give the direct transport evidence of the opposite signs of the spin helicity in TSS and the outer Fermi surface of Rashba 2DEG in 3D TIs, opening ways for potential applications in 3D TI-based spintronics.

Point-contact spectroscopy of several topological materials reveals a phase transition to a low temperature phase that is characterized by low-energy modes superimposed on an energy gap showing a Bardeen-Cooper-Schrieffer (BCS) type of criticality. This behavior is not accompanied by a bulk superconductivity, which points to either local superconductivity or to the emergence of an unfamiliar ground state specific to topological matter. As indicated experimentally [1] and suggested theoretically [2], one of these can be a correlated many body state at surface atomic steps in topological crystalline insulators, exhibiting low-energy excitations. Here we show [3], employing a soft point-contact method that a conductance gap with a broad zero bias conductance peak or Andreev-type characteristics develop at junctions of Ag with topological surfaces of diamagnetic, paramagnetic, and, most notably, ferromagnetic quaternary PbSnMnTe. However, our state of the art structural characterization and magnetometry has not revealed presence of any superconducting nanoclustering. Nevertheless, the temperature dependence of the gap shows a BCS-like critical behavior with the critical temperature up to 4.5 K and the magnitudes of the critical fields independent of the orientation of the magnetic field in respect to the surface plane. This implies the emergence of a collective low-temperature phase, whose appearance is insensitive not only to the magnetic state of the metallic part of the junction, but also to the magnetic character of the topological material. The body of the accumulated evidences indicates that this new phase can be linked to carriers occupying 1D topological states adjacent to surface atomic steps, which undergo a transition to a collective state at sufficiently low temperatures and magnetic fields. EC-01. High Spin Hall Conductivity and Current-Induced Magnetization Switching by α-W. *W. Liao*[1], T. Chen[1], Y. Ferrante[3], S.S.P. Parkin[2] and C. Pai[1] *1. Materials Science and Engineering, National Taiwan University, Taichung, Taiwan; 2. Max Plank Institute of Microstructure Physics, Halle, Germany; 3. IBM Research-Almaden, San jose, CA, United States*

The spin Hall effect from 5d transition metal can convert charge current into spin current that can further exert spin-orbit torques to switch the magnetization of adjacent magnetic layers. Among all 5d transition metals, amorphous-W (or β-W) has the largest damping-like spin-orbit torque efficiency ~ 0.20-0.50. However, compared to other materials systems which also possess large spin-orbit torque efficiency such as Pt [1], amorphous W is less favorable due to its relatively high resistivity ($\rho^{\text{amorphous-W}}$~ 200-300 μΩ-cm), and therefore requires higher power consumption to achieve current-induced magnetization switching. In this work, we find that W in its conductive and crystalline phase (α-W) has the possibility to possess larger spin-orbit torque efficiency with lower resistivity ($\rho^{\alpha\text{-W}}$~ 20-40 μΩ-cm). Through comprehensive study on W/CoFeB/MgO and the reversed MgO/CoFeB/W, we find that although α-W shows lower spin-orbit torque efficiency ~ 0.04 [2-3], the spin Hall conductivity of α-W ($|\sigma_{SH}^{\alpha\text{-W}}|=3.71\times10^5\ \Omega^{-1}m^{-1}$) is roughly three times higher than that of amorphous-W ($|\sigma_{SH}^{\text{amorphous-W}}|=1.05\times10^5\ \Omega^{-1}m^{-1}$), which suggests that we can possibly achieve higher spin-orbit torque efficiency in α-W by further tuning its resistivity [4-6]. Moreover, we perform current-induced magnetization switching using α-W as the spin Hall source, which has not been reported previously. Our findings suggest that conductive and high spin Hall conductivity α-W is promising for future low power consumption spin-orbit torque memory application.

EC-02. Ultra-Low Switching Current Density in All-Amorphous W-Hf/CoFeB/TaO_x Films. *K. Fritz*[1], L. Neumann[2] and M. Meinert[1] *1. Center for Spinelectronic Materials and Devices, Department of Physics, Bielefeld University, Bielefeld, Germany; 2. Argelander Institute for Astronomy, Bonn University, Bonn, Germany*

In our previous work [1], we investigated the spin Hall effect of W-Hf thin films, which exhibit a phase transition from a segregated phase mixture to an amorphous alloy below 70% W. Accompanied by a jump in resistivity, the spin Hall angle shows a pronounced maximum at the composition of the phase transition. A maximum spin Hall angle of θ_{SH} = -0.20 was obtained for amorphous $W_{0.7}Hf_{0.3}$. Due to their amorphous character, the films are expected to contain few pinning centers and, therefore, to show fast domain wall motion, making them interesting in the context of current induced SOT switching. Using polar Kerr microscopy, we study current induced domain wall motion and magnetization switching of all-amorphous $W_{0.66}Hf_{0.34}$/CoFeB/TaO_x stacks with perpendicular magnetic anisotropy and large spin Hall angle. We observe current induced domain wall motion without an in-plane assist field, indicating Néel-type domain walls. Investigations of magnetization switching as a function of H_x and current pulse-widths τ reveal switching current densities as low as 3×10^9 A/m² in the dc limit. We accredit the low switching current densities to a weak pinning [2], caused by the amorphous character of the sample and the associated small grain size with respect to the domain wall width [3]. Our assumption is supported by observations of the switching process, which takes place via nucleation and subsequent expansion of a single, smooth domain. Measurements of the domain displacement upon current injection for $\mu_0 H_x = 0$ reveal a low depinning current density of 3.9×10^{10} A/m² at a pulse width of 500 ns. We verify the correlation between switching and depinning current density by investigations of a Ta/CoFeB/MgO/Ta reference sample, which shows critical current densities of at least one order of magnitude larger, respectively.

EC-03. Spin Planar Hall Effect. *V. Amin*[1,2], P. Haney[2] and M.D. Stiles[2] *1. University of Maryland, College Park, MD, United States; 2. National Institute of Standards and Technology, Gaithersburg, MD, United States*

Ferromagnets generate spin currents under an applied electric field. For example, the charge current driven by an electric field in ferromagnets is spin-polarized because majority and minority carriers have different conductivities. However, in the presence of spin-orbit coupling, the spins of individual electrons in ferromagnets are tilted from the axis of the exchange field. One consequence of this misalignment is that, under an applied electric field, electrons can carry a substantial spin current flowing perpendicularly to the electric field with spin directions both longitudinal and transverse to the magnetization. These spin currents are associated with several mechanisms including the spin Hall effect and the spin anomalous Hall effect. In this talk, we explore another mechanism that it is closely related to the Hall current arising from the anisotropic magnetoresistance. We refer to this phenomenon as the spin planar Hall effect, and present first principles transport calculations giving its strength and magnetization dependence in transition metal ferromagnets. The strength of the generated spin currents is proportional to the charge current conductivity of the ferromagnetic layer. We compute the full spin current tensor to probe all spin directions and compare the spin currents associated with the spin planar Hall effect to all spin currents allowed by symmetry. We find that in Co, the spin current with spin direction transverse to the magnetization has an associated conductivity of approximately 3000 [cm Ohm]$^{-1}$, which exceeds most estimates of the spin Hall conductivity in Pt. To help guide the interpretation of experiments, we also present calculations of the spin planar Hall effect in magnetic heterostructures to quantify their transmission through interfaces and the spin torques they exert. This work was supported by the Cooperative Research Agreement between the University of Maryland and the National Institute of Standards and Technology Center for Nanoscale Science and Technology, Award No. 70NANB14H209, through the University of Maryland.

EC-04. Manipulating spin currents with graphene-based heterostructures. *F. Casanova*[1,2] *1. CIC nanoGUNE, San Sebastian, Spain; 2. IKERBASQUE, Bilbao, Spain*

The integration of the spin in charge-based electronic devices has revolutionized both sensing and memory capability in microelectronics. Further development in spintronic devices requires electrical manipulation of spin current as well as spin-charge interconversion for logic operations. Graphene has raised as an outstanding spin transporter due to its weak spin-orbit coupling (SOC) [1]. However, a strong SOC is required for an electrical control of the spin state, as in the seminal proposal of Datta and Das [2], or to achieve spin-charge interconversion, via the spin Hall effect [3]. In this talk, I will show how SOC can be induced in graphene by proximity with another material, allowing us to manipulate spin currents. A very simple approach by combining Pt with a graphene channel already shows a very large spin-to-charge voltage output at room temperature [4], opening up exciting opportunities for spin-orbit logic circuits. A radically different approach is by engineering a van der Waals heterostructure which combines graphene with MoS_2, a transition metal dichalcogenide with strong SOC and semiconducting properties. The spin transport in the graphene channel is modulated between ON and OFF states by tuning the spin absorption into the MoS_2 layer with a gate electrode [5]. Our demonstration of a spin field-effect switch using 2D materials identifies a new route towards spin logic operations for beyond CMOS technology. Furthermore, the van der Waals heterostructure at the core of our experiment allows us to unambiguously demonstrate experimentally [6] a predicted spin Hall effect in graphene due to spin-orbit proximity with the MoS_2 [3]. The combination of long-distance spin transport and spin Hall effect in different parts of the same material gives rise to an unprecedented spin-to-charge conversion efficiency, opening up exciting opportunities in a variety of future spintronic applications [6].

Spin current is the central concept in spintronics. The effective generation and detection of spin current have been intensively studied so far in this field. Recently, it has been demonstrated spin currents can detect magnetic fluctuations in magnetic metals in a very sensitive manner [1,2]. Spin glass, a magnetic ordering state with complex spin structures, is a typical example to demonstrate it. According to recent spin Hall effects (SHEs) in a spin glass CuMn [2], the SH signal starts to decrease at a temperature labeled as T^*, which is 4 times higher than the spin frozen temperature T_{fM} determined from the magnetization measurement. Due to the randomness of the Mn impurities in Cu, most of the Mn spins are randomly frozen below T_{fM}, but the SH signal continuously decreases even below T_{fM}. This experimental fact indicates the real spin frozen temperature T_f of the nanowire might be lower than T_{fM}. In this work, we have performed SHE measurements in $Cu_{99.5-x}Mn_xBi_{0.5}$ alloys with much higher Mn concentrations (x = 4.2, 8.2 and 10.6) than the previous work [2], in order to investigate the SH signals at much lower temperatures than T_{fM}. We have measured the SHEs with the spin absorption method [3] in the lateral spin valve structure (see the inset of Fig. 1). Figure 1 shows η, the SH angles of $Cu_{99.5-x}Mn_xBi_{0.5}$ normalized by that of $Cu_{99.5}Bi_{0.5}$, as a function of temperature. η starts to decrease at T^*, and becomes completely zero at a temperature indicated by the arrow in Fig. 1. From comparison with the theoretical calculation, the real spin frozen temperature T_f of nanowire is the temperature where η becomes zero. To support our conclusion, we plot T_f, T_{fM} and T^* as a function of the Mn concentration x in Fig. 2. For all the investigated x region, T_f is always lower than $T_{fM,}$ and increases almost linearly with increasing x. The present result demonstrates that the SHE measurement is a powerful method to detect the magnetic property in a tiny sample, which cannot be realized by the superconducting quantum interference device.

Metallic magnetic heterostructures consisting of ferromagnetic (FM) and non-magnetic (NM) thin films are revealed as novel sources of THz radiation combining the field of THz physics with the field of spintronics. Recent studies have nicely shown the effect in different FM/NM systems considering the influence of the layer thicknesses, substrates, geometrical arrangement and excitation energy [1-4]. However, in these former studies the significance of the crystal structure of the metallic layers was not yet investigated. Here, we reveal the defect density of the crystal structure as a major factor to engineer the THz generation regarding electric field amplitude and bandwidth of the spectrum. To support the experimental findings, we employ a theoretical model based on the Boltzmann transport equation that accounts for the differences in elastic electron scattering lifetime in the layers and for the transmission of spin-polarized hot carriers at the FM/NM interface. We experimentally show the role of the defect density by studying relaxed epitaxial, deformed epitaxial and fully non-epitaxial Fe/Pt bilayers. We control the emitted THz spectra by modifying the defect density that results in (a) changing the elastic electron-defect scattering lifetime in Fe and Pt and in (b) the interface transmission for spin-polarized, non-equilibrium electrons. A decreased defect density increases the electron-defect scattering lifetime which results in a significant enhancement of the THz-signal amplitude and shifts the spectrum towards lower THz frequencies. Furthermore, we introduce the parameter of the interface transmission that is correlated to the ability of the interface to transfer spin currents into the NM layer. The transmission influences the spectral amplitude of the emitted THz field but conserves the composition of the spectrum.

Magnon-based spintronic applications enable a promising alternative to charge-driven devices for information transport and processing [1]. We explore key aspects of magnon spintronics necessary to functionalize such spin currents: we develop the efficient interconversion of spin and charge information by the (inverse) spin Hall effect in the binary alloy $Cu_{1-x}Ir_x$ [2]. In this material, the spin Hall effect exhibits a complex composition dependence, with a maximum spin Hall angle near 40% Ir content. Beyond that, DC and THz signals are compared, showing similar behavior showing functionality of the spin-to-charge conversion up to THz speeds. To functionalize the spin transport for instance for magnon logic as a key requirement of magnon spintronics, the spin-dependent (inverse) spin Hall effect in metallic ferromagnets like Co or $Co_{60}Fe_{20}B_{20}$ is demonstrated [3]. We then use this to build a magnon spin-valve type element: in ferromagnetic resonance spin pumping and non-local spin transport measurements it is shown that the spin detection efficiency strongly depends on the angle between that ferromagnet's magnetization and the spin current polarization vector [4]. We explain this by the distinct properties of spin-up and spin-down electrons in the ferromagnet and allows to implement a spin valve like effect with an amplitude of up to 120% [4]. Finally to purely control the transport also in a lateral geometry, we use gates that allow us to control the spin propagation [5].

EC-08. Influence of alloying Ta and V on spin-orbit torque efficiency in W/CoFeB/MgO junctions. *G. Kim*[1], Y. Kim[1], I. Cha[1], T. Kim[1], M. Lee[1] and Y. Kim[1] *1. Materials science and engineering, Korea University, Seoul, The Republic of Korea*

Spin-orbit torque (SOT) can efficiently manipulate the magnetization using in-plane current injection in normal metal/ferromagnet/oxide (e.g., W/CoFeB/MgO) structures. The SOT can be utilized for low energy writing operation in MRAM devices as well as fast domain wall motion in patterned strips. However, one of the main impediments to realize SOT devices is a low charge-to-spin conversion efficiency as quantified by a physical property called spin Hall angle (SHA). To increase the value of SHA, previous studies focused on modifying the fabrication method of the W layers either by reactive sputtering [1] or by multistep deposition [2] to preserve metastable beta-W phase which offers the highest SHA among various 3d-5d transition metals. Recently, theoretical calculation predicts that Ta incorporation in the beta-W lattice can enhance the spin Hall conductivity of the W itself [3]. In this study, we considered adding vanadium (V) in the W layer to investigate its influence on the SOT behaviors while maintaining the perpendicular magnetic anisotropy (PMA) in the W/CoFeB/MgO junctions. We chose V because it has the same number of outermost electrons as Ta. Thus, we expected the electrical property of V is similar to that of Ta. Different compositions of Ta and V in W/W-Ta (or V)/CoFeB/MgO/Ta films were sputter-deposited and underwent 300°C annealing. Subsequently, Hall bar devices with widths of 5 μm were patterned by photolithography. To estimate the effective field of SOT in our sample, we employed the low-frequency harmonics method and domain wall depinning and propagation model [4]. We only considered the damping-like torque (DLT) component because the field-like torque (FLT) contribution is known to be at least an order of magnitude smaller. Unlike Ta, V-alloyed devices showed PMA up to about 70 at% of V alloying. In the case of V, the SHA value reached about 0.5 compared to that of pure W which is 0.36. However, a nonlinear SOT behavior upon V compositional change remains unknown at the moment.

EC-09. Self-Induced Inverse Spin Hall Effect in Ferromagnets: Demonstration through Non-Monotonous Temperature-Dependence. O. Gladii[1], L. Frangou[1], A. Hallal[1], R.L. Seeger[1], P. Noel[1], G. Forestier[1], S. Aufftet[1], M. Rubio-Roy[1], P. Warin[1], L. Vila[1], S. Gambarelli[2], M. Chshiev[1] and *V. Baltz*[1] *1. Univ. Grenoble Alpes / CNRS / CEA, SPINTEC, Grenoble, France; 2. Univ. Grenoble Alpes / CEA, Symmes, Grenoble, France*

The generation of a spin current and its further conversion to a charge current have attracted considerable attention, facilitating advances in fundamental physics and closely related applications in the field of spintronics. In this work, we investigated the overlooked and incompletely understood self-induced inverse spin Hall effect in spin pumping ferromagnetic resonance experiments [1,2]. When magnetic moments are precessing, the angular momentum of 3d-electrons is transferred to 4s-conduction electrons leading to a spin-polarized current in the ferromagnet. A diffusive flow of spins is further caused by non-uniform magnetization ascribed to asymmetric spin relaxation at the different interfaces. Spin-orbit interactions in the ferromagnet further ensures spin-charge conversion via the inverse spin Hall effect. We performed systematic temperature-, thickness- and angular- dependent measurements of transverse voltage in spin pumping ferromagnetic resonance experiments with permalloy films (NiFe). Our experimental data revealed non-monotonous temperature-dependence of the self-induced transverse voltage. The experiments were found in qualitative agreement with our results of first-principle calculations unravelling the skew scattering and the side-jump plus intrinsic

contributions to the temperature-dependent spin Hall conductivity. More specifically, similar amplitudes but opposite signs were calculated for the two contributions. We obtained similar sets of experimental data whatever the material in contact with NiFe: SiO2, MgO, AlOx oxides, Cu and Pt metals, supporting the bulk origin of the effect. Insights on the direction of the self-induced current were obtained by addition of a buffer or capping reference layer of Pt to the stack. This study contributes to our understanding of self-induced inverse spin Hall effect in ferromagnets. It further underlines that the self-induced conversion in the ferromagnet can be as efficient as that of noble metals like Pt, as a caveat for the need to carefully consider them when investigating spin-orbit-related effects in materials for spintronics [3].

EC-10. Giant spin Hall effect in ultrathin Au/Si multilayers. *M. El Hadri*[1], J. Gibbons[2], Y. Xiao[1], H. Ren[1], H. Wang[1], A. Hoffmann[2] and E. Fullerton[1] *1. Center for Memory and Recording Research, University of California, San Diego, La Jolla, CA, United States; 2. Materials Science Division, Argonne National Laboratory, Lemont, IL, United States*

The investigation of the spin-orbit coupling effect in Au has gained increased interest in the past decade, since such a heavy metal combines the properties of a relatively long spin diffusion length [1] and strong spin-orbit coupling. While initial studies by Seki *et al*. reported a giant spin Hall angle (SHA) of 0.11 in Au (10 nm) [2], follow up thickness dependence studies showed an absence of such a giant SHA in thicker Au films [3-6], thus questioning the microscopic origin of the giant spin Hall effect in Au. To further elucidate the microscopic origin of the spin Hall effect in Au, we investigated the non-local transport in single Au films and ultrathin Au/Si multilayers patterned into mesoscopic Hall bar structures (Fig. 1a). We showed that the effective spin Hall angle of Au is inversely proportional to the thickness and is significantly enhanced in ultrathin Au/Si multilayers, where the thickness of the individual Au layers is scaled down to 2 nm (Fig. 1b). This variation behavior was further corroborated by independent spin-torque ferromagnetic resonance measurements. Finally, we investigated the spin-orbit torque efficiency in Au/Tb_xCo_{1-x} and $[Si/Au]_N/Tb_xCo_{1-x}$, where the top ferrimagnetic TbCo layer shows robust perpendicular magnetic anisotropy. Our observations provide insights into the microscopic origin of the giant spin Hall effect in Au, highlighting the significant role of ultrathin Au in emerging spintronic devices. Current-induced spin-orbit torque (SOT) originating from the spin-Hall effect (SHE) in heavy metal/ferromagnet (HM/FM) systems has attracted attention due to their potential application in the efficient manipulation of magnetization of nano magnets in SOT-MRAM, skyrmion and domain wall devices. For the application to a large scale integration, the efficient SOT operation (high spin Hall angle $|\theta_{SH}|$) in low resistivity (ρ_{xx}) HM is necessary [1]. One of the ideas for realizing this is increase in an intrinsic SHE. Taking into account the recent ab initio electronic structure calculation [2] and rigid band model, studying SHE in $Pt_{1-x}Au_x$ is one of the good candidates. Actually, a maximum magnitude of $|\theta_{SH}|$ was observed in $Pt_{0.75}Au_{0.25}$/Co system by measuring harmonic response, and a maximum magnitude of ρ_{xx} was also observed at same alloy composition (x=0.25) [3]. However, it is not clear whether mechanism of a high $|\theta_{SH}|$ is related to the increase in an intrinsic SHE. In this paper, we prepared $Pt_{1-x}Au_x$/CoFeB/MgO systems with various $Pt_{1-x}Au_x$ thicknesses and x under sputtering conditions using Kr gas by which Pt with high ρ_{xx} was observed. These systems are patterned into the microscale Hall bar by photolithography and Ar ion milling, and annealed at 300°C. SHE in $Pt_{1-x}Au_x$/CoFeB/MgO system with various x by means of spin Hall magnetoresistance (SMR) was studied. As a result, we found that the amplitude in SMR signals increases with increasing x, even though the ρ_{xx} values of $Pt_{1-x}Au_x$ monotonically decrease with increasing x as shown in inset of Fig.1. The analysis based on the drift diffusion model reveals that the increase in SMR originates from an enhancement of $|\theta_{SH}|$ (Fig. 1). These results indicate that the increase in $|\theta_{SH}|$ for $Pt_{1-x}Au_x$ systems is clearly related to increase in an intrinsic SHE. In this presentation, we will report the details of SMR, θ_{SH} and spin diffusion length. This work was supported by the JST OPERA (JPMJOP1611) and JSPS KAKENHI (15H05699, 19H00844).

Recently, pure spin current has been proposed for next-generation energy efficient spintronic devices. At the interface of ferromagnetic (FM) – nonmagnetic (NM) bilayer, there is spin-mixing due to electron scattering, influenced by magnetic defects. In this work, the impact of the imaginary component of spin mixing conductance is decoupled by longitudinal and transverse magnetoresistance measurements in CoFeTaB(CFTB)-Pt interfaces, in conjunction with polarized neutron reflectometry (PNR) which provides information on magnetic dead-layers and x-ray resonant magnetic reflectivity (XRMR) which provides element specific information on proximity induced magnetization in Pt. Structures consisting of Pt/CFTB/Pt, Pt/CFTB and CFTB/Pt thin-films were sputter deposited onto Si/SiO2 substrates. Magnetoresistance measurement was undertaken in three angular sweep geometries (xy (α), yz (β) and xz (γ) planes). Room-temperature PNR, XRMR and x-ray diffraction (XRD), were used to isolate the various contributions to the magnetoresistance. Proximity-induced magnetization in Pt is observed to be larger at the CFTB/Pt interface in comparison to Pt/CFTB interface (Fig 1). PNR reveals a reduced magnetic moment at the upper CFTB region within the sample. XRD measurement suggests that interfacial moment formation in Pt due to proximity effect has a dependence on the microstructure. Interpretation of the complicated interplay of magnetoresistance phenomena reveals that the majority of the in-plane magnetoresistance originates from the spin-Hall effect in Pt (spin Hall magnetoresistance (SMR) ratio of ~0.2) [1,2]. Hall-geometry measurement showed the transverse SMR effect, which indicates a significant contribution from the imaginary component of the spin-mixing conductance [3]. This is attributed to magnetic polarization of Pt, as confirmed from XRMR, which causes the precession of the spin current about the local Pt moment at the interface resulting in tilting of the interfacial spin polarization relative to that generated by the spin-Hall effect [4].

EC-13. Temperature dependent spin Hall angles of Pt thin films with different crystalline structures. *H. Wang*[1], Y. Xiao[1] and E. Fullerton[1]
1. University of California, San Diego, La Jolla, CA, United States

Spin-orbit coupling plays a central role in modern spintronic research [1] and to the formation of many exotic quantum phases in strongly correlated material systems [2]. To date, the spin Hall angle, the figure of merit for spintronic applications, has been intensively studied in a variety of material systems spanning from transition metals, semiconductors, to complex oxides. A comprehensive understanding of its underlying mechanism promises to bring new functionalities to the next-generation energy efficient spin Hall devices. Here, we deposit CoNi multilayers with perpendicular magnetic anisotropy on a series of 5*d* heavy metal Pt thin films with different crystalline structures [Fig. 1(a)]. The spin Hall angles obtained by harmonic Hall measurements follow a monotonic increase in the order of single crystalline Pt, polycrystalline Pt, and doped Pt thin films [Fig. 1(b)]. Remarkably, they exhibit distinct temperature dependent variation behavior, underlining the multiple contributing mechanisms of spin-orbit coupling in Pt thin films with different crystalline structures [3]. Our results also point to the possibility of tuning the spin-to-charge conversion efficiency by engineering the crystalline textures in a variety of transition metals. ED-01. Interactions of Chiral Magnetic Textures with Electrical Currents Studied with X-ray Microscopy. *S. Finizio*[1], K. Zeissler[2], A. Huxtable[3], S. Wintz[1,4], S. Mayr[1,5], J. Bailey[1,6], M. Langer[1], G. Burnell[3], C.H. Marrows[3] and J. Raabe[1] *1. Paul Scherrer Institut, Villigen PSI, Switzerland; 2. National Physical Laboratory, Teddington, United Kingdom; 3. University of Leeds, Leeds, United Kingdom; 4. Max Planck Institut für Intelligiente Systeme, Stuttgart, Germany; 5. ETH Zürich, Zürich, Switzerland; 6. EPFL, Lausanne, Switzerland*

After recent developments in the design and manufacturing processes of perpendicularly magnetized (PMA) materials exhibiting anti-symmetric exchange (or Dzyalonshinsky-Moriya – DM) interaction, the study of the chiral magnetic textures stabilized in these materials has attracted much attention in the magnetism research community. Chiral magnetic configurations include e.g. chiral domain walls, helical states, and magnetic skyrmions. In particular, magnetic skyrmions, chiral magnetic configurations exhibiting a non-trivial topology, have been extensively investigated. This is due to their interesting properties, which include an energy barrier against annihilation at defect sites [1], and the possibility of manipulating them with low current densities [2], leading to the proposal to employ these magnetic configurations as an information carrier [3]. The possibility to manipulate these magnetic textures with electrical currents is not limited to magnetic skyrmions. Various effects, including e.g. spin-orbit torques (SOT), have been discovered and employed to electrically manipulate these spin configurations, and the study of these effects and their consequences has also enjoyed an heightened attention in the recent years. The experimental investigation of these chiral spin configurations and of their electrical manipulation requires a non-invasive technique capable of visualizing the magnetic configuration at sub-um spatial resolution, and of resolving the dynamical processes at sub-ns temporal resolution under *in-operando* conditions. A suitable set of techniques encompassing all of these requirements is given by time-resolved X-ray microscopy. In particular, time-resolved scanning transmission X-ray microscopy has been successfully employed for the investigation of numerous dynamical processes in chiral magnetic systems. In this contribution, after an overview of time-resolved X-ray microscopy techniques, we will present the experimental investigation of the manipulation of various chiral magnetic configurations with electrical currents using time-resolved X-ray microscopy at high spatial and temporal resolution. In particular, we will focus on the study of the current-induced domain wall motion (CIDWM) of Neel-type magnetic domain walls [4], and on the nucleation and manipulation of Neel-type magnetic skyrmions [5]. The SOT-induced CIDWM of Neel-type domain walls was investigated on Pt/CoB/Ir microwires of different geometries. Here, we could directly visualize the effect of the wire's geometry on the motion and inertia of the domain wall. These investigations will be employed to provide a direct experimental verification of the theoretical models currently used to describe the CIDWM. As mentioned above, it has been proposed to employ magnetic skyrmions to encode digital information. Proposed designs of skyrmionic data processing devices include variations of the magnetic racetrack memory [3]. Such designs usually rely on three components: nucleation/deletion [5,6], current-driven motion [7], and electrical detection [8] of the magnetic skyrmions. Here, we present a time-resolved X-ray microscopy investigation of the skyrmion nucleation dynamics in absence of external magnetic fields achieved by the injection of an electrical current pulse across a nano-engineered nucleator structure fabricated on top of a Pt/CoB/Ir microwire. With these measurements, we could demonstrate the reliable current-induced nucleation of magnetic skyrmions in absence of external magnetic fields with pulse widths down to 100 ps, and observe that the nucleation process is driven by a synergy between SOT-induced switching of the magnetization and thermal effects due to the Joule heating of the current pulse. Part of this work has received funding from the EU-H2020 programme (Grant No. 654360) having benefitted from the access provided by PSI in Villigen within the framework of the NFFA-Europe Transnational Access Activity.

Magnetic skyrmions can be stabilized at room temperature with sub-100 nm sizes in multilayer films and are promising candidates for next-generation in-memory computing applications. The structure and stability of these small skyrmions is derived from the chiral interaction generated at the ferromagnet/heavy metal interfaces [1]. Although nominally symmetric structures like Pt/Co/Pt multilayers have negligible DMI, asymmetric structures such as Ir/Co/Pt, Pt/Co/MgO, and Ir/Fe/Co/Pt can acquire large values of DMI needed to stabilize small skyrmions. These stack structures also offer a large latitude of tunability – one can access a wide phase-space of magnetic textures, manipulating their size, density and configurations (isolated or lattice array) by varying the thickness of individual layers [2]. To understand the role of the various interactions in generating magnetic textures, we investigated this tunable stack structure using a series of complementary magnetic microscopy techniques – magnetic force microscopy (MFM), magnetic transmission soft x-ray microscopy (MTXM) and Lorentz transmission electron microscopy (L-TEM). Combined with previous theoretical work, we differentiate between domain walls of Bloch and Néel character, and further

between achiral bubbles, chiral bubbles and skyrmions (see e.g. Fig. 1) [3]. Next, using a combination of microscopic imaging and magnetometry techniques, we elucidate that skyrmions and chiral bubbles have contrasting thermodynamic signatures – which point to a dichotomy in their creation and annihilation mechanisms, which are then verified using field-dependent Lorentz microscopy measurements. Direct comparisons with micromagnetic simulations elucidate the microscopic mechanisms underlying the nucleation, propagation and destruction of these magnetic textures. This work establishes a platform for quantifying the helicity, topology, and stability of functional room temperature skyrmions, paving the way for the development of skyrmion-based devices.

Magnetic domain wall (DW) skyrmions are 360° transitions of magnetization along a chiral Néel DW with a topological charge of C=±1. Much like 2D skyrmions originate from magnetic bubbles and the Dzyaloshinskii-Moriya interaction (DMI), DW skyrmions are the successor to vertical Bloch lines (VBLs). The structure of these objects has been calculated analytically and through micromagnetic energy minimization with excellent agreement and has been predicted to display a unique signature in Fresnel mode Lorentz transmission electron microscopy (LTEM).[1] DW skyrmions are predicted to be stable in ultrathin magnetic films where the magnetization is uniform through its thickness and DMI is appreciable. Here we experimentally image DW skyrmions by LTEM using the tunable Pt/Co/Ni/Ir system.[2] $[Pt/(Co/Ni)_M/Ir]_N$ multi-layers were deposited by magnetron sputtering onto Si_3N_4 membranes. Fresnel mode LTEM was performed on an aberration-corrected FEI Titan G2 80-300 operated in Lorentz mode. Micromagnetic simulations were performed using M[3] and used to calculate theoretical Fresnel mode images.[3] LTEM images of M=4-10, N=1 samples display a significant Bloch component of the DW which fades with decreasing M. However, clusters of VBLs are found including 2π VBLs which are topological equivalent to, but much larger than, DW skyrmions. This suggests DW skyrmions could be supported if DMI is further increased via a reduction in M. Further decreasing M to 3 (with N=2 to preserve TEM contrast) supports the formation of chiral Néel DWs. Dipole-like contrast is observed along DWs from the formation of DW skyrmions as predicted from simulated LTEM images. A perpendicular magnetic field is applied *in situ* to drive DW motion where pinning is observed at the location of DW skyrmions. As the field is increased, DW skyrmions annihilate concurrent with an abrupt movement of the DW. Factors governing DW skyrmion stability and *in situ* behavior will be discussed along with their prospects for future spintronic applications.[4]

Magnetic skyrmions are nanoscale whirling spin configurations. Their small size, topological protection and the fact than they can be manipulated by small in-plane current densities have opened a new paradigm to manipulate the magnetisation at the nanoscale. This has led to proposal for novel memory and logic devices in which the magnetic skyrmions are the information carriers. The recent observation of room-temperature magnetic skyrmions [1,2,3,4] and their current-induced manipulation [4,5,6,7] in sputtered ferromagnetic nanotracks have lifted an important bottleneck toward the practical realisation of such devices. Notably, due to their quantised topological charge, moving magnetic skyrmions are subject to a gyrotropic force which leads to their deviation from the trajectory imposed by the current [5,6,7]. This "skyrmion Hall effect" is an important issue for reliable current-induced manipulation in track geometries as it tends to drive the skyrmions towards the edge of the track, leading to their annihilation. Recently, it was proposed that the use of Synthetic AntiFerromagnetic (SAF) multilayers would allow to suppress the skyrmion Hall effect due to opposite gyrotropic forces on the skyrmions in each AF-coupled ferromagnetic layers, allowing in turn a faster and more reliable current-induced skyrmion motion [8,9]. Here we report on the observation and current-induced nucleation of skyrmions in SAF multilayers at room temperature and zero external magnetic field. SAF composed of (Pt/Co/Ru) multilayers with vanishing magnetisation and perpendicular magnetic anisotropy were grown using magnetron sputtering. Using X-ray microscopy XMCD-PEEM, we observed the chiral Néel texture of SAF skyrmions and DWs at zero external field. Using STXM, we demonstrated the reproducible current-induced nucleation/annihilation of SAF skyrmions with diameters in the 100 nm range induced by the local injection of ns-long pulses at zero field. Time-resolved pump-probe STXM experiments reveal that the nucleation occurs within the first ns of the current pulse injection. Our results pave the way for the current-induced manipulation of SAF skyrmions in technology-relevant sputtered magnetic tracks.

ED-05. Antiferromagnetic skyrmions in synthetic antiferromagnetic multilayers at room-temperature. W. Legrand[1], *F. Ajejas*[1], A. Haykal[2], Y. Sassi[1], A. Finco[2], S. Chouaieb[2], D. Maccariello[1], S. Collin[1], K. Bouzehouane[1], A. Vechiola[1], N. Reyren[1], V. Cros[1], V. Jacques[2] and A. Fert[1] *1. Unité Mixte de Physique CNRS/Thales, Palaiseau, France; 2. Laboratoire Charles Coulomb, Université de Montpellier and CNRS, Montpellier, France*

Magnetic skyrmions are non-collinear chiral spin textures stabilized in magnetic materials by interfacial Dzyaloshinskii-Moriya interaction (DMI). Recently room-temperature skyrmions in ferromagnetic films and multilayers has been demonstrated and they show promise for encoding information bits in new computing technologies [1]. Despite many recent progresses, ferromagnetic order in thick layers or multilayers [2-3] generates dipolar fields

that prevent from reaching expected ultra-small skyrmion sizes. Moreover, in ferromagnetic systems, a transverse deflection of moving skyrmions is present that hinder their efficient manipulation. Antiferromagnetic skyrmions could lift these limitations [4-5]. Here we demonstrate that room-temperature antiferromagnetic skyrmions can be stabilized in synthetic antiferromagnetic (SAF) systems. We elaborate a material system in which perpendicular magnetic anisotropy, antiferromagnetic coupling and chiral order can be adjusted concurrently. Utilizing interlayer electronic coupling to an adjacent bias layer, we demonstrate by Magnetic Force Microscopy that the spin-spiral state obtained in a SAF system with vanishing perpendicular anisotropy can be turned into isolated antiferromagnetic skyrmions (see Fig. 1). These observation of small AF skyrmions in SAF has been also achieved using NV microscopy in which the potential perturbation from the tip are not existing. In addition, we provide model-based estimations of their size and stability, showing that room-temperature stable antiferromagnetic skyrmions below 10 nm in radius can be anticipated in further optimized SAF systems [6]. Antiferromagnetic skyrmions in SAF systems may thus solve major issues associated to ferromagnetic skyrmions for low-power spintronic devices. ED-07. Skyrmion diffusion in thin film multilayers. *U. Nowak*[1]
1. Physics Department, University of Konstanz, Konstanz, Germany

Skyrmions are topologically protected quasi-particles that can appear in ferromagnetic thin-films multilayers and are increasingly discussed as possible building blocks for spintronic applications. Skyrmion diffusion [1] has been demonstrated in a recent combined experimental and theoretical study [2]. While being of fundamental interest as the type of diffusion yields information on transport and dissipation processes, thermally activated diffusion processes can also serve as a sensitive tool to analyze system properties. We use the stochastic Landau-Lifshitz-Gilbert equation to simulate diffusive motion of Skyrmions in a PtIr/Fe-bilayer on a Pd surface. Here, the frustration of the isotropic exchange interactions in connection with the Dzyaloshinskii-Moriya interaction is responsible for the creation of skyrmionic structures with various topological charges [3]. We demonstrate the dependence of the diffusive motion on the topological properties and on the Gilbert damping parameter by calculating the diffusion coefficient for skyrmionic structures with different topological charges. Our simulations reveal that in this system skyrmionic structures are deformed by the Dzyaloshinskii-Moriya interaction rendering them elongated. This deformation leads to anisotropic diffusive behavior and rotational Brownian motion in a periodic potential, which in combination lead to a transition from anisotropic Brownian motion at short time scales to isotropic on longer time scales.

Ordered magnetic skyrmion lattices presents a lush playground of new and interesting physics to explore. This opportunity is provided, in part, due to the non-trivial topological nature of the skyrmion. Currently, a significant effort is being made to realize skyrmion-driven devices. These efforts are focused on designing and developing materials that can support skyrmions under ambient conditions. We have recently fabricated thin-films of amorphous Fe and Gd multilayers that support skyrmions and skyrmion lattices at room temperature and zero applied magnetic field. These skyrmions are stabilized by dipolar interactions, rather than the Dzyaloshinskii–Moriya interaction (DMI). By varying the film thickness and alloy composition we can alter the balance of the dipole interactions relative to the exchange and anisotropy, thus facilitating control of the skyrmion size, pitch, and field stability. Using small angle neutron scattering (SANS), we demonstrated that once formed these dipole skyrmions are stable over a large field and temperature range (including positive/negative/zero magnetic field and temperatures between 10K and 325 K, in a single film). Interestingly, we observe temperature and field dependent changes in the scattering vector (Q) for peak scattering related to the skyrmion lattice spacing. We observed two effects while changing the magnetic field; i). ramping the field results in a decrease in Q suggesting an increased skyrmion lattice, and ii). when applying an field in the opposite direction to (i), to that used to establish the skyrmion lattice we observe an increase Q before leaving the lattices stability window. The origin of this change in scattering vector has led us to identify a key requirement necessary for the range of stability that we have observed in these amorphous thin films. ED-09. Thermal Brownian Motion of Skyrmion for Ture Random Number Generation. *Y. Yao*[1], X. Chen[1], W. Kang[1] and W. Zhao[1]
1. Beihang University, Beijing, China

The current driven skyrmion motion and its application for racetrack memory have been extensively studied in theories and in experiments [1,2]. However, the thermal induced dynamics of skyrmion at room temperature leads to various problems for racetrack memory. Meanwhile, a wide variety of concepts or prototypes have been proposed by utilizing the dynamics of skyrmion. In this work, we exploit and take the advantages of thermal Brownian motion of skyrmion [3-6] for random number generation. In our design, a skyrmion is generated at the center of an elliptical disk consisting of a rectangular region and two semicircular regions. With no external excitation, the skyrmion is only affected by regional boundaries and thermal disturbance, and its dynamics are consistent with Brownian motion, as shown in Fig. 1(a). In this case, a random data bit sequence can be obtained by periodically detecting the position of the skyrmion relative to the center. Specifically, if the skyrmion locates in the left region, indicating a bit of "0", otherwise, indicating a bit of "1" or vice versa. In order to obtain a reliable random data bit sequence, the detection interval is suggested to be over 10 ns depending on the temperature. The corresponding distribution map of the skyrmion location is shown in Fig. 1(b). We can find that probability of bit "0" or "1" equals to ~50% given a long enough data bit sequence (e.g., over 1000 bits). The National Institute of Standards and Technology (NIST) test results, as shown in Table I, show that our proposed design can achieve true random number generator (TRNG) at ultra-low power. Furthermore, we can easily configure the probability between bit "0" and bit"1" by modulating the equilibrium position of the skyrmion with anisotropy gradient. This work provides a ultra-low-power TRNG for stochastic or probabilistic computing [3-7] by exploiting the naturally thermal induced Brownian motion of skyrmion. More details will be presented in the conference.

Topological non-collinear magnetic textures called skyrmions are the subject of intense research due to their stability and nontrivial dynamics. They represent key components for future technologies such as racetrack memories [1,2] or bio-inspired computing devices [3]. In such systems, an important requirement is the controlled generation of skyrmions. Here we discuss in detail how a skyrmion gas can be generated through the trochoidal motion of an initial antiskyrmion seed [4]. The dynamics is driven by current-induced spin-orbit torques, which deform the antiskyrmion core and leads to the emergence of the helicity as a dynamical variable. During trochoidal motion, a skyrmion–antiskyrmion pair is nucleated from the deformed core, much in the same way as a vortex–antivortex pair being nucleated prior to vortex core reversal. In contrast to the vortex core case, the skyrmion–antiskyrmion pair separates because skyrmions and antiskyrmions execute different motion under these torques [4]. Skyrmions readily propagate away from the region of generation through linear motion, while the trochoidal motion of antiskyrmions mean they remain more localized to the generation region. Remarkably, each antiskyrmion created becomes a subsequent source of pair generation. Increased scattering between antiskyrmions leads to annihilation, which results in an overall excess of skyrmions in the system. An example of the generation from a single antiskyrmion is shown in Fig. 1. We investigated how the generation rate and skyrmion excess depend on the spin-orbit torque parameters. Due to the attractive interaction between skyrmions (through the frustrated exchange interaction), a crystallite of the excess skyrmions gradually forms. These results provide insight into how skyrmion ensembles may be created in realistic materials. ED-11. Skyrmions in Ta/CoFeB-wedge/MgO. *C. Denker*[1], S. Nielsen[2], H. Heyen[1], E. Lage[2], Y.L. Junk[1], J. Walowski[1], M. Münzenberg[1] and J. McCord[2] *1. Institut fuer Physik, Universitaet Greifswald, Greifswald, Germany; 2. Institute for Materials Science, Christian-Albrechts-Universitaet zu Kiel, Kiel, Germany*

Magnetic skyrmion racetrack memories are interesting candidates for future data storage applications. We investigate different generation approaches as well as pinning center distribution and strength for magnetic skyrmions in Ta/CoFeB/MgO trilayers. This layer stack forms a bottom electrode with a tunnel barrier of a magnetic tunnel junction (MTJ) which are promising for the electrical reading and writing of skyrmions. Continuous CoFeB thickness wedges provide precise control for the relative average thickness of 3-6 pm defining the magnetic anisotropy. Skyrmions appear as a part of the out-of-plane hysteresis in a 13(6) pm wide window of CoFeB thickness directly followed by a transition to in-plane magnetic anisotropy at 1383(40) pm. This parameter range is extended by 10(6) pm using pulsed in-plane fields for skyrmion generation. Zero-field stable skyrmion bubbles nucleate from a slightly out-of-plane tilted in-plane remanent magnetic field application. The diffraction limit for diameter measurements in magnetooptical Kerr microscopy is circumvented by intensity evaluation leading to a noise-limited size limit below 100 nm. External magnetic field and effective anisotropy allow tuning the skyrmion size and density. In addition, we investigate energy landscapes for skyrmions by current induced hopping motion in a stripe with regions of different defect types and densities, since skyrmion motion tracking allows us to access the pinning center distribution and strength. We access the hopping regime by applying 50 μs long current pulses of about 5 x 10^{12} A/m^2 with a repetition rate of 20 Hz in a 10 μm wide stripe (Fig. 1). We observe forward and backward motion at an overall average speed of about 1 μm/s, corresponding to 1 mm/s during the current pulses, taking the duty cycle into account. While the Hall angle is masked in the individual traces by the influence of an inhomogeneous energy landscape, it is distinguishable in the average of the traces.

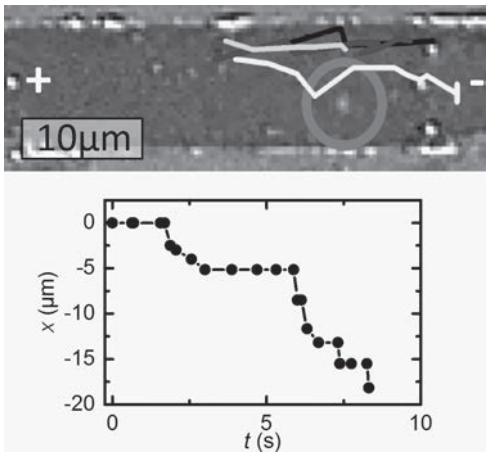

Fig. 1: 4 Representative tracked skyrmions. The red highlighted skyrmion is heavily pinned and immobile. The typical displacement vs. time dependence in the direction of the electrons in the graph of the yellow trace clearly indicates hopping motion

EE-01. Magneto-electric driven antiferromagnetic domain reversal and domain wall dynamics. *K. Toyoki*[1], Y. Shiratsuchi[1], H. Yoshida[1], S. Watanabe[1], Y. Kotani[2], T. Nakamura[2] and R. Nakatani[1] *1. Department of Materials Science and Engineering, Graduate School of Engineering, Osaka University, Suita, Japan; 2. Japan Synchrotron Radiation Research Institute, Sayo, Japan*

Antiferromagnetic (AFM) spintronics offers the variety of new physics such as the ultrafast spin/domain wall (DW) dynamics as well as the promising application such as the ultrahigh density magnetic storage. Controlling AFM spins is a main difficulty in this field and we have been demonstrated that the magneto-electric (ME) effect is one of the solutions to resolve the problem [1-3]. Cr_2O_3 is a proto-typical ME-AFM material and the AFM order parameter (the Néel vector) was switchable by the ME field, i.e., the simultaneous application of magnetic (*H*) and electric (*E*) fields. One of the remaining questions is the switching process including the dominant dynamics, which we investigated in this work based on magnetic domain observations using the scanning soft X-ray magnetic circular dichroism microscope [4]. Pt/Co/Au/Cr_2O_3/Pt stacked film was used as the sample. First, the sample was cooled to 285 K, below the Néel temperature of Cr_2O_3 under H = -4 kOe to induce the exchange bias. At 285 K, H (+40 kOe) and variable E (DC or pulse) were simultaneously applied to control the ME-AFM domain state. The magnetic domain pattern was observed after removing the ME fields, i.e. H = 0 kOe and E = 0 V/m. In these processes, the negative H was not applied and the positive exchange bias is only the driving force to switch the magnetic domain state in removing H (+40 kOe to 0 kOe). The element-specific domain imaging revealed that ferromagnetic and AFM domains were spatially coupled [5] meaning that the FM domain is a replica of the ME-AFM domain and resultantly, the exchange bias polarity. Namely, the change in the observed FM domain pattern corresponds to that of the ME-AFM domain inducing the positive exchange bias. The results indicate that the switching process of the ME-AFM magnetization is proceeded by the nucleation of the reversed ME-AFM domain and the propagation of DW, in similar fusion of the ordinal FM materials [6]. The change in the propagation length with the pulse duration gives the ME-AFM DW velocity v. With increasing E, v exponentially increases followed by linear increase indicating the change from the creep motion to the DW flow. The highest v in the studied ME condition is ~22 m/s at $E = 1.3\times10^3$ kV/cm [7].

Antiferromagnetic (AF) thin films are currently attracting considerable excitement for low dissipative spintronic devices [1,2]. However, most of conventional real-space magnetic microscopy techniques cannot probe the AF order at the nanoscale because magnetic moments are mostly compensated, resulting in very low magnetic signals. This is a major obstacle to the fundamental understanding of nanoscale AF order and its response to external stimuli, such as spin polarized currents or electric fields. To release the full potential of AFs for next-generation spintronics, the nanoscale control and imaging capabilities that are now routine for ferromagnets must be extended to AF materials. Here we show that scanning magnetometry based on a single nitrogen–vacancy (NV) defect in diamond is ideally suited for imaging complex AF orders at the nanoscale, even under ambient conditions. As a proof of principle, we report on the first real-space visualization of a non-collinear AF order in a thin film of bismuth ferrite $BiFeO_3$(BFO), a room-temperature multiferroic material in which the AF order is intimately linked to the ferroelectric one via magnetoelectric coupling. We first image the cycloidal AF order in a BFO thin film and demonstrate that magneto-electric coupling can be exploited to manipulate the cycloid propagation direction by an electric field [3]. We then investigate the effect of epitaxial constraint on the behaviour of the AF order in strained BFO thin-films [4]. Different substrates were used for the growth in order to tune the strain. Using scanning NV-magnetometry, we proved that tuning strain can stabilize different propagation directions of the cycloid, can change the plane in which the cycloid rotates or can collapse the cycloid into G-type antiferromagnetic domains in highly strained films. These results demonstrate how BFO can be used to design reconfigurable AF spin textures on demand.

EE-03. Mapping Spin Textures in Epitaxial Oxide Ferromagnet-Antiferromagnet Heterostructures with X-ray Photoemission Electron Microscopy. *R.V. Chopdekar*[1], Y. Jia[2], M. Lee[2] and Y. Takamura[2] *1. Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA, United States; 2. Materials Science and Engineering, University of California, Davis, Davis, CA, United States*

Interest in antiferromagnetic (AFM) spintronic devices has surged due to the possibility of obtaining ultrafast magnetization dynamics with no stray field,[1] and complex oxide heterostructures offer a route to tailor AFM

spin textures via their many degrees of freedom and sensitivity to epitaxial strain. However, an absence of stray field makes visualizing AFM domain structures difficult though conventional techniques. We show that X-ray photoemission electron microscopy (X-PEEM) combined with both x-ray linear and circular dichroism can spatially resolve the ferroic domain structure and quantify spin axis orientation in AFM and ferromagnetic (FM) layers of a model system of alternating FM $La_{0.7}Sr_{0.3}MnO_3$ and G-type AFM $La_{1-x}Sr_xFeO_3$ (x=0 or 0.3). In contrast to thicker layers where the spin axis cants out of plane,[2] in the limit of few unit-cell thick layers for (001)-oriented samples the AFM spin axis lies in the plane of the film. For (111)-oriented superlattices, a subset of spins cant along low-index <110> directions and exhibit spin flop coupling to the FM layer, and a subset of spins have spin axes that lie within the (111) plane.[3] The coupling at AFM/FM interfaces for both orientations allows for control of the AFM domain structure through magnetization rotation of the FM layer, and we have recently shown that shape anisotropy offers an additional degree of freedom to control complex oxide AFM domain orientation.[4] X-PEEM with variable x-ray polarization offers a powerful local probe to determine the AFM spin axis on the scale of single AFM domains, and enables a fuller understanding of how the similar energy scales of shape anisotropy and interfacial exchange can be engineered in order to design spin textures in oxide heterostructures.

EE-04. Electric control of antiferromagnetic/ferromagnetic order.

I. Fina[1,2] 1. Institut de Ciència de Materials de Barcelona (ICMAB-CSIC), Bellaterra, Spain; 2. IGSresearch, La Poble de Mafumet, Spain

Devices mainly based on antiferromagnetic materials will not easily substitute those based on ferromagnetic materials. However, the research during the last years on antiferromagnetic materials for applications has raised exponentially [1,2]. Antiferromagnetic materials concentrate numerous features that encourage the research on its integration in devices for both information processing and storage: i) antiferromagnetically-coupled moments are not altered by moderate magnetic fields, ii) the absence of dipolar interactions allow the stability of multiple magnetic configurations, iii) the nearly null stray fields reduces the cross-talk among neighboring elements within the same device and makes them invisible for the commercial magnetic read-devices, iv) they are more abundant in nature than ferromagnets and generally display higher magnetic ordering temperatures. These exclusive characteristics make antiferromagnetic materials very interesting for some niche applications, for instance, security. The same fundamental characteristic that makes antiferromagnetic materials interesting, the absence of net magnetic moment, hampers their characterization because null magnetic moment makes their manipulation (write) and measurement (read) challenging. In my talk, I will cover my contributions on the process of "writing in antiferromagnets". I will focus on its writing by using external magnetic fields, by the help of either the exchange spring effect [3,4] or heat [5,6], as reviewed in ref. [1]. However, as one might anticipate, these methodologies are very costly from the energetic point of view, and simplify the read process remains as a challenge [2]. Electric control of antiferromagnetic order at low temperature is possible in a variety of antiferromagnetic materials [7,8]. However, I will mainly focus on the thermal and electric control of the combined antiferromagnetic/ferromagnetic orders present at room temperature in FeRh films [9-11]. The electric control of antiferromagnetic/ferromagnetic orders produce large effects in an energy efficient manner. The coexistence between both magnetic orders can help to simplify the reading process, while preserving some of the main characteristics that make antiferromagnetic materials interesting. Potential routes towards applications will be discussed.

EE-05. Multi-stimuli manipulation of domains in multiferroics.

J. Chauleau[1] 1. SPEC, CEA Saclay, Gif-sur-Yvette, France

Antiferromagnets (AF) are currently in the limelight thanks to recent breakthroughs demonstrating the efficient effect of spin currents in interacting with the AF order parameter [1,2]. So far, due to the lack of net magnetization, controlling AF distributions has been rather challenging. Current-induced AF control also opens new perspectives in Terahertz magnetization dynamics. On the materials side, antiferromagnets represent the large majority of magnetic materials. Some of them show several simultaneous ordered phases and are commonly called 'multiferroics'. As a result, when the AF order is coupled to a net polarization, it may be controlled by applying a voltage. Generally speaking, multiferroic materials [3] are the focus of an intense research effort due to the significant technological interest of multifunctional materials as well as the rich fundamental physics lying in the coupling of various order parameters. Among all multiferroics, $BiFeO_3$ (BFO) is a material of choice because its two ordering temperatures (ferroelectric FE and AF) are well above room temperature. In addition a large magnetoelectric coupling has been demonstrated in single crystals as well as in thin films. Second harmonic generation has proven to be a powerful and elegant way to assess complex multiferroïc textures and to unentangle the different contributions at play [4]. In this presentation, we will present a study demonstrating the possibility to use second harmonic generation (SHG) to access the micron sized distribution of AF domain

(Figure 1) in a multiferroic thin film [5]. Subsequently, we will study their ultrafast dynamics by assessing the time evolution of the multiferroic texture when subjected to an intense femtosecond light pulse. Eventually we will discuss how they could be efficiently manipulated by the internally optically rectified sub-picosecond electric fields. This opens the door to an all-optical terahertz control the AF order, independently of the electric polarization, but still using the magnetoelectric effect.

Chirality, a foundational concept throughout science, may arise at ferromagnetic domain walls[1] and in related objects such as skyrmions[2]. A vast literature has emerged in recent years concerning these topological objects and their potential use in memories or magnetic-based logic. Chiral textures should also exist in other types of ferroics such as antiferromagnets for which theory predicts that they should move faster for lower power[3], and ferroelectrics where they should be extremely small and possess unusual topologies[4,5]. A significant effort is now being devoted to generating such structures in ferroelectrics and antiferromagnets but so far with limited success. We will present here the concomitant observation of antiferromagnetic and electric chiral textures at domain walls in the room-temperature ferroelectric antiferromagnet $BiFeO_3$[6]. This observation is achieved by combining several reciprocal and real-space characterization techniques. Both electric and antiferromagnetic chiralities are evidenced at room-temperature in this multiferroic compound where domain walls represent very particular regions in space where the different orders have to adapt. We reveal here the presence of both electric chirality and periodic chiral antiferromagnetic objects along the domain walls. These are backed by dynamical atomistic spin simulations able to reproduce the observed textures. The mechanisms underlying their formation and their relevance for electrically controlled topological oxide electronics and spintronics will be discussed.

The coupling of ferroelastic and ferromagnetic order parameters in materials offers a means to achieve novel multiferroic applications. We observe that one dimensional ferroelastic domains in $LaCoO_3$ thin films are intimately linked to its magnetization. Unidirectional structural modulation is achieved by the selection of substrate or growth plane, which produces broken in-plane rotational symmetry. Structural modification either through film growth or application of pressure is shown to affect the magnetism. These modifications perturb the crystal field energy, which leads to an unexpected in-plane anisotropy of the orbital configuration and the magnetization. Here, we will present the structural and magnetic depth profile of a $LaCoO_3$ film under hydrostatic pressure (0 to 1.6 GPa). We observe the that the structural density increases more in the center of the $LaCoO_3$ than at the interfaces. Additionally, we find that the magnetization decreases considerably (20% per GPa) with increasing pressure. Work funded by the U.S. Department of Energy, Basic Energy Sciences

EE-08. Possible Emergence of a Skyrmion Phase in Ferroelectric $GaMo_4S_8$. *H. Zhang*[1], J. Chen[1], P. Barone[2], K. Yamauchi[3], S. Dong[1] and S. Picozzi[2] *1. School of Physics, Southeast University, Nanjing, China; 2. Institute for Superconducing and Innovative Materials and devices (CNR-SPIN), Consiglio Nazionale delle Ricerche, Chieti, Italy; 3. Institute of Scientific and Industrial Research, Osaka University, Ibaraki, Osaka, Japan*

$GaMo_4S_8$ is a member of the lacunar spinel AM_4X_8 family (A = Ga and Ge; M = V, Mo, Nb, and Ta; X = S and Se), which have shown an incredibly rich physical phenomenology. Moreover, an extended Néel-type Skyrmion lattice phase was observed in GaV_4S_8 and GaV_4Se_8.[1-3] This was consistent with symmetry considerations, predicting a Néel-type Skyrmion lattice phase to be observed in polar magnets with C_{nv} crystal symmetry. As for $GaMo_4S_8$, a structural transition was observed from point group T_d to C_{3v} at $T_s \approx$ 45.5K. At high temperatures, the structure shows ideal Mo_4

tetrahedron, with equivalent Mo ions and Mo-Mo bond-lengths. However, in the low-temperature polar structure, the Mo_4 cluster is compressed along the [111] direction, leading to a difference between apical (Mo_1) and planar (Mo_2) ions. Furthermore, $GaMo_4S_8$ was found to be ferromagnetic below $T_c \approx 19.5$K, with one unpaired electron for each Mo_4 cluster. Stimulated by large potential interests in $GaMo_4S_8$, we performed both Density Functional Theory calculations and Monte Carlo (MC) simulations. By means of PBEsol+*U* approach and using the Berry phase method, we first focus on ferroelectric properties. We estimate a polarization along the [111] direction of about 1.4μC/cm^2, consistent with Mo_1-Mo_2 bonds to be shorter than Mo_2-Mo_2 bonds. From the magnetic properties point of view, the magnetization is found to be quite homogeneous within the Mo_4-tetrahedron, the magnetic moments being $0.24\mu_B$ for Mo_1 and $0.22\mu_B$ for Mo_2. We find a sizeable Dzyaloshinskii-Moriya (DM) interaction, with a ratio of DM with respect to Heisenberg exchange interactions (*J*) up to 0.74. In addition, due to the magnetocrystalline anisotropy in $GaMo_4S_8$, anisotropic spin exchange interactions (*J*) and single ion anisotropy are considered. Finally, a classical spin model was used as basis for MC simulations, considering DM, anisotropic spin exchange interactions (*J*) and single ion anisotropy, as evaluated from first-principles. While the magnetic ground state is found to be a spin cycloid at low temperatures, we predict the emergence of a Néel-type Skyrmion lattice phase in the phase diagram upon applying a magnetic field. EE-09. Presence of Conductive Path at the Grain Boundaries of Multiferroic $GaFeO_3$. *S. Ghose*[1] and K. Mandal[1] *1. CMPMS, SNBNCBS, Kolkata, India*

Multiferroic Gallium Ferrite ($GaFeO_3$) is a promising material for the application in advanced device fabrication due to its substantial magnetoelectric coupling [1,2]. But the presence of high leakage in $GaFeO_3$ shadows the possibility of its application [3,4]. The conduction mechanism behind this exceptionally high leakage current in $GaFeO_3$ is still not identified properly. Here we have investigated the variation of leakage conduction with the changes in morphologies especially at the grain boundaries due to the heat treatment temperature during sample preparation. A partial decomposition is identified at the grain boundaries above 1325 ^{0}C though the melting temperature of $GaFeO_3$ is 1520 ^{0}C [5]. Ridge like structures form at the grain boundaries due to this partial decomposition. These ridges have introduced conducting paths which act as conducting channels for the leakage electrons to propagate through the material. Interestingly, C-AFM image shows that oxygen vacancies at the near grain boundaries produce poor conductive regions. Small polaron hopping could be the effective transport mechanism present at the grain boundaries of $GaFeO_3$.

EE-10. Ion irradiation effect in complex oxides: Another degree of freedom or complexity? *S. Zhou*[1], C. Wang[1], P. Pandey[1], M. Helm[1], S. Gemming[1,6], C. Chang[2], R. Ganesh[3], D. Chen[4] and Y. Chu[5] *1. Institute of Ion Beam Physics and Materials Research, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany; 2. Department of Physics, National Cheng Kung University, Tainan, Taiwan; 3. The Institute of Mathematical Sciences, Chennai, India; 4. Institute for Advanced Materials and Guangdong Provincial Key Laboratory of Optical Information Materials and Technology, South China Normal University, Guangzhou, China; 5. Department of Materials Science and Engineering, National Chiao Tung University, Hsinchu, Taiwan; 6. Institute of Physics, Technische Universität Chemnitz, Chemnitz, Germany*

Inter-relations among charge, spin, orbital and lattice parameters are largely demonstrated in multi-functional oxide materials, which exhibit a variety of exotic properties, ranging from superconductivity, insulator-metal transition, colossal magnetoresistance, charge ordering, and orbital ordering, etc. In particular, tilting a delicate energy balance in lattice interactions and kinetics, achieved by temperature, pressure or chemical control, may result in exotic phenomena in these systems. However, fine-tailoring such interactions has proven difficult. In this context, defect engineering by ion irradiation, which can introduce strain and electronic disorder, has emerged as a powerful technique to fine tune complex phases of oxide thin films. In this contribution, we show that ion irradiation can modify the magnetic and electrical transport properties in a broad variety of materials, including spinel $NiCo_2O_4$, perovskite $BiFeO_3$, $SrRuO_3$ and $LaNiO_3$ [1-4]. Diverse magnetic, structure and magneto-transport modifications, which are inaccessible by

conventional film growth methods, have been obtained. For instance, the transport in $LaNiO_3$ can be driven from metallic phase into an Anderson insulator by directly tuning the electronic mean free path via irradiation-induced disorder [4]. In $BiFeO_3$, we have obtained a super-tetragonal phase with the largest c/a ratio ~ 1.3 that has ever been experimentally achieved in $BiFeO_3$ [2]. This may lead to strong polarization enhancement. By comparing the effect in different materials, we will also point out the complexity in understanding the tailoring of oxides by ion beams.

EE-11. Concept of artificial magnetoelectric materials via geometrically controlling curvilinear helimagnets. *O. Volkov*[1], U. Roessler[2], J. Fassbender[1] and D. Makarov[1] *1. Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany; 2. Leibniz Institute for Solid State and Materials Research Dresden, Dresden, Germany*

Magnetoelectric materials are of the great interest due to their unique coupling of the magnetic and electrical order parameters, offering exciting prospectives for energy efficient memory, logic and sensor devices. However, a sizeable magnetoelectric coupling for technologically relevant applications is obtained for a limited set of single-phase bulk materials. Typically, this restriction can be removed by using two-phase materials, containing strain-coupled magnetoelectric heterostructures based on piezoelectric-magnetostrictive bilayers. Although the concept is promising, there is a clear limitation regarding the fact that strain-induced changes result in the modification of all intrinsic magnetic parameters, in particular anisotropic couplings. Ideally, it would be advantageous that electric field control of magnetic state is achieved without change of global intrinsic magnetic parameters. We propose a novel type of artificial magnetoelectric material [1], which allows an electric field-induced deterministic switching between magnetic states without influencing intrinsic magnetic parameters. The proposal refers to geometrically curved helimagnets [2,3] embedded in a piezoelectric matrix or sandwiched between two piezoelectric layers. In contrast to typical strain-coupled magnetoelectric heterostructures, we exploit the geometric coupling between the piezoelectric matrix and curvilinear helimagents. Namely, a small geometrical deformation causes a drastic modification of magnetic state of the helimagnet through a magnetic phase transition between a homogeneous magnetic state and a periodical one. Resulting transformations of the average magnetization from non-zero to zero value can be uniquely assigned to logical “1” and “0”. This paves the way towards the realization of novel magnetoelectric devices with geometrically tunable and deterministically switchable magnetic states. We provide not only the general concept but also show analytical validation for a prototypical example of torsional nanospring helimagnets. Furthermore, we put forth a discussion on the feasibility of the experimental realization of the concept including the choice of materials and fabrication approaches.

The brain displays many signatures of non-linear dynamical behavior, including synchronization and complex transient behavior. These observations have inspired a whole class of neuromorphic concepts based on complex networks of interconnected non-linear nodes. Hardware systems for neuromorphic computing are usually tested using the so-called reservoir computing neural network architecture [1], a machine learning approach. One of the preferred tasks for benchmarking such devices is automatic speech recognition [2-7]. However, this task requires acoustic transformations from sound waveforms with varying amplitudes to frequency domain maps that can be seen as feature extraction techniques (see Fig. 1). Depending on the conversion method, these may obscure the contribution of the neuromorphic hardware to the overall speech recognition performance. Here, we quantify and separate the contributions of the acoustic transformations and the neuromorphic hardware to the speech recognition success rate [8]. We show that the non-linearity in the acoustic transformation plays a critical role in feature extraction. We compute the gain in word success rate provided by a reservoir computing device compared to the acoustic transformation only (see Fig. 2) and show that it is an appropriate benchmark for comparing different hardware. Finally, we experimentally and numerically quantify the impact of the different acoustic transformations for neuromorphic hardware based on magnetic nano-oscillators.

EF-02. Meander Domain Wall Device as a Synaptic Element for Neuromorphic Computing. *N. Sernicola*[1], T. Jin[1], D. Kumar[1], W. Lew[1], R. Sbiaa[2] and S. Piramanayagam[1] *1. Division of Physics and Applied Physics, School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore; 2. Department of Physics, Sultan Qaboos University, Muscat, Oman*

Artificial intelligence (AI) has recently become an integral part of our daily lives and its applications are plentiful and growing. The vast majority of these applications rely on algorithms running on a traditional von Neumann architecture, where the physical separation of the processing unit from memory causes a bottleneck that greatly increases power consumption, especially for AI applications. In contrast, the human brain is capable of performing highly complex tasks, consuming just 20 W. Neuromorphic computing (NC) is a new computational paradigm that tries to emulate the functioning of the brain[1]. Recently, a synaptic application of domain wall devices has been proposed based on the multiple states of anomalous Hall resistance[2]. In our study, we have investigated a magnetic tunnel junction (MTJ) synaptic device with a meander structure, which has the potential to exhibit much higher changes in resistance and controllable pinning, which is suitable for commercial applications. CoFeB based MTJs were prepared in the form of meander domain wall devices, where the position of the DW, which is controlled by spin orbit torque (SOT), dictates multiple resistance states. Figure 1 shows the scanning electron microscope images of the meander devices. In this meander structure, the corners act as pinning sites. Figure 2 shows the simulation results of the pinning of a domain wall along a corner of a nanowire. The simulation results confirm that the edges of the meander structure pin the domain walls. The experimental results of the electrical measurements will be presented.

EF-03. Neuromorphic computing with magnetic Josephson junctions. *M.L. Schneider*[1], C.A. Donnelly[2], A. Wynn[3], I.W. Haygood[1], S.E. Russek[1], M. Pufall[1], P. Hopkins[1] and W.H. Rippard[1] *1. NIST, Boulder, CO, United States; 2. Electrical Engineering, Stanford, Palo Alto, CA, United States; 3. MIT Lincoln Laboratory, Lexington, MA, United States*

Neuromorphic computing can improve both the speed and efficiency of many computational tasks such as image recognition and internet search. Our recent work on Josephson junctions with magnetic nano-particles in the barrier demonstrated devices with quasi-analog control of the Josephson critical current. These devices can tune the Josephson critical current by more than 1,000 % by adjusting the amount of spin order between the nano-particles. [1] These devices can be combined with naturally spiking Josephson junctions to implement artificial neural networks directly in hardware. The single flux quantum pulses produced by Josephson junctions in the voltage state are analogous to the action potentials in biological neurons and superconducting transmission lines act as axons distributing the signals with near lossless transmission. The magnetic nano-clustered Josephson junctions form a high-speed energy efficient synaptic element that can control the weighting to form a spiking neural network. We combine these elements to make a new neuromorphic architecture with the potential to be applied to problems that are currently addressed by artificial neural networks.[2] We will also present our recent experimental results which confirm agreement between our simulated synaptic design and circuits fabricated with the MIT-Lincoln Laboratory Josephson junction process. Figure 1 shows the simulated synaptic transfer covering the critical current tuning range demonstrated in a clustered magnetic Josephson junction (squares), which are in good agreement with the 4 test circuits shown in circles. The agreement between these test circuits enables more rapid development of neuromorphic architectures that include these novel magnetic Josephson junctions.

EF-04. Mode Attraction and Antiresonance in a Dynamic Rashba System with Spin-Orbit Torques. *I. Proskurin*[1,2] and R.L. Stamps[1] *1. Department of Physics and Astronomy, University of Manitoba, Winnipeg, MB, Canada; 2. Institute of Natural Sciences and Mathematics, Ural Federal University, Ekaterinburg, Russian Federation*

Mode attraction has recently attracted attention in optomechanical, opto-magnonic, and optodynamical systems inside microwave cavity resonators. Together with negative-mass instability, this effect has been experimentally realized in an number of systems including cavity magnon-polaritons and cold atom ensembles [1,2]. On grounds that this type of behavior should be ubiquitous and is expected in a wide variety of nonequilibrium driven systems [3]. An interesting class of meta-materials where this type of instabilities can be probed is the spin-orbit torque oscillators where a spin current in the Rashba layer is able to produce an antidamping effect on the magnetic oscillator. Experimentally, a transition from the resonance to the antiresonance has been reported in Py/Pt bilayers [4]. We propose that this effect is related to the level attraction between the ferromagnetic resonance in Py layer and the interband electron transitions in the Pt layer. We theoretically identify a level attraction regime in a coupled electron-magnon system. We show how this effect is related to the relative dynamic population of the Bloch band and interband transitions. This theory is applied to the Rashba Hamiltonian interacting with a magnetic oscillator in the antidamping torque geometry. In this case, the transition from the usual hybridization between the magnons and the resonant interband electron transitions to the mode attraction regime depends on dynamic spin accumulations that can be produced by a spin current flowing in the Rashba material. We estimate the relevant physical parameters, such as the threshold current strength, necessary for experimental detection. The resonant instability in spin-orbit torque systems, which is described by the mode attraction scenario, can be interesting for future designing of fully quantum spintronic devices such as transducers and quantum amplifiers.

EF-05. Synchronization and Chaos in Spin Torque Oscillator with Two Free Layers. *T. Taniguchi*[1] *1. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan*

Spin torque oscillator (STO) as a microwave source for microwave assisted magnetization reversal (MAMR) has been an exciting research subject for a decade [1-4]. Microwave emitted from an STO is applied to magnetic recording bits in a hard-disk drive, and reduces the reversal field. The latest design of STO for MAMR consists of two ferromagnetic layers called spin-injection and field-generation layers, where the former injects spin current into the latter and excites the magnetization oscillation [5]. Importantly, both layers can be regarded as free layers because the STO has no pinned layer. The magnetization dynamics of this STO is still not fully understood, yet an effort to experimentally observe the dynamics was reported recently [6]. In this work, a theoretical study on the magnetization dynamics in an STO consisting of two free layers, namely CoFe and NiFe used in the experiment [6], is presented [7]. Two layers are coupled via dipole interaction and spin-transfer effect. Solving the Landau-Lifshitz-Gilbert equation, we find three dynamical phases, as shown in Fig. 1. The first one is a synchronization in low current region, where the oscillation frequencies of two layers are identical. Note that synchronized magnetization oscillations cannot be detected by the conventional method employing tunnel or giant magnetoresistance (MR) effect. This is because the relative angle between the magnetizations is constant in the synchronized state; see also Fig. 1, where the oscillation frequency of MR is zero. In fact, no MR signal was observed experimentally in low current region [3]. However, it does not necessarily indicate that there is no magnetization oscillation. We believe its existence in the low current region, and is applicable to MAMR. The second phase is the magnetization oscillations with different frequencies. The third phase is chaos, which serves no contribution MAMR but might be interesting for other applications such as random number generator. This work was supported by NEDO.

EF-06. Nonlinear dynamics of spin-torque nano-oscillators with delayed feedback. J. Williame[1], A. Difini Accioly[1], D. Rontani[2], M. Sciamanna[2] and *J. Kim*[1] *1. Centre de Nanosciences et de Nanotechnologies, CNRS, Univ. Paris-Sud, Université Paris-Saclay, Palaiseau, France; 2. Laboratoire Matériaux Optiques, Photonique et Systèmes, CentraleSupelec, Université de Lorraine, Metz, France*

Delayed feedback, whereby the output signal of a system is sent back into its input with amplification and delay, can result in a variety of nonlinear behaviors [1]. For spin-torque nano-oscillators (STNOs) in which magnetization is driven into self-oscillation by spin-transfer torques, delayed feedback can improve spectral properties such as the emission linewidth [2,3]. Here, we present theoretical results on the complex transient response and chaotic behavior in STNOs subject to delayed feedback. We considered model oscillator systems in which the output is generated by changes in the tunneling magnetoresistance, which is subsequently fed back as variations in the input drive current [4]. Fig. 1 shows possible phases for a macrospin oscillator operating near the transition between the in-plane (IPP) and out-of-plane (OPP) precession regimes. By tuning the delay and amplification of the self-injected signal, we have identified new dynamical regimes in this system such as chaos, IPP/OPP switching with complex transients, and oscillator death. Fig. 2 shows the power spectral density as a function of delay in the nonlinear oscillator [5], where the frequency is strongly dependent on the amplitude. For this system, well-defined modulated states evolve to chaotic behavior as the delay is increased. These delayed feedback schemes open up a new field of exploration for STNOs, where complex transient states might be useful for applications such as reservoir computing [6]. This work was supported by the Agence Nationale de la Recherche under Contract No. ANR-17-CE24-0008 (CHIPMuNCS).

EF-07. Macrospin simulation with dry friction of a spintronic memristor based on angular variation of TMR. *M. Mansueto*[1], A. Chavent[1], U. Ebels[1], R. Sousa[1], L. Buda-Prejbeanu[1], I. Prejbeanu[1] and B. Dieny[1] *1. CEA - IRIG, Spintec, Grenoble, France*

Nowadays, brain-like networks are the best example of efficient and low power consumption computational tool for big data analysis tasks. In this context, the development of a proper hardware is essential and memristive devices, with their synapse-like behavior, represent a key element for this purpose. Our objective is to conceive a spintronic memristor based on the angular variation of TMR in an in-plane junction with the magnetic state controlled by spin transfer torque. One of the main challenge is represented by the realization of a special magnetic media (FL) able to stabilize the magnetization along several directions in the plane of the layer. Here we are developing such a media by exploiting the ferromagnet/antiferromagnet (F/AF) coupling in a trilayer F/AF/F [1]. For critical thicknesses of the AF layer, the strength of the coupling at the frustrated interface ensures the stability of the magnetization independently on its direction. Here we demonstrate that such system can be well described by inserting a dry friction term in the LLG equation for which the total damping is $a = \alpha + b/(dM/dt)$, with α the Gilbert damping and b the dry friction parameter [2] (model used in [3],[4],[5],[6]). For a thin film system with zero anisotropy, macrospin simulations show that the magnetization can be stabilized in any in-plane direction (isotropic coercivity). The possibility to control the magnetization position has been investigated considering a static and a rotating in-plane magnetic field. The STT effect from an out-of-plane polarizer (POL) has also been simulated with and without a static in-plane field. For all the four cases, an analytical solution has been found and compared to the macrospin simulations with good agreement. Finally, simulations of the full device (as in the inset) show the expected memristive behavior through the application of short pulses (100ps) and of a transverse in-plane magnetic field that insures the monotonicity of the resistance variation with the voltage polarity between the parallel P and antiparallel AP state. Fig a) shows the resistance variation under the effect of voltage pulses as in c). The memristive behavior is shown in b) where a transverse in-plane field is applied.

EF-08. Pronounced Scaling of the Tunnel Spin Polarization of Fe/MgO/silicon Contacts with MgO Thickness. *A.M. Spiesser*[1], H. Saito[1], S. Yuasa[1] and R. Jansen[1] *1. Spintronics Research Center, AIST, Tsukuba, Japan*

The discovery of giant tunnel magnetoresistance in crystalline Fe/MgO/Fe magnetic tunnel junctions[1,2] greatly accelerated the development of practical spintronic applications. Inspired by this success, crystalline MgO has also widely been used in semiconductor spintronic devices. Indeed, it has been shown that a charge current across a FM/MgO/semiconductor tunnel junction results in spin injection into the semiconductor[3-6]. With this approach, we recently demonstrated the creation of a giant spin accumulation in Si using Fe/MgO tunnel contacts[6]. However, some important questions remain, such as how the tunnel spin polarization (TSP) varies as a function of the MgO thickness and what is the role of symmetry-based spin filtering due to coherent tunneling in Fe/MgO tunnel contacts on Si. Here we report on these two aspects[7]. The Fe/MgO contacts were deposited on a Si substrate having a 70 nm-thick heavily-doped Si(001) channel and a MgO thickness (t_{MgO}) varying from 0.75 nm to 2.3 nm. The spin current produced by a charge current across the Fe/MgO/Si tunnel junction was measured using the standard 4-terminal nonlocal geometry. The TSP was extracted from the magnitude of the nonlocal spin-valve and Hanle signals. As shown in Fig. 1, the TSP depends sensitively on t_{MgO}, increasing from values below 1 % at small thickness, to values in the 90 to 95 % range for t_{MgO} above 2 nm. Such a near-perfect spin polarization of the tunnel current indicates that symmetry-based spin filtering due to coherent tunneling occurs in Fe/MgO tunnel contacts on Si, despite the significant lattice mismatch. The unexpected drop of the TSP below 1 nm of MgO is attributed to the lower crystalline quality of thin MgO layers, as supported by TEM. The scaling of the TSP can be well described (Fig. 1) by assuming coherent spin-dependent tunneling, but excluding the first 0.7 nm of MgO, which has lower quality. The pronounced scaling of the TSP with MgO thickness, as revealed here, has important implications for achieving large magnetoresistance in Si-based devices.

EF-09. Spin Signals in Two-terminal Devices with a Nonmagnetic Channel and Ferromagnetic Tunnel Contacts. *R. Jansen*[1], A.M. Spiesser[1], H. Saito[1], Y. Fujita[1], S. Yamada[2], K. Hamaya[2] and S. Yuasa[1] *1. 1National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; 2. Osaka University, Toyonaka, Japan*

Spintronic devices typically consist of a combination of ferromagnetic (FM) and non-magnetic (NM) materials in various device geometries. Nonlocal 4-terminal devices have been instrumental in fundamental studies of spin accumulation and pure spin currents. But since 4-terminal devices are not easily integrated in practical spintronic systems, attention is shifting to two-terminal (2T) lateral devices. Unlike nonlocal devices, spin signals in 2T devices are not very well understood. Here we report on spin transport in 2T devices with a Si channel and Fe/MgO tunnel contacts. We reveal two aspects that are crucial for the understanding of the 2T spin signals: (i) The conversion of the spin accumulation in the channel into a detectable voltage across a biased tunnel contact is shown to be strongly nonlinear [1], causing the spin-detection efficiency P_{det} of the FM tunnel contact to be different from the tunnel spin polarization, and strongly bias dependent. Consequently, contrary to expectation, the two FM contacts do not contribute equally to the detected spin signals. In fact, most of the 2T spin signal is generated at one of the FM contacts, while for the other contact, the bias polarity is such that $P_{det} \sim 0$ so that it contributes little or nothing. (ii) Spin voltages in 2T devices are shown to contain not only the expected contributions due to spin transport from one electrode to the other, but also local contributions from the spin accumulation in the Si created and detected at each of the two contacts separately [2]. The salient features of the 2T spin signals therefore differ from those in nonlocal devices. For instance, the 2T Hanle signals for parallel (P) and antiparallel magnetization (AP) have unequal amplitude (figure 1). The local and transport contributions to the 2T spin signal can be disentangled and described by the same set of device parameters as the nonlocal spin signals measured in the same devices [3]. Our conclusions apply also to 2T devices with a channel made from other semiconductors (GaAs, Ge), normal metals, or two-dimensional materials such as graphene and van der Waals crystals.

EF-10. Understanding of mechanism for gate-controlled spin accumulation in Si-based lateral spin valve. *S. Lee*[1], F. Rortais[1], R. Ohshima[1], Y. Ando[1], Y. Suzuki[2], H. Koike[3] and M. Shiraishi[1] *1. Department of Electronic Science and Engineering, Kyoto University, Kyoto, Japan; 2. Graduate School of Engineering Science, Osaka University, Toyonaka, Japan; 3. Advanced Products Development Center, TDK, Ichikawa, Japan*

One of the main advantages of semiconductor as spin transport channel is that both charge- and spin- transport properties can be modified by a gate voltage. Even if much effort has been dedicated for Si-based spin transistor, because of its long spin lifetime, the origin of the variation of the spin accumulation with applied gate voltage is still unclear [1, 2]. In this research, we aimed to understand the physical origin and the dominant mechanisms of the gate-controlled spin accumulation voltage in Si-based lateral spin valve device. For our research, we used Silicon-on-insulator based lateral spin valve (LSV) device, which consists of two ferromagnetic contacts and two nonmagnetic contacts on the top of the non-degenerate silicon channel with a carrier density of 5×10^{17} cm^{-3}. In addition, a gate voltage (V_G) was applied between the back side of the sample and a nonmagnetic contact of the device. V_G dependences of the electrical channel conductivity (σ_{Si}) and the spin diffusion length (λ_{Si}) of the LSV device, shown in figure 1, demonstrate the importance of σ_{Si} which was modified by several orders of magnitudes with applied V_G. Finally, local 3-terminal spin accumulation voltage (ΔV_{L3T}) was measured at various injection currents (I_{inj}) and applied V_G as summarized in figure 2. The control by a gate of the spin accumulation voltage is well described by a competition between spin drift effect and the conductivity mismatch. At positive V_G, the spin drift effect is decreased because the drift velocity is reduced by the accumulated carriers. However, at negative V_G the spin resistance of the channel is enhanced, which is increasing the conductivity mismatch and so reducing the spin injection/detection efficiency. At high I_{inj} and negative V_G, because drift velocity is reaching the saturation, the conductivity mismatch is the dominant mechanism. Both effects were included in our 1-dimensional model to explain the experimental results of the spin signal dependence with V_G. Our experimental demonstration of the competition between the conductivity mismatch and the drift effect, paves the way toward an efficient gate voltage control of spin signals.

EF-12. Crystalline-orientation Dependent Charge-spin Conversion and SOT Switching of Epitaxial Pt Films. *Y. Xiao*[1], H. Wang[1] and E. Fullerton[1] *1. Center for Memory and Recording Research, La Jolla, CA, United States*

The discovery of spin Hall effect (SHE) in heavy metals leads to effective charge current to spin current conversion [1,2]. The spin current can be employed to manipulate magnetic moment reorientation by spin-orbit torque (SOT). Similar to the anomalous Hall effect (AHE) in ferromagnets, the SHE in nonmagnetic conductors is contributed by spin skew scattering [3], side jump scattering [4] and intrinsic scattering [5]. In this context, engineering the crystallinity and defects in heavy metals provides an approach to delve in the underlying mechanism. Here, we fabricate Co/Ni multilayers with perpendicular magnetic anisotropy (PMA) on a series of epitaxial Pt layers with different crystalline orientations and doped impurities. The epitaxy nature of Pt and magnetic anisotropy of Co/Ni structures are confirmed by X-ray diffraction (XRD) (Fig. 1a) and vibrating sample magnetometry (VSM) (Fig. 1b) measurements, respectively. The charge-to-spin conversion efficiencies of different Pt layers are studied by SOT switching and harmonic Hall measurements (Fig. 1c, Fig. 1d). The measured spin Hall angles (SHA) of Pt layers with different textures and purities exhibit pronounced variations which can be correlated to the electrical resistivity and defects providing insights into the dominant scattering mechanism behind the spin Hall effect in heavy metals. This work was supported as part of Quantum Materials for Energy Efficient Neuromorphic Computing, an Energy Frontier Research Center funded by the U.S. DOE, Office of Science.

EF-13. Magneto-Seebeck Tunneling on the Atomic Scale. *C. Friesen*[1], H. Osterhage[1], J. Friedlein[1], A. Schlenhoff[1], R. Wiesendanger[1] and S. Krause[1] *1. Institute of Applied Physics and Interdisciplinary Nanoscience Center Hamburg, University of Hamburg, Hamburg, Germany*

The ongoing effort to fabricate electronic and spintronic devices at ever smaller size scales inevitably leads to a dramatic increase in heat generation. This ultimately sets a limit on the devices that can be constructed. Thus a detailed understanding of the coupling between charge, spin, and heat transport at the nanometer scale is a critical prerequisite for the design of such devices [1]. The tunneling of spin-polarized electrons across a magnetic tunnel junction, driven by a temperature gradient, is a fundamental process for the thermal control of electron spin transport, and previous studies have confirmed that large switching ratios are possible [2]. The possible applications of this effect, e.g. the efficient conversion of waste heat into spin currents, or the magnetic control of heat transfer on the atomic scale, have implications both for basic research and future technological applications. We experimentally investigated the atomic-scale details of this magneto-Seebeck tunneling by approaching a magnetic probe tip to a magnetic sample at cryogenic temperatures, with vacuum serving as the tunneling barrier [3,4]. By using a laser to heat the tip and measuring the resulting thermopower across the junction, while scanning across the spin texture of the sample, spin-resolved Seebeck coefficients are determined with atomic-scale lateral resolution. These direct tip-heating results were confirmed using predictions from rectification compensation and bias spectroscopy [3]. The experiments were performed at low temperatures and in UHV conditions, on the Fe/W(110) multilayer system (T = 50 K) [5], as well as on the Fe monolayer on Ir(111) (T = 25.3 K) [6], using a bulk Cr tip and active bias compensation [7]. The non-collinear spin structures present in these sample systems, and the atomic-scale lateral resolution of spin-polarized scanning tunneling microscopy, allowed for the imaging of a continuous range of relative tip-sample magnetization orientations. The results will be presented in terms of spin-averaged effects (including spin-orbit coupling) and magneto-Seebeck tunneling. Finally, a possible realization of a purely heat-driven magnetic sensor will be envisaged, potentially being an atomic-scale building block for integrated circuits in future spintronics devices.

EG-01. Higher Order Magnetic Anisotropy in a Perpendicularly Magnetized Epitaxial Ultrathin Fe Layer under Various Applied Voltage. *A. Sugihara*[1], T. Nozaki[1], H. Kubota[1], H. Imamura[1], A. Fukushima[1], K. Yakushiji[1] and S. Yuasa[1] *1. National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan*

Recently, voltage-controlled magnetic anisotropy (VCMA) effect at a ferromagnetic metal/dielectric material interface attracts much attention as the key technology for voltage-torque magnetic random access memory (MRAM). For the stable operation, VCMA coefficient ξ is required to be 600-1500 fJ/Vm.[1)] However, demonstrated ξ value (≲290 fJ/Vm) in magnetic tunnel junctions (MTJs) is much lower than the required value and its improvement is the current main issue. To make a strategy to improve ξ value, we need more systematic studies on the relationship between magnetic anisotropy and VCMA effect which give clues to clarify the mechanism of VCMA effect. In this study, we investigated the thickness and applied voltage dependences of first and second order magnetic anisotropy, K_1 and K_2 respectively, in an ultrathin Fe film. A fully epitaxial MTJ consisting of Cr buffer/ultrathin Fe free layer (t_{Fe})/MgO barrier (2.3 nm)/Fe pinned layer (10 nm) was grown on an MgO(001) single crystal substrate. In this film, easy axis of the free layer is perpendicular and that of the pinned layer is in-plane. The film was fabricated into micrometer-sized devices to measure tunnel magnetoresistance (TMR) curves under the application of in-plane magnetic fields and various electrical voltages (V) at room temperature. K_1 and K_2 were evaluated with Sucksmith-Thompson method[2)] from magnetization curves given from the TMR curves. Figure shows V dependence of K_1, K_2, K_1+K_2, intrinsic K_1 (K_{1int}), and effective uniaxial magnetic anisotropy $K_{u,\,eff}$ evaluated by the area method for t_{Fe} of (a) 0.40 nm and (b) 0.64 nm. They show clearly different trend that all the magnetic anisotropy constants have strong dependence on V at t_{Fe} = 0.40 nm while have virtually no dependence on V at t_{Fe} = 0.64 nm. We can also find that change in K_1 term is partly compensated by that in K_2 term at t_{Fe} = 0.40 nm. ξ value in the K_1 term reaches -600 fJ/Vm, being two times higher than that of effective one observed in the Cr/Fe/MgO systems.[3)] These results imply that individual control of K_1 and K_2 is the key factor for enhancement of the VCMA coefficient.

EG-02. Voltage-controlled tunability of threshold current and frequency in spin Hall nano-oscillators. *H. Fulara*[1,2], M. Zahedinejad[1], R. Khymyn[1,2], M. Dvornik[1], S. Fukami[3], S. Kanai[3], H. Ohno[3] and J. Åkerman[1,2] *1. Department of Physics, University of Gothenburg, Gothenburg, Sweden; 2. NanOsc AB, Kista, Sweden; 3. Laboratory for Nanoelectronics and Spintronics, Research Institute of Electrical Communication, Tohoku University, Sendai, Japan*

Spin Hall nano-oscillators (SHNOs) have recently emerged as one of the most promising spintronics devices as they are CMOS compatible tunable microwave nanoscale sources and exhibit robust mutual synchronization phenomena both in long chains and two-dimensional arrays desired for neuromorphic computing applications [1,2]. However, more complex cognitive tasks in neuromorphic vowel recognition have been limited so far due to the lack of fine control over an individual SHNO of these synchronized networks [3]. It would be highly advantageous if an energy efficient route such as electrostatic gating can potentially manipulate the device functionalities in order to perform more complex tasks using synchronized SHNO networks for novel applications. Here we demonstrate how electrostatic gating can substantially modulate the operational characteristics, such as threshold current and auto-oscillation frequency, in nano-constriction based W(5nm)/CoFeB(1.7nm)/MgO(2nm) electrically gated SHNOs. High frequency microwave measurements carried out in SHNO devices clearly exhibit a large overall modulation of about 22% in threshold current with ΔV_G = 4V and frequency tunability with a rate of 12 MHz/V (see Fig. 1). Our detailed analysis employing spin-torque ferromagnetic resonance (ST-FMR) measurements suggest that the observed noticeable tunabilities are caused by the voltage-controlled Gilbert damping constant [4], interfacial magnetic anisotropy [5], and spin Hall efficiency in our SHNOs. The unusual observation of simultaneous achievement of large spin Hall efficiency and low damping constant contrary to spin-transparency models is indicative of voltage controlled reversible changes in the electronic structure at the

CoFeB/MgO interface. Our findings pave a way for an energy efficient fine control of individual oscillators in chains or arrays of SHNOs manipulating the synchronization behavior for neuromorphic computing applications [3].

EG-03. Pseudo-magnetization as a New Order Parameter for Voltage Controlled Magnetism. *O. Hassan*[1], K.Y. Camsari[1] and S. Datta[1]
1. Electrical and Computer Engineering, Purdue University, West Lafayette, IN, United States

Traditional spintronic devices process information by encoding it in the orientation of magnetization. This requires a write operation that ensures a deterministic 180° switching of magnetization direction to flip "0" to "1". On the other hand, voltage controlled magnetism (VCM) by voltage control of magnetic anisotropy or by synthetic multiferroics naturally lead to ±90° switching of magnetization, that necessitates assisting mechanisms such as spin-transfer-torque or magnetic fields in addition to VCM. Here, we show how a new order parameter which we call *pseudo-magnetization*, that encodes magnetic anisotropy information rather than magnetization, combined with the unique characteristics of low barrier nanomagnets (LBM) [1] can be used for applications in memory and unconventional computing paradigms. Using an experimentally established circuit model [2] that describes the physics of synthetic multiferroics such as coupled magnetostrictive and piezoelectric materials (for example PMN-PT/CoFeB) we show how pseudo-magnetization can be imprinted and read-out directly by electrical voltage [3,4] without the use of magnetic tunnel junctions.

EG-04. Voltage-induced dynamic magnetization switching with low write error rate. *T. Nozaki*[1], T. Yamamoto[1], H. Imamura[1], M. Endo[2], T. Nozaki[1], M. Konoto[1], H. Ohmori[2], Y. Higo[2], H. Kubota[1], A. Fukushima[1], M. Hosomi[2] and Y. Suzuki[1,3] *1. Spintronics Research Center, AIST, Tsukuba, Japan; 2. Sony Semiconductor Solutions Corp., Atsugi, Japan; 3. Graduate School of Engineering Science, Osaka Univ., Toyonaka, Japan*

Dynamic magnetization switching using a voltage-controlled magnetic anisotropy (VCMA) effect is an ultimate writing technology for future spintronic devices, such as voltage-torque MRAM. We have performed fundamental demonstrations of the VCMA effect in fully solid state devices[1]*, repeatable voltage-induced dynamic switching*[2] *and large enhancement of VCMA effect by an introduction of heavy metal materials*[3]*. An important remaining technical issue for developing a voltage-torque MRAM is the demonstration of low write error rate (WER).* In this work, we performed systematic investigations to realize the reliable switching from the viewpoints of materials design and the electrical control of spin dynamics. Macro-spin model simulation revealed that high thermal stability, *i.e.* high perpendicular magnetic anisotropy (PMA), and low damping constant are key parameters to suppress the write error[4]. Firstly, in conventional CoFeB/MgO based magnetic tunnel junctions, we maximized the PMA and VCMA coefficient by optimizing the CoFe composition and post-annealing process[5].

Figure 1 shows an evaluation example of pulse duration dependence of WER for the MTJ with the free layer of 1.1 nm-thick $(Co_{50}Fe_{50})_{80}B_{20}$ post-annealed at 250°C. WER of lower than 10^{-6} has been achieved by a single pulse voltage application. We also found that WER can be reduced by intentional control of pulse shape[6]. For example, Figure 2 shows the rise- and fall- time dependence of WER. Introduction of fall-time of 0.15 ns resulted in the reduction of WER. Optimal fall-time, which causes the uncompensated PMA, can suppress the relaxation dynamics after the switching process, leading to the reduction in the WER. For further reduction in the WER, enhancement in the VCMA coefficient is also demanded. Recent activities on the materials design using a heavy metal doping technique will also be introduced. Large VCMA coefficient surpassing -350 fJ/Vm has been observed in the Ir-doped Fe layer with an introduction of optimized CoFe termination layer.

EG-05. Voltage-torque-driven magnetization switching using microwave-superimposed voltage pulse. *T. Yamamoto*[1], T. Nozaki[1], H. Imamura[1], S. Tamaru[1], K. Yakushiji[1], H. Kubota[1], A. Fukushima[1], Y. Suzuki[1,2] and S. Yuasa[1] *1. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan; 2. Graduate School of Engineering Science, Osaka University, Toyonaka, Japan*

Voltage-torque (VT) provides unique ways of manipulating the magnetization in ferromagnetic thin-films, as exemplified by the induction of ferromagnetic resonance (FMR) [1] and magnetization switching [2]. Since the VT-driven magnetization switching is mediated by magnetization precession around an effective field, the switching probability (P_{sw}) exhibits a periodic oscillation as a function of write pulse width. However, the magnetization damping gradually reduces the precession angle and thus it is generally difficult to achieve a well-controlled magnetization switching using a long write pulse. In this work, we tackle this technological issue by attempting to *swing* the magnetization using the VT. We show that the VT generated from a microwave voltage effectively counteracts against the magnetization damping and that substantially improves P_{sw} over a wide range of pulse width. The VT-driven magnetization switching is investigated for a CoFeB/MgO/CoFeB magnetic tunnel junction (MTJ). Microwave voltages as well as square voltage pulses are simultaneously generated by using an arbitrary waveform generator. We employed waveform correction procedure as described in Ref. [3] to ensure that the waveform applied to the MTJ becomes just as we designed. Figure 1 displays the result of VT-driven magnetization switching using microwave-superimposed voltage pulses. As expected from the VT-driven FMR experiment [1], a substantial improvement of P_{sw} is obtained when f is set to the FMR frequency ($f = f_0$). However, the most remarkable improvement of P_{sw} is observed for $f = 2f_0$. We employ a simple model to explain the experimental observations, and also show that the VT can actually swing the magnetization with the utmost efficiency when $f = 2f_0$. This work was partly supported by ImPACT Program of Council for Science, Technology.

EG-06. Voltage Induced 180 Degree Switching of the Néel Vector in a Ferrimagnet by Solid-State Ionic Gating. *M. Huang*[1], L.M. Caretta[1], J. Bartell[1] and G. Beach[1] *1. Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, MA, United States*

The rapid increase of data being generated nowadays requires denser and more energy efficient data storage than is currently available. Controlling magnetism by an electric field is a promising way to manipulate magnetism that could enable ultralow-power, high-density magnetic memory and logic devices [1], [2]. However, 180 degree switching of magnetization is not straightforward because the electric field does not break time-reversal symmetry. Motivated by the recent discovery that hydrogen pumping in an solid state structure can be used to control magnetic anisotropy in metallic heterostructures [3], here we examine the effects of proton gating on ferrimagnetic order in rare earth-transition metal alloys. Prior work has shown that hydrogen loading into ferrimagnets can control their compensation temperature [4]. Here we show that the dominant lattice of GdCo ferrimagnetic thin films at room temperature can be reversibly toggled by hydrogen loading/unloading into the material controlled through a gate voltage in an all-solid-state structure. We examine Pd(6nm)/CoGd(6nm)/Pd(10nm)/GdOx(30nm)/Au(3nm) structures with perpendicular magnetic anisotropy. In these structures, a positive gate bias applied to the top electrode generates protons through hydrolysis of ambient moisture in the air, as shown previously [3]. We find that proton injection into the CoGd leads to a significant decrease in the compensation temperature, which we attribute to a decrease in the Gd moment due to hydrogen localization near the rare earth. With a fixed perpendicular bias field, we show that a gate voltage can induce 180° magnetic switching of the sublattices by shifting the magnetic compensation temperature above and below room temperature. We show that this switching can occur on relatively fast timescales and is reversible over at least 100 cycles. The study provides a new direction in magneto-ionic control of magnetism and a new route towards low power nonvolatile magnetic memory.

Voltage control of magnetism has been a forefront subject of spintronics research for many years[1,2]. Among the few suggested methods, magneto-ionic control of magnetism has demonstrated significant modulation of magnetic anisotropy on the order of ~ 1 erg cm^{-2} [3,4]. However, prior work[3-5] utilized voltage-induced oxygen migration, which suffered from irreversible oxidation damage[5] and high operation temperature[4]. Recently, it has been demonstrated that, hydrogen-based magneto-ionic devices could offer enhanced device capabilities such as high reliability (>2000 cycles) and fast switching (~100 ms) at room temperature (RT).[6] In these devices, solid-state electrochemical water splitting using atmospheric humidity was shown[6] to provide a source of mobile protons that could be driven through a gate oxide to reversibly switch the magnetic properties. Here we demonstrate that the performance, in particular "switching speed", of hydrogen-based magneto-ionic devices can be significantly enhanced using yttria-stabilized zirconia (YSZ) gate oxide. We first compared the device switching efficiencies using various oxide materials, including gadolinium-doped ceria (GDC), barium cerium yttrium zirconate (BZCY) and YSZ, which are all well-known proton conducting oxides. Hydrogen-induced anisotropy modulation was observed in all devices (Fig. 1), revealing the generality of this mechanism. However, switching speed was oxide-dependent and the fastest for YSZ. We then systematically study the YSZ thickness-dependent switching speed, and as shown in Fig. 2, we demonstrate sub-5 ms magnetic anisotropy switching, exceeding the temporal resolution of current measurement set-up and exhibiting ~ two orders of magnitude faster than the state-of-the-art device reported to date at RT.[6] In this talk, we will also discuss further engineering that could push the switching speed down to the 10~100 times of nanoseconds.

EG-08. Impact of spin transfer torque on the write error rate of a voltage-torque MRAM. *H. Imamura*[1] and R. Matsumoto[1] *1. Spintronics RC, AIST, Tsukuba, Japan*

Voltage-torque (VT) switching is an attractive method for low-power writing of a magnetoresistive random access memory (MRAM), which is based on voltage control of magnetic anisotropy [1-7]. The basic structure of a magnetic tunnel junction for VT MRAM is the same as that for spint-ransfer-turque (STT) based MRAM except for the value of resistance-area product. VT MRAM has much larger resistance-area product than STT MRAM to suppress the current density, or energy loss by Joule heating at the operating voltage. Although Joule heating reduces as the resistance increases, the read time increases with increase of the resistance because it is determined by the *RC* time constant, where *R* and *C* are the resistance and capacitance of the MRAM cell, respectively. The resistance of the MRAM cell should be designed to balance the energy consumption and read time. The write error rate (WER) is another key metric to characterize the performance of the MRAM cell. The WER of STT-MRAM can be lowered below 10^{-11} by increasing the applied current density [9]. The WER of VT MRAM is still higher than that of STT MRAM, which ranges form 10^{-3} to 10^{-5} [6-8]. Attempts are being made to reduce the WER by improving materials [7] as well as by shaping voltage pulse [8]. Until now the WER of VT MRAM has been studied in the high-resistance condition to eliminate the effects of STT. However, for practical application, the resistance should be lowered to decrease the read time. It is important to know the minimum current density (J) below which the impact of STT on the WER is negligible. Here we theoretically analyze the WER of a perpendicularly magnetized VT MRAM with special attention to the impact of STT [10]. We show that the STT assists or suppresses the precessional motion of the magnetization depending on the direction of the initial state, i.e. up-polarized or down-polarized. There is a characteristic value of the current density above which the precessional motion, and therefore magnetization switching, is forbidden by the STT for one direction of the switching. We found that for typical material parameters the WER is insensitive to STT below a current density of 10^{10} A/m^2 as shownin Fig. 1.

Department of Electrical Engineering, KULeuven, Leuven, Belgium*

The Voltage Control of Magnetic Anisotropy (VCMA) effect has been widely demonstrated using MgO as the functional oxide [1, 2]. Recently, we showed an increase of the VCMA effect up to above 200 fJ/Vm using a $SrTiO_3$\Co\Pt trilayer. The ultrathin (10 nm) layer of $SrTiO_3$ is grown using Atomic Layer Deposition and has a relative permittivity k around 40. However, the mechanism driving the anisotropy change in $SrTiO_3$\Co\Pt remains unclear. One hypothesis may be that the larger permittivity of $SrTiO_3$ enhances the accumulated charge, and hence the VCMA [3]. To understand the mechanism, we measure the VCMA effect in $SrTiO_3$\Co\Pt trilayers as a function of decreasing temperature, between 300K and 5K. At first, the effect decreases from the room temperature value of 186 fJ/Vm down to 165 fJ/Vm at 100K (see Fig. 1). Below 100K, the VCMA effect drops more sharply, down to 30 fJ/Vm at 50K and becomes indistinguishable below. The decrease of the VCMA effect strength is unexpected according to previous reports [4]. Capacitance-Voltage (CV) measurements were performed to measure the permittivity k of the STO as a function of decreasing temperature (Fig. 1). They show that the k-value also decreases by 5% down to 77K. The decrease of the permittivity is ascribed to de-activation of defects in the ALD- grown STO layer, which leads to a decrease in the apparent dielectric constant [5]. The decrease of the VCMA amplitude is not proportional to the change in the permittivity, which shows that an additional effect is at play; in particular, the sudden drop at the lowest temperatures suggests that another mechanism arises and suppresses VCMA altogether. The impact of the temperature onto the band structure at the STO\Co interface may play a crucial role in the effect reported here.

EG-10. Electric-field induced spin pumping in an in-plane magnetized CoFeB/MgO junction. *A. Deka*[1], B. Rana[2], R. Anami[1], K. Miura[3], H. Takahashi[3], Y. Otani[4,2] and Y. Fukuma[1,2] *1. Computer Science and Systems Engineering, Kyushu Institute of Technology, Iizuka, Japan; 2. Center for Emergent Matter Science, RIKEN, Wako, Japan; 3. Research and Development Group, Hitachi Ltd., Kokubunji, Japan; 4. Institute for Solid State Physics, University of Tokyo, Chiba, Japan*

Recently the possibility of controlling magnetization of a ferromagnetic metal by applying an electric-field at its interface was demonstrated by Weisheit *et al* [1]. It has the potential to eliminate the need for high charge current densities of the order ~1×10^{11} Am^{-2} that is typically required to control magnetization in spin transfer torque or spin orbit torque experiments. However, voltage torque on magnetization is zero for an in-plane or out-of-plane magnetized films. So an external bias field is always needed to tilt the magnetization away from the film plane or normal [2]. Here we will present our observation that by inducing an interfacial in-plane magnetic anisotropy, we can have a non-zero voltage torque in an in-plane magnetized CoFeB film. This enables us to demonstrate electric-field induced spin pumping from an in-plane magnetized CoFeB thin film into an adjacent heavy metal (Ta) layer. As shown in Fig. 1, the resulting DC inverse spin Hall voltage obtained from the electric-field induced spin pumping is observed to be over 10 times higher compared with the spin pumping induced by magnetic fields [3]. Such a control of the interfacial magnetic anisotropy proposes a new design for future ultralow power spintronic devices, wherein the excitation and switching of magnetization can be controlled purely by electric-fields.

EG-11. Study of GHz VCMA Precessional Switching Speed in BEOL-Compatible Perpendicular MTJ. *Y. Wu*[1,2], W. Kim[1], S. Couet[1], K. Garello[1], S. Rao[1], B.F. Vermeulen[1,2], S. Van Beek[1], S. Kundu[1], S. Houshmand Sharifi[1], F. Yasin[1], J. Swerts[1], D. Crotti[1], J. Van Houdt[1,2], G. Groeseneken[1,2] and G.S. Kar[1] *1. IMEC, Leuven, Belgium; 2. KULeuven, Leuven, Belgium*

Magnetization switching by voltage control of magnetic anisotropy (VCMA) effect allows for lower power and ultra-fast writing (sub-ns) of perpendicular magnetic tunnel junction (pMTJ) devices [1,2]. VCMA functions in applying electric-field (*EF*) that removes the energy barrier (E_b) to induce precessional switching [1]. The precession frequency f_P, in other words, the switching speed ($V_S = 2f_P$), varies with both *EF* and in-plane magnetic field (B_{IP}) [2,3]. In this work, we use BEOL-compatible MgO/CoFeB/Ta based pMTJ devices to study their characteristics of VCMA-induced precessional switching. We first measure the switching probability (P_S) distribution as a function of pulse width (*PW*). f_P is estimated by fitting the first period of P_S *vs. PW (see* Fig.1(a) inset). V_S is clearly characterized by two representative regimes. First, below the critical *EF* (EF_C), there is a non-precessional phase where switching occurs by thermal activation, hence no switching speed can be deduced. Second, above EF_C is the acceleration regime, in which higher *EF* increases progressively V_S (Fig. 1(a)). Such EF_C varies with B_{IP}, since B_{IP} contributes in lowering the energy barrier along its direction. This variation is also studied and examined by micromagnetic simulation (Fig. 1(b)). In the acceleration regime, a positive energy difference (ΔE) induces precessional switching, in which f_P is expressed as γB_{eff}. Additionally, there is a characteristic *EF* (EF_{C0}) that can remove E_b without assistance of B_{IP}. At such EF_{C0}, B_{IP} will contribute completely in executing precessional switching, where f_P can be approximated as γB_{IP}, and V_S is a characteristic speed of $2\gamma B_{IP}$. Both experimental and simulation results agree well with the prediction (Fig. 2). This work was supported by IMEC's Industrial Affiliation Program on MRAM devices.

EG-12. Voltage Tuning of Switching Probability in Voltage-controlled Switching. *A. Fukushima*[1], T. Yamamoto[1], T. Nozaki[1], K. Yakushiji[1], H. Kubota[1] and S. Yuasa[1] *1. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan*

We have developed a new type of random number generator (RNG), named spin dice, which employs stochastic switching events in MTJs [1]. In the case of voltage-controlled switching [2], switching of both directions, parallel (P) to antiparallel (AP), and AP to P, are caused by the same unipolar voltage pulse, and random numbers are generated by mixing the both switching results. In addition, when the switching probabilities of P to AP and AP to P have the same voltage dependence [3], average of the generated random numbers becomes nearly identical, as shown in Fig. 1(a), which shows that the change in switching probability is not directly related to the average of generated random numbers. In order to precisely measure the switching probability, classification of the switching events depending on the initial state (P or AP) is necessary, which however, becomes costly and complicated. By tuning the switching probability to 0.5, we divide the generated random numbers in every 2-bits and count the occurrence of 4-pattern (00, 01, 10, 11). For the ideal random numbers, the occurrence frequency of the 4-patterns should be the same. Figure 1(b) shows the voltage dependence of the occurrence of the 4-patterns. Contrary to voltage dependence of the average of generated random numbers, frequencies of the 4-patterns change linearly against the voltage and the voltage dependence of the frequency of (00, 11) has opposite sign to that of (10, 01). Consequently, it is possible to generate well balanced random numbers by tuning the occurrence frequency of the 4-patterns to be the same value 0.25. It is important for a well-balanced randomness source to tune the switching probability under the unipolar bias (voltage or magnetic field) where P to AP and AP to P switchings are mixed. Further, intentional control (manipulation) of the switching probability could be useful to realize a probabilistic computing element such as p-bit [4]. This work was funded by ImPACT Program of Council for Science, Technology and Innovation (Cabinet Office, Government of Japan).

EG-13. Giant Electric Field Modulation of Magnetism in Ferrimagnetic Heusler Heterostructures. Q. Sun[1], S. Kwon[1] and *N. Kioussis*[1] *1. California State University, Northridge, Northridge, CA, United States*

The demand for higher density, higher speed, and more energy-efficient magnetoelectric random access memory (MeRAM) requires the search of novel materials and magnetic tunnel junction stacks with voltage-controlled magnetic anisotropy (VCMA) efficiency greater than the 1000 fJ/(Vm) challenge.[1] To date, the realization of MeRAM relies primarily on ferromagnetic (FM) based heterostructures, which exhibit low perpendicular magnetic anisotropy (PMA) and low VCMA efficiency. On the other hand, the E-field manipulation of magnetism in *ferrimagnetic* Heusler nanojunctions, which are considered to be potential candidates in spintronic devices, remains unexplored thus far both theoretically and experimentally. In this talk, we will present predictions of ab initio electronic structure calculations of the VCMA of Ir/Mn_3Ga/MgO heterostructures, in which the ultrathin ferrimagnetic Mn_3Ga has the tetragonal DO_{22} structure.[2] We find that the Mn_{II}-Mn_{II}- (Mn_I-Ga-) terminated interfaces exhibit large out-of-plane (in-plane) magnetic anisotropy (MA). More importantly, the calculations reveal colossal PMA and VCMA efficiency of about one order of magnitude higher than the values reported today. We demonstrate that both the MA and VCMA depend critically on the heavy metal thickness. We also predict a sign reversal of the VCMA efficiency from the Mn_{II}-Mn_{II} to the Mn_I-Ga-terminated interface. We demonstrate that the dominant contribution to both the PMA and VCMA arises from the strong spin-orbit-coupling of Ir and the E-field induced shift of the Ir *d*-derived orbitals. These findings provide useful guiding rules in the design of more energy-efficient ferrimagnetic-based MeRAM devices. Supported by NSF Grant No. ERC TANMS-1160504

EH-01. A New Generation of MnBi Permanent Magnets.
G.C. Hadjipanayis[1], A. Gabay[1] and J. Cui[2,3] *1. University of Delaware, Newark, DE, United States; 2. Iowa State University, Ames, IA, United States; 3. Ames Laboratory, Ames, IA, United States*

MnBi magnets, notable for the positive temperature coefficient of their coercivity, are recognized as promising rare-earth-free alternatives to the lower-grade rare-earth magnets, such as the bonded Nd-Fe-B magnets. The intrinsic magnetic properties of the key MnBi "low-temperature phase" (LTP) allow for a maximum energy product $(BH)_{max}$ up to 20 MGOe. The powder metallurgy approach using ball-milled fine powders has been nearly universally explored in numerous earlier studies – ultimately yielding MnBi powders with a nominal $(BH)_{max}$ up to 15 MGOe [1]. However, sintering of the fine MnBi powders into anisotropic magnets is accompanied by a partial loss of both the LTP and coercivity, so the $(BH)_{max}$ reported for the magnets sintered from single-crystal powders does not exceed 8.4 MGOe [2]. Here, we present a new approach to manufacturing of bulk MnBi magnets which involves neither the fine milling nor the lengthy homogenization process which is usually required to initially obtain the LTP. Instead, melt-spinning of the appropriately alloyed MnBi is used to generate nanograins of the "high-temperature phase" which later transform into larger, but still submicron LTP grains [3]. The melt-spun ribbons are compacted to a full density at the low temperature of 150 °C and then subjected to a short (less than an hour) annealing at 260-300 °C in a moderately strong magnetic field of 30 kOe to increase the LTP fraction to 97-98% and to partially align the easy magnetization directions of the LTP crystallites. The best magnets are characterized by LTP grains approximately 0.5 um in size and they exhibit at room temperature a remanence of 7 kG, a coercivity of 5 kOe and a $(BH)_{max}$ up to 11.5 MGOe; more importantly, the $(BH)_{max}$ remains greater or equal to 10 MGOe for the temperatures between 5 °C and 125 °C. We will discuss the development of the material based on the structural and thermal data and identify the research areas in need of further exploration. In particular, the observed negative correlation between the texture and the coercivity, which is hindering further improvement of the new MnBi magnets, remains poorly understood. The work was supported by the US DOE through grants EE0007794 and DE-FG02-90ER45413.

EH-02. The Effect of Sn Addition on the Magnetic and Physical Properties of Mn-Bi Magnetic Materials.
J. Park[1], Y. Yang[1], J. Kim[1] and C. Choi[1] *1. Functional Powder Material Department, Korea Institute of Materials Science, Changwon, The Republic of Korea*

Ferromagnetic low temperature phase (LTP) MnBi alloy possesses maximum energy product, $(BH)_{max}$, of about 17 MGOe at 290 K [1], therefore, LTP MnBi is a promising candidate to fill the gap between rare-earth and rare-earth free permanent magnets. However, the low phase transformation (PT) temperature and segregation of Mn from MnBi liquid at 446 °C [2] are the major obstacles to producing a high density bulk magnet for high efficiency sustainable energy applications. Therefore, in this work, we have fabricated Sn diffused MnBi powders and bulks at lower temperature than the PT temperature to prevent phase decomposition and increase the density. LTP MnBi powder was prepared by ingot casting using induction melting, followed by crushing, sieving, and magnetic separation. The obtained powder was then mixed with Sn submicron powder using low energy ball milling in ethanol. The mixed powder was dried in a glove box and annealed/hot pressed at 245 °C for 30 min to produce a high density Sn diffused LTP MnBi bulk magnetic materials. Figure 1 shows the Sn wt.% dependence of the density for the Sn diffused LTP MnBi bulk magnetic materials. The density increases with increasing Sn wt.% up to 2 %, then begin to decrease with increasing Sn content. It was found that the small amount of Sn preferentially reacts with remaining Bi, and excessive Sn reacts with MnBi. The variation of the Bi/MnBi phase ratio in Fig. 2 indicates that the increasing Sn content promotes the formation of LTP MnBi, therefore, results in the enhanced M_r/M_s ratio and $(BH)_{max}$. In this presentation, detailed experimental procedures and analyses of physical and magnetic properties of the Sn addition to MnBi alloy will be discussed.

EH-03. Effect of Quench Rate on the Magnetic Properties of Cr Doped MnBi Melt Spun Ribbons. *K. Anand*[1], N. Christopher[1] and N. Singh[1]
1. Physico Mechanical Metrology Division, CSIR-National Physical Laboratory, Delhi, India

The ferromagnetic intermetallic compound MnBi in its low-temperature phase (LTP) has long been a material of interest, particularly in the field of rare-earth-free permanent magnet materials. However, because of the decomposition of LTP MnBi into $Mn_{1.08}Bi$ and liquid Bi upon heating to 628 K, its synthesis is a matter of concern. In view of the potential of melt spinning and the scope of optimizing various process parameters, the present study is focussed on the effect of quenching rate on $Mn_{47}Bi_{50}Cr_3$ ribbons. Addition of Cr to MnBi led to decoupling of structural and magnetic transition temperature, resulting in the formation of a stable compound. The ribbons produced via melt spinning at different wheel speeds of 20, 25, 30 and 35 Hz, were analyzed for its phase, microstructure and magnetic properties. Due to a higher rate of cooling induced on the melt, the crystallite size as determined from Scherer's formula decreased from 80 nm to 32 nm for the ribbons melt spun at 20Hz and 35Hz respectively. This was confirmed from the microscopic studies as well, where grain size as observed from scanning electron microscopy (Fig. 1) is found to be inversely proportional to wheel speed and cooling rate. This could be attributed to the high cooling rate causing an increased number of nucleation sites and reduced grain size, which in turn leads to a high value of coercivity. The maximum coercivity of 11.1 kOe and saturation magnetization of 55 emu/g is obtained for the ribbons melt spun at 25Hz (Fig. 2). This suggests that the initial grain size and the magnetic property of the ribbon depend on the crystal growth rate, heterogeneous nucleation frequency, and the time required for solidification on the surface. By optimizing the process parameters associated with melt spinning technique, high performance nanocrystalline $Mn_{47}Bi_{50}Cr_3$ alloy has been synthesized by carefully adjusting the wheel speed and thereby controlling the quench rate.

EH-04. Phase Transformation and Large Coercivity in Severely Deformed MnAl Alloys Doped with B+N Elements. P. Si[1], H. Ge[1], *C. Choi*[2] and J. Du[3] *1. College of Materials Science & Engineering, China Jiliang University, Hangzhou, China; 2. Powder & Ceramic Division, Korea Institute of Materials Science, Changwon, The Republic of Korea; 3. School of Material Science & Engineering, Shanghai University, Shanghai, China*

The B-N-doped MnAl alloys were prepared by using induction melting and post annealing process. Elemental doping is usually employed to stabilize the metastable binary MnAl alloys [1, 2]. It has been well-known that C can stabilize the ferromagnetic τ-phase MnAl effectively. The boron-doped τ-MnAl has also been studied previously [3, 4]. Herein we show that the co-doping of B+N elements can also stabilize the τ-phase MnAl, which were obtained by controlling the cooling process of ε-phase from high temperatures and by annealing the water-quenched ε-phase at elevated temperatures, respectively. The massive phase transformation of ε→τ in the B-N-doped MnAl is activated at 680 K and accomplished at 760 K, as shown in Fig. 1. Coercivity development is crucial for applications of MnAl-based alloys as magnets [2-7]. Ball milling is most frequently employed to develop coercivity in magnetic powders of MnAl-based alloys [2-8]. However, the coercivity decreases significantly when the milled magnetic powders were consolidated into bulk [8]. In this work, the coercivity of the τ-phase MnAl doped with B+N was developed by using a high-pressure severe deformation process, during which bulk samples with large coercivity were obtained directly from the original τ-phase bulk alloys. The microstructure and the magnetic properties of the samples were studied.

EH-05. Enhancement of Maximum Energy Product in Exchange-Coupled Fe_3O_4 Coated $BaFe_{12}O_{19}$ Nanocomposites. F. Mohseni[1,2], R.C. Pullar[2], J.M. Vieira[2] and *J.S. Amaral*[1] *1. Department of Physics and CICECO, University of Aveiro, Aveiro, Portugal; 2. Department of Materials and Ceramic Engineering and CICECO, University of Aveiro, Aveiro, Portugal*

Recent economic and environmental concerns have prompted intensive research on the development and optimisation of rare-earth free permanent magnets, in particular of ferrites. M-type barium hexaferrites ($BaFe_{12}O_{19}$, BaM) are a type of technologically important, low-cost permanent magnet, with high Tc and high resistance to oxidation and corrosion. Their magnetic performance can be improved upon by exploring exchange-coupling mechanisms, to increase their competitiveness with existing rare-earth magnets [1, 2]. The present investigation explores the exchange-coupling mechanism and shows the correlation between the structural, microstructural, compositional and magnetic properties of BaM hexaferrite and Fe_3O_4 nanocomposites. Via a sol-gel auto combustion method, flake-like BaM particles were prepared and afterwards coated with magnetite nanoparticles using a hydrothermal method. The exchange-spring mechanism was then optimized via the control of nanocomposite phase fractions and heat treatment conditions. Electron microscopy results show that 10 nm sized magnetite nanoparticles were developed as the shell of ultra-thin BaM nanoparticles. We observed the exchange coupling between the hard and the soft magnetic phases requiring no post-heat treatment. The obtained flake-like BaM/Fe_3O_4 nanocomposite exhibits a saturation magnetization of 90 emu/g and a coercivity of ~ 3.5 kOe at room temperature for the sample with a BaM to magnetite weight ratio of 9:1. The magnetic measurements indicate an >50% increase in the saturation magnetization (Ms) in each of the nanocomposite samples compared to the annealed BaM. The results also show a 75% increase in the energy product (BH)max at room temperature in the BaM/Fe_3O_4 9:1 hard/soft nanocomposite, compared to the parent hard phase, which is significantly larger than previous studies [3, 4]. The results are significant in the sense that a simultaneous >30% enhancement in the Ms and the (BH)max of the prepared nanocomposite compared to a commercial BaM powder.

EH-06. High Coercivity of Rare-earth Free Alnico Thin Film. X. Han[1], H. Won[3], M. Choi[3], L. Guo[1], Z. Liu[1], R. Wang[1,2], L. Li[1], Y. Hong[3,2] and *F. Yan*[1,2] *1. Department of Metallurgical and Materials Engineering, The University of Alabama, Tuscaloosa, AL, United States; 2. Alabama Transportation Institute, The University of Alabama, Tuscaloosa, AL, United States; 3. Department of Electrical and Computer Engineering and Center for Advanced Vehicle Technologies, The University of Alabama, Tuscaloosa, AL, United States*

The microstructure of Alnico IX permanent magnet (PM) is composed of spinodally decomposed ferromagnetic $L1_0$ Fe-Co rich (α_1) rods embedded in paramagnetic $L1_2$ Al-Ni rich (α_2) matrix. The coercivity (H_{ci}) of Alnico is originated from a shape anisotropy of α_1 rod, instead of magneto-crystalline anisotropy (K_1), resulting in low H_{ci} of 1.4 kOe compared to that of K_1 based PM. To enhance H_{ci} and understand its mechanism, Alnico V was sputter deposited on Si/SiO_2 (100) substrate wafer, showing increase in H_{ci} from 0.74 to 1.8-6.5 kOe [1-3]. The papers postulated that this increase may be attributed to inter-diffusion between Si/SiO_2 substrate and sputtered Alnico V films, yet without providing solid evidence. Especially, α_1 composition was investigated for magnetic properties in neither thin film nor bulk form, but mostly, direct deposition of Alnico V on Si/SiO_2. In this paper, we have sputter deposited α_1 phase alloy ($Fe_{52}Co_{35.8}Al_{5.6}Ni_{5.3}Ti_{0.9}Cu_{0.4}$) on (111) oriented Pt(100 nm)/TiO_2/SiO_2/Si substrate to study the effects of inter-diffusion and annealing on the H_{ci} for various α_1 film thickness (t = 100-140 nm). Fig. 1 shows the magnetic hysteresis loop of as-deposited and annealed films with different t. As-deposited 100 nm thick film is magnetically very soft with H_{ci} = 0.05 kOe. In contrast, after annealing at 800 °C, H_{ci} remarkably increases to 5.4 kOe for 140 nm film, exhibiting pronounced enhancement with increasing t. To understand the mechanism, X-ray diffraction pattern and the elemental line-scan profiles of energy x-ray dispersive spectroscopy across the thin film layers and interfaces were performed. The results shown in Fig. 2 reveal that the increase in H_{ci} is attributed to inter-diffusion among Co, Fe, and Pt in the annealed film, resulting

in the formation of large K_1, 50 nm spherical tetragonal $L1_0$ (Co, Fe)Pt phase, thereby large H_{ci}. This work was supported in part by NSF-I/UCRC for EV-STS under Grant No. 1650564 and NSF-CMMI under Grant No. 1463301.

Nanoporous magnets have attracted the growing interest of researchers for possible applications in the field of nano-biotechnology. In addition, a variety of novel functionalities may be found by impregnation of other functional materials into the pores to form new nanocomposites. It is known that Fe-Pt alloys composed of an ordered face-centered-tetragonal FePt ($L1_0$-FePt) phase have gained considerable attention for the fabrications of high performance permanent magnets and ultrahigh density magnetic data storage media due to the extremely high magnetocrystalline anisotropy. Template-based techniques via annealing with FePt nanoparticles were used to fabricate an ordered nanoporous structure with an $L1_0$-FePt phase [1], but this method is technically difficult and time-consuming to implement. In this work, for fabricating nanoporous magnets by simple and effective approach, the Fe-Pt-B nanocomposite alloys [2] consisting of hard $L1_0$-FePt and soft Fe_2B magnetic phases have been electrochemical etched in H_2SO_4 aqueous solution. The structure and properties of the etched alloys were investigated. A novel nanoporous alloy with a single $L1_0$-FePt phase has been fabricated by etching an $Fe_{60}Pt_{10}B_{30}$ nanocomposite alloy. The Fe_2B phase is selectively removed from by electrochemical etching, while the preserved $L1_0$-FePt phase forms a uniform open bicontinuous interpenetrating ligament–channel structure with a ligament size of ~15 nm. The nanoporous $L1_0$-FePt alloy possesses a very high coercivity of 18.5 kOe. For understanding the magnetic behavior of the nanoporous alloy, the micromagnetic simulation has been carried out.

EH-08. Co nano-cluster inclusions in $L1_0$-FePt matrix as a model system of nanocomposite magnets. C. Paléo[1], F. Wilhelm[2], T. Epicier[3], V. Dupuis[1] and *D. Le Roy*[1] *1. Univ. Lyon 1, ILM, Villeurbanne, France; 2. E.S.R.F., Grenoble, France; 3. INSA Lyon, Villeurbanne, France*

Nanocomposite materials is a promising route to develop new permanent magnets with unprecedented performances. Theoretical calculations predicted a potential energy product of 1 MJ/m^3, which is twice as large as the one of best $Nd_2Fe_{14}B$ magnets produced today [1]. But these calculations also pointed out the absolute necessity to confine the softer phase in nano-sized grains, typically smaller than 10 nm, which cannot be obtained with conventional process for mass scale material fabrication. So far only very few experimental works with encouraging results have been reported on such exchange-spring magnet [2]. Further experimental investigations are needed to assess the full potential of nancomposite for designing high energy product magnetic materials. We recently prepared Co@FePt transition metal (TM)-based nanocomposite films from low energy cluster beam deposition technique (LECBD) of Co clusters, *in situ* embedded in FePt matrix independently produced by alternative electron gun [3,4]. This nanofabrication route gives a fine control over the microstructure. Co cluster inclusions can be selected in size prior their deposition, between 1 and 10 nm. The cluster to matrix volume ratio is adjusted controlling the thickness of each Co, Fe, Pt individual layers. Annealing is a crucial step to drive the initial Fe and Pt multilayers to the high-magnetic anisotropy $L1_0$ phase with a limited cluster-matrix interdiffusion. X-rays Diffraction revealed a thermal transition to a chemically ordered $L1_0$-FePt alloyed matrix with a partial texture on Si substrate while environmental-TEM and EDX analyses allowed us to observe the partial diffusion of the Co clusters in the hard matrix. Recently, X-ray absorption spectroscopy measurements (EXAFS, XLD and XMCD) were performed on annealed Co@FePt nanocomposite at Fe and Co K-edges at the ESRF. The structural analysis proved that the Co clusters don't entirely mix with the matrix during annealing. The study of such model system could give insights about the role of the nanostructure on magnetic hardness and could thus guide the development of mass scale synthesis processes. This work is supported by the ANR collaborative project "SHAMAN": Soft in HArd MAgnetic Nanocomposites (2017-20).

EH-09. A Two-dimensional Magnet Based on the Shell-Ferromagnetic Effect. *A. Cakir*[1] and M. Acet[2] *1. Metallurgical and Materials Engineering, Mugla Sitki Kocman University, Mugla, Turkey; 2. Physics, Duisburg-Essen University, Duisburg, Germany*

Shell-ferromagnetism is a macroscopic monopolar effect which occurs when off-stoichiomentric Hesulers in the form $Ni_{50}Mn_{45}X_5$ (*X*: Al, Ga, In Sn, Sb) are temper-annealed at 650 K in a magnetic-field. In this top-down process, the material decpomposes and results in the formation of 2-5 nm full-Heusler cubic ferromagnetic $Ni_{50}Mn_{25}X_{25}$ laminar precipitates embedded coherently

in an antiferromagnetic tetragonal $Ni_{50}Mn_{50}$ matrix [1]. The spins at the interface shell layer become strongly pinned in the direction of the annealing field. The precipitates have a coercivity exceeding 15 T, but comprise at most 10 % of the material so that the magnetization remains low; at most at 8 Am^2kg^{-1}. It would be desirable to have this coercivity with the full magnetization of the full-Heusler, namely 80 Am^2kg^{-1}, which would give a large energy product. To overcome this issue, we prepare this time with a bottom-up process two-dimensional $Ni_{50}Mn_{50}/Ni_{50}Mn_{25}X_{25}/Ni_{50}Mn_{50}$ multilayers with 100/5/100 nm thicknesses. The layers are initiallly incoherent, but after temper-annealing at 650 K in a magnetic field, the coherency increases, and the spins at the interface become strongly pinned in the direction of the annealing field as in the case of the shell-ferromagnet leading to a two dimensional magnet.

EH-10. Rehabilitation of "Failed" Ferromagnetic Materials.
A. Palasyuk[1], T.N. Lamichhane[1,2], V. Taufour[3], O. Palasyuk[1,4], S. Bud'ko[1,2] and P. Canfield[1,2] *1. Ames Laboratory, Ames, IA, United States; 2. Department of Physics and Astronomy, Iowa State University, Ames, IA, United States; 3. Department of Physics, University of California, Davis, Davis, CA, United States; 4. Department of Material Science and Engineering, Iowa State University, Ames, IA, United States*

To find new, practical, magnetic materials is a highly challenging task since great efforts have been already invested world-wide in exactly this activity. A vast variety of approaches, materials systems, and techniques have been tried, most unsuccessfully. A new approach – *rehabilitation* – is proposed as a state-of-the-art strategy for finding new magnetic materials. The idea is based on converting materials that lack the desired ferromagnetic ground state, uniaxial anisotropy and/or required crystal structure into strong ferromagnets. This is achieved by tuning of the "failed" materials with dopants that leads to the appearance of the required permanent magnet characteristics and makes these compounds suitable for use as potential magnets. For example, in $(Fe_{1-x}Co_x)_2B$ at $x = 0.3$, the undesirable easy-plane magneto-crystalline anisotropy changes to the desired easy-axis anisotropy. Similarly, the theoretical work found that Sb substitution into the planar ferromagnet Fe_3Sn rendered this material uniaxial with significant anisotropy [1], and ongoing experimental work shows ways towards practical realization and "rehabilitation" of this rare-earth-free ferromagnet. In another case, the Pauli paramagnet $CeCo_3$, upon being doped with nonmagnetic Mg, exhibits sufficiently strong magnetic characteristics (a Curie point of 450 K and substantial uniaxial anisotropy) to warrant consideration as a permanent magnet [2], see Figure. Finally, there is the $Ce_2(Co,Fe)_{17}$ system. Having excellent intrinsic characteristics, i.e., magnetization above 1.3 T and Curie temperatures above 500 °C, this system possesses rather weak uniaxial magnetocrystalline anisotropy (with anisotropy fields of ~ 1 – 1.5 T). However, our recent experiments show that introduction of refractory metals into this system "rehabilitates" its anisotropy characteristics close to practical values of ~ 2.5 – 3 T, keeping other important parameters (magnetization and Curie temperature) on the same high level. Our method of rehabilitation greatly increase the number of potential compounds for development as accessible permanent magnets.

EH-11. First Principles Study of Doped RE-TM_5 Systems for the Development of Hard Magnetic Properties.
H. Ucar[1], R. Choudhary[2] and D. Paudyal[2] *1. Chemical and Materials Engineering, California Polytechnic University, Pomona, Pomona, CA, United States; 2. Ames Laboratory, Ames, IA, United States*

In this study, we explore the influence of substitutional and interstitial impurities in RE-TM_5 (RE: rare earth, TM: transition metal) compounds on their hard magnetic properties such as magnetic anisotropic energy, (MAE), and saturation magnetization, M_s using density functional theory (DFT). The structure of RE-TM_5 is that of a $CaCu_5$ as the prototype (P6/mmm, No.191), and it can be described as alternating layers of hexagonal nets formed by the TM atoms (2c) with the RE sitting at the center of the net, and planes of TM atoms (3g) arranged in a Kagome network. The favorable arrangement of this TM_5 network is possibly driving the formation of a large orbital magnetic moment of TM atoms that couples with the spin moment via SO coupling which leads to large MAE and M_s values [1-3]. This was predicted by a first principles study that found comparable MAE values for the YCo_5 as well as the hypothetical Co_5 having the same $CaCu_5$ structure with yttrium replaced by a vacancy [4]. Inspired by the earlier research, we investigate here the role of interstitial dopings - nitrogen, boron, hydrogen - at the tetrahedral interstices of RE-TM_5 as well as the substitutional dopings, most notably cerium, at the RE site in determining the MAE and M_s. In addition, we elucidate the role of exchange correlation approximations such as local spin density approximations (LSDA) and generalized gradient approximation (GGA) formulation in determining the MAE and M_s by analyzing their corresponding density of states (DOS) as shown in table 1 and fig. 1. As indicated with arrows, the change in DOS between the [100] axis (shaded curve) and the [001] axis (dashed lines) within the GGA is more significant than the LSDA method especially for the Co($3g_2$) site. This difference might be one of the reasons for MAE value within the GGA being higher and closer to the experimental findings. This research is supported by the Critical Materials Institute, an Energy Innovation Hub funded by the U.S. Department of Energy, Office of Energy Efficiency and Renewable Energy, Advanced Manufacturing Office.

EH-12. Data integration approach for multiple-sublattice ferromagnetism in rare-earth permanent magnets based on *ab initio* electronic structure and neutron diffraction measurements.
M. Matsumoto[1], T. Hawai[1] and K. Ono[1] *1. High Energy Accelerator Research Organization, Tsukuba, Japan*

Rare-earth permanent magnet (REPM) requires both of strong magnetization and accordingly strong coercivity all through the given operation temperature range for practical utilities like traction motors of electric vehicles. Main-phase ferromagnets in REPM are made of at least two sublattices, namely, transition-metal (TM) sublattice for high-temperature ferromagnetism and rare-earth (RE) sublattice for uni-axial magnetic anisotropy as the intrinsic source of coercivity. Often each of the TM and RE sublattice is further split into multiple sublattices: the champion magnet compound $Nd_2Fe_{14}B$ is made of two Nd sublattices, Nd(4f) and Nd(4g), and six Fe sublattices, Fe($16k_1$), Fe($16k_2$), Fe($8j_1$), Fe($8j_2$), Fe(4e), and Fe(4c) and the particular roles of those sublattices have been discussed: Nd(4g) sublattice contributes more to the intrinsic magnetic anisotropy [1], also helps with Ce to enhance the intrinsic magnetism [2], and Fe($8j_1$) sublattice seems to be preferred by Co [3,4]. Given that the site preference of dopant elements can critically influence the possible merit of a ferromagnet in question, we implement a data integration approach between theory and experiment to quantitatively analyse the site occupation of dopants, magnetic moments and the lattice structure in order to assess the intrinsic properties of REPM compounds as realistically as possible. Rietveld analysis of neutron diffraction data is combined with *ab initio* electronic structure calculations to determine the relevant observables self-consistently between the experimental data derived from the diffraction pattern and the *ab initio* data for the ferromagnetic state. Results for (Sm,Zr)$(Fe,Co,Ti)_{12}$ [5] are presented to reveal the background mechanism behind the apparent site preference of the dopants Zr, Co, and Ti distribution all over RE and TM sublattices in the host ferromagnet, $SmFe_{12}$. Such integrated data elucidates the missed points behind the apparent observation and helps to build the right strategy for the improvement of intrinsic magnetism in REPM.

EH-13. Correlation Corrections in Rare-Earth Transition-Metal Permanent Magnets.
R. Skomski[1], B. Balasubramanian[1] and D.J. Sellmyer[1] *1. Physics and Astronomy & NCMN, University of Nebraska, Lincoln, NE, United States*

Electron-electron interactions going beyond the local spin density approximation (LSDA) yield corrections to the description of metallic permanent magnets. We use model calculations to estimate these correlation corrections, which involve two or more Slater determinants. The LSDA works well for iron-series elements, including atomic-scale imperfections and disordered alloys. The approximation is based on an independent-electron density functional that allows a description in terms of individually rotating spins [1], and the same is true for extensions such as the LSDA+*U*. Quasi-local extensions involving gradients improve quantitative predictions, but the example of Hartree-Fock calculations, which are highly nonlocal without going beyond the independent-electron picture, show that locality is not the primary consideration. In fact, many features of the transition-metal sublattices of permanent magnets are Heisenberg-like [2], and the quantum-mechanical treatment of these strongly correlated model yield quantum spin liquid (QSL) corrections [3] to quantities such as the Curie temperature. These corrections scale as $1/z$, where z is the number of nearest neighbors. The rare-earth sublattice is much more severely affected by correlations. In principle, density-functional theory provides an exact description of the rare-earth ground state, but there is no general expression for the density functional [4] and known density-functional approximates for high correlated systems look very different from LSDA. As an example, we discuss Sm^{3+}, where the spin $S = 5/2$, or 5 μ_B, and the orbital moment $L = 5$, or 5 μ_B, are antiparallel and may naively be expected to yield a zero net moment. In fact, from Hund's rules it is well-known that $g = 2/7$ for Sm^{3+}. This indicates that spin and orbital moment form an obtuse angle in the vector model and explains the observed Sm contribution to the magnetization. The example of Sm^{3+} shows that the corresponding moment error is comparable to the moment itself, and this can also be shown to be true for the magnetocrystalline anisotropy, affecting both sign and magnitude. — This research is supported by DOE BES (DE-FG02-04ER46152).

EI-01. 2D Magnetism and Novel Spintronic Devices. *C. Gong*[1]
1. University of Maryland, College Park, MD, United States

Magnetism, one of the most fundamental physical properties, has revolutionized significant technologies such as data storage and biomedical imaging, and continues to bring forth new phenomena in emergent materials and device architectures. The recently discovered magnetic 2D van der Waals materials (hereafter abbreviated as "2D magnets") [1,2] provide ideal platforms to enable the atomic-thin, flexible, lightweight magneto-optic and magnetoelectric devices. The seamless integration of 2D magnets with dissimilar electronic and photonic materials further opens up exciting possibilities for unprecedented properties and functionalities. In this talk, I will speak on our experimental observation of the 2D magnetism in 2D magnets, and show the possibility of using such atomically thin magnetic flatlands to develop novel spintronic devices [3,4] such as low-power magnetoresistive memories, high-efficiency spin field-effect transistors, and phase-change bio- or chemical sensors.

EI-02. Magnetic interactions and excitations in 2D van der Waals materials. *L. Ke*[1] *1. Ames Laboratory, Ames, IA, United States*

The magnetic 2D van der Waals (m2DvdW) materials [1,2] have received significant attention recently due to their potential applications in spintronics. It is of great interest to unravel the underlying magnetic mechanisms that could guide the bandstructure engineering to improve the magnetic properties in these systems. We investigate the origins of magnetic properties such as exchange interactions, magnetocrystalline anisotropy (MA), and magnetic excitations in magnetic 2D van der Waals materials. To unravel the origin of MA in these systems, we use a recently-developed realistic tight-binding Green's function framework [3] to compute and resolve MA energy (MAE) efficiently into sublattices. We found that the inter-sublattice contribution (between the magnetic-atom sublattice and the heavy-atom sublattice) to MAE is significant. Magnetic interactions and spin-wave dispersions in various m2DvdW systems are calculated using a linear response method. Results are compared with available inelastic neutron scattering measurements. Finally, methods beyond density functional theory are used to investigate the effects of non-local potentials on the magnetic properties in m2DvdW systems. This work is supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, Materials Sciences and Engineering Division, and Early Career Research Program. Ames Laboratory is operated for the U. S. Department of Energy by Iowa State University under Contract No. DE-AC02-07CH11358.

EI-03. The Effect of High Pressure on Ferromagnetic Properties of the van-der-Waals Materials VI_3 and CrI_3. M. Kratochvilova[1], *K. Uhlirova*[1], J. Valenta[1], S. Son[2,3], P. Proschek[1], J. Prchal[1], V. Sechovsky[1] and J. Park[2,3]
1. Department of Condensed Matter Physics, Charles University, Prague, Czechia; 2. Center for Correlated Electron Systems, Institute for Basic Science, Seoul, The Republic of Korea; 3. Department of Physics and Astronomy, Seoul National University, Seoul, The Republic of Korea

Despite belonging to well-studied layered transition metal trihalides, the VI_3 and CrI_3 compounds received significant attention only recently [1-6]. They are reported ferromagnetic (FM) at temperatures below T_C = 50 K [1] and 61 K [5], respectively. Calculations predict that the FM order may persist into monolayer form [7, 8], suggesting that VI_3 and CrI_3 could be promising materials for spintronics. In bulk materials the interlayer exchange interactions play an important role. The hierarchy of exchange interactions and dimensionality of magnetism can be effectively tuned by hydrostatic pressure particularly due to the weak van der Waals bonding between the FM layers. Recently published magnetization data in lower hydrostatic pressures (p £ 1 GPa) suggest pressure-induced increase of T_C, both, in VI_3 [1] and CrI_3 [6]. We measured the magnetic properties of the VI_3 and CrI_3 single crystals at ambient and high hydrostatic pressures up to 3.5 GPa. The peak in the $\chi'(T)$ dependence of VI_3 confirms T_C = 50 K at ambient pressure. Besides, 3 additional side peaks in $\chi'(T)$ data are observed between 52 and 60 K. These $\chi'(T)$ anomalies are almost intact by increasing p up to 0.8 GPa. Above 0.8 GPa, all peaks merge into one and T_C increases abruptly to 60 K at 1.6 GPa. This result is in line with the p evolution of magnetization around T_C [1]. From 1.6 and 3.5 GPa, T_C increases linearly at a rate of 4.1 K/GPa. A significantly different behavior was observed in CrI_3. A single peak in $\chi'(T)$ is observed at T_C = 60 K in ambient pressure and stays at the same temperature in pressures up to 1.5 GPa in contrast to data from Ref. [6]. Between 1.5 and 3 GPa, T_C decreases linearly at a rate of - 2.3 K/GPa. Besides the dominant peak in χ' corresponding to T_C, another peak at T_1 = 50 K emerges in 0.7 GPa, showing analogous T vs. p evolution. The observed contrasting pressure dependence in the VI_3 and CrI_3 compounds indicates considerably different hierarchy of interlayer exchange interactions in the two compounds. Results will be discussed considering also data from the uniaxial-stress and higher hydrostatic-pressure (> 3.5 GPa) experiments which are in progress.

EI-04. Magnetic Spectroscopy of One-Dimensional Iron Chains.

A. Baker[1], N. Vargas[4], F. Torres[2], M. Kiwi[2], T. Willey[1], I. Schuller[4] and C. Monton[3] *1. Materials Science Division, Lawrence Livermore National Laboratory, Livermore, CA, United States; 2. Universidad de Chile, Santiago, Chile; 3. University of Texas, San Antonio, TX, United States; 4. University of California, San Diego, CA, United States*

We report on unusual magnetic properties that arise in one-dimensional (1d) iron (Fe) chains with lengths of 10 – 200 nm, in thin film and superlattices. The Fe chains are grown using iron phthalocyanine (FePc) molecules, and in superlattices with metal-free-phthalocyanines (H2Pc). The Pc molecules act as templates for their metal centres, leading to arrays of independent, highly-oriented 1D chains [1]. The coercivity of the films is constant, but in superlattices increases with chain length, due to a combination of direct exchange and Dzyaloshinskii-Moriya interactions, where the magnetization reversal is governed by chiral symmetry breaking at the FePc/H2Pc interfaces. XAS measurements reveal the presence of hybridization and disorder at the interfaces, a potential mechanism for such interactions. XMCD sheds further light on the highly anisotropic magnetic character of the samples, with strong quenching or enhancement of spin angular momentum as magnetization is rotated from parallel to perpendicular to the chain. The orbital angular momentum, in contrast, is significantly more isotropic than previous reports [2], although still largely unquenched. The versatility and control offered in these samples provides a versatile testbed of 1D magnetism and the crucial role of interfaces in the magnetic states that arise.

EI-05. Chiral magnetic ordering in ultra-short 1D iron chains.

M. Kiwi[1], N. Vargas[2], F. Torres[1], A. Baker[3], J. Lee[3], T. Willey[3], I. Schuller[2] and C. Monton[4] *1. Physics, Universidad de Chile, Santiago, Chile; 2. Physics, University of California, San Diego, San Diego, CA, United States; 3. Material Science Div., Lawrence Livermors National Lab, Berkely, CA, United States; 4. Physics, Univ. of Texas, San Antonio, San Antonio, TX, United States*

The discovery of unconventional atomic-scale chiral ferromagnetic ordering in one-dimensional (1D) ferromagnetic chains is reported. The iron chain superlattices (SLs) were fabricated by a novel method that allows for precise control of composition and length, only a few atoms long (7 to 200 atoms), as shown in Fig. 1. The magnetic response is strongly dependent on the boundary conditions imposed on the end atoms of the Fe chains by electronic hybridization with H. The coercive field increases with the Fe chain length with hybridized boundaries (SLs), whereas in chains not subject to hybridization the coercive field remains constant (films). This implies that the electronic environment of the end atoms determines the magnetic response of these 1D chains [1,2]. The evolution of the coercive field with the length of the 1D chains is systematic and monotonic. Surprisingly, the films have a coercive field independent of chain length (Fig. 2) whereas the SLs show a definite increase as a function of length well beyond any possible experimental error. This linear dependence extends to the shortest lengths (t_{FePc}= 3 nm and 5 nm), which could only be measured in SLs. Remarkably, there is a significant difference between the coercive field evolution with FePc thickness between films and the SLs for the same total length of the chains compared to the single layer in the SLs. The relevance of this discovery is that it seems to contradict the Mermin-Wagner theorem [3], which asserts that in for one or two-dimensional Heisenberg systems with isotropic short ranged interactions, there can be no spontaneous ferro- or antiferromagnetic long-range order at T>0. However, a semi-classical model that includes short-range exchange and Dzyaloshinskii-Moriya interactions quantitatively explains the results [4].

EI-06. Magnetic Correlations at Different Length Scales in the Solid Solution Alloy Ni-V Close to the Ferromagnetic Critical Point Revealed with Small Angle Neutron Scattering. *A. Schroeder*[1], S. Bhattarai[1], J.L. Lussier[1], A. Gebretsadik[1] and K.L. Krycka[2] *1. Physics, Kent State University, Kent, OH, United States; 2. NIST, Gaithersburg, MD, United States*

We present small angle neutron scattering (SANS) data (non polarized, half polarized and full polarized using a He3 cell as spin filter) collected at NG7SANS at NIST on well characterized polycrystalline Ni(1-x)V(x) samples with x=0.10 and x=0.11 with confirmed random atomic distribution [1]. These ferromagnetic (FM) samples are close to the quantum critical point x_c=0.116 where the FM order of Ni is suppressed with critical temperatures T_c approaching zero. Magnetization and muSR data recognized a quantum Griffiths phase with coexisting static order and magnetic fluctuations [1]. SANS is an ideal tool to reveal the different magnetic correlations length scales in this disordered FM but resolving the small magnetic scattering remains a challenge since it is dominated by the nuclear contribution of Ni. We will show the advantages of a polarization analysis [2] in identifying the main magnetic contributions at different length scales in Ni-V. Through angular dependent spin flip scattering we can recognize magnetic short-range fluctuations in both compounds that are strongest at T_c but remain still present at the lowest temperature (see Figure 1). Neutron depolarization at very low magnetic fields and increased Porod-terms below T_c indicate the onset of long-range order within domains. The angular dependence of non spin flip interference terms reveals the anisotropic magnetic scattering of aligned domains and frozen short range clusters in enhanced magnetic fields. These data confirm magnetic correlations at various length scales (from micrometer to 5nm) in Ni-V close to the quantum critical point.

EI-07. Secnond Spin Phase Transition in Spin Spiral $ZnCr_2Se_4$ at Low Temperatures. *S. Park*[1], S. Kwon[2], S. Lee[1], S. Khim[3], D. Bhoi[3], C. Park[3] and K. Kim[3] *1. Department of Physics, KAIST, Daejeon, The Republic of Korea; 2. University of Waterloo, Waterloo, ON, Canada; 3. Department of Physics and Astronomy, Seoul National University, Seoul, The Republic of Korea*

In the past decades, bond frustrated Heisenberg antiferromagnet $ZnCr_2Se_4$ has attracted attention in various aspects. $ZnCr_2Se_4$ undergoes a transition to a Spiral spin order occurs at T_N=21 K in zero magnetic field. As the applied magnetic field increases, the spin state changes to conical structure and then to the fully saturated ferromagnet [1]. Magnetoelectricity[2] and pseudo Goldstone mode[3] were explained based on this understanding. At low temperatures, the magnetic susceptibility shows unusual field dependence[1,4] applied during cooling, which has been simply regarded as an effect due to the multidomain state. In this work, we report magnetic susceptibility and Cr and Se NMR results obtained at various temperatures and fields. As the temperature decrease below 6 K, the magnetic susceptibilities of the zero field cool and field cool split like a spin glass. The NMR relaxation rates in Fig. 1 shows a lambda-shape anomaly near the temperature of the susceptibility split. Both experimental results suggest the existence of additional spin phase transition. The transition temperature depends on the applied magnetic field. The intensity of the low frequency peak of the Cr and Se NMR spectra (inset of Fig.2.) rapidly decays approaching the transition and then revives at lower temperatures as in Fig.2. This is understood as the transition from the incommensurate spiral spin order to the random spin distribution.

EI-08. Giant Antiferromagnetic Response in a Two-dimensional Spin-orbit Mott Insulator. *L. Hao*[1], D. Meyers[2], H. Suwa[1], J. Yang[1], H. Xu[3], C. Batista[1], M.P. Dean[2] and J. Liu[3] *1. Department of Physics and Astronomy, University of Tennessee, Knoxville, TN, United States; 2. Department of Condensed Matter Physics and Materials Science, Brookhaven National Laboratory, Upton, NY, United States; 3. Department of Materials Science and Engineering, University of Tennessee, Knoxville, TN, United States*

Antiferromagnetic (AFM) materials started to gain traction owing the advantages of reliability, ultrafast dynamics, etc. in spintronic applications. In this regard, Mott insulators can be an appealing candidate because of the robust AFM ground state due to the strong electron-electron correlation. Moreover, exploring AFM order is fundamentally important for understanding emergent phenomena, like high-*T*c superconductivity and quantum criticality. In our recent work, we investigated AFM order in layered iridates, which is a newly established Mott system similar to cuprates but features a strong spin-orbit coupling. By building the spin-orbit Mott insulators as superlattices composed of perovskite $SrIrO_3$ and $SrTiO_3$, we gained controllability in the strength and sign of interlayer exchange interaction [1]. This enables one to reach the two-dimensional limit of the antiferromagnet, where the ordering temperature is only governed by magnetic anisotropy. The two-dimensional antiferromagnet preserves a hidden SU(2) symmetry, which was first proposed in cuprates but never experimentally realized. More specifically, model analysis reveals that Dzyaloshinskii–Moriya interaction in the square-lattice magnet does not contribute to the spin anisotropy. The extremely strong two-dimensional critical fluctuations enable us to achieve giant AFM responses to sub-tesla uniform external fields. The observed field-induced logarithmic increase of the AFM ordering (Fig. 1) demonstrates a new pathway for designing efficient AFM spintronics [2].

EI-09. Spin disorder near nonmagnetic impurities in $YMnO_3$. *S. Lim*[1], H. Sim[2,3], K. Park[2,3], J. Park[2,3] and S. Lee[1] *1. Department of Physics, KAIST, Daejeon, The Republic of Korea; 2. Center for Correlated Electron Systems, Institute for Basic Science (IBS), Seoul, The Republic of Korea; 3. Department of Physics and Astronomy, Seoul National University, Seoul, The Republic of Korea*

Magnetic moment is induced around nonmagnetic impurities in geometrically frustrated magnets due to readjustment of neighboring spins. This vacancy-induce magnetism is in contrast to the magnetic impurities in nonmagnetic bath. We studied effects of nonmagnetic Al/Ga impurities in magnetic bath $YMnO_3$ by the magnetization, heat capacity, and NMR measurements. Suppression of Neel order with increasing doping rate was evidenced by the heat capacity and M-T curve which also shows the Curie tail. We found that the vacancies in frustrated magnets release the local frustration partially by readjustment of the spin directions around the impurity. A Monte-Carlo simulation [1] predicts that a nonmagnetic impurity in 120° spin structure carries magnetic moment of $\langle m \rangle \sim 0.04S$. Impurity moment estimated from our susceptibility data is $\langle m \rangle \sim 0.1S$. Interestingly, our NMR results show that the amplitude of the impurity moment $|m|$ is an order of magnitude bigger than that of the bulk average value $|\langle m \rangle|$. Triangular spin structure predicts the angle-dependent spectrum with 60° symmetry, while the observed spectrum (Fig. 1) was not. This means that the direction of the neighboring spins generating the hyperfine field at a nonmagnetic impurity site is quite random. The magnitude of the impurity moment estimated from the distribution of the hyperfine field is $|m| \sim S$. The spins compensating the missing magnetic moment near a nonmagnetic impurity in $YMnO_3$ are disordered.

EI-10. Understanding Magnetic Exchange Interactions through the Pressure Dependence of the Susceptibility in FeCoNiCuMn High Entropy Alloys. *A.E. Perrin*[1], S.K. McCall[2], M. McElfresh[2], D.E. Laughlin[1] and M. McHenry[1] *1. Materials Science and Engineering, Carnegie Mellon University, Pittsburgh, PA, United States; 2. Lawrence Livermore National Lab, Livermore, CA, United States*

Curie temperature engineering in metals with direct exchange interactions is based on understanding the dependence of Tc on interatomic distances and magnetic d-orbital overlap that determine J_{ex} as described by the Bethe-Slater curve. The Bethe-Slater curve predicts the dependence J_{ex} on D/d, with D the transition metal interatomic spacing and d the spatial extent of magnetic d-orbitals. We analyze the pressure (P) dependence of the Curie temperature, T_c, in a FeCoNiCuMn high entropy alloy (HEA), considering d-orbital contraction to explain changes in magnetic exchange interactions (J_{ex}) with reference to the Bethe-Slater curve. We combine considerations of d-radius contraction based on the composition dependence of T_c in g-Fe-Ni with experimental magnetic measurements of T_c (Fig. 1a) and data for the P-dependence of lattice constants (Fig. 1b) to calculate the contribution of changes in atomic spacing and d-orbital radii to J_{ex}. Unlike many textbook discussions of the dependence of J_{ex} on D, we show that the contraction of the d-orbitals with P accounts for the majority of the T_c change in this HEA system, which is very clear when the term accounting for the change in atomic spacing is plotted against the term accounting for change in d-orbital extent (Fig. 1c).

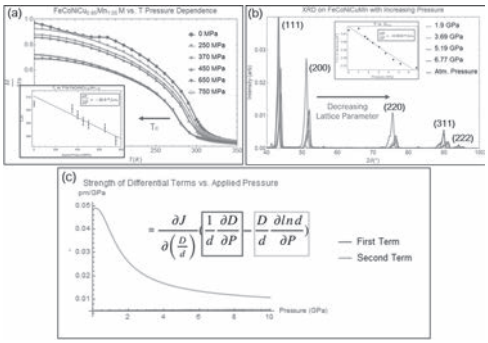

Fig.1 (a) Magnetization versus temperature for an FeCoNiCuMn HEA with linearly decreasing T_c versus pressure. (b) XRD data showing linearly decreasing atomic spacing with applied pressure. (c) The strength of the contributions from atomic spacing deriative term versus d-orbital extent derivative term to the change in T_c vs pressure.

EI-11. Influence of sample quality on the physical properties of the S=1 antiferromagnetic spin-ladder CaV_2O_4. S. Hiller[1], S. Guitarra[1], A. Caneiro[2], M. Salamon[3] and *D. Niebieskikwiat*[1] *1. Departamento de Física, Universidad San Francisco de Quito, Quito, Ecuador; 2. Instituto Balseiro - Centro Atómico Bariloche, Bariloche, Argentina; 3. The University of Texas at Dallas, Richardson, TX, United States*

In this work we study the magnetic and transport properties of different CaV_2O_4 samples. This compound presents quasi one-dimensional (1D) V chains, with an antiferromagnetic (AFM) S=1 spin-ladder ground state. Due to this 1D characteristic, it is expected that the physical properties of CaV_2O_4 are very sensitive to impurities, defects, and disorder in general. Indeed, different previous works show dissimilar results about the magnetic response of this vanadium oxide. Here, we study several CaV_2O_4 samples prepared by different methods and conditions (solid-state and wet-chemical routes), showing the influence of the sample quality on the physical properties of this material. We find that defects in CaV_2O_4 induce local ferromagnetic correlations that generate exchange bias. Also, electrical transport can be satisfactorily described by a Variable-Range Hopping (VRH) model with a characteristic exponent for each sample determined by the density of defects in the V chain. Notably, the nitrate decomposition route produces a better quality sample with a higher order temperature.

EP-01. Non-volatile NDR-assisted Magnetic Half-adder. *Z. Lu*[1] and X. Zhang[1] *1. School of Material Science & Engineering, Tsinghua University, Beijing, China*

Conventional logic gates in computers based on CMOS are volatile and require frequent communication with external storage units, which causes the von-Neumann bottleneck that limits computers' speed [1]. Magnetic logic device, however, benefiting from magnetic material's non-volatile feature, has become a promising candidate to achieve logic-in-memory architecture to solve this problem[2]. In order to build the counterpart of CMOS-based arithmetic logic units (ALU) using spin-based logic devices, both logic functions and arithmetic functions should be achieved. In recent years, widespread research has been conducted and people have found several ways to realize simple logic gates such as AND, OR, NAND, NOR and NOT[3][4], but only few based on STT-MTJ could perform arithmetic functions in experiments because of risk of tunnel barrier breakdown and complex peripheral CMOS circuit[5]. Here, we proposed a noval non-volatile magnetic logic device working at room temperature based on coupling of anomalous Hall effect of Ta/CoFeB/MgO multilayers with perpendicular magnetic anisotropy (PMA) and negative differential resistance (NDR) phenomenon in semiconductor. With simple peripheral circuit consist of semiconductor elements with NDR, our device not only could perform Boolean logic operations AND, NOR, XOR and XNOR, but could also work as a half-adder without cascading. Since the logic function of our device was not resulted from spin transfer torque, there was little risk of device breakdown caused by tunneling barrier damage. By randomly changing the logic input of our device continually, the reliability of our device was also confirmed. Since our device is current-driven, it has the potential to bridge the von-Neumann bottleneck by integrating computing with memory writing via spin orbit torque-induced magnetization switching.

EP-02. Closely packed magnetic tunnel junction arrays for reservoir computing. *H. Kubota*[1], K. Yakushiji[1], A. Fukushima[1], S. Tamaru[1], S. Tsunegi[1], T. Taniguchi[1], A. Sugihara[1], T. Nozaki[1], T. Yamamoto[1], T. Nozaki[1], S. Yuasa[1], M. Goto[2,3], K. Takahashi[2], H. Nomura[2,3] and Y. Suzuki[2,3] *1. National Institute of Industrial Science and Technology (AIST), Tsukuba, Japan; 2. Osaka University, Toyonaka, Japan; 3. CSRN-Osaka, Toyonaka, Japan*

Magnetically coupled nanomagnets have been investigated for many years as an energy-efficient resource of computation[1]. The magnetic coupling causes magnetic frustration, which can drive information processing with low energy cost. High integration of the nanomagnets, which is established in modern MRAM technology[2], would enhance the computational capability. Recently reservoir computing, which is one of the frameworks in recurrent neural network, is intensively investigated because of simple learning process and high compatibility with electronic hardware[3-6]. H. Nomura et al. simulated that a dipole-coupled 2x10 magnetic dot array can perform binary logic functions using reservoir computing scheme[7]. In this study, we develop a physical reservoir using an MTJ array. In the array, the gap between MTJ dots (*g*) should be very small (~20 nm) so that the magnetic coupling is strong enough. Individual electric access to the dots is necessary to detect magnetizations in the dots influenced by the coupling. The MTJ films prepared by a UHV magnetron sputtering had a stack of buffer layer/Co-Pt based fixed layer/MgO/CoFeB free layer/MgO cap layer/metal cap layer, where CoFeB free layer was basically perpendicularly magnetized. The film had an MR ratio of about 100% and resistance-area product of about 3 $\Omega\mu m^2$. After deposition, the films were patterned into 8×8 MTJ arrays with various *g* and diameter of dot (*d*) using EB lithography combined with etching and lift-off technique. Fig. 1 shows a SEM image of the fabricated reservoir, in which fine patterns of top leads (Cu) were connected to central 2×6 dots. Cross-sectional TEM observation indicated that the MTJ dots had tapered shape and that the free layers in neighboring dots were isolated. The smallest *d* and *g* were 60 nm and 20 nm, respectively. Such a small gap can realize strong magnetic coupling required in the reservoir computing operation. This research and development is partly supported by the Ministry of Internal Affairs and Communications.

EP-03. Investigation of Radiation Effect on Magnetic Tunnel Junction against Proton and Ion Beam. *J. Park*[1], J. Kim[1], J. Ryu[1], J. Jeong[1] and B. Park[1] *1. Materials Science and Engineering, Korea Advanced Institute of Science and Technology (KAIST), Daejeon, The Republic of Korea*

Conventional semiconductor-based electronic devices can cause errors when they are exposed to cosmic rays. Magnetic memory has been proposed as an alternative because it consists of a metal structure free from radiation-induced errors in principle. Although there are several reports on the radiation hardness of magnetic random access memory (MRAM) [1,2] and magnetic tunnel junction (MTJ) [3,4], their radiation conditions were limited to a dose level of up to $1x10^{12}cm^{-2}$ and an energy of MeV ranges. In this study, we investigate the radiation hardness of MTJ for proton and Cr ion beams of dose levels up to $1x10^{14}cm^{-2}$ using an in-plane MTJ of Ta(5)/Pt(10)/IrMn(30)/CoFeB(5)/MgO(2)/CoFeB(10) /Ru(5) and a perpendicular MTJ of W(4)/CoFeB(1.2)/MgO(3.5)/CoFeB(2.0)/W(4)/Ru(5) structures, where the numbers in parentheses are in nm. We observed that the magnetic hysteresis and tunnel magnetoresistance (TMR) of MTJs were not affected by proton irradiation of an energy of 20 MeV and dose levels up to $1x10^{14}cm^{-2}$, thus demonstrating good radiation hardness in response to the proton beam (Fig. 1). On the other hand, when a MTJ was irradiated by a Cr ion beam of an energy of 20 keV and dose levels up to $1x10^{14}cm^{-2}$, its magnetic properties or TMR deteriorated (Fig. 2). Simulation study shows that the protons penetrate through the entire MTJ structure, leaving negligible displacement damages, whereas Cr ions deposit within the MTJ structure, inducing significant damage. Our study suggests that the degradation of the MTJ may stem from radiation-energy dependent displacement damage in the magnetic layers, which can be avoided by the introduction of a proper protective layer.

EP-04. Six-State Magnetic Tunnel Junction Memory Driven by Spin Hall Effect. *M. Alawein*[1], S. Amara[1], S. Wasef[1], U. Myrzakhan[1] and H. Fariborzi[1] *1. Electrical Engineering, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia*

This work reports the fabrication and characterization of a memory based on spin Hall effect driven nanomagnet with six-fold configurational anisotropy [1]. The proposed memory (Fig. 1(a)) is comprised of a $Pt/Ni_{81}Fe_{19}$ (Py) multilayer, and its states are written and read electrically. The six-state nanomagnet is made by patterning a 3-nm-thick Py in the shape of an equilateral triangle [2] to introduce a six-fold configurational anisotropy (Fig. 1(b)), the presence of which is verified by OOMMF (Fig. 1(c)). For writing, a charge current is passed between a pair of pads. The charge current in Pt generates a transverse spin current that switches the Py magnetization. The magnetic information is read via a magnetic tunnel junction (MTJ), which can be either symmetric or asymmetric, where the latter type consists of a tilted elliptical layer and is used to remove resistance degeneracy. The reading is done by measuring the MTJ resistance which varies according to [3–5] $R_\beta = (1/2)(R_P + R_{AP}) - (1/2)(R_{AP} - R_P)\cos(\beta)$ where R_P and R_{AP} are the resistances in the parallel and antiparallel states, respectively. After every read operation, a writing process follows by passing a current of magnitude I_{write} = 10 mA. Figs. 2(a) and 2(b) shows tunnel magnetoresistance (TMR) plots for the symmetric and asymmetric MTJs, respectively. For the symmetric (asymmetric) MTJ, a minimum resistance separation of 6.3% (3.5%) was observed. In addition, in Fig. 2(c) we show TMR plots of five different asymmetric MTJ samples, and in Fig. 2(d) we show resistance-time curve of an asymmetric MTJ. We have also investigated the memory's read endurance by performing pulsed measurements until the MgO breakdown (Fig. 2(e)).

EP-05. $L1_0$-(MnCo)Al thin film with high perpendicular magnetic anisotropy grown on Pt seed layer. *L. Yu*[1], M. Oogane[1], M. Tsunoda[2] and Y. Ando[1] *1. Department of Applied Physics, Tohoku University, Sendai, Japan; 2. Department of Electrical Engineering, Tohoku University, Sendai, Japan*

Spin-orbit torque (SOT) induced magnetization switching in heavy metal (HM) / ferromagnetic metal (FM) heterostructures has been devoted lots of research attention as it shows promise for future ultrafast and power conservation magnetic memories [1]. For FM layers, magnetic thin films with high perpendicular magnetic anisotropy (PMA) are needed, which promote research of Mn-based alloys, such as $L1_0$-MnAl with high PMA [2]. These Mn-based alloys have always been deposited on buffer layers such as Cr, CoGa, etc. [3-4], instead of heavy metals or heavy metal-based alloys which were well studied to possess a high spin Hall angle, such as Pt and PtMn [5-6], and the properties such as magnetic features and crystal structures of these Mn-based alloys deposited on Pt or PtMn are still unrevealed. In this work, we report the crystal and magnetic properties of $L1_0$-(MnCo)Al thin films (light-doped Co into MnAl) deposited on Pt seed layer. All the samples were prepared by magnetron sputtering system. The stacking structures were MgO(001) sub. / Pt (5) / $Mn_{0.97}Co_{0.03}Al$ (20) / Ta (3) in nm. The substrate temperature (T_s) has been tuned from 150°C to 400°C during the deposition of MnCoAl layer. The crystal structure and magnetic properties were respectively measured by X-ray diffraction (XRD) and superconducting quantum interference device (SQUID). Fig. 1 shows the XRD patterns of the prepared films with various T_s. The $L1_0$ MnCoAl (001, 002) peaks are the signature of crystallization in tetragonal $L1_0$ phase. 001 and 002 peaks disappeared when T_s above 300°C, which indicate the transition to other phases. On the other hand, the intensity of Pt (002) peak decreased with increasing T_s, which was considered that Pt diffused into (MnCo)Al layers at a high temperature. Fig. 2 shows the magnetic properties of prepared samples shown in Fig. 1. Although PMA magnitude K_u^{eff} decreased rapidly with temperature above 300°C corresponding to the phase transition which has been observed in Fig. 1, we have achieved a high K_u^{eff} of 4 Merg/cc at T_s = 300°C in the (MnCo)Al films grown on Pt seed layer.

EP-06. STT-MRAM Error Correction Technology Based on LDPC Coding. *X. Zhang*[1] and Y. Jiang[1] *1. Internet of Things Engineering, Jiangnan University, Wuxi, China*

Spin-transfer torque magnetic random access memory (STT-MRAM) is a new generation non-volatile memory. It is regarded as the most popular memory because of its fast reading/writing speed and "unlimited" endurance [1]. As a single device, STT-MRAM is consistent of a magnetic tunnel junction (MTJ) and a metal oxide semiconductor (MOS). STT-MRAM implements information writing by controlling the direction and magnitude of current flowing through the MTJ. The information reading is performed by detecting the voltage across the MTJ. The writing error of MTJ is usually occurs when the pulse width is less than the switch time or the applied current is less than the switch current I_{CO}. The reading error occurs when the read current is larger than I_{CO}, resulting in an error flip from 1 to 0 or 0 to 1. In STT-MRAM arrays, a single cell's read and write failures will cause the row or the column to fail. It is necessary to design error correction circuits in the array of STT-MRAM to improve overall performance. Well known, static random access memory (SRAM), dynamic random access memory (DRAM), and Flash use error-correcting codes (ECC) to reduce the error rate [2-4]. Recently, some researchers have paid more attention to studying ECC in STT-MRAM. C. Yang et al studied the Bose-Chaudhuir-Hocquenghem (BCH) error correction mechanism for STT-MRAM [5]. As the storage capacity of MRAM increases, the error rate gradually increases. BCH will not be able to meet the requirements. As we all known, the performance of the Low Density Parity Check (LDPC) code not only approaches the Shannon limit, but also has strong error correction capability. In this work, we used LDPC code with higher error correction capability in STT-MRAM for the first time, as far as the authors know. Firstly, we introduced the basics of the STT-MRAM model and LDPC codes. Secondly, we designed and simulated LDPC codes for STT-MRAM read and write failures. Finally, the results are discussed and analyzed. Our research shows that LPDC codes

have the advantages of high coding rate and fast decoding speed compared to other ECCs. This work is supported by the National Natural Science Foundation of China (No.61774078).

EP-07. Industrial Level Thermal Model of STT-MTJ Device with Parameter Extraction. *Y. Jiang*[1] and L. Jiang[2] *1. Jiangnan University, Wuxi, China; 2. UC Berkeley, Berkeley, CA, United States*

Spin-Transfer Torque RAM (STT-RAM) has emerged as a potential candidate for Universal memory. The development of industrial level spice model of STT-MTJ device is a key aspect of exploring the potential of STT-RAM. Several SPICE compatible MTJ models have been reported in the past for the simulation of the spintronic circuit. For a SPICE model to be useful in industrial level in MRAM simulation work, the model should be applicable at different temperature and at the same time be fully-compatible with SPICE. To satisfy these requirements, the industrial level thermal model with parameter extraction is proposed in the paper. To set up a compact model to describe the thermal properties of the MTJ device, three key parameters, conductance at 0 K (G_0), polarization at 0 K (P_0) and a material-dependent constant (α), are extracted from experimental measurements. The influence of the temperature on the conductance of the MTJ device can be described accurately by using the extracted parameters. Simulation based on the compact temperature model is conducted to demonstrate the feasibility of the designed thermal model, showing wide range of linearity. Beyond the static thermal property, the dynamic thermal reaction is also included in the thermal model. To verify the above analysis, the thermal reaction is observed by the model's simulation. The simulation results are shown in Fig.1, corresponding to different states, varied from 1.03 ns to 3.31 ns. It can be seen that the thermal transition can be done in nano-seconds at suitable pulse amplitude. Above all, the thermal model for spin-transfer-torque operated magnetic tunnel junction (STT-MTJ) is proposed and described in Verilog-A language, which led to more accurate electrical simulations while maintaining better efficiency without obvious additional run time and memory resource.

EP-08. Passive and active microwave signal detection using magnetic tunnel junctions with perpendicular magnetic anisotropy. *A. Sidi El Valli*[1], V. Iurchuk[1], N. Lamard[1], A. Chavent[1], J. Langer[2], J. Wrona[2], B. Dieny[1], I. Prejbeanu[1], L. Vila[1], R. Sousa[1] and U. Ebels[1] *1. Univ. Grenoble Alpes, CEA, CNRS, G-INP, IRIG-SPINTEC, Institute of Engineering Univ. Grenoble Alpes, SPINTEC, Grenoble, France; 2. Singulus Technologies AG, Kahl, Germany, Kahl, Germany*

Perpendicular magnetic tunnel junctions (pMTJs) are key elements for the development of spin transfer torque magnetic memories (STT-MRAM). pMTJs exploit the interfacial perpendicular magnetic anisotropy (iPMA) to define the out-of-plane orientation of the free (FL) and reference layers (RL) [1]. Meanwhile pMTJs are also expected to provide microwave spintronic functions such as rf signal generation and detection giving added value for multifunctional operation. Here we report on the microwave signal detection of such pMTJs with similar stacks as presented in [2] and evaluate the obtained performances for applications such as rf power harvesters [3] and frequency selective demodulators. The detection method is based on the rectification effect that generates a DC voltage signal when the frequency of the rf input signal to be detected is close to the FL or RL ferromagnetic resonance frequency. Measurements were performed (i) without dc current (passive detection) and with dc current (active detection), (ii) under in-plane and out of plane static magnetic fields as well as (iii) for devices of different FL magnetization orientation by varying the FL thicknesses: t_{FL}=1.4 out-of-plane and t_{FL}=1.8 nm in-plane. It is found that the DC output voltage V_{dc} lies in the 1-10mV range for the different measurement conditions and devices. For devices with t_{FL}=1.8 nm, we demonstrate a strong dependence of V_{dc} on the device diameter, with an increase by a factor of three (five) reaching values of 5mV (V_{dc}=28mV) when reducing the diameter from 150 nm to 40 nm for passive (active) detection at input power levels of -5 dBm. These findings give prospect to utilize pMTJs as nanoscale microwave detectors for power harvesting and/or for short range communication applications. The authors acknowledge funding support from the Fondation Nanosciences, Grenoble; from ERC MagiCAL (N° 669204) and the EU Horizon 2020 project GREAT (No. 687973).

EP-09. The Design of 1Gb Parallel STT-MRAM with Pipeline Architecture. *G. Zhang*[1] and Y. Jiang[1] *1. School of Internet of Things Engineering, Jiangnan University, Wuxi, China*

Spin transfer torque (STT) magnetic RAM (MRAM) is the only emerging memory technology that combines endurance, speed and energy efficiency of SRAM and DRAM with non-volatility of flash. In write operation, the STT-MRAM memory array receive the addresses and control commands through control register. And the input data and clock signals are submitted into the memory array by a register. Compare with conventional STT-MRAM, the pipeline architecture of STT-MRAM has an additional register between memory array and sense amplifier as shown in Fig.1. The first decode output A0 from the previous clock can be latched by the additional register in the rising edge of the next clock. So the decode output A1 can be fetched in the second clock, and the A0 can be amplified by SA at the same time. In the third clock, the address A2 can be decoded and the A1 can be latched. As a result, the total data read time will be greatly shortened as shown in Fig.2. Therefore the pipeline STT-MRAM has the better real-time response and lower-latency memory access. It is necessary for STT-MRAM to improve the read efficiency. Until now, there have been a great number of studies in pipeline architecture of various memories, such as DRAM, SRAM, and Flash [1-3]. Recently, K. Swaminathan *et al* have utilized the characteristics of STT-MRAM for providing protection of all storage structures in the pipeline, which can reduce soft error vulnerability and enhance system reliability [4]. In this paper, 1Gb parallel STT-MRAM with pipeline architecture has been demonstrated. Firstly, 1Gb STT-MRAM memory array is divided into suitable several blocks to enhance operation efficiency. Secondly, based on the design of blocks and SA, an additional register is

arranged between each decoder and SA. Finally, the overall circuit structure is simulated and discussed. The results show that the pipeline architecture of 1Gb parallel STT-MRAM can greatly shorten the total read time and enhance the read performance.

EP-10. Synchronization of Stochastic Magnetic Oscillators Based on Thermally Stable Magnetic Tunnel Junctions by Supply Voltage Modulation. *Y. Lv*[1], R. Bloom[1], B.R. Zink[1] and J. Wang[1] *1. Department of Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States*

Synchronization of stochastic oscillators is one of the key tasks for developing oscillator based probabilistic computing schemes. Spintronic stochastic oscillators made of thermally unstable magnetic tunnel junctions (MTJs) can be synchronized by alternating current applied on the MTJ generating alternating spin-transfer torque (STT)[1]. On the other, a thermally stable MTJ can also be driven by a static voltage source to act as a stochastic oscillator[2]. In this work, we experimentally demonstrate synchronization of stochastic magnetic oscillators based on such thermally stable MTJs As shown in Fig. 1, when the MTJ is in antiparallel (AP) state, it switches to parallel (P) state due to reduced energy barrier by magnetic field (H_{ext}) and thermal fluctuation. When in P state, the MTJ draws more current from the supply voltage source, and more STT switches it back to AP state. In this way, thermally stable MTJ is driven to stochastically oscillate between two states. Then we add a square wave modulation to the supply voltage (Fig. 1, left). When the supply voltage is slightly higher, stronger STT favors P to AP transition, while when the supply voltage is lower, external field makes AP to P transition more likely. Therefore, although the oscillation of MTJ is still stochastic to some extent, it is clearly synchronized to the supply voltage modulation. Fig. 2 shows experiment results. The V_{supply} is modulated as a square wave on an offset; the V_{MTJ} is the MTJ's current sensed by a resistor that represents its oscillation (high voltage is P state). The MTJ's oscillation is synchronized to supply voltage modulation while exhibiting some randomness. Furthermore, correlation between the V_{MTJ} and V_{supply} is shown as C_M XNOR C_S (and its time average). The XNOR of the two is greater than 0.5 so that the synchronization is confirmed.

EP-11. Micromagnetic study of fast switching mechanism in perpendicular double MTJ with a switchable reference layer. *C. Yoshida*[1], T. Tanaka[1], T. Ataka[1] and A. Furuya[1] *1. Fujitsu Limited, Kawasaki, Japan*

It has been reported that a dynamic double magnetic tunnel junction (DD-MTJ) with a fixed reference (FR) and a switchable reference (SR) layers showed a high thermal stability, a low switching current, and good manufacturability [1, 2]. In this study, we investigate the effect of SR layer on spin transfer torque (STT) switching in a perpendicular 30 nm DD-MTJ (Fig. 1(a)) using micromagnetic simulation [3] including thermal fluctuations at 300K. Time evolutions of normalized z-component of the magnetization ($<M_z>$) of SR, F1, F2, and FR layers are shown in Figs. 1(b) and (c). Under a negative voltage, initial P/P (SR↓/F1-F2↓) state first switched to AP/P state (SR↑/F2-F1↓). Once two reference layers (SR and FR) becomes antiparallel, the spin torques coming from both side add up to accelerate the speed of switching. After switching to AP/AP state (SR↑/F2-F1↑), the spin torque acting on SR layer and eventually became P/AP state (SR↓/F2-F1↑) [1]. Similarly, under a positive voltage, initial P/AP states switches to final P/P state in the reverse order. Since STT-switching is a probabilistic event, 100 switching trials were simulated under the voltage of -2 and 2.5 V for the

DD-MTJ at 300K. Then switching time of first SR reversal (t_{SR}) and subsequent free layer reversal (t_{SR+F}) were obtained at 80% switching probability (Fig. 2). The fast STT switching was achieved in the MTJ with small $M_{s\text{-}SR}$ of 0.25 T; the switching time was reduced by 41% at V = -2.0 V and by 22% at V = 2.5 V compared to the single reference MTJ. Note that switching time of DD-MTJ (t_{SR+F}) includes the switching time of SR (t_{SR}) which increases with increasing $M_{s\text{-}SR}$. We found that the DD-MTJ with smaller $M_{s\text{-}SR}$ is a promising as a high-performance cache for embedded applications.

EP-12. Coupled Spin-Torque-Oscillator based Distance Computation: *M. Pufall*[1], W.H. Rippard[1], E. Jué[1], M. Koo[2], Y. Shim[2], k. Roy[2], G. Csaba[3] and W. Porod[4] *1. National Institute of Standards and Technology, Boulder, CO, United States; 2. Purdue University, Lafayette, IN, United States; 3. Pazmany University, Budapest, Hungary; 4. Notre Dame University, South Bend, IN, United States*

Recent research on spin torque oscillators (STOs) has shown the possibility of using coupled oscillator network as a core computing primitive for non-Boolean computation, because they are CMOS compatible, highly integrable, scalable, and frequency/phase tunable. A basic computation that is amenable to non-Boolean hardware is the degree-of-match between two vectors, which can be parametrized by a distance metric such as the Euclidean distance norm L2. In this poster, we describe the design and experimental demonstration of a new architecture for a hybrid spintronic/CMOS hardware prototype that computes a multi-dimensional norm.[1] The hybrid system is composed of an array of four injection-locked STOs (see Figure) and a CMOS detector, we experimentally demonstrate a system composed of giant magnetoresistance (GMR)-based STO devices. We theoretically show that phase dynamics of the system inherently introduce non-linearity that makes the system appropriate to measure the distance between two multi-dimensional vectors, that when loaded into the hybrid system, produce an output voltage that is proportional to the L2^{2} norm. The experimental results are then used to parametrize larger-scale simulations of coupled oscillator computing using realistic device parameters, and demonstrate that oscillator-based distance computation scales favorably with increasing input dimension and are tolerant to device variations. In the poster, we estimate the energy efficiency of such an architecture. In addition, we also quantitatively analyze noise propagation in the detection circuit, which uses several stages of amplification to detect the phase response from the GMR devices used, and discuss the impact of improving STO device performance (e.g., MR, phase noise) on the distance computation.

EP-13. Time-Resolved Study of the Switching of Spin Transfer Torque Random Access Memories. *P. Bouquin*[1,2], S. Rao[2], S. Couet[2], S. Kundu[2], D. Crotti[2], J. Swerts[2], G.S. Kar[2] and T. Devolder[1] *1. Centre de Nanosciences et Nanotechnologies, Palaiseau, France; 2. IMEC, Leuven, Belgium*

We use time-resolved measurements to study the switching mechanism in STTMRAM [1]. Our samples are disk-shaped pillars of diameter ranging from 25 nm to 150 nm [2]. We study the devices time-resolved conductance response to fast rising voltage steps. Following [3] we describe the switching in two steps: an incubation delay during which the conductance is quiet followed by a fast change of the conductance called the transition time. We study the impact of the diameter of the disk and of the voltage step amplitude on both delays. The statistics of the incubation delay span from the μs to the ns range when increasing the applied voltage. The transition time also decreases with increasing voltage but at a slower rate. We observe an event-to-event variability in the switching path for the larger diameters (Fig. 1), but much less for the smaller one. This variability also depends on voltage: for the largest voltages applied it is not observed and all switching events present a sharp transition. Thus, two regimes can be identified: for low voltages the total switching time is given by the incubation delay (not shown), while for larger voltages one should solely consider the transition time (Fig. 2). Varying the diameter has an impact on both delays. The incubation delay cannot be decreased as fast for the smaller devices compared to the larger ones for the same voltage range. The transition time is also linked to the diameter since the switching path that undergoes the magnetization in such a disk is expected to depend on disk size [4]. The variability in the switching path observed at larger diameter can be explained by domain wall related phenomena such as oscillations of the wall position or pinning. We can extract a characteristic diameter for those phenomena, which gives information on the size dependence of the switching path on real devices.

EP-14. Thermally assisted STT switching MRAM cell using hybrid memory layer consisting of CoPd/Pd and Co/Pd multilayers. *W. Zhao*[1], T. Kato[1], D. Oshima[2], Y. Sonobe[3], S. Takahashi[3] and S. Iwata[2] *1. Department of Electronics, Nagoya University, Nagoya, Japan; 2. Institute of Materials and Systems for Sustainability, Nagoya University, Nagoya, Japan; 3. Sumsung R&D Institute Japan, Yokohama, Japan*

Spin transfer torque (STT) switching is considered as a promising writing scheme to realize a Gbit-class magnetic random-access memory (MRAM). Memory cells with high thermal stability Δ and low switching current density J_c are required for the high-density MRAM. We have designed bi-multilayers (MLs) stack with a high Curie temperature (T_C) Co/Pd and a low T_C CoPd/Pd MLs for the memory layer to realize the efficient STT-switching [1, 2]. In this work, we fabricated GMR junctions using the hybrid memory layer with a stack of $[Co/Pd]_{3\text{-}N}$ / $[CoPd/Pd]_N$ and investigated structural dependence of J_c and Δ at various of temperatures to study the switching efficiency of the hybrid memory layer. The layer stack of Si substrate with a surface oxide layer / Ta (10) / $Cu_{70}Ta_{30}$ (150) / Pt (5) / $[Pt (1.0) / Co (0.6)]_6$ ML / Cu (2.5) / $[Co (0.6) / Pd (1.0)]_{3\text{-}N}$ ML / $[Co_{48}Pd_{52} (0.4) / Pd (1.2)]_N$ ML / Cu (5) / Ta (5) (thickness is in nm) was sputter deposited and fabricated into a current perpendicular to the plane giant magneto-resistance (CPP-GMR) junctions with pillar diameters of 120-300 nm. STT switching of the hybrid memory layer was confirmed by measuring the resistance of the CPP-GMR pillar after injecting the current with a pulse width τ of 10 μs - 100 ms. The intrinsic critical current density J_{c0} was estimated by extrapolating the STT switching current density J_c to τ = 1 ns, and the thermal stability factor Δ was estimated from the slope of the pulse width dependence of J_c. Fig. 1 shows the temperature dependence of Δ and J_{c0} of the hybrid memory layer with $N = 0$ and 2. J_{c0} and Δ for $N = 0$ was almost constant up to ~170°C. On the other hand, significant reduction of J_{c0} and Δ was confirmed for $N = 2$ at high temperature of ~170°C. Interestingly, Δ for $N = 2$ was almost constant up to 100°C then reduced significantly. This tendency is quite attractive for thermally assisted MRAM suggesting the hybrid memory layer is suitable to realize the efficient MRAM cells.

EP-15. Spintronic Processing in Memory for Convolutional Neural Network Based on STT-MRAM. *H. Zhang*[1], W. Kang[1], Y. Zhang[1] and W. Zhao[1] *1. Beihang University, Beijing, China*

The traditional von-Neumann computer architecture is facing increasingly serious problems due to the limitation of the band width between the CPU and memory. In this situation, processing-in-memory is considered as a promising method to solve this bottleneck issue[1]. Recently, emerging nonvolatile memories (NVMs) has shown a fascinating prospect to realize PIM because of their inherent characteristic [2-6]. In this paper, we leverage STT-MRAM with an improved sequential logic method as the logic paradigm to realize convolutional neural network computing. Here, the STT-MRAM is selected from the NVMs because it has more mature technology and better application prospects. As shown in Figure.1, different logic functions can be realized within one write and read cycle. [7]. Besides, a one-bit full adder can be achieved within 5 write and read cycles based on this logic paradigm [8]. For the convolutional neural network, the basic is the convolutional computing. Figure.2 (a) shows the realization of a multiplication operation between two 4-bit operands. First, the operand X is stored 4 times with shift. Then, the 4 rows perform "and" logic operations with each bits of Y, respectively. In the end, add these 4 rows together to obtain the product. As shown in figure.2 (b), the convolutional kernel computing is consists of 9 multiplication operations and 8 add operations. Besides, as shown in figure.2 (c), a block contains 8 sub-arrays, which can perform logic operations simultaneously, and a memory is consists of many blocks. Therefore, it can support high parallelism calculations. By disassembling the computing process, when the convolutional kernel is 3X3 and the precision is 4-bit, one single convolution computing can be achieved within ~90 write and read cycles in one block.

EP-16. Domain Wall Mediated Reversal Dynamics in Perpendicular Magnetic Tunnel Junctions with SAF Free Layer. *O. Bultynck*[1,2], V. Nguyen[2], S. Couet[2], D. Wan[2], E. Raymenants[1,2], B. Soree[1,2], M. Heyns[1,2], I. Radu[2] and T. Devolder[3] *1. KU Leuven, Leuven, Belgium; 2. imec, Leuven, Belgium; 3. Novel magnetic devices, C2N, Palaiseau, France*

In this work, we study the spin transfer torque induced magnetic reversal dynamics of a conventional dual-MgO CoFeB reference [1] versus a synthetic antiferromagnetic (SAF) free layer (FL) in a magnetic tunnel junction (MTJ) device. SAF thin-films exhibit increased magnetic domain wall (DW) velocities [2], and reduced pinning [3] compared to their ferromagnetically coupled counterparts. These properties are attributed to the presence of DMI and antiferromagnetic exchange coupling, leading to a stabilized Néel DW configuration. These properties are expected to be key for DW motion based devices, such as the racetrack memory [4] or the spin-torque majority gate [5]. We apply a time-resolved conductance measurement technique [6] which allow us to study the evolution of the perpendicular magnetic component down to the ns timescale (Fig.1). The measured responses contain a stochastic incubation delay before switching onset, and subsequent dynamics during the reversal time. Multiple dynamics with diverse physical origins are identified during the MTJ reversal process, such as: DW pinning, DW oscillation, backhopping, and self-heating. Exponentially distributed pinning times dominate the dynamics in the thermal regime of the dual-MgO reference devices. This is strongly suppressed in the SAF based devices (Fig.2). In the intrinsic regime, the DW velocity become the limiting property, with the SAF devices having shorter reversal times (Fig.2 inset). We conclude that the domain wall physics at play in a SAF stack can help enhance the reversal in the confined dimensions of a patterned device.

We have found that perpendicular magnetic anisotropy (PMA) Co_xPd_{100-x} alloys are a simple means of pinning the reference layer in CoFeB-MgO based magnetic tunnel junctions [1]. Composition, thickness and seed layers were varied. After optimization of the CoPd alloy composition with respect to coercivity, perpendicular anisotropy and magnetoresistance at a nominal Co concentration of 25 atomic percent, various seed layers were investigated [2]. The coercivity was found to be significantly higher for Ta/Pd and Ta/Ru/Ta seed layers. Structural characterization of these stacks by X-ray diffraction and high resolution cross-sectional transmission electron microscopy revealed that the CoPd alloy grown on the Ta/Pd seed layer had much better crystallinity than that grown on MgO or Ta [3]. Magnetic force microscopy was performed on these stacks to observe the switching properties and matched with first order reversal curves (FORC) as shown in Figure 1. The switching process begins with nucleation and dendritic growth of a spongy region which expands to fill the film [4]. The sharp drop in M produced by this switching gives very fine structure in the FORC distribution, which is clearly seen in a new visualization program, FORC+ [5-6].

EQ-01. Stoichiometry Controlled Ultrafast Demagnetization in $Co_2Fe_XMn_{1-X}Si$ Heusler Alloy. S. Pan[1], T. Seki[2,3], *A. De*[1], K. Takanashi[2] and A. Barman[1] *1. Condensed Matter Physics and Material Sciences, Satyendranath Bose National Centre for Basic Sciences, Kolkata, India; 2. Institute for Materials Research, Tohoku University, Sendai, Japan; 3. Center for Spintronics Research Network, Tohoku University, Sendai, Japan*

Ultrafast demagnetization is a vital research field in magnetism since its discovery in 1996. $Co_2Fe_XMn_{1-X}Si$ Heusler alloy (HA) with perfect stoichiometric ratio (X) has band gap in minority spin band leading to very low magnetic damping and longer demagnetization time. Very few articles [1-2] demonstrate the ultrafast demagnetization in $Co_2Fe_XMn_{1-X}Si$ HA with only X=0 (CMS) and X=1 (CFS). As the earlier reports lack the variation of ultrafast demagnetization time with intermediate X values, the exact mechanism behind ultrafast demagnetization in this HA remains an open question. Here, we experimentally investigate the ultrafast demagnetization in $Co_2Fe_XMn_{1-X}Si$ with different values of X, i.e. the ratio between Fe and Mn. The time-resolved traces of Kerr rotation have been analyzed using three temperature model [3] to extract the ultrafast demagnetization time (τ_M). Interestingly, we obtain maximum τ_M of ~350 fs for X = 0.4 as shown in Fig. 1. On both side of X=0.4, τ_M decreases. This trend follows the variation of density of states (DOS) at Fermi level (E_F) with X. In HA because of low DOS at E_F, the spin-orbit coupling mediated spin-flip scattering channels become narrower and therefore, τ_M enhances. Fig. 1 also represents the variation of magnetic Gilbert damping constant (α) with stoichiometry. α shows the lowest value for X=0.4 in contrast to τ_M. Fig. 2 represents the variation of τ_M with $1/\alpha$ which fits with a linear equation. This indicates that both damping and ultrafast demagnetization are controlled by the same spin-orbit coupling strength owing to the DOS at E_F. As the DOS increases, spin-orbit coupling mediated spin-flip scattering increases and τ_M decreases with increasing α and vice-versa. In addition, the inverse relation in between α and τ_M proves the presence of dominant inter-band scattering in HA [4].

EQ-02. Reconfigurable Magnonic Band Structure with Field-Bifurcation Dynamics in Coupled Ferromagnetic Nanodot Array. A.K. Mondal[1], C. Banerjee[1], A. Adhikari[1], A.K. Chaurasiya[1], S. Choudhury[1], *A. De*[1], J. Sinha[1,2] and A. Barman[1] *1. S. N. Bose National Centre for Basic Sciences, Kolkata, India; 2. SRM Institute of Science and Technology, Kattankulathur, India*

The quest for advanced spin-based computational technology began a few decades ago with the understanding that the charge-based technology would cease to fulfill the ever-increasing demands of miniaturization, speed, and energy consumption. The field of magnonics, a sub-field of modern magnetism, aims to meet some of these demands using spin waves (SWs), a coherent propagation of magnetic excitation arising from precession of magnetic moments. Periodically modulated ferromagnetic nanostructures, i.e. magnonic crystal (MC), give rise to allowed and forbidden magnonic bands[1]. They have already shown great potential in building various on-chip microwave communication devices. In this work, we have studied the static and dynamic magnetic properties of a MC in the form of a two-dimensional array of rounded rectangular nanodots made of $Ni_{80}Fe_{20}$. The competition between the demagnetizing and the shape anisotropy fields gives rise to a tunable spin configuration, resulting in a transition from magnetic leaf state to S-state upon decreasing the magnetic field from saturation. Finally, a magnetic vortex state is formed at AC demagnetization state, as observed by magnetic force microscopy. We have further studied the magnonic band structure (MBS) by Brillouin light scattering technique and plane-wave method (PWM) by numerically solving the linearized Landau-Lifshitz equation[2]. Our results reveal a fully reconfigurable MBS and band gap (BG) at different bias field (H), namely H = 850 Oe (leaf-state) and H = 330 Oe (S-state). Interestingly, a remarkable shift in the position of the BG at H = 330 Oe in vortex-state give rise to a new phenomenon, namely the bifurcation dynamic[3]. In the vortex-state, the competition between the asymmetric distribution of magnetic field components probably gives rise to an asymmetric periodic magnetic potential energy leading towards the shift in the MBS and BG in this system. EQ-03. Microwave Power Controlled Nonlinear Ferromagnetic Resonance in $Ni_{80}Fe_{20}$ Nano-Cross Array. K. Adhikari[1], S. Sahoo[1], A.K. Mondal[1], *A. De*[1], Y. Otani[2,3] and A. Barman[1] *1. S. N. Bose National Centre for Basic Sciences, Kolkata, India; 2. Institute for Solid State Physics, Kashiwa, Japan; 3. CEMS-RIKEN, Wako, Japan*

Ferromagnetic nano-cross structures manifest a variety of anisotropic spin-wave (SW) properties[1-2], which are crucial for their applications in spintronic and magnonic devices. Here, we demonstrate a rigorous experimental and micromagnetic simulations study about the effect of microwave excitation power (P) on ferromagnetic resonance (FMR) in $Ni_{80}Fe_{20}$ (permalloy; Py) nano-cross array. The experimental results show a remarkable microwave power-dependent shift of the FMR frequency where the sign of the frequency shift depends on the strength of the applied bias magnetic field (H). For lower H values, the power-dependent shift is positive in frequency, whereas for higher H values the power-dependent shift is negative in frequency, above a certain threshold power (P_{th}). Further interesting properties including SW mode softening and mode splitting have also been efficiently controlled by varying P value. To explain the origin of the power-dependent frequency shift, we start with the macrospin model in linear regime, which is possible in nano-cross array system only at higher H values when all spins are parallel to bias field direction. In such a case, the FMR frequency decreases with the increment of P. However, at lower H values, spins of vertical arms in nano-cross align nearly perpendicular to H due to strong configurational anisotropy, which is likely the reason for increment of FMR frequency with the increase of P at lower H values. The rf field which is perpendicular to the bias field does not allow sharp change of static spin configuration with the increment of bias field at higher P values which is the reason for nearly vanishing of SW mode softening. Remarkably, numerically simulated spatial distribution of power and phase profiles reveal that at P = -15 dBm, the lowest frequency SW mode shows a mixed backward volume (BV; n) and Damon Eshbach (DE; m) like character with mode quantization numbers n=6, m=3. Whereas at P = +4 dBm, both the newly generated SW modes due to SW mode splitting show incoherent character. The rich magnetization dynamics of nano-cross array are promising for applications in microwave assisted fast magnetic storage, logic and communication devices.

The recent demonstration of neuromorphic computing with spin-torque vortex oscillators [1-3] has opened a path to energy efficient data processing. The success of this demonstration hinged on the intrinsic short-term memory of the oscillators. In this study [4], we extend the memory of the spin-torque nano-oscillators through time-delayed feedback. We leverage this extrinsic memory to increase the efficiency of solving pattern recognition tasks that require memory to discriminate different inputs. The large tunability of these non-linear oscillators allows us to control and optimize the delayed feedback memory using different operating conditions of applied current and magnetic field. A single oscillator with time multiplexing projects the initial problem in a higher dimensional state, turning it into a linearly separable problem. We tested this computation scheme on a temporal pattern recognition task, sine and square waveform classification, which requires memory and non-linearity. The error rate drops from 10.8 % without feedback to 0.16% with feedback (see Fig. 2).

Abreu Araujo, J. Grollier *et al., Nature* 563, 230–234 (2018) [4] M. Riou, F. Abreu Araujo, J. Grollier *et al.*, *arXiv:1905.02695* (2019)

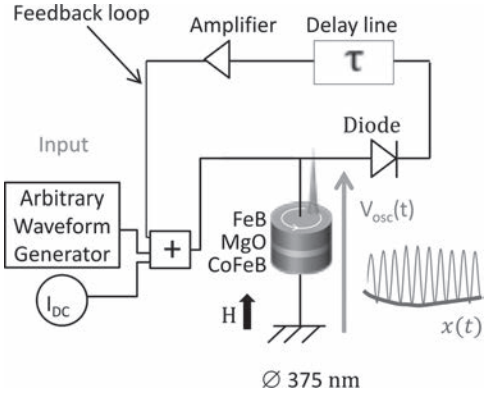

Fig. 1: Experimental setup. The spin-torque vortex oscillator is subjected to a DC current and a perpendicular magnetic field giving rise to an oscillating voltage V_{osc}. The time-varying input is generated by an arbitrary waveform generator. A diode allows measuring the amplitude of the oscillations x(t), which is used for computation. Finally, the feedback loop consists of an electronic delay line and an amplifier.

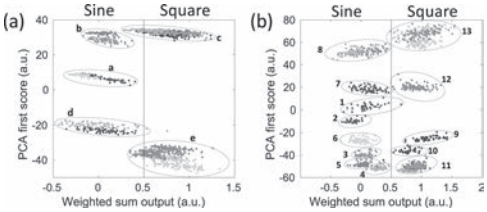

Fig 2: 2D visualization of the higher dimension mapping obtained from the experiments for all the different inputs: (a) without feedback. Five clusters are observed. The separation between sine and square cases is the vertical black solid x = 0.5. For perfect recognition, points corresponding to sine input should be left to this line and points corresponding to square input should be to the right. Without feedback, several points are mixed up between sine and square cases. The error rate is 10.8 %, (b) with feedback. Thirteen clusters are observed confirming that feedback enables the oscillator to separate inputs by remembering sequences of two consecutive inputs. The final classification is almost perfect with only 0.16 % error rate.

EQ-05. Influence of Vortex Configuration on the Spin-torque Diode Effect for Unbiased RF Energy Harvesting. *M. Jotta Garcia*[1], S. Wittrock[1], J. Moulin[2], S. Menshawy[1], R. Ferreira[3], A. Spin-torque nano-oscillators (STNOs) are spintronic devices based on the excitation of precession modes in frequencies ranging from 100 MHz up to tens of GHz [1]. A particular layout for these devices is one in which the free layer exhibits a vortex magnetization in its equilibrium state, presenting four possible polarity/chirality magnetic configurations. The spin-transfer induced precession of the vortex core in STNOs is especially relevant because, in addition to being a model system for the study of magnetic dynamics, they provide excellent signal characteristics and are promising candidates for next-generation devices and applications, such as rf

generation [2], detection [3] or bio-inspired computing [4]. Here, we focus on the detection and harvesting of low-power rf signals, in the case where the STNO is operating in the sub-critical regime. Two different rf-to-dc modes appear in vortex-based STNOs, the spin-torque diode effect [5] and the vortex core expulsion [6]. While the vortex core expulsion mode allows for larger detection sensitivities, it occurs only above a certain rf power threshold and it relies on the application of a dc current [3]. The spin-torque diode effect, on the other hand, is a rectification effect which does not require any biasing or external magnetic field, and is expected to increase in sensitivity with decreasing rf power [7], down to the device's detection threshold, making it highly suitable for energy harvesting applications. This effect can be seen, even without any external stimulus, in all the vortex configurations i.e. chirality and core polarity. However, their influence on the rectified signal's amplitude and shape has yet to be fully described. Here, we investigate through noise measurements how the different configurations affect the spin-torque diode response. Furthermore, in order to achieve high sensitivities and low rf power thresholds, we explore the connection in series of multiple STNOs with very close resonance frequencies, both experimentally and through simulations. The work is supported by the French ANR project "SPINNET" ANR-18-CE24-0012.

EQ-06. Coupling of spin waves propagating along domain walls with magnetic vortex in thin-film nanostrip cross-structure. *H. Park*[1], J. Lee[1], J. Yang[1] and S. Kim[1] *1. Department of Material Science and Engineering, Seoul National University, Seoul, The Republic of Korea*

A spin wave is the collective excitation occurring in the lattice of spins. It was recently demonstrated that the energy density required to switch or transfer single-digit information in spin-wave-based devices is less than that in conventional electronic transistors[1]. With the aid of nanotechnology[2], the quite large feature size of current magnonic devices fabricated by optical lithography can be down-scaled to several nanometers. Thus, spin waves provide a new pathway for future information processing devices in terms of energy-cost efficiency. Furthermore, spin-wave modes confined in narrow potential wells of magnetic domain walls have been intensively studied owing to their aspects of fundamental interest as well as their possible applications to logic gates[3]. Confinements of spin waves inside narrow, sub-100nm channels such as domain walls[4] promise to further reduce power consumption in magnonic devices and to increase the relatively low group velocities of spin waves[5]. Here, we report on a micromagnetic simulation study of interactions between spin waves propagating along narrow domain-wall channels and a magnetic vortex in a thin-film nanostrip cross-structure. The specific modes of the spin waves propagated well in the narrow potential wells of the domain walls, and then interacted with a magnetic vortex when they went through the vortex soliton. Via this interaction, characteristic eigenmodes of the vortex motions appeared, resulting in elliptical gyration motions of several specific frequencies[6]. The gyration motions could be interpreted by the sum of clockwise and counter-clockwise circular eigenmodes excited by spin waves of corresponding resonance frequencies[7]. According to the action-reaction effect, the phases and amplitudes of the spin waves after their interaction with the vortex were modified differently in the three different arms.

EQ-07. Determination of magnetization alignment speed by observing nucleation process of magnetic vortices. *T. Ohkochi*[1,2], M. Oura[2], H. Osawa[1], A. Yamaguchi[3,2], H. Fujiwara[4,2], A. Sekiyama[4,2] and T. Kinoshita[1] *1. Japan Synchrotron Radiation Research Institute, Sayo, Japan; 2. RIKEN/SPring-8, Sayo, Japan; 3. University of Hyogo, Kamigori, Japan; 4. Osaka University, Toyonaka, Japan*

Magnetic vortices are formed in micron-sized magnetic thin film discs as a consequence of competition between magnetstatic- and exchange-energies. [1] These two magnetic energies have been known for a long time as important parameters to describe microscopic and macroscopic magnetic structures in materials in the equilibrium state. Although investigations of the dynamics of magnetic vortex cores which are already formed have been carried out intensively [2,3], time-constant of the emergence of these energies has not been discussed so far. This study is attempted to solve the question "How fast can the magnetizations align?", by observing the nucleation process of the magnetic vortices just after the transient demagnetization by laser heat pulses, using photoemission electron microscopy combined with magnetic circular dichroism effect (XMCD-PEEM, Fe $L_{2,3}$-edge). The experiments have been performed at BL17SU in SPring-8. "As-grown" $Ni_{81}Fe_{19}$ (permalloy) thin-film discs with their diameter up to 6 μm formed clear magnetic vortex structure, reflecting very soft property of the permalloy's magnetizations (Fig. 1). However, as shown in Fig. 2, most of the discs whose diameter exceed 3 μm showed random multi-domains after the ultrafast laser pulse irradiation (Ti: Sapphire (λ=800 nm), 100 fs-width, 20 mJ/cm^2), while all the discs smaller than 2 μm-diameter formed vortex structure as expected in the equilibrium state. Considering that the typical magnetization recovery time of metallic alloy systems after the demagnetization by femtosecond pulses is approximately 100 ps, [4] the experimental result shows that the magnetic exchange energy works very quickly within the recovery time (otherwise, neither vortex nor multi-domain (microscopically aligned magnetizations) structures would not be formed) and that the spreading velocity of the magnetostatic energy is tentatively determined to 2 (μm) / 100 (ps) = 20 (m/s).

EQ-08. Core Orbit of a Rigid Vortex Magnetic Texture. D. Carvajal[1], *A. Riveros*[2] and J. Escrig[2,3] *1. Departamento de Matemática y Ciencia de la Computación, Universidad de Santiago de Chile, Santiago, Chile; 2. Departamento de Física, Universidad de Santiago de Chile, Santiago, Chile; 3. Center for the Development of Nanoscience and Nanotechnology (CEDENNA), Santiago, Chile*

In physics, conserved quantities are key to understand and describe physical phenomena. These conserved quantities are formally related by the Noether theorem and the lagrangian description both in classical mechanics and field theory. Here we found the orbit equation of the trajectory of the core center for a rigid vortex texture in terms of two conserved physical quantities, namely the energy E and a vector with direction perpendicular to the orbit-plane, $A = -L + G\,|r_c\,|2 / 2$ where G, L and r_c are the topological gyrovector, standard angular momentum and core position of the vortex texture, respectively. Also, the condition for bounded orbits are explicitly obtained. We show analytically, through a similar strategy for the orbit description of the reduced mass in the well know Kepler problem [1], that in absence of a dissipation term, for small deviation of the core [2], the orbit trajectory is bounded between two concentric circles, with the dot center outside the core motion region (Fig1a). Instead, under a dissipation dyadic term proportional to the damping coefficient, A is no longer conservative, and by solving numerically the generalized Thiele equation [3] we show that the core moves into the dot center (a similar behavior was observed in Ref.[4], by micromagnetic simulations using OOMMF[5].) or moves away, depending of the chirality of the vortex texture and the intensity of the applied in plane magnetic field (Fig1b,c respectively). We acknowledge support from Fondecyt under grants 3180470, 1150952 and Financiamiento Basal para Centros Científicos de Excelencia, CEDENNA, grant FB0807.

EQ-09. Coupling between gyrating motion and breathing mode of a magnetic skyrmion. *K. Wang*[1], S. Ying[1] and G. Xiao[1] *1. Department of Physics, Brown University, Providence, RI, United States*

Magnetic skyrmions, together with their dynamics including trajectories of the centre of skyrmion mass and breathing modes (oscillatory variation of the skyrmion radius) have been generating considerable interest for both fundamental and technology reasons.[1-5] The trajectories illustrate the nature of skyrmion motion. They allow us to determine the value of inertial mass.[3] Breathing modes have been observed for both stable and dynamically stabilized skyrmions.[5] These Gigahertz eigenmode dynamics have been proposed to be information carriers, as analogous to propagating spin waves. Coupled gyrating motion and breathing modes between neighbouring skyrmions have been explored.[1,2] However, coupling between the two modes of a skyrmion, and theoretical descriptions, remain elusive. In this work, we identify both gyrating motion and breathing modes when manipulating skyrmions in a racetrack.[4] The gyrating motion of a skyrmion is suggested, via a Thiele equation derived from the micromagnetic model, to be coupled to the breathing mode dynamics. We study spin-orbit torque and boundary effects on collective motions of both modes. We note that the mass density is a more meaningful parameter compared with the inertial mass when studying the skyrmion dynamics.

EQ-10. Dissipative magnetic solitons: nucleation and annihilation timescales and multiple soliton modes. *N. Statuto*[1], C. Hahn[3], J. Hernàndez Ferras[1], A.D. Kent[2] and F. Macià[1] *1. University of Barcelona, Barcelona, Spain; 2. New York University, New York, NY, United States; 3. Physikalisch-Technische Bundesanstalt, Braunschweig, Germany*

Collective magnetic excitations, such as spin waves are attracting a growing interest for their potential in technological applications. In particular, dissipative droplet solitons (DD) and their topological homologous, known as dynamical skyrmions (DS) [1], were proposed as the building blocks for new applications beyond binary computing and memory devices [2]. Those magnetic excitations can be created in magnetic thin films with uniaxial anisotropy by a spin-polarized current flowing through an electrical nanocontact. Applications require high control of the nucleation and annihilation of magnetic solitons as well as an understanding of their intrinsic stability and their behavior against external perturbations. Here, we combine experimental data and micromagnetic simulations to understand the creation and the annihilation process for both DD and DS as well as their stability [1,3]. Simulations and room-temperature data indicate that creation and annihilation processes present different timescales since the creation process has associated an incubation time that depends sensitively on the initial magnetic state of the nanocontact [3]. Low-temperature data shows the existence of different and quantized DD modes that are accessed by varying applied fields and currents [4] and those different accessible modes in addition to their nonlinearity and stochasticity, which could be exploited in neuromorphic [2] or reservoir computing [5].

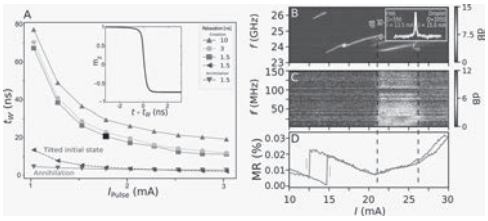

Fig.1: A, Incubation time for annihilation and creation process as a function of the applied current pulse amplitude. Tilted magnetization at the initial state reduce the incubation time. High (B) and low (C) and dc (D) resistance as a function of the applied current at fixed perpendicular field of 850 mT and in-plane field applied of 50 mT. Droplet nucleates at 12.5 mA with a quality factor up to 2000 (inset). Then at 21mA the main high-frequency peak splits into three weaker peaks with lower frequencies, the low-frequency noise increase and the MR shows a change in trend.

EQ-11. The effects of Dzyaloshinskii Moriya interactions on the dynamics of magnetic vortices. *C.M. Quispe Flores*[1], K. Livesey[2] and K. Buchanan[1] *1. Physics, Colorado State University, Fort Collins, CO, United States; 2. Physics, University of Colorado, Colorado Springs, CO, United States*

We have studied the effects of the DMI on the resonance frequencies of magnetic vortices confined in magnetically soft cylindrical nanodots using two approaches: micromagnetic simulations and semi-analytical solutions of the linearized Landau-Lifshitz (LL) equation. Simulations show that without DMI only the odd radial-type modes are excited, whereas when we increase the DMI strength, higher order modes are excited including even modes as shown in Fig.1. Semi-analytical solutions were obtained based on the approach outlined in \cite{guslienko2005vortex} where the linearized LL equation is reduced to a single integro-differential equation that is solved numerically as an eigenvalue problem. The effective torque exerted by the DMI produces two uncoupled integro-differential equations, and the problem is consequently more complicated than the dipolar-only solution. The solution to the LL equation can be expressed as an eigenvalue problem of the form $ i \lambda_n \mathbf{m}_n(\rho) = \int_V \hat{\Gamma } (\rho,\rho′) \mathbf{m}_n(\rho') d^3 \mathbf{r} $ where radially-symmetric solutions are assumed, and the imaginary λ_n values are related to the eigenfrequencies by $ \omega_n =-i \gamma M_0 \lambda_n $. Using this approach, the kernel $\hat{\Gamma } (\rho,\rho') $ may contain the magnetostatic \cite{guslienko2011magnetostatic,kostylev2007dipole}, exchange and DMI contributions. When the DMI is non-zero, the static effective fields must be included in the dynamic calculations since the static magnetization $\mathbf{M}_0$ is tilted by an angle $\psi(\rho)$ with respect to the azimuthal direction, where $\psi(\rho)$ is well described by a Cauchy function. Thus, it is necessary to locally rotate the orthogonal system (ρ,ϕ,z) to a new orthogonal system (ρ',ϕ',z) tilted by the angle $\psi(\rho)$ to ultimately obtain the system eigen-frequencies under the assumptions $|\mathbf{m}|<<|\mathbf{M}_0|= M_s$ and $\mathbf{M_0} \times \mathbf{H_{eff,0}}=0 $. The results for zero DMI agree quite well with experimental results and theoretical calculations reported in \cite{guslienko2005vortex}, and our calculations agree well with micromagnetic simulations performed with DMI.

EQ-12. Time-dependent ab initio insight to the ultrafast demagnetization mechanism. *Z. Chen*[1] and L. Wang[1] *1. Lawrence Berkeley National Laboratory, Berkeley, CA, United States*

Laser induced ultrafast demagnetization process has a great potential in future spintronic devices. Ever since its discovery, this subject has been studied intensively. However, the fundamental physics is still not well understood. There are several long-standing problems regarding the demagnetization mechanism. One major issue is the remarkable underestimation in ab initio simulation. At the same intensity of laser, the theoretical demagnetization rate can be ten times smaller than the experimental observation. Here, we present an ultrafast real-time time-dependent density functional theory method, together with atomic Landau-Lifshitz-Gilbert model, to investigate this problem. Our results show that one important reason for the underestimation is the missing of initial spin disorder, which can significantly enhance the demagnetization to the experimentally observed rate. This spin disorder connects the electronic structure theory with the phenomenological three-temperature model. We have also systematically studied the roles of various interactions which are heavily debated. In particular, we found that electron-electron interaction and spin-orbit interaction play extremely important roles, while electron-phonon and light-spin interactions are not essential.

EQ-13. Analytical calculation of fringe field and magnetization in $V[TCNE]_{x\sim2}$ cylindrical disks. *D.R. Candido*[1,2] and M.E. Flatté[1,2]
1. Department of Physics and Astronomy and Optical Science and Technology Center, University of Iowa, Iowa City, IA, United States; 2. Pritzker School of Molecular Engineering, University of Chicago, Chicago, IL, United States

The collective magnetic excitations in magnetic materials – also known as magnetostatic spin waves [1,2] – have been investigated and studied due to their long spin lifetimes and absence of ohmic losses. These spins waves are created through the application of an alternating magnetic field in ferrimagnetic materials. Here, we solve the Maxwell's equations in the magnetostatic limit for a ferrimagnetic $V[TCNE]_{x\sim2}$ disk [3] on top of a diamond substrate. More specifically, we calculated analytically the spectrum, the magnetization and the fringe fields using the pinning condition at both bottom and top surfaces. We also perform the relaxation of the used pinning condition and investigate its consequence in both fringe fields, spectrum and magnetization. We calculate those quantities for in plane and out of plane magnetic fields. The material is based on work supported by the U.S. Department of Energy, Office of Basic Energy Sciences, under Award Number DE-SC0019250.

EQ-14. Parallel-pump FMR based Non-linear Magnon Dynamics in Magnetic Insulators. *A. Venugopal*[1], T. Qu[1] and R. Victora[1] *1. Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States*

Non-linear magnetic response of magnetic insulator materials is often used in the realization of radio-frequency (RF) devices such as Frequency Selective Limiters (FSLs) [1]. These devices are used at the front end of communication receivers to limit power levels of RF signals that exceed a certain preset threshold. In order to design FSLs with better performance, much remains to be understood in terms of generation as well as subsequent interactions of magnons created by RF pumping. We have used high-performance parallel computation based CUDA simulations and a theoretical model for magnon scattering to explore the direct and parametric generation of magnons, excited by microwaves in parallel pumped configurations [3]. The sample is 1-100 um thick and we use periodic boundary conditions. The DC magnetic field is applied in-plane and the RF field is linearly polarized and parallel to the DC field. We first determine the dispersion relation which plays a vital role in the understanding of nonlinearly generated magnons. We then study the effect of ferrimagnet thickness, RF frequency, power, and DC magnetic field, on properties like frequency response, operational bandwidth, and power absorption of the material (Figure 1). It is found that the degree of non-linearity can be controlled using parameters like RF power and damping of the magnetic system. Analytically, Holstein and Primakoff based analysis is used to arrive at the threshold RF amplitude. We also study non-linear damping in the magnetic system which arises at RF powers higher than the corresponding threshold. Excellent agreement over a wide range of fields (Figure 2) between high power experimental and simulation results has been obtained using only low power parameters.

Rare earth-transition metal (RE-TM) alloys are multisublattice ferrimagnets, which gained huge scientific attention due to the fast and highly damped spin dynamics useful for ultrafast ringing-free precessional switching in magneto-optical recording. Femtosecond laser-induced magnetization reversal was initially observed in Gd-based ferrimagnetic alloys [1]. We have demonstrated magnetic anisotropy controlled ultrafast magnetization dynamics as a function of film thickness in e-beam evaporated amorphous Gd-Fe films [2]. Employing a two-color time-resolved magneto-optical Kerr effect (TRMOKE) magnetometer [3] the ultrafast demagnetization, remagnetization, precession and damping have been investigated (Fig. 1(a)). A weak out-of-plane magnetic anisotropy (~10^5 erg/cc) developed in the films with increasing thickness is quantified from the field dispersion of precessional frequency and static magnetic characterizations. This feature is contradictory to conventional ferromagnetic thin films. The direction of the bias magnetic field is varied from in-plane to out-of-plane configuration. Tunability of the orientations of magnetization is achieved due to the growth of the anisotropy. The frequency and decay time for Kittel mode and perpendicular standing spin-wave (PSSW) modes were modulated from 0.3 ns to 0.9 ns with the variation of frequency (Fig. 1 (a)-(c)). The role of several extrinsic effects, *i.e.* two-magnon scattering, magnetic inhomogeneity, and multimodal dephasing, in opening up additional energy dissipation channels has been elucidated. Effective damping of the films is found to vary over a broader range of 0.02 to 0.15 which may find applications in various magnonic and spintronic devices. Department of Physics, Oakland University, Rochester, MI, United States*

We have investigated the phonon transport modulated by magnetization dynamics in Ni/$LiNbO_3$ hybrid heterostructures. In these devices, we excite at microwave frequencies surface acoustic waves (SAW) using interdigitated transducer. The SAW then drives subsequently ferromagnetic resonance FMR in the Ni film, which we analyze by considered both phonon attenuation and generation. At the microscopic level, angular momentum conversation requires the simultaneous transformation of angular momentum from magnons to phonons. Therefore, the line shape of the phonon transport transmission power is significant to study magnon-phonon interaction and the concomitant transformation of angular momentum in this process. Fig. 1(a) shows a schematic illustration of the magnon-phonon interaction during SAW driven FMR. Due to the magnon-phonon interaction, phonons will redistribute angular momentum and energy between magnons and phonons, which can enhance SAW transmission. Fig. 1 (b) shows the magnetic field H dependence of the transmission power at $\theta = 60°$ for an annealed device. The attenuation of the phonon results in dips in the transmission power via FMR absorption at FMR filed. At the same time, the magnon and phonon interaction enhances the phonon transmission at the higher field ($\eta>1/2$), which results in peaks for the transmission power, as shown in Fig. 1 (b). The parameter η is related to the magnon-phonon interaction, at a different frequency (f = 3.56 GHz, 2.24 GHz, 1.61 GHz, and 0.97 GHz), and can be obtained as 3.1, 3.0, 3.6 and 7.1 from the theoretical fits for the annealed device. When $\eta \leq 1/2$, only the peaks near field are observed in the transmission power, which agrees with the line shape for the as-grown device. Thus, the magnon-phonon coupling becomes more pronounced for annealed devices.

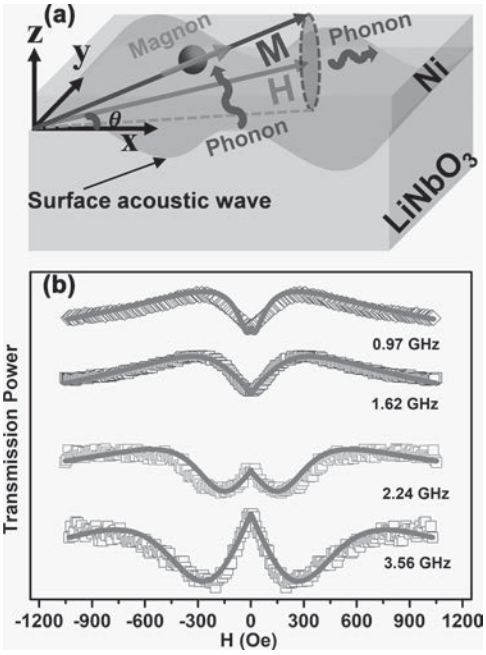

Figure 1 (a) shows schematic illustration of magnon-phonon interaction during SAW driven FMR; (b) shows magnetic field *H* dependence of the transmission power for an annealed device at θ = 60°. The symbols are experiment data, and solid lines are theoretical fits.

Heusler compounds are exciting materials for future spintronics applications because they display a wide range of tunable electronic and magnetic interactions such as metallicity, superconductivity, and giant magneto-resistance. However, the ultimate speed at which spins can be manipulated in materials is still an open question. We use a femtosecond light pulse to directly transfer spin polarization from one element to another in a half-metallic Heusler material, Co_2MnGe. This spin transfer initiates as soon as light is incident on the material, showing that we can spatially transfer angular momentum between neighboring atomic sites on timescales less than 10 fs. The observation is made possible by the ability of ultrafast high harmonic pulses to simultaneously and independently probe the magnetic state at two atomic sites, Co and Mn, during laser excitation. We find that the magnetization of Co is enhanced by the laser pulse, while that of Mn rapidly quenches. By comparing our measurements to density functional theory, we show that the optical excitation *directly* transfers spin from one magnetic sub-lattice to another, via preferred spin-polarized excitation pathways. The enhancement of ferromagnetic order demonstrates direct manipulation of spins via light, thus providing a path towards spintronic logic devices such as switches that can operate on few femtosecond or even faster timescales.

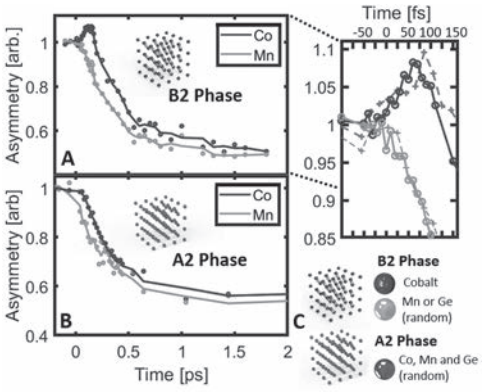

Fig. 1 Element resolved ultrafast magnetization dynamics following excitation by femtosecond laser in the (A) half-metallic B2 phase. Co magnetization increases as Mn decreases. (B) Element resolved ultrafast magnetization dynamics in the non half-metallic A2 phase. There is no enhancement of the Co magnetization.

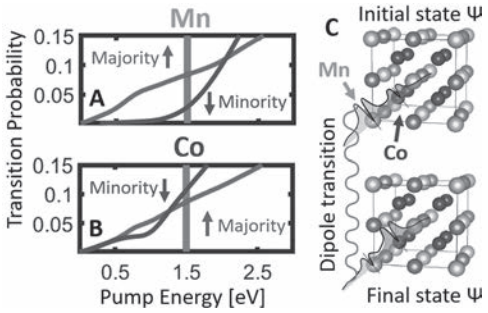

Fig. 2 The probability for exciting a spin up (majority) vs. spin down (minority) electron from the valence band in the B2 phase for different pump energies in (A) Mn sites. For a 1.55 eV pump, the probability is higher for spin up electrons to be excited from Mn. (B) Probability for excitations in Co sites. In contrast to the Mn result, the probability is higher for minority electrons to be excited in Co.

ER-04. Ultrafast Demagnetization Processes in Low-Damping Ni-Ferrite Films. R. Knut[1], *R. Malik*[1], R. Stefanuik[1], Y. Kvashnin[1], D. Thonig[1], A. Gupta[2], O. Eriksson[1], O. Karis[1] and D.A. Arena[3] *1. Uppsala University, Uppsala, Sweden; 2. Univ. of Alabama, Tuscaloosa, AL, United States; 3. Univ. of South Florida, Tampa, FL, United States*

Thin films of spinel ferrites are oxide ferrimagnets with multiple technological uses including improved integrated microwave circuits, spin filters, and other spintronic applications. However, spinels have non-trivial crystal structures and thin films can exhibit a high degree of crystallographic defects such as antiphase boundaries (APBs). Symmetry matching and reducing lattice strain of Ni-ferrite [$NiFe_2O_4$ or NFO] spinel films on different single crystal substrates have been shown to be effective methods for controlling APBs and improving properties such as Gilbert damping and inhomogenous linewidth broadening [1]. NFO has an inverse spinel structure where Ni^{2+} cations reside on O_h coordinated sites surrounded by six O^{2-} ions while the Fe^{3+} cations are split between O_h and T_d sites. We have investigated the role of lattice strain on the ultrafast demagnetization and spin dynamics of NFO films grown on spinel substrates with different amounts of compressive lattice strain ranging from highly strained (~3%) to nearly-unstrained films. We use the HELIOS fs-scale EUV laser source coupled to a transverse MOKE (T-MOKE) apparatus [2] to examine both the static spin-asymmetry as well as the the spin dynamics of the Ni and Fe cations resolved to specific O_h and T_d sub-lattices in the inverse spinel structure. The T-MOKE static asymmetry spectra across the Fe and Ni $M_{2,3}$ core levels exhibit large variations in both amplitude and relative orientation as a function of lattice strain. The time-resolved spectra reveal the sub-ps demagnetization process of the

different NFO films as well as the long timescale magnetization recovery and resonance modes in the ferrimagnetic samples. We corroborate our experimental observations with detailed calculations of the static dielectric tensor and spin asymmetry, generated from first-principles methods, and time-resolved simulations of spectra based atomistic spin dynamics.

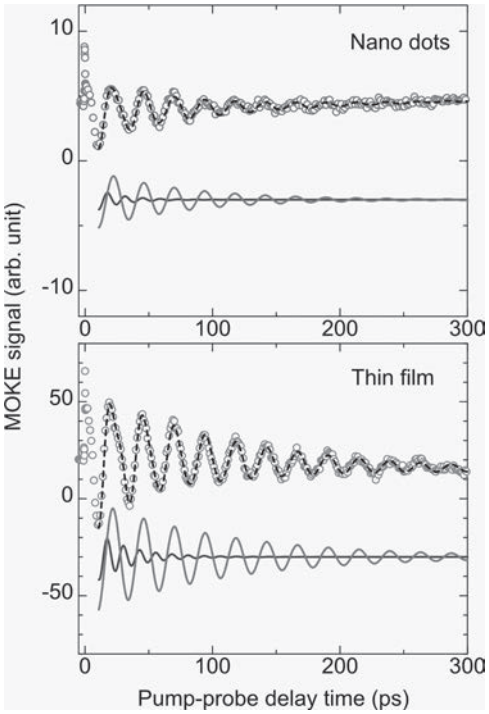
ER-05. Stacking Order Dependent Sign Change of Microwave Phase Due to Eddy Currents in Nanometer-Scale NiFe/Cu Heterostructures.
O. Gladii[1], R.L. Seeger[1], L. Frangou[1], G. Forestier[1], U. Ebels[1], S. Aufftet[1] and *V. Baltz*[1] *1. Univ. Grenoble Alpes / CNRS / CEA, SPINTEC, Grenoble, France*



In ferromagnetic resonance (FMR) experiments, eddy currents need to be carefully considered to accurately determine damping and other related spintronic properties such as spin-mixing conductance and the spin-Hall angle in spin-pumping experiments, especially when characterizing low-damping materials. This type of effect has been thoroughly studied for film thicknesses above the skin-depth limit. In contrast, below this limit, the effects of eddy currents were most often neglected, except e.g. for a study on ac charge currents [1], and for series of comprehensive studies focused on microwave screening/shielding in ferromagnetic/non-magnetic(F/NM) metallic multilayers [2,4]. A recent experimental study revealed how the Oersted field - due to eddy currents in the NM layer - affects the dynamics of F magnetization, and more specifically, how it distorts the resonance lineshape [5]. Using a coplanar stripline transducer, we investigated experimentally the broadband FMR response of few nanometer-thick NiFe/Cu and Cu/NiFe bilayers [6]. The main contribution of our study is that it represents systematic experimental evidence of a stacking-order-dependent sign-change of the microwave phase. The effect could be ascribed to eddy currents generated in the Cu layer in the sub-skin-depth regime by the time varying magnetic fields in the experiment. Distinct sets of experimental data - layer thickness-, frequency- and size- dependences, were consistent with a simple quantitative analysis encompassing the main features of the phenomenon. Remarkably, the model could account for the difference in the thickness-dependence of Cu-resistivity due to the inversion of the growth order. These results contribute to our understanding of the impact of eddy currents below the microwave magnetic skin-depth and explain the contributions to lineshape asymmetry reported in stripline experiments. They also provide a straightforward way to detect the contributions of eddy currents from NM-adjacent conductors, as a caveat for the need in some cases to take these contributions into account.

ER-06. Optical detection of magnetization dynamics for synthetic ferrimagnetic thin film and nano dots.
S. Iihama[1,2] and S. Mizukami[1,2] *1. WPI Advanced Institute for Materials Research (AIMR), Tohoku university, Sendai, Japan; 2. Center for Spintronics Research Network (CSRN), Tohoku university, Sendai, Japan*

Recently, synthetic ferrimagnet (SyF) or antiferromagnet with perpendicular magnetic anisotropy has been attracted much attention for reference magnetic layer in magnetic memory devices. To measure magnetization dynamics in SyF are indispensable to understand the static and dynamic magnetic properties. Time-resolved magneto-optical Kerr effect (TRMOKE) using femtosecond laser pulse is a promising technique to measure ultrafast magnetization dynamics up to sub-terahertz frequency [1]. The detection of magnetization dynamics for nano dots where diameter down to 40 nm has been reported by using microwave [2], optical [3] as well as combined technique [4], however the measured frequency is limited up to ~ 20 GHz. Here, we studied high frequency dynamics for both blanket and patterned SyF films with large perpendicular magnetic anisotropy (PMA) using TRMOKE. The SyF stacking structures studied compose of a bottom Co/Pt multilayer and top CoFeB layer, which are antiferromagnetically coupled through Ir layer. The SyF thin film was patterned into 20-nm-diameter dot arrays. The wavelength, duration, repetition rate of the femtosecond laser pulse used for the pump-probe TRMOKE measurement were 800 nm, 120 fs, and 1 kHz, respectively. The probe laser was tightly focused onto the film. Figure shows TRMOKE results for SyF nano dot arrays and thin film where 1.8 T external magnetic field with the field angle 70 degree from film normal were applied. Magnetization precession for both thin film and nano dot arrays were clearly observed. Dotted curves show fitting results by using two sinusoidal decayed function. Evaluated two oscillation modes, corresponding to in-phase and out-of-phase modes, are shown as red and blue solid curves in the figure. The measured two frequency were ~ 40 and 75 GHz, respectively. The life-time of magnetization precession for nano dot arrays are found to be shorter than that for thin film. This work was partially supported by KAKENHI (Nos. 19K15430), and Sasakawa foundation.

ER-07. Study of Static and Dynamic Properties of Planar Dumbell Shaped Structure of $Ni_{20}Fe_{80}$.
S. Khanal[1,2], P. Sherpa[2] and L. Spinu[2] *1. Physics and Mathematics, Charles University, Prague, Czechia; 2. AMRI, University of New Orleans, New Orleans, LA, United States*

Artificially patterned magnetic structures have drawn significant attention in the field of magnetism. Well-engineered structures allow accomplishing fine-tuning of both static and dynamic properties [1]. In this study, dumbbell-shaped structures of $Ni_{80}Fe_{20}$ were fabricated on the top of the signal line of the Coplanar Waveguide using electron beam lithography, sputtering and lift-off technique. Magneto-Optic Kerr Effect (MOKE) magnetometer was used to investigate the static properties. In addition, dynamic responses were probed through the Vector Network analyzer based ferromagnetic resonance (VNA-FMR) spectroscopy. Static and dynamic characterizations were

carried out along and perpendicular to the Dumbell. Nucleation, propagation, and annihilation of the vortexes in the system show unique configuration during the magnetizing process (figure 1). For dynamic characterization, microwave frequency was swept for each field step and the Scattering parameter of the microwave was tracked. The modulated response of spin waves from the components of the dumbbell was clearly noticed. The spatial variation of spin waves at the external magnetic field of 1000 Oe is presented in figure 2 when microwave frequency was scanned. The sizes of dots were varied to tune both static and dynamic response in a controlled manner. Magnetic hysteresis loops and ferromagnetic resonance spectra were reproduced with Micromagnetic simulation and corroborated with the experimental results. The spectral analyses of FMR spectra were performed at different field and frequency to better understand the experimental results.

ER-08. Chaotic Dynamics and Thermal Switching in AC-driven Nanomagnets. M. d'Aquino[1], *S. Perna*[2] and C. Serpico[2] *1. Department of Engineering, University of Naples "Parthenope", Naples, Italy; 2. DIETI, University of Naples Federico II, Naples, Italy*

The understanding of magnetization dynamics in nanoscale magnets subject to time-harmonic (AC) excitations and thermal fluctuations is of crucial importance both from fundamental and application points of view[1]. Magnetization dynamics of uniformly magnetized particles subject to AC fields has been traditionally studied in connection with ferromagnetic resonance[2], where magnetization oscillations are excited around a stable equilibrium. The amplitude of such oscillations follows the classical resonance curve peaked around the Kittel frequency[2]. At moderate AC powers, nonlinearity may lead to foldover[3]. At larger AC powers, for submicron particle dimensions, the spin-wave instabilities[4] are strongly inhibited by exchange interactions[1]. Thus, even at considerably large AC powers, nonlinear dynamics in nanomagnets exhibits mostly a spatially uniform mode of oscillations. In this work, we consider AC-driven magnetization dynamics for single-domain bistable nanomagnets in the presence of weak thermal noise. The presence of saddle points leads to enormous complexity in AC-excited dynamics where the chaotic behavior is often dominant. We study these phenomena with a special emphasis on the interplay between chaos and thermal excitations. A special perturbation technique based on Melnikov function[5] is developed in order to predict AC amplitude threshold values for the onset of deterministic chaos produced by microwave external fields or AC spin-torque. The reduction of the stability margin of magnetic nanoparticles' equilibria at finite temperature in the presence of AC-driven chaotic dynamics is then discussed in terms of basin erosion[6] (see fig. 1). In this respect, chaotic dynamics of the aforementioned type has been recently demonstrated by experimental observations on nanoscale magnetic tunnel junctions[7], which show that chaos can be the dominant mechanism which controls thermally-activated switching dynamics in AC-driven conditions.

ER-09. Non-reciprocal phenomena in non-equilibrium magnetization dynamics. *A. Galda*[1,2] and V. Vinokur[2] *1. James Franck Institute, University of Chicago, Chicago, IL, United States; 2. Materials Science Division, Argonne National Laboratory, Lemont, IL, United States*

The understanding of out-of-equilibrium spin transport, magnetization dynamics, and phase transitions is one of the major challenges of contemporary magnetics. In this work, we introduce the non-Hermitian spin Hamiltonian formalism that fully describes the time evolution of non-equilibrium magnetic systems in presence of Gilbert damping and angular-dependent spin-orbit-torques. The Hamiltonian approach to non-equilibrium spin dynamics provides a concise and illustrative representation of the underlying non-conservative fields and forces acting in driven dissipative magnetic systems. It offers a convenient way to determine exact system parameters necessary for minimizing the detrimental effects of noise and dissipation in the system, and explains the origin of non-linear spin-orbit terms in the corresponding Landau-Lifshitz-Gilbert equation. The Hamiltonian admits branch point singularities that appear as chiral exceptional points, where both eigenvalues and eigenstates coalesce. We will discuss the appearance of these exceptional spectral points in relation to parity-time symmetry, and how this provides access to a wealth of topological effects unique to non-Hermitian spin systems, e.g. asymmetric spin transport and spin filtering, and non-reciprocal magnetization dynamics.

Time evolution of a non-Hermitian magnetic system when encircling the exceptional point. The system's final state depends on the encircling direction, illustrating the non-reciprocity of non-Hermitian parametric driving.

ER-10. Experimental Detection of Dynamic Phase Transitions in $Co_{1-x}Ru_x$ Thin Films. *J.M. Marin*[1,2], P. Riego[1,3], E. Oblak[1], G.E. Campillo[4], J.A. Osorio[2], O.L. Arnache[2] and A. Berger[1] *1. CIC nanoGUNE, Donostia-San Sebastian, Spain; 2. Instituto de Física, Universidad de Antioquia, Medellin, Colombia; 3. IKERBASQUE, Fundación Vasca para la Ciencia, Bilbao, Spain; 4. Facultad de Ciencias Básicas, Universidad de Medellín, Medellin, Colombia*

In this work, $Co_{1-x}Ru_x$ (10$\underline{1}$0) ultrathin films (20 nm) were grown by co-sputter deposition at room temperature in Ar atmosphere at 3 mTorr for $0 \leq x \leq 26$ at.%, to experimentally study the presence of dynamic phase transitions (DPT) by using an ultrasensitive transversal magneto-optical Kerr effect (T-MOKE) set-up. A ferromagnetic system under the influence of a time-dependent external field H(t), can shift their time-magnetization M(t) response as function of H(t) period (P) and its amplitude (H_0). Therefore, as P gets closer to the system's relaxation time, M(t) is unable to follow H(t) anymore, leading to a symmetry breaking at a critical period (P_c) where the system undergoes a DPT [1,2]. So, for $P>P_c$, the mean time-dependent magnetization, i.e, the dynamic order parameter $\langle Q \rangle$ is zero and the system is at a dynamically disordered state, while for $P<P_c$ we have a dynamically ordered state ($\langle Q \rangle \neq 0$). Furthermore, an additional small time-independent bias field (H_b) is the conjugated field to $\langle Q \rangle$, and thus it can alter the systems dynamic response in both ordered and disordered regimes [2]. Hence, in our experimental set-up, dynamic and static magnetic fields where applied to the samples using an electromagnet with minimal coercivity and low latency. High field stability was reached by implementing an iterative routine to minimize field variations for H_0 and H_b closer to ±1 Oe, for frequencies up to 300 Hz. T-MOKE ultrasensitive configuration enable an enhanced signal-to-noise ratio 20 times higher than that for the conventional one [3]. Hence, N (> 250) independent real-time full hysteresis loops were recorded as function of the field period, H_b and H_0 field amplitudes to determine $\langle Q \rangle$ values under fast resolved conditions. These experimental settings enable the exploration of both $\langle Q \rangle(H_b,P)$ and $\langle Q \rangle(H_b,H_0)$ DPT's phase diagrams (Fig. 1), evidencing the presence of metamagnetic fluctuations (sidebands) in the disordered regime for our whole sample range.

ER-11. Precession damping in $[Co_{60}Fe_{40}/Pt]_5$ multilayers with varying magnetic homogeneity investigated with femtosecond laser pulses. *M.A. B. Tavares*[1], L.H. F. Andrade[1], M.D. Martins[1], G.F. Moura Gomes[2,3], L.E. Fernandez-Outon[3,1] and F.M. Matinaga[3] *1. Nanotechnology, CDTN/CNEN, Belo Horizonte, Brazil; 2. PPGMCS, Unimontes, Montes Claros, Brazil; 3. 3 Depto de Fisica - UFMG, Belo Horizonte, Brazil*

Using femtosecond light pulses to study ultrafast magnetization dynamics has been a fruitful approach for investigating magnetic materials [1-3]. Here we report on the ultrafast magnetization dynamics of $[Co_{60}Fe_{40}/Pt]_5$ multilayers (MLs) which were synthesized with varying magnetic textures. The controlled growth rate of the Pt buffer layer modified the anisotropy fields and magnetic domain sizes of the MLs (S1-S4) as verified by VSM, MFM and simulations with MuMax3 software. Details of sample growth and characterization are presented in [4]. The time-resolved measurements were done with 100 fs laser pulses at a fluency ~0.2 $mJ.cm^{-2}$ in a degenerate pump and probe setup [1-3]. After photoexcitation by 100 fs pump pulses, we observed a ultrafast demagnetization of the ML's in hundreds of fs followed by a partial remagnetization, which occurs in ~1.5 ps. As displayed in Fig. 1a for the MLs with largest domain sizes a damped precession of the magnetization is observed to decay with a time constant of ~133 ps and its frequency varies from 5.8 GHz to 9.8 GHz as the magnetic field increases from 276 mT to 427 mT. We determined the efective damping (α) fitting the experimental data with the Landau-Lifshitz-Gilbert equation (Fig. 1b and Fig.1c) [1-3]. Expectedly, the decay time (η) increases for higher fields reaching a constant value of ~ 135 ps. For fitting the experimental data in Figure 1b we used the saturation magnetization and anisotropy field measured from VSM (± 5%) and a value of g=2.45 for Pt/Co/Pt layers as reported in ref. [5]. This large value of g may be related to additional orbital moment from the Co/Pt interface [5]. As shown in Fig. 2, α decreases from 0.18 to 0.04 for MLs with increasing magnetic domain sizes (S1-S4). These α values may be related to an enhanced scattering and spin pumping effects from Pt adjacent layers [3-5-6]. Finally, we note that the precession frequency (extracted fitting the data to LLG) increases from 2.04 GHz to 11.5 GHz as the anisotropy field of the MLs increases from 6.5 kOe to 13 kOe.

ER-12. Detection of torque effects in Co/Pt via ferromagnetic resonance. *Y. Weng*[1,2], C. Liang[1] and J.G. Lin[2,3] *1. Graduate Institute of Applied Physics, National Taiwan University, Taipei, Taiwan; 2. Center for Condensed Matter Sciences, National Taiwan University, Taipei, Taiwan; 3. Center for Atomic Initials for New Materials, National Taiwan University, Taipei, Taiwan*

Charge current-induced torque effect [Oersted (T_o) and spin-orbit torque (T_s)] on the magnetization dynamics of ferromagnet (FM)/metal bilayer is interesting from the aspect of fundamental physics as well as applications in spintronic devices. T_o is induced by charge current (J_c) gradient in a FM and T_s is due to spin action on magnetization. The behavior of T_o and T_s can be analogous to the field and damping torque, respectively. The torque-induced variation of damping constant ($\alpha \equiv \gamma W/4\pi f$) of magnetization can be determined from a change of the linewidth (W) of ferromagnetic resonance (FMR) spectrum. Thus, the current dependence of α provides a quantitative estimation for spin Hall angle (θ_{SHE}) which is defined as the conversion rate of charge current to spin current via spin-orbit coupling. However, the torque effect often was hindered due to heating-induced artifacts. In this work, we particularly pay attention to minimize the Joule heating effects in order to investigate the intrinsic torque effects in cobalt (Co)/platinum (Pt) bilayer with an applied J_c ranging from -60 to 60 mA. The way to distinguish T_o and T_s is by applying $\pm J_c$ on the plane of film along the two directions: transverse and parallel to the magnetic field. [1] This is because T_s can only occur in the transversal case and its direction depends on the direction of J_c. For transversal (parallel) case, the value of normalize linewidth $W^* \equiv [W(J_c)/W(0)]$ decreases from 1.000 to 0.945 (1.000 to 0.929) with J_c increases from 0 to 60 mA. The change of W* is mainly related to the T_o. For transversal case, the variation of α is not symmetric with respect to J_c=0. The $\Delta\alpha$, $\Delta\alpha \equiv [\alpha(+J_c)-\alpha(-J_c)] \propto \theta_{SHE} J_c$, increases from 0 to 0.376×10^{-4} with $|J_c|$ changing from 0 to 60 mA. Based on the asymmetrical part of α [red line in Fig. 2(b)], the θ_{SHE} of Pt is obtained as 0.20, which is higher than θ_{SHE} measured by ST-FMR for Co/Pt system (~0.11). [2]

ES-01. Exploring magnetic resonance with a compass. *D. Nelson*[1], E. Cookson[1], M. Anderson[1], D. McKinney[2] and I. Barsukov[1] *1. Physics and Astronomy, UC Riverside, Riverside, CA, United States; 2. Santa Rosa Academy, Menifee, CA, United States*

Magnetic resonance plays an important role in today's science, engineering, and medical diagnostics. Learning and teaching magnetic resonance is challenging since it requires advanced knowledge of condensed matter physics and quantum mechanics. Driven by the need to popularize this technologically impactful phenomenon, we develop an inexpensive table-top demonstration experiment. It unveils the magnetic resonance of a hand-held compass in the magnetic fields of a permanent magnet. The setup provides an immediate visualization of the underlying physical concepts and allows for their translation to broad student audiences. This work was supported by the National Science Foundation under Grant No. ECCS-1810541.

ES-02. Magnetic Fields Web Series: Engaging Middle School Students in STEM. *P. Pena Martin*[1], J. Isberg[1], E. Ertekin[1,3], V. Lorenz[1,2] and N. Mason[1,2] *1. Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 2. Department of Physics, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 3. Department of Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, United States*

Web based media can make scientific content accessible to audiences far beyond the scientific community. We created a web series called "Magnetic Fields" that aims to introduce materials science, particularly concepts related to magnetism, and promote themes more general to STEM fields, such as persistence and the scientific process, through use of characters and a story geared towards a middle school audience. The goal is to build and maintain interest in science at an age where this tends to drop off. The four-episode arc follows a group of high school characters as they encounter a strange new material during a class field trip to a laboratory. The series is directed by John Isberg, with professional actors making up most of the cast. The series was initiated by scientists in the Illinois MRSEC, and the storyline was developed in collaboration with MRSEC students and faculty. The episodes were released in May 2019 through Youtube. We report on the process of creating this series, response to it upon release, and discussion of its use as an educational tool. The authors acknowledge primary support of the NSF through the University of Illinois at Urbana-Champaign Materials Research Science and Engineering Center DMR-1720633.

ES-03. In-class experiments with smart phones for teaching upper-level electricity and magnetism. A. Davidson[1], A. Ranjan[2] and *X. Fan*[1] *1. Physics and Astronomy, University of Denver, Denver, CO, United States; 2. Cherry Creek High School, Greenwood Village, CO, United States*

Interactive-engagement method such as studio physics [1, 2], has demonstrated higher learning gains than traditional lecturing in intro-level physics classes. However, there have been limited applications in upper-level classes, such as Electricity and Magnetism (E&M), possibly because experiments on E&M topics can be too costly and sophisticated to be carried out in the classroom. Smart phone, which is equipped with magnetic field sensors, radio signal detectors and light sensors, provides a convenient platform for carrying out E&M-related experiments. In this poster, we will present three examples of the implementation of smart-phone-based studio physics in an E&M class for Physics majors: (1) Detection of earth magnetic field inclination; (2) quantifying skin depth of aluminum foil with cellphone tower signals; and (3) Measurement of Brewster's angle. Besides sensitive sensors, smart phone also has computational power, which can be explored to further expand the breadth and depth of the smart-phone-based studio physics. Due to the wide accessibility of smart phones and the simplicity of experimental setup, we expect this teaching technique can be easily transferred to other institutes in the world.

Lab sessions in physics education connect the fundamental concepts to practical examples and are effective measures of the students' understanding and reasoning through ultimate real-world tests. Many topics in condensed

matter physics are known to be challenging to convey in both lectures and labs. In addition, these topics are usually resource demanding, which has been one of the challenging issues. Here, we introduce and demonstrate the use of virtue lab modules for teaching physics labs and for effectively integrating research and education. Experiments that are relevant to magnetism and spintronics include, but not limited to, spin current detecting, microwave energy harvesting, and spin-based thermoelectric effects. An important highlight of these modules is the highly-interactive laboratory learning platform. In the class, each piece of experimental hardware (e.g. electrometers, oscilloscopes, etc) will be paired with a computer-based virtual module. The individual modules mimic the hardware, which the students can use to become familiar with the hardware, acquire real-time feedback, and visualize the data acquisition dynamics, on-demand and risk-free. The virtual component is also helpful for demonstrating delicate, shared hardware in class, without risk of damaging the actual instrumentation. These individual components are connected to a central operating system and the experiment can be re-programmed by simple coding and user-interfaced commands [1]. Work at Oakland University is supported by NSF DMR-1808892.

ET-01. Quantitative Evaluation and Reduction of Error in Computation of the Demagnetization Tensor. *M.J. Donahue*[1] and D. Porter[1] *1. Applied and Computational Mathematics Division, National Institute of Standards and Technology, Gaithersburg, MD, United States*

Given two rectangular prisms (cells) with edge dimensions $h_x \times h_y \times h_z$ offset from one another by $\underline{r}$, the average field $\underline{H}$ in one prism arising from a uniform magnetization $\underline{M}$ in the other can be written as $\underline{H} = -N\,\underline{M}$, where N is the 3×3 symmetric demagnetization tensor. By computing N for all offsets across a 3D lattice, the self-magnetostatic field can be efficiently computed for arbitrary shapes and magnetization. Analytic closed-form expressions are known for N [1], but these suffer numerically from catastrophic cancellation at large offsets $R=|\underline{r}|$. We find the error using the analytic forms is $\approx \varepsilon R^3/(h_x h_y h_z)$, irrespective of the cell geometry, where ε is the floating point rounding error (10^{-16} for 8-byte double precision). It is better for large R to switch to asymptotic approximations. This method was used in [2], but only for cubic cells ($h_x=h_y=h_z$) and with a simple dipole asymptotic approximation. In this work asymptotic approximations are developed for general rectangular prisms with $O(1/R^{11})$ truncation error, as compared to $O(1/R^5)$ for the dipole approximation. However, the asymptotic error varies with cell geometry. This affects the optimal crossover point and maximal error, as seen in Fig. 1, where the scaled crossover offset and error grow as the cell geometry varies from 1×1×1 up through 10×1×1. The asymptotic error can be reduced by subdividing each prism into smaller subcells, but this is computationally costly in simulations with extended dimensions or periodic boundary conditions. The geometry effect can be accounted for by scaling by maximum cell edge length (Fig. 2), which allows for frugal application of prism subdivision while retaining high accuracy. This can provide a 100-fold speed-up in computation of N for plate-like cells common in micromagnetic modeling of thin films.

ET-02. Microresonator-integrated magnetic tunnel junctions allowing for thermal gradient sign reversal designed using COMSOL simulations. *H. Cansever*[1], J. Lindner[1], A. Niesen[2], T. Huebner[2], G. Reiss[2], J. Fassbender[1,3] and A.M. Deac[1] *1. Institute of Ion Beam Physics and Materials Research, HZDR, Dresden, Germany; 2. Center for Spinelectronic Materials and Devices, Bielefeld University, Bielefeld, Germany; 3. Institute of Solid State Physics, TU Dresden, Dresden, Germany*

In magnetic tunnel junctions (MTJs), it was theoretically predicted that magnetization dynamics can be induced by thermal gradients via thermal-spin transfer torques (T-STTs), similar to STTs induced by applied voltages[1]. We recently proposed an approach based on microresonators (μR) in order to detect T-STT terms acting on the free layer of an MTJ device by means of investigating the ferromagnetic response of an MTJ exposed to a cw laser in open-circuit conditions. The linewidth of the ferromagnetic signal is modified by the damping-like torque induced by thermal gradient, while the frequency is subject to changes induced by the field-like torque[2]. Here, we used COMSOL simulations to determine the temperature profile of Co2FeAl/MgO/CoFeB MTJs, when the MR structure is considered, see Fig 1. In this design, the structure is defined with laterally larger Co2FeAl (CFA) layer below CoFeB (CFB) layer. This allows for the laser beam to be focused on the CFA layer surface, in order to heat the bottom electrode of the MTJ rather than the top, as commonly investigated[3-6]. The temperature of both layers and temperature differences (ΔT) as a function of lateral width are shown in Fig 2. The temperature on the CFA layer decreases laterally about 25K towards to center of the structure and yields a ΔT over the barrier of about 680mK, if a gold pad is placed on the CFA layer, in the position where the laser is shined on (Fig 2). Without the gold pad and leaving the MgO on the CFA unpatterned, the ΔT over the barrier is reduced almost by factor of 2, and is estimated to be around 320mK and 270mK respectively. When both layers have gold contacts, ΔT drops to 20mK (Fig 2). Consequently, the magnitude and the sign of ΔT over the barrier can be engineered by appropriately designing the design of the device, which would allow for T-STTs induced by thermal gradients of different sign to be investigated experimentally in a single MTJ.

ET-03. Topological states and skyrmions in thick spherical shells. *D.A. Rodríguez Cid*[1,2], F. Valencia[1,2], M. Kiwi[1,2] and F. Torres[1,2]
1. Departamento de Física, Universidad de Chile, Santiago, Chile; 2. Centro para el Desarrollo de la Nanociencia y la Nanotecnología, CEDENNA, Santiago, Chile

Magnetic topological structures have lately attracted much attention due to their potential technological applications such as information carriers and magnetic storage process [1, 2]. These states emerge naturally in low dimensional structures due to local curvature effects [3, 4] which induce effective magnetic interactions [5, 6, 7]. We studied the magnetization ground state, reversal modes and structural stability of nanoscopic hollow spherical shells numerically by micromagnetic simulation (with OOMMF) and by molecular dynamics simulation (with the Molecular Dynamics Simulator LAMMPS). We studied thick hollow nanospheres and their magnetic properties with several external radii R_e and thickness T. We performed simulations for the hysteresis loops and different reversal modes, such as as vortex, onion, whirligig, and skyrmion states were found, depending on the thickness T and the external radius R_e as shown in Fig. 1. While the onion, and whirligig states have already been observed [7], the skyrmion illustrated in Fig. 2 has not. In a two dimensional structure topological stable skyrmions have a topological charge Q = +1 or -1, while the ground state is topologically trivial Q = 0. In contrast, a planar skyrmion structure embedded in a spherical shell is topologically trivial Q=0, while the ground state is not trivial. We show that thick spherical shells display a non trivial topological skyrmion state.

ET-04. On Hysterisis Based Random Number Generation. *C.E. Korman*[1] and I. Mayergoyz[2] *1. Electrical and Computer Engineering, George Washington University, Washington, DC, United States; 2. Electrical and Computer Engineering, University of Maryland, College Park, MD, United States*

Random number generation has many important applications, examples of which include cryptography, Monte Carlo simulations, statistical sampling and gambling. For these reasons, random number generation is a standard software (or hardware) component of modern computers. In the talk, we shall discuss a new hysteresis-based technique for random number generation which can be efficiently implemented by using modern spintronics based nano-technology. The central idea of this random number generation is the utilization of random switching of rectangular hysteresis loops (see Fig. 1). This approach naturally leads to the generation of random binary

numbers as the outputs of rectangular hysteresis loops (see Fig. 2). Mathematically, this random switching can be treated as a repeated sequence of two exit problems for stationary stochastic processes. These exit problems can be reduced to the solution of initial boundary value problems for the appropriate backward Kolmogorov equations. The analytical solution of these boundary value problems can be carried out for the Ornstein-Uhlenbeck process which is the only stationary Gaussian Markov process (see Ref. 1). The latter is relevant for the development of stationary techniques for random number generation. Another (alternative) approach to the analysis of the above random switching based on stochastic processes on graphs will be discussed in the talk, as well (see Ref. 2). In the discussion, special attention will be paid to the trade-offs between the strength of thermal noise which drives the random switching of rectangular hysteresis loops and the widths of these loops which is usually controlled by magnetic anisotropy of nano-magnetic hysteretic elements. Furthermore, the effect of the sampling rate on the stationary distribution of randomly generated binary numbers will be investigated as well. At the nano-scale, rectangular hysteresis loops can be realized by using standard nano-magnetic elements. For this reason, it is conceivable that hysteresis based random number generation may find many important applications in future spintronics based computer systems.

ET-05. General nature of the step-induced frustration at ferromagnetic/antiferromagnetic interfaces: Topological origin and quantitative understanding. X. Chen[1], T. Ji[1], L. Sun[1], B. Miao[1], Y. Millev[2] and *H. Ding*[1] *1. National Laboratory of Solid State Microstructures, Department of Physics and Collaborative Innovation Center of Advanced Microstructures, Nanjing University, Nanjing, China; 2. American Physical Society, New York, NY, United States*

We present a study of the magnetic configuration due to step-induced magnetic frustration at ferromagnetic/antiferromagnetic (FM/AFM) interfaces. At a substrate monatomic step edge, a 180° domain wall emerges. In the ultrathin limit of the capping layer, its width increases linearly with the thickness, whereby the initial slope of growth is found to depend only on the ratio of the inter-layer and intra-layer Heisenberg exchange constants, regardless of the presence the magneto-crystalline anisotropy in the system. These findings are in good agreement with previous experimental observations [1]. As the thickness grows beyond the ultrathin regime, the corresponding thickness dependence departs from linearity and tends to its bulk value. We propose a physically appealing form for the thickness dependence, which follows a universal behaviour in both cases of an AFM domain wall on top of the FM layer and a FM domain wall on top of an AFM substrate. The analytical insights are supported by conclusive, detailed micromagnetic simulations of two independent varieties: (i) the Monte Carlo method, and (ii) the object oriented micromagnetic framework. While the quantitative details of the study are naturally dependent on the specific material parameters of the complex magnetic system, the global features of the spin texture in the capping layer are dictated by the topological step-edge defect. The latter is quantifiable by a winding number of ±1/2 [2].

ET-06. Massively parallel O(N) space-time hierarchical dipole-dipole method implemented in the VAMPIRE code for atomistic spin dynamics. *S. Jenkins*[1], R.W. Chantrell[1] and R.F. Evans[1] *1. Physics, University of York, York, United Kingdom*

Atomistic spin models[1] provide a natural bridge between electronic and micromagnetic length scales but are computationally expensive. In particular calculation of the long-range dipole-dipole interactions which causes complex magnetic structures, such as magnetic domains, vortices or Skyrmions. At the continuum level these interactions can be calculated assuming a uniform magnetization within a volume of but for atomistic simulations the continuum approximation does not accurately reflect the local dipole-dipole interactions and leads to systematic errors. A brute force atomistic dipole-dipole approach is infeasible for the timescales or lengthscales needed to extract useful data. The current approach in the code uses a dipole tensor [4] but the computational cost and memory usage scales with the square of the problem size. Here we present modifications to the VAMPIRE software package [1] to include accurate and scalable calculation of dipole-dipole interactions. We have developed a space-time hierarchical calculation of the dipole field calculation with order improved *O(N)* scalability with problem size. Our approach combines exact near-field computation of the dipole field with an *M*-Level hierarchical representation of the far-field dipole field [5], shown schematically in Fig. 1. The method is hierarchical in time and space, since the far-field time-evolution of the magnetization is much slower than the near-field which changes on the femtosecond timescale. Our improved algorithm enables the inclusion of accurate dipole-dipole interactions in atomistic simulation for large system sizes in the micrometre range for the first time. The massive improvement in scalability from the tensor calculation is shown in Fig.2. This major code improvement will allow large scale atomistic spin model simulations, bridging the gap between current simulation size ranges and those used in devices or investigated experimentally.

ET-07. Micromagnetic Study of Soft Magnetic Nanowires. *F. Ahmadi*[1], M.J. Donahue[2], Y. Sozer[3] and I. Tsukerman[3] *1. Electrical and Computer Engineering, Youngstown State University, Youngstown, OH, United States; 2. Applied and Computational Mathematics Division, National Institute of Standards and Technology, Gaithersburg, MD, United States; 3. Electrical and Computer Engineering, University of Akron, Akron, OH, United States*

Magnetic nanowires (NWs) have vast applications in novel logic devices, data storage, permanent magnets, sensors, and biomedicine [1-5]. The higher shape anisotropy of NWs compared to their thin film and nanoparticle counterparts make them promising nanostructures for soft and hard magnetic materials. For instance, permanent magnets need to exhibit a high coercivity and energy product [3], while magnetic sensors require a low coercivity and hysteresis loss [6]. Such large-scale applications can be obtained by tuning the diameter, aspect ratio, and structure of the NWs. To control the magnetic properties of a densely packed array of NWs, one needs to understand the interwire and intrawire interactions, which is still challenging. In this paper, micromagnetic analysis of an array of long NWs embedded in a nonmagnetic matrix is studied. It is found that for NWs with diameters on the order of a hundred nanometers, the total energy is a sum of Zeeman and magnetostatic energies, while the anisotropy and exchange energies are negligible. Figure 1 shows the normalized Zeeman, magnetostatic, and total energies vs. an external magnetic field applied along the long axis of the NWs. The minimum magnetostatic energy corresponds to the maximum Zeeman energy, whereby half of the NWs are magnetized parallel to the external field, while the rest of the NWs are magnetized antiparallel to the external fields. The study shows a vortex behavior of the magnetic moments in the magnetization reversal process. Additionally, the average hysteresis loop area of the nanocomposite is inverse proportional to the NW diameter in the range from 20 to 200 nm. The results pave the way for designing of NW-based devices such as optimized magnetic sensors for biomedical applications with a trade-off between miniaturization and energy loss.

ET-08. Role of the shape anisotropy in curved magnetic slabs. *S. Castillo*[1], R. Corona[2,3], P. Landeros[4,3] and D. Altbir[2,3] *1. Departamento de Ingenieria, Universidad Autonoma de Chile, Santiago, Chile; 2. Física, Universidad de Santiago de Chile, Santiago, Chile; 3. CEDENNA, Santiago, Chile; 4. Física, Universidad Tecnica Federico Santa María, Valparaiso, Chile*

During the last decade, a strong interest has been focused on the properties of curved magnetic structures [1-3]. An important aspect in these systems is the possibility of controlling the magnetic behavior at the nanoscale by changing the curvature. One example of this behavior is magnetic nanotubes that exhibit chiral magnetic effects originated from the non-local dipolar interaction in the curved structure [4]. This interest has been reinforced by the development of a theory that allows calculating the exchange energy of nanomagnets with arbitrary shapes [5,6]. From the experimental side, curvature changes of magnetic properties in cylindrical magnetic segments with different radii of curvature were addressed by Streubel *et al.* [7], concluding that such geometric decrease magnetostatic interactions allowing higher areal density when used for racetrack memory devices. We develop a methodology that allows studying a magnetic slab that is progressively curved this study is done through modeling a truncated nanotube magnetic. Our results can be interpreted assuming that curvature generates an effective anisotropy in the structure and evidence that curvature contributes to strongly decrease the energy barriers. When we increase curvature, the magnetization tilts out of the surface, favoring the nucleation of transversal domain walls. Therefore, the use of curvature can be used to tailor energy barriers and the domain wall in the magnetic slab. ET-09. Micromagnetics of thin films based on k-space fast convolution.

V. Scalera[1], *G. Tortora*[1], C. Serpico[1], S. Perna[1] and M. d'Aquino[2]
1. Department of Electrical Engineering and ICT, University of Naples Federico II, Naples, Italy; 2. Department of Engineering, University of Naples "Parthenope", Naples, Italy

The numerical studies of magnetization dynamics in micromagnetic systems with spatially distributed magnetization crucially rely on the computation of magnetostatic fields generated by the ferromagnet. The solution of the magnetostatic problem can be written as convolution of an appropriate Green's function with the magnetization vector field. Since the Green's function is long-range, after discretization of the problem in N cells, the direct numerical computation of the convolution integral has a computational cost scaling as N^2. In this work, we use, as it is often done in micromagnetics, the Fast Fourier Transform (FFT) method to reduce the computational cost to N log N. We consider micromagnetic systems with thin-film geometry where the magnetization can be considered costant across the thickness of the magnet. In this situations, only the field averaged across the thickness is relevant to the magnetostatic interations and both the magnetization and the averaged field inside the magnet depend only on two spatial variables. The usual approach to deal with this type of problem is to use FFT to compute the discretized version of the convolution integral relating the field and the magnetization [1]. Our algorithm, on the other hand, is based on the discretization of the integral relation between the field (averaged across the thickness) and the magnetization in the reciprocal space (k-space) [2]. The connection in the k-space is given by the Fourier transform of the Green function which, in the case of thin-films, can be written in a special form taking into account the thin-film geometry [3]. The advantage of this k-space method is that it can be used both for structure that are infinite or finite in one or both in-plane directions. In fact, this approach is the one usually preferred in the study of spin-waves dynamics in infinite structures. In the talk, the accuracy of the method is studied by comparing the results with analytical calculations (fig.1) and with those obtained by the usual approach by varying mesh size. In addition, we will study different techniques for the zero-padding used to eliminate the influence of periodic replica of the sources introduced by the FFT.

ET-10. Iron Loss Modeling and Analysis of Grain Oriented Silicon Steel Sheet under Harmonic Magnetization.

X. Zhao[1], R. Wang[1], L. Li[2] and R. Liu[2] *1. North China Electric Power University, Baoding, China; 2. North China Electric Power University, Beijing, China*

I. INTRODUCTION With the development of ultra-high voltage direct current (UHVDC) transmission system, application of nonlinear power electronic devices generates rich harmonics [1]. High order harmonics are superimposed on the fundamental component of 50Hz, which make it difficult to model the hysteresis and loss characteristics accurately [2]. II. METHODOLOGY AND MODEL The main experimental setup includes computer for displaying data, measuring system, and specimen silicon steel sheet. A single sheet tester (SST) made by BROCKHAUS is used to measure the magnetic and loss properties of GO silicon steel sheet (B27R095). The magnetic induction intensity are given in (1). Different harmonic excitations can be achieved by controlling the following three parameters, harmonic order k, amplitude ratio η and phase difference φ_k. $B(t)=-B_{1m}\cos(\omega t)-B_{km}\cos(k\omega t+\varphi k)$ (1) $\eta=B_{km}/B_{1m\ (2)}$ When the ferromagnetic materials are magnetized by harmonic voltage, iron loss will be dependent on the hysteresis and eddy current. Based on the theory of loss separation, the dynamic magnetic intensity can be divided into the following three parts, $H=H_h+H_{cl}+H_{ex}$ (3) where H_h refers to the static magnetic intensity, which can be fitted by Preisach model based on first order reversal curves (FORC) under harmonic excitation. An improved method is put forward to determine Hcl related to the eddy current loss. Considering the skin effect, the undetermined coefficients of time-varying functions can be obtained by the simulation of the measured dynamic hysteresis loop. Hex denotes the magnetic intensity corresponding to excess loss. III. RESULTS AND ANALYSIS The static and dynamic hysteresis loops under different harmonic parameters are simulated, and the total loss is calculated from the loop area (see Fig. 1). The results show that the hysteresis loop and loss under harmonic excitation determined by the proposed method is in practically good agreement with the simulated one. The total core loss will increase with harmonic order k and amplitude ratio η. Further results of the magnetic modeling and validation of the model will be presented in detail in the full paper.

ET-11. The dynamic susceptibility tensor of nanostructured systems and the spectra of interface pinned walls. S.M. Martins Jr.[1], L.L. Oliveira[2], *A.L. Dantas*[2] and A.S. Carriço[1] *1. Department of Physics, Federal University of Rio Grande do Norte, Natal, Brazil; 2. Department of Science and Technology, State University of Rio Grande do Norte, Natal, Brazil*

We report a theoretical discussion of the spectra of domain walls (DW) sequences formed in Py stripes exchange coupled to two-sublattices vicinal antiferromagnetic substrates.(1,2) The DW are located at the edges of terraces holding magnetic moments from opposite substrate sublattices, and the terrace length sets the distance between consecutive DW. We have obtained a generalized dynamic susceptibility tensor, which may be applied to any nanostructured magnetic systems. These systems are likely to display inhomogeneous magnetization patterns. Apart from the anisotropy, Zeeman and dipolar energies, the exchange energy also contributes to the excitation spectra. A theoretical frame which gives both the equilibrium pattern and the excitation spectra is a valuable tool. Each polarized spectrum obtained from the diagonal elements (xx, yy and zz) of the susceptibility tensor, captures only the excitations which holds oscillations along the respective direction, allowing an association of spectral features with the domains (aligned in the x-direction) and the DW (with the center aligned in the y-direction). For large values of the terrace width, sequences of DW with the same chirality (SCHI) and those with alternate chirality (ACHI) have the same spectral densities. If the terrace length is below a threshold value, each domain wall is at the reach of the dipolar field of neighboring DW, and the stripe overall spectra are affected by the relative chirality of consecutive DW. For instance, a 240nm long, 50nm wide and 10nm thick Py stripe, with three 80nm long terraces and two DW, subjected to an interface exchange field of 15 kOe, has the same excitation spectra for SCHI and ACHI sequences of DW. However, a 300nm long Py stripe, holding five 60nm long terraces and four DW, has different spectral densities for SCHI and ACHI DW sequences. The DW modes have oscillations in the xz-plane. For the SCHI (ACHI) sequence the lowest DW mode frequency is f=3.7GHz (2.3GHz) and is localized at the DW region near the stripe boundaries, where the local field has the lowest value of 17kOe. The largest DW mode frequency is f=15.2GHz (11.7GHz), for oscillations at the DW centers, where the local field is largest, with a value of 27kOe.

ET-13. Magnetization Reversal Spin-Transfer-Torque Driven in Perpendicular Shape Anisotropy Magnetic Tunnel Junctions.
N. Caçoilo[1,2], S. Lequeux[1], N. Strelkov[1,3], B. Dieny[1], *I. Prejbeanu*[1], R. Sousa[1] and L. Buda-Prejbeanu[1] *1. Université Grenoble Alpes, CNRS, CEA, Grenoble INP, IRIG-SPINTEC, Grenoble, France; 2. Department of Physics & I3N, University of Aveiro, Aveiro, Portugal; 3. Department of Physics, Lomonosov Moscow State University, Moscow, Russian Federation*

The concept of Perpendicular Shape Anisotropy Spin-Transfer-Torque Magnetic Random Access Memory (PSA-STT-MRAM) consists in significantly increasing the thickness (L) of the storage layer of a conventional p-STT-MRAM to values close or above to the cell diameter to achieve shape anisotropy. The total anisotropy has thus a bulk contribution due to the shape anisotropy (SA) and an interfacial contribution (iPMA), provided by the FeCoB/MgO interface. The combination of these sources of anisotropy allows to extend the downsize scalability of STT-MRAM towards sub-10nm technological nodes [1, 2] thanks to a significant reinforcement of the thermal stability factor. It was also reported, using a string method, that upon increasing the thickness of the free layer, the most probable energy path between the two stable states of the memory evolves from a macrospin-like behaviour to a domain wall (DW) nucleation/propagation process [1]. The storage layer thickness is affecting the stability but also the writing operation of the cell. In this work, we have studied the magnetization reversal mechanism of the PSA-STT-MRAM induced by STT. Micromagnetic simulations have been carried out for various aspect ratios (diameter, thickness), the dependence of the switching time and the reversal behaviour have been analysed as a function of the applied voltage [Fig 1 and 2]. Above a threshold voltage, due to the spin-transfer-torque at the interface with the MgO, a transverse-DW motion [3] is nucleated and propagated towards the top surface. Upon increasing the thickness, the DW spends longer time in the middle of the pillar as seen in the inset of [Fig.1] and thus the switching time is considerably increased. Even though the nucleation of a DW is still present at the lowest thickness investigated (L=30nm, diameter=20nm), the magnetization switching is faster for shorter pillars, [Fig.2]. The simulations performed including stochastic thermal field indicate that this mechanism of reversal is robust against the thermal fluctuations.

ET-14. Micromagnetic Simulations of First-Order Reversal Curves in Nanowire Arrays Using MuMax3. *R. Eimerl*[1], K. Muster[1] and R. Heindl[1] *1. Physics & Astronomy, San Jose State University, San Jose, CA, United States*

We used micromagnetic software MuMax3 [1] to model first-order reversal curves (FORC) in ordered arrays of magnetic nanowires. Our goal is to simulate the reversal processes in nanomagnet arrays and to map individual reversals to features in the FORC diagram. We simulated a set of reversal curves for a 3x3 array of nanowires, one μm in length and 80 nm in diameter. The nanowires are arranged in a square packing scheme, with a nearest neighbor distance of 200 nm. The average magnetization of each nanowire was recorded along with the total magnetization of the system at each field step. The reversal curves are transformed into the FORC distribution plotted in Fig. 1, showing that interacting nanowires create the so-called 'wishbone' FORC distribution. Two field distributions, one with constant coercive field and wide range of interaction fields (IFD) and one with constant interaction field varying coercive fields (CFD), are clearly visible [2]. Fig. 2 shows the relative FORC, indicating nine major changes in the magnetization of the system; these nine features are magnetization reversals of individual nanowires. By recording reversal process for all nine nanowires along the FORC curves, we are able to relate various switching processes to features in the FORC distribution. The location of the IFD along the coercive axis represents the nanowire's intrinsic coercivity, and the extent of the IFD along the interaction axis represents the upper and lower limits of the interaction field experienced by the system. We find that the CFD shows the real switching events, but the coercivity at which these reversals occur depends on the current state of the interaction field.

ET-15. Optimized Lateral Inhibition in Magnetic Domain Wall Tracks for Neuromorphic Computing. *C. Cui*[1], N. Hassan[2], C.H. Bennett[3], M.J. Marinella[3], J.S. Friedman[2] and J.C. Incorvia[1] *1. Electrical and Computer Engineering, The University of Texas at Austin, Austin, TX, United States; 2. Electrical and Computer Engineering, The University of Texas at Dallas, Dallas, TX, United States; 3. Sandia National Laboratory, Albuquerque, NM, United States*

Lateral inhibition is the neuron behavior that an active neuron cell prevents the firing of its less-active neighbors. It is a neural strategy commonly present in human brain[1]. So far, this important feature of neurons is either missing from devices or implemented through additional circuitry. Recently, an integrate-and-fire neuron based on magnetic domain wall (DW) racetracks has been demonstrated in modeling to be inherently inhibitory[2]. In Fig.1a, two adjacent magnetic nanowires have current-driven DW motion along +*y* via spin transfer torque. Neuron 1 (N1) with higher current density and DW velocity has a larger chance to "fire". Its stray field aligns Neuron 2 (N2) magnetization near DW2 in -*z*. DW2 motion is thus impeded, mimicking lateral inhibition. However, magnetic field has very limited control over average DW velocity in the precession regime of motion shown in this initial work. In this work, we show that significant lateral inhibition can be achieved with current- and field- induced DW motion below Walker breakdown[3] (WB). To this end, stray field must be controlled below Walker field for the inhibited neuron to operate in sub-WB regime. One way to realize such control is to vary the neuron spacing. We simulate in Mumax3 two side-by-side wires 32nm wide x 1.5nm thick x 3μm long using standard

material parameters for Co. In Fig.1, the wires are spaced apart 30nm. We see in Fig.1b simulation snapshot that when N1 has current density J_1 = 2 x 10^{12}A/m^2 and N2 J_2 = 1 x 10^{12}A/m^2, DW2 is inhibited compared to Fig.1c where when J_1 = 0 A/m^2 DW2 travels farther in the same amount of time. In Fig.2, we simulate DW2 velocity for wire spacings from 10 to 80 nm for both cases. The dip in inhibited velocity curve suggests an interaction strength for maximum lateral inhibition. We will further show optimized parameters for lateral inhibition implementation in magnetic DW neuron design via material and geometry engineering.

ET-16. A Hopfield Neural Network-Based Bouc-Wen Model for Magnetic Shape Memory Alloy Actuator. Y. Wang[1], C. Zhang[1], Z. Wu[1] and *M. Zhou*[1] *1. Department of Control Science and Engineering, Jilin University, Changchun, China*

With the development of modern science, the smart actuators are widely used in micro-nano positioning technology. As one of the smart actuators, magnetic shape memory alloy (MSMA) actuator, which is capable of positioning with the nanometer resolution, large energy density and small volume, has attracted much interest [1]. However, there are some difficulties in application of MSMA actuator, namely, 1) asymmetric loop between ascending and descending branches and 2) the output of MSMA actuator depends on the input frequency, which causes the deterioration of positioning accuracy in the system response. Therefore, precise modeling of MSMA actuator is the key to its applications. In this paper, a Bouc-Wen (BW) model is innovatively identified online by Hopfield neural network (HNN) to describe the hysteresis of MSMA actuator. BW model is a kind of differential equation hysteresis model. Compared with other models, such as Prandtl-Ishlinskii model, it has fewer parameters to be identified. Nevertheless, BW model is rate-independent. Identifying the applicable parameters is a significant part of modeling BW model. Neural network has the features of the nonlinear mapping property to be applied to adjust the model parameters online [2]. As a kind of fully interconnected recursive neural network, HNN has feedback connections from output to input and each neuron in HNN is connected to others. Hence, it has more computing power and better global searching capability. In this paper, HNN is innovatively used to identify the parameters of BW model online. Because it has ability of associative memory, it possesses the dynamic nonlinearity and can adjust the parameters of BW model adaptively. The identification results are shown in Fig. 1 and Fig. 2. The maximum modeling error rate at 1Hz and mixed frequency signal is 0.37% and 1.75%, respectively. The BW model identified in this paper can accurately describe the hysteresis of MSMA actuator at different input excitation. Therefore, the ability of precise modeling by HNN-based BW model is certified.

ET-17. Ferromagnetic Branch Design of Alnico for High Coercivity.

H. Won[1], Y. Hong[1,2], M. Choi[1], R. Wang[3,2] and F. Yan[2,3] *1. Department of Electrical and Computer Engineering and Center for Advanced Vehicle Technologies, The University of Alabama, Tuscaloosa, AL, United States; 2. Alabama Transportation Institute, Tuscaloosa, AL, United States; 3. Department of Metallurgical and Materials Engineering, The University of Alabama, Tuscaloosa, AL, United States*

A low coercivity (H_{ci}) of Alnico is attributed to the presence of a branch (B) between two ferromagnetic Fe-Co-rich rods (α_1-phase) that are embedded in a non-magnetic Al-Ni-rich matrix (α_2-phase) [1-3]. L. Ke observed the effects of B position on Z-axis on H_{ci} using micromagnetic simulation (MS) and concluded that the B connected in the bottom of the rod, namely U-shaped, showed low H_{ci} due to starts of magnetization reversal [4]. However, there is still a lack of studies on U-shaped structure for various B thickness ($T_{B\alpha1}$), width ($W_{B\alpha1}$), and position. Thus, this paper investigated the effects of various types of B on H_{ci} of U-shaped structure using MS. We used the following two conditions in the simulation: i) $T_{B\alpha1}$ for $W_{B\alpha1}$ of 40, 66, and 100% of the length of α_1-phase rod ($L_{\alpha1}$) while length of α_2-phase ($L_{\alpha2}$) is 10 nm and ii) B positions (middle- (MBC) and edge- (EBC) B -connected) while $W_{B\alpha1}$ and $L_{\alpha2}$ are 40% of $L_{\alpha1}$ and 10 nm, respectively. For $L_{\alpha1}$, 10 and 25 nm were chosen to represent coherent (ideal) and curling (real) rotations that occur in Alnico. Fig. 1 shows the structure of alnico used in the simulation. The element was divided into 1×1×2.5 nm^3 cell size and 2 Oe field steps with an aspect ratio (c/a) of 8 and simulated using LLG micromagnetic simulator v2.63b [5] for H_{ci}. Fig. 2 shows the change in H_{ci} with $T_{B\alpha1}$ under the above two conditions. The H_{ci} remains constant for all $L_{\alpha1}$ and $W_{B\alpha1}$ when $T_{B\alpha1}$ exceeds 30 nm. In Fig. 2(a), the H_{ci} increases as the $W_{B\alpha1}$ increases regardless of $L_{\alpha1}$, thereby, suggesting thicker $W_{B\alpha1}$ for higher H_{ci}. For the second condition shown in Fig. 2(b), for $L_{\alpha1}$ of 10 nm, MBC position shows 23% higher H_{ci} than EBC position, but for $L_{\alpha1}$ of 25 nm, EBC position shows 8-9% higher H_{ci} than MBC position. Thus, to obtain a higher H_{ci} than 5 and 2 kOe, design of Alnico with thicker $W_{B\alpha1}$ with MBC position for $L_{\alpha1}$ of 10 nm and EBC position for $L_{\alpha1}$ of 25 nm are recommended, respectively.

EU-01. A Multiphysics Assessment on Permeability Tuning Techniques in Power Inductors. *V. Cabral do Nascimento*[1], S. Moon[2], S. D. Sudhoff[1], K. Byerly[2], P. Ohodnicki[2] and R. Beddingfield[2] *1. Electrical and Computer Engineering, Purdue University, West Lafayette, IN, United States; 2. National Energy Technology Laboratory, Pittsburgh, PA, United States*

This paper investigates the benefits of spatial permeability optimization in the magnetic core in electromagnetic devices, using the achievable properties obtained through strain annealing treatment of Metal Amorphous Nanocomposite (MANC) alloys [1], [2]. This capacity introduces a new design element that can result in superior performance. However, the device characteristics result from a multitude of aspects besides the material properties, including its geometry and operational context (e.g. frequency, current waveform, and temperature constraints). A permeability profile can be heuristically selected to improve the performance of a device with a given geometry, but in order to fully leverage the capacity of spatial dependent permeability engineering, the geometry and permeability profile should be optimized simultaneously. The work herein presented compares viable solutions using permeability tuned ungapped inductors against traditional gapped devices, using multi-objective design optimization. This approach enables the determination of Pareto optimal fronts consisting of a set of optimal solutions against competing objectives (e.g. mass and loss) under imposed constraints. Pareto optimal fronts are a powerful tool to evaluate the true contributions of new technology in a certain application, since during the optimization the fundamental trade-off between competing objectives is identified. Also, in the inductor optimization, the device miniaturization and material savings are often limited not by the electromagnetic performance metrics, but rather thermal limits. This implies that a thorough optimization paradigm includes multi-physics aspects. The models used for the proposed assessment rely on coupling the electrodynamic behavior of the winding bundle, the magnetic solution of the inductor and the thermal model concerning the heat transfer between core, winding and ambient. The case studies included in this work evaluates AC and DC inductors with toroidal and racetrack parametrized geometries.

EU-02. Study on the Performance of HCFCL Considering Different Magnetic Materials. J. Yuan[1], *Z. Zhang*[1], P. Gan[1] and H. Zhou[1] *1. School of Electrical Engineering and Automation, Wuhan University, Wuhan, China*

The saturated-core fault current limiter (SCFCL) is a promising way to suppress high fault current[1,2]. In order to increase DC bias capability and reduce core loss of SCFCL, our research team proposed a novel hybrid-type SCFCL (HSFCL)[3]. The topology of HSFCL is shown in Fig. 1(a). Its equivalent electric circuit and equivalent magnetic circuit are shown in Fig. 1 (b) and Fig. 1 (c). In order to make HSFCL have better sensitivity and current limiting performance, four different soft magnetic materials are selected to compare their effects on performance of HSFCL in this paper[4]. Fig.2(a) shows the B-H curves of four chosen soft magnetic materials (silicon steel 30Q130, ferrite H5B2, permalloy 1J50 and amorphous alloy NANO-amorphous). Ferrite and amorphous alloy have high sensitivity and rapid response speed because of their large slope of the magnetization curve μ_e and relatively small saturation magnetic flux density B_s. However, when a short-circuit fault occurs, if B_s is very small and the slope of the magnetization curve μ_e is large, soft magnetic materials will reverse saturation

the current-limiting inductance L_{fcl} will be small. In order to compare the current-limiting performance of four ferromagnetic materials, four types of HSFCL models are built in ANSYS. As is shown in Fig.2(b), HSFCL with all four materials has obvious current-limiting effect. Among the four materials, HSFCL with silicon steel has the best current-limiting effect, but as we discussed before, silicon steel has the slowest demagnetization speed. Different magnetization curves of four soft magnetic materials also lead to difference in core loss and permanent magnet stability of HSFCL. Detailed comparisons and experimental results will be shown in the full paper. The simulation shows that amorphous alloy with rapid demagnetization speed and relatively large B_s may be the best choice for HSFCL. And the material with large B_s like silicon steel and rapid demagnetization speed like amorphous alloy may be a future research direction of magnetic materials.

EU-03. Study of thermal characteristics in variable inductor employing magnetic nanofluids driven by a high-frequency pulsed voltage source.
H. Lee[1] *1. Changshin University, Changwon-si, The Republic of Korea*

The characteristics of temperature rise were conducted experimentally and were tested numerically by adopting the multiphysics analyses technique in a variable inductor employing magnetic nanofluids(EFH series, Ferrotec Corporation). Recently, we presented a variable inductor which was developed by introducing the magnetic nanofluids resulting in the higher efficiency and the lower voltage shock in switching operation [1]-[2]. In a power inductor with high frequency, the temperature rise is critical issue and designers want to predict temperature rise while the circuit is operated. The core loss in this variable inductor is the main source of temperature rise in magnetic materials such as ferrite core and magnetic nanofluids for power electronics applications. The loss mechanism for ferrite is well known and relatively easily obtained the loss data from the manufacturer. However, for the magnetic nanofluid, such information is not readily available in the literature[3]-[4]. In order to evaluate the loss mechanism for the magnetic nanofluids, we first determined the electrical conductivity by use of our numerical results and measured the B-H curves with different temperatures. Finally, we measured and analyzed the inductance and temperature rise along with the average operating currents as shown in Fig. 1. The predicted temperature rise for a variable inductor showed good agreement with the experimental data and the developed magnetic-thermal-fluidic analysis technique can be employed to design a variable inductor with a high-frequency pulsed voltage source.

EU-04. Research on Hot-spot Temperature of Transformer with Nanopartical TiO_2.
X. Yang[1], G. Xu[1], Y. Zhang[3], L. Li[2], W. Fu[3], S. Ho[3] and Q. Yang[1] *1. Electircal Engineering, Hebei University of Technology, Tianjin, China; 2. Tianjin Polytechnic University, Tianjin, China; 3. The Hong Kong Polytechnic University, Hong Kong, Hong Kong*

With the increase of total economy, the power supply, which injects vigor into our society, has the more crucial position. Whereas the power transformer acts as the significant element of power systems, the hot-spot temperature inside the transformer tank should be calculated and measured accurately. Due to the hot-spot temperature has restricted the development of transformers, especially the oil-immersed transformer, so how to decrease the hot-spot temperature is a challenge for the researchers, engineers and manufacturers. Mineral transformer oil inside the transformer tank plays an essential role in transferring thermal, which produced by core loss, copper loss, stray loss and anomalous loss. Note, in 1995 Stephen had presented an innovative new class of heat transfer fluids, by suspending metallic nanoparticles to mineral transformer oil, exhibiting high thermal conductivities

compared to those of fluids without adding nanoparticles. Then the characteristics of cooling of transformer oil with nanoparticles can present excellent performance. Therefore, TiO_2 nanoparticles decorated with oleic acid to reduce agglomeration are added to mineral transformers oil as the coolant of a transformer. The transformer oil with different mass of fraction (0.005%, 0.01%, 0.02%, 0.05%, 0.1%, 0.2%, etc.) TiO_2 nanoparticle shows various performance through simulation and measurement. Through simulation and comparison finding the point of optimum operating temperature for each concentration. Then summarizing the optimum concentration from the results. During the measurement, the signal-phase transformer with power 500VA whose brand is DELIXI is adopted. The diameter of TiO_2 particles is under 100nm. Measuring the temperature of transformer oil adopts thermocouples on the different position inside the transformer tank. Then, to compare and analyze those results among each other, the best fraction is chosen as the ideal parameters, which can be as a reference for engineers or manufactures.

EU-05. A Novel Iron Core Structure Design for Power Transformers Considering Magnetostriction and Joints. *J. Li*[1], B. Qu[2] and K. Yu[3]
1. State Key Laboratory of Control and Simulation of Power System and Generation Equipments, Tsinghua University, Beijing, China; 2. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China; 3. Global Information and Telecommunication Institute, Waseda University, Tokyo, Japan

The magnetic-force-deformation model due to magnetostriction (MS) and Maxwell stress model caused by joints are developed based on the major sources of vibration and acoustic noise in power transformer iron core in this paper. On the basis of forces created by the two sources, structure finite element method (SFEM) is used to calculate the iron core vibration, and then calculate the acoustic noise. Meanwhile, a three dimensional (3-D) structure model of power transformer is constructed, the natural frequencies and vibration modes of each order modal of the main system components are obtained according to the modal analysis, and sufficient experimental testing is used to verify all the steps of the study in detail. In the end, a novel structure design of iron core with the core and winding position interchange is put forward. The testing results of the prototype show that it is an effective means to reduce vibration and acoustic noise of power transformers. 1. The magnetic field force will be fed into SFEM with Maxwell stress produced on the interface between iron core and air to calculate the deformation of the magnetic materials when magnetostrictive modeling is performed. The simplest MS tests will be carried out by using a single closed circle or rectangular electrical steel sheet. 2. Then, a sheet with joint will be used to analyze the vibration and modeling calculation. Maxwell stress caused by joints and magnetostrictive force due to the sheet MS are all actually included in the model. Later, further complicated two or more pieces of sheets are designed up and down on the joint of the simple circle or rectangular sheet to simulate the joints forms in the iron cores of transformers with the magnetic flux transition circulation though the joints. 3. Compared to conventional power transformers, a novel structure design of iron core for power transformer is put forward, with the core and winding position interchange, and there are many design advantages. Comparisons between simulation and test data are used to verify the effect of vibration and noise reduction of the novel iron core structure design.

EU-06. High frequency properties of Fe-1.5wt% Si powder cores.
J. Ahn[1], K. Lee[1], D. Lee[1] and J. Kim[1] *1. Hanyang University, Ansan, The Republic of Korea*

In order to improve the performance of electro-magnetic devices, these devices have been continuously required to increase the operation frequency and reduce the dimensions. Fe-Si alloys have been widely used in motors, inductors, etc., due to their high Bs and low magnetic anisotropy. However, the ductility and Bs of Fe-Si alloys decreased with increasing the Si content. It is, therefore, important to develop a new processing method for Fe-Si powder cores with high electrical resistance [1]. In this study, Fe-1.5wt%Si powders were coated of phosphate to minimize core losses. 2, 3 and 4wt% of phosphoric acid were added to acetone and 0.001wt% of sodium nitrite was added as a reaction accelerator. The FeP coating on Fe-Si powders with a size of 50~125μm were conducted in a thermostatic flask at 30°C for 30min. Before the FeP coating, the Fe-1.5wt% Si powders were heat treated at 1050°C in H_2 for 5hr to confirm a loss change due to crystal growth. The powders were compacted under a pressure of 1950MPa to form a toroidal shape. Then the compacts were annealed at 500°C for 30min under an Ar atmosphere. As shown in the Fig. 1, the FeP coating layer uniformly covers powders, and its thickness was less than 50nm. The density of the coated compacts reached a relative density of 97% despite the addition of Si and the FeP coating. Although the amount of phosphoric acid was changed, the density did not show any significant changes. This means that these powders have good ductility to form powder cores. As shown in the Fig. 2, there are not any significant differences between cores except the H_2 annealed core. The core loss of the cores is around 5.5W/kg at 50Hz, which is compatible to non-oriented commercial Fe-3.2wt%Si steel. The Eddy current loss was shown to be very low due to the high electrical resistivity of the compact. At 2kHz, the annealed core measured a core loss of 170W/kg while other cores measured around 230W/kg. These results clearly show that the Fe-1.5wt%Si powder cores coated with a FeP layer instead of Si electrical steels are applicable to devices working at a relatively high frequency.

EU-09. Analytical Modeling of Multiple Segment Permanent Magnet Eddy Current Brake with Hybrid Secondary.
B. Kou[1], *W. Chen*[1,2] and L. Zhang[1] *1. Harbin Institute of Technology, Harbin, China; 2. Harbin University of Science and Technology, Harbin, China*

I. INTRODUCTION Compared with the electric excitation brake, permanent magnet eddy current brake has the advantages of compact structure, high efficiency and high reliability[1]-[4]. The secondary of non-magnetic reaction material with high conductivity is generally used for low-speed braking. The magnetic reaction secondary with high permeability is widely used in high-speed braking, such as high speed train braking systems. However, in the ejection experiment, it is necessary to brake the ejection object from high speed to low speed, in order to avoid the ejection object broken. The hybrid secondary eddy current brake is the combination of the non-magnetic reaction secondary and the magnetic reaction secondary eddy current brake, which can make the secondary have higher braking force in both high speed and low speed. In this paper, a multiple segment permanent magnet linear eddy current brake with hybrid secondary was presented as shown in Fig.1. First, the structure and working principle were introduced. Then, the nonlinear analytic model is derived using the Maxwell's equations. The iron secondary was split into thin sheets of constant permeability, determined by an iterative procedure. The analytic model takes into account higher harmonics and secondary saturation. Therefore, the accuracy is observably improved. Finally, the accuracy of the analytical model is verified by the finite element method. II. MODEL VALIDATION Fig. 2(a) is the iron secondary and the copper secondary braking force characteristic. The maximum braking force of the copper plate appears at a low speed range (about 5m/s). As the speed increases, the braking force decreases rapidly. Fig. 2(b) shows the resultant breaking force of the two conductor plates. The secondary braking force maintains a stationary value from high speed to low speed.

EU-10. Numerical Study on Nanofluids Natural Convection Heat Transfer inside Power Transformer Windings. *Y. Zhang*[1], S. Ho[1], W. Fu[1], H. Wu[1] and X. Yang[2] *1. The Hong Kong Polytechnic University, Hong Kong, Hong Kong; 2. Hebei University of Technology, Tianjin, China*

I. Introduction Temperature rise is the major factor that limits the further advancement of power transformers in capacity and compactness. Although the thermal performance is improved through arranging the windings and cooling ducts reasonably, the inherent thermal conductivity of transformer oil is relatively small. Nanofluid is an innovative approach to improve the thermal conductivity of base fluid through dispersing nanoparticles of large thermal conductivity into it. The performance of nanofluid under natural convective mechanisms and in simple geometry has been studied numerically [1], which gives promising solutions when compared with the base fluid. In order to apply the nanofluid in transformer cooling, numerical method combined with the multiphase mixture model is employed to study the heat transfer inside nanofluid filled transformer windings in this paper. II. Numerical modeling The low-voltage windings of an ON transformer rated at 66 MVA are divided into four passes by the oil washers [2]. Except for the first pass, which has two more discs and an additional oil washer, each pass contains 19 discs. As is shown in Fig. 1, a 2-D axisymmetric model is built for the windings using the commercial software packages (Fluent) for fluid analysis. The coolant of the transformer is replaced by the SiC/oil nanofluid with the concentration of 1%, and the mixture model is introduced to the governing equations for the nanofluid. To determine the pattern of fluid motion, the nanofluid flow in the winding is treated as a conventional single-phase flow. The Reynolds number calculated for this problem is about 1000, which is much smaller than the critical value (2100) for laminar flow. Hence all the flows studied in this paper are laminar and no turbulence model is required. The second order upwind scheme is used for the spatial discretization of momentum and energy, and the problem is finally solved with the pressure-based solver in a coupled manner. The contours of the temperature of the winding cooled by nanofluid are shown in Fig. 2, and detailed results will be reported in the full paper.

EU-11. Modeling of Suspension Force on the Novel Integrated Five Degrees of Freedom DC Magnetic Levitated High-Speed Motor. *T. Zhang*[1], Z. Wang[1] and X. Ye[1] *1. Huaiyin Institute of Technology, Huai'an, China*

With the development of industrial technology, the speed of rotor is increasing, and the requirement of bearing performance is getting higher and higher. New types of bearings such as air bearing, liquid bearing and magnetic bearing have adopted. The magnetic bearings suspend the rotor by electromagnetic force, so that there is no mechanical contact between the rotor and the stator. Therefore, magnetic bearings have the advantages of no friction and wear, high rotor displacement accuracy, high supporting speed, no lubricants, and long service life [1]-[4]. Recently, magnetic bearings have been applied in flywheel energy storage, high-speed machine tools, turbo-molecular pumps and other equipment, and will replace traditional bearings in more fields, especially in vacuum, ultra-clean, ultra-high-speed, aerospace, nuclear energy, etc. In this paper, a three DOFs DC HMB is proposed, which is driven by three DC amplifiers in radial and axial direction, respectively. The characteristics of the three DOFs DC magnetic bearing are compactness, short axial length, simple control and automatic decoupling in the *x-y* direction. Firstly, the structure and suspension mechanism are introduced. Secondly, based on the equivalent magnetic circuit method, the

mathematic models are deduced. Finally, the simulation is carried out by the 3D finite element analysis. The theory analysis and simulation results have shown that the proposed hybrid magnetic bearing can achieve stable suspension, and the mathematic models are correct. A schematic diagram of the proposed five-DOF magnetic bearing is shown in Fig.1(a). The magnetic circuit of the proposed five-DOF magnetic bearing is schematically shown in Fig. 1(b). Fig. 2(a) shows the magnetic density. When the control winding currents are 0 to 5A, the variation curves of the suspension forces of the five-DOF DC magnetic bearing with respect to the control winding currents are shown in Fig. 2(b). The results of finite element simulation are basically in agreement with the theoretical values.

EU-12. Analytical Calculation to Evaluate Influence of Structural Parameters on Performance in a Single-sided HTS Linear Induction Motor. *W. Qin*[1] *1. Electrical Engineer, Beijing Jiaotong university, BEIJING, China*

With the development of superconducting technology, high temperature superconducting (HTS) LIM has been developed successfully shown as in Fig.1(a). Duo to the low ac loss and the high current density, the HTS LIM has the advantages such as low volume, light weight, high efficiency and high power density, and so on [1]–[2]. However, the structure of HTS LIM is very different from conventional LIM, and the material properties as the electrical conductivity and the magnetic permeability are more complicated than the conventional materials. Fig.1(b) shows the relationship of the critical current and background feild in the HTS tapes. To evaluate the performance of the HTS LIM, the traditional analysis methods should be modified by considering the material properties of the HTS. Previously, the influence of structural parameters on performance was presented in which the HTS motor was modeled using numerical methods such as FEA[1]–[4]. Although numerical methods are capable of providing the accurate results, it is a serious problem when optimization is applied. In order to reduce the computation burden further, the HTS LIM has been analytically modeled with considering the slot parameters, critical current and slot leakage flux density and so all shown as in Fig.2. The flux density and force created by this analytical model are compared with FEM and experimental measurement shown as in Fig.2 and Tab.1, respectively. The implementation of analytical method and the influence of structural parameters on performance in the HTS LIM will also be discussed in the full paper.

EV-01. Design and Fabrication of Miniature Magnetoelectric Antennas Using a Solidly Mounted Resonator Structure. *N. Sun*[2], Y. Gao[1], M. Sanghadasa[3] and N. Sun[2,1] *1. Winchester Technologies LLC, Burlington, MA, United States; 2. Electrical and Computer Engineering, Northeastern University, Boston, MA, United States; 3. U.S. Army Combat Capabilities Development Command Aviation & Missile Center, Redstone Arsenal, AL, United States*

One of the key challenges to state-of-the-art antennas lies in their size miniaturization. Conventional antennas rely on an EM wave resonance and require a size of more than one tenth of the EM wavelength λ_0. In this work, a new miniature magnetoelectric (ME) antenna is presented utilizing the multilayer Bragg reflector structure of a solidly mounted resonator (SMR) to enhance small scale antenna gain up to -16 dBi. The antenna radiates using a magnetoelectric heterostructure consisting of AlN and FeGaB, as the piezoelectric and magnetostrictive films respectively, with resonator diameters of 500 um and 1000 um. Different ME resonator shapes and sizes are designed, fabricated and compared along with varying anchor widths and lengths to provide better impedance matching. The acoustic resonance in the heterostructure films operates with an out-of-plane mode of vibration so that the thickness of each layer was optimized to produce a resonant frequency at 1.5 and 2.45 GHz to allow for seamless on-chip integration with WiFi, Bluetooth and GPS devices. The SMR structure replaces the freestanding membrane structure [1] with a Bragg acoustic reflector for concentrated energy confinement. The Bragg reflector was designed and fabricated with a quarter wavelength mode configuration to create maximum particle displacement in the AlN and FeGaB layers. Three periods of alternating low and high acoustic impedance films, using silicon dioxide and tungsten respectively, were deposited on top of a silicon substrate to provide greater acoustic resonance within the ME heterostructure. Antenna gain measurements were performed in an anechoic chamber using a GSG probe and a reference horn antenna linked to a vector network analyzer. The robust features of the SMR has more advantages compared to its FBAR freestanding membrane counterpart allowing for low cost monolithic integration, high operating frequency, better thermal dissipation and structural stability that will be vital for small-scale antennas and other wireless applications.

EV-02. Characteristics Analysis and Experimental Verification of a High-Speed Permanent Magnet Synchronous Generator with Magnetic Saturation Reactance Derived from Short Circuit Analysis. *H. Lee*[1], J. Lee[1], T. Bang[1], K. Shin[1], J. Nah[1] and J. Choi[1] *1. Electrical Engineering, Chungnam National University, Daejeon, The Republic of Korea*

In the initial design of a high speed permanent magnet synchronous generator (PMSG), the characteristics of voltage, current, and output can be calculated by using the equivalent circuit method (ECM). This is required to calculate

circuit constants in accurately, to obtain more precise output characteristics [1]. In general, when the ECM is applied to a PMSG, an equivalent circuit is constructed by using no-load reactance without considering magnetic saturation. However, this cannot predict the change in electromagnetic power characteristics because of the variation in magnetic saturation under load conditions. Therefore, in this paper, the magnetic saturation reactance is derived by using a short circuit analysis of a high speed PMSG. This is applied to the equivalent circuit to predict the output characteristics more accurately. PMSGs have a lower magnetic saturation under a load condition than under a no-load condition. Therefore, the inductance value changes. Fig. 1 shows the analysis model and the magnetic flux density distribution. Fig. 1(a) shows the analysis model. Fig. 1(c) shows the magnetic flux density under no-load analysis and that from a short-circuit analysis. Fig. 2 shows the results of the short-circuit analysis and load analysis. Fig. 2(a) shows a short-circuit current, and Fig. 2(b) shows the induced voltage and short-circuit current according to the rotation speed. Figs. 2(c) and 2(d) show the output characteristics obtained by applying the reactance derived from each result obtained from the rated speed. The results of the equivalent circuit composed of the derived circuit constants agree better with the finite element method than with the previous method. More detailed and experimental data will be presented in the full paper.

EV-03. Experimental Verification and Electromagnetic Characteristics Analysis of Wound-Rotor Synchronous Generator Using Magnetic Equivalent Circuit Method. *D. Kwon*[1], C. Kim[1], T. Bang[1], I. Yoon[1] and J. Choi[1] *1. Electrical Engineering, Chung-Nam National University, Daejeon, The Republic of Korea*

Global energy consumption has increased rapidly in recent decades. Improving energy efficiency using distributed energy resources (DER) is a key area of study. Hydroelectric power generation usage in DER systems is increasing [1]. There are typically two types of hydropower generators, induction generators and synchronous generators. The Wound-Rotor Synchronous Generator (WRSG) can maintain the rated voltage according to the load fluctuation, and is optimal for hydropower generators, coping with the change of operation characteristics [2]. The finite element method (FEM) is used for electromagnetic characteristics analysis of a WRSG, but its analysis time increases with size. This paper analyzed the magnetic field characteristics of a synchronous generator with a salient pole structure using a simple magnetic equivalent circuit (MEC) method to reduce the analysis time while considering saturation region. In the MEC, the analysis accuracy is increased by considering the non-saturated rotor shoe. Additionally, the FEM and MEC results were validated against experimental data. Figure 1. (a) shows the rotor core structure model and the WRSG FEM analysis. Figure 1. (b) shows the magnetic flux density for a 270 A DC in the rotor windings, and rotor shoe and pole. The MEC is shown in Fig 2. (a). For a salient pole structure, the rotor shoe is not saturated and is shown as an unsaturated reluctance in the MEC. The magnitude change of the no-load flux density with varying field current was compared for the MEC and FEM as shown Fig 2. (b). The FEM analysis and experimental results were compared to verify the short-circuit ratio and the generator V-curve, as shown in Fig 2. (c). and (d). Detailed analysis and results for the MEC are presented in the full paper.

EV-04. Design Criteria and Experiments Considering the Mechanical Characteristics of High-Speed Permanent Magnet Synchronous Generators of 8kW and 40krpm Class. *J. Lee*[1], K. Shin[1], G. Jang[1], T. Bang[1], D. Ryu[1] and J. Choi[1] *1. Electrical Engineering, Chungnam National University, Daejeon, The Republic of Korea*

High-speed permanent magnet machines are being applied to various industrial fields due to their many advantages such as application of direct-drive system without gear system, high power density, high efficiency, and miniaturization [1]-[2]. High-speed permanent magnet machines mainly use rare-earth-based permanent magnets having high magnetic flux density and coercive force. However, due to high-speed operation, structures to prevent damage and scattering of permanent magnets are essential in the design of a rotor, and it is indispensable to determine the mechanical characteristics [3]. In this study, we analyze and test a synchronous generator considering the mechanical characteristics of a rotor and a stator of Unmanned Aerial Vehicle (UAV) system operating at a high speed of 40 krpm. The structure of the designed high-speed synchronous generator is shown in Fig. 1 (a), and the rotor size of the generator was derived using the TRV equation. A sleeve was used to prevent the magnet from damage during high-speed operation. Sleeves must be accompanied by a design that takes into account the mechanical characteristics that change with thickness and, therefore, the electromagnetic characteristics. Thus, the thickness of the sleeve and the permanent magnet, considering the mechanical characteristics at the rated speed rotation, are selected through the rotor structure analysis, as shown in Fig. 1 (b). Fig. 1 (c) shows the comparison of the line-to-line counter-electromotive force at no load of the designed generator, obtained through the FEM and test. Fig. 1 (d) is a graph comparing the generated voltage and current during the load, obtained through the test according to the speed of the FEM and generator. The performance of the designed generator was evaluated by constructing a back-to-back system using a high-speed motor as shown in Fig. 2. The design criteria, analysis results, and measurements of the high-speed PMSM will be presented in more detail in the final paper.

EV-05. Experimental Verification and Analysis of Temperature Characteristics of Induction Generator Considering Stator Loss Distribution. *C. Kim*[1], G. Jang[1], D. You[2], C. Baek[1] and J. Choi[1] *1. Electrical engineering, Chungnam National University, Daejeon, The Republic of Korea; 2. Fire Safety Engineering, Chungnam State University, Chungnam, The Republic of Korea*

Induction generators are commonly used in hydropower installations owing to their numerous advantages such as reduced unit cost, ruggedness, ease of maintenance, and self-protection against severe overloads and short circuits. However, these advantages are a result of the cooling system and heat dissipation system of the induction generator. An accurate temperature analysis and verification of induction generators is therefore essential. In this study, the electro-magnetic characteristics and the temperature characteristics of the induction generator are analyzed, and the reliability of the analysis is verified experimentally. Electromagnetic loss in induction generators is mainly caused by eddy current losses, stator core losses, and copper losses. In this paper, the stator loss is analyzed, and the loss distribution is checked for each stator element. In the no-load operation, the copper losses and rotor eddy current losses can be neglected. Therefore, only the stator core loss is modeled as a heat source and the thermal analysis is performed. Fig. 1 (a) shows the analysis model of the induction generator. The rotor of the induction generator consists of a rotor bar and a rotor core, while the stator

consists of a stator winding and a stator core. Fig. 1. (b) and (c) show the rotor and stator fabrication models, respectively. Fig. 2 (a) shows the core loss per stator element. The stator consists of a shoe, tooth, yoke, etc., and it is possible to confirm that the loss distribution is different for each element. This is expressed as the amount of loss according to density, which can be seen in Fig. 2. (b). Model 1 is the heat source model for the total loss of the stator and Model 2 is the heat source model considering the loss distribution of each element. The result of the temperature analysis is shown in Fig. 2. (c). More detailed discussions, analysis results, and experimental results will be presented in the final paper.

EV-06. Electromagnetic analysis of interior permanent magnet motor with dual and single layer magnet rotor. C. Baek[1,2], *C. Kim*[2] and J. Choi[2] *1. R&D, Hanon-systems, Daejeon, The Republic of Korea; 2. Electrical engineering, Chungnam National University, Daejeon, The Republic of Korea*

The permanent magnet synchronous motor (PMSM) is considered a promising candidate for several industrial applications owing to its high torque density and efficiency. These advantages make the PMSM suitable for several types of components of electric vehicle systems [1-2]. In general, the PMSM structure comprises a distributed winding type stator and a surface mounted permanent magnet type rotor. This structure exhibits a sinusoidal electric characteristic for the convenience and robustness of control; however, it also has the disadvantages of heavy weight and an inner wire cooling limitation. To overcome these disadvantages, i.e., to directly connect to the load, to improve the inner wire cooling, and to be light and compact, the concentrated winding type stator is a good proposal [3]. This study proposes an electric compressor target setup process and PMSM design process, and investigates the dual layer (delta-shape) of the interior permanent magnet type rotor design to reduce the number of magnets in the concentrated winding type. The dual magnet position parameters are calculated using ANSYS Maxwell's finite element method for the optimum torque ripple at the main operating point of the electric compressor. Additionally, the magnet volume and weight are compared with those of the existing distributed winding type single IPM motor of a vehicle refrigerant compressor application. Fig.1. (a) Proposed dual layer concentrated winding permanent magnet synchronous motor. Fig.1. (b) Magnetic flux density distribution at 6,500 rpm and 6.5 Nm. Fig.2. Proposed dual layer concentrated winding permanent magnet synchronous motor test result (000–6,400 rpm at 6.6 Nm). More detailed discussions, analysis results, and experimental results will be presented in the final paper.

EV-07. Core loss analysis of a permanent magnet synchronous motor of an electric vehicle refrigerant compressor. C. Baek[1,2], *C. Kim*[2] and J. Choi[2] *1. R&D, Hanon-systems, Daejeon, The Republic of Korea; 2. Electrical engineering, Chungnam National University, Daejeon, The Republic of Korea*

In this paper, the results of the core loss analyses of a permanent magnet synchronous motor in the refrigerant compressor of an eco-friendly automobile are analyzed and compared. Based on the results, the method for more accurate core loss calculation is presented. First, the iron loss is analyzed using the classical Steinmetz equation, which is based on frequency

decomposition. [1][2] However, the harmonics of core loss not considered in this approach. As the power-density of the permanent magnet synchronous motor is considerably high, it is necessary that the harmonics of core loss are considered during core loss calculation. Therefore, the results obtained using the classical Steinmetz equation are compared to those obtained using the improved generalized Steinmetz equation (IGSE), in which the minor loop hysteresis loss is taken into account.[3] To consider the changes in effective resistance that occurs due to the skin effect, the eddy current loss is also analyzed using the homogenization technique. Finally, the improved hysteresis loss also is performed the consideration of the DC bias, using a commercial finite element analysis software, and it will be compared. Figure 1(a) shows the stator and rotor of a concentrated winding permanent magnet synchronous motor used for operating the refrigerant compressor in an air-conditioner of an eco-friendly vehicle. Figure 1(b) is at 6500rpm & 6.5Nm, shows the magnetic flux density distribution. Figure 1 (c) shows the flowchart of calculating the eddy current loss using the classical Steinmetz equation, the hysteresis loss calculating also based on the minor loop. The results obtained are listed in table I, and those calculated under a DC bias using the modified method are listed in table I. More detailed discussions, analysis results, and experimental results will be presented in the final paper.

EV-08. Quasi-3D Electromagnetic Analysis and Experimental Verification of Multi-pole Magnetization BLDC Motor. *H. Shin*[1], G. Jang[1], J. Lee[1], J. Nah[1] and J. Choi[1] *1. Chungnam National University, Daejeon, The Republic of Korea*

Brushless DC (BLDC) motors that use permanent magnets (PMs) have high power densities and incur low maintenance costs. Therefore, they are widely used in many applications. This paper presents a quasi-3D electromagnetic analysis of a multi-pole magnetization BLDC motor. The analysis model shown in Figure 1(a) has five permanent magnets (PMs) of multi-pole magnetization that makes two poles into one magnet. If the number of PMs are halved, the assembling time and manufacturing tolerance are also halved. In the multi-pole magnetization process, a polar separation section is generated by the structure of the magnetizer. To consider this section, a function of the magnetization pattern, which is shown in Figure 1(b), is applied to the analysis model. The function is assumed to decrease linearly in the polar separation section. As a result, the magnetic flux at the center of the PM is small as shown in Figure 1(c). This method will be verified by conducting an experiment on a manufactured multi-pole magnetization model in the final paper. Figure 2(a) shows a 3D configuration of the analysis model. These configurations require 3D analysis for accurate prediction of the electromagnetic characteristics. However, this consumes a considerable amount of time, making it inefficient in the design process. Therefore, in this paper, a quasi-3D electromagnetic analysis that corrects the 3D configuration to a 2D one is performed. The PM overhang is corrected by changing the operating point of the PM as shown in Figure 2(b) [1], and the housing-integrated rotor core is corrected by increasing the rotor core thickness. The validity of the quasi-3D electromagnetic analysis is verified by comparing the flux density at the air gap and the phase induced voltage at a no-load condition, as shown in Figure 2(c) and 2(d). Detailed explanations and experiment results will be presented in the final paper.

EV-09. Experimental and Comparative Study of Electromagnetic and Mechanical Aspects of a High-Speed Motor Using SmCo and Ferrite Permanent Magnets. *J. Woo*[1], T. Bang[1], C. Kim[1], I. Yoon[1] and J. Choi[1]
1. Electrical engineering, Chungnam National University, Daejeon, The Republic of Korea

A high-speed permanent magnet (PM) motor generally uses a rare-earth PM with a high coercive force and high residual magnetic flux density for the rotor structure. However, rare-earth PMs are expensive and are susceptible to price fluctuations based on the supply of rare-earth elements. Although it has low residual magnetic flux density, using a ferrite magnet instead of a rare-earth PM can ensure a more stable production of the rotor at a low cost. The diameter of the PM increases when using a ferrite magnet, and the sleeve thickness that withstands stress also changes. Additionally, the amount of interference between the sleeve and the PM should be set while considering the limit of the yield stress. In this paper, comparative study of a high-speed motor using smco and ferrite PMs at electromagnetic and mechanical aspects were performed through the analytical methods and the experiments, suggests that ferrite PM can replace rare-earth PM. An analytical method of stress analysis was performed to compare the stress due to the interference between the sleeve and the PM, for a set sleeve thickness based on the rotor diameter. Fig.2. (a) and (b) show the stress distribution caused by the interference. It shows that the stress generated by the selected interference does not reach the yield stress of the PM. In addition, circuit parameters including the air-gap magnetic flux density, back-EMF, and inductance of each model were derived using an analytical electromagnetic analysis. Fig.2. (c) shows the air gap magnetic flux densities according to the PM material in comparison with FEM and Analytical results, and Fig.2. (d) shows a comparison of the back-EMF of the rare-earth and ferrite PMs. A final comparison was carried out using the FEM and an experimental analysis. Further discussion and results are provided in the full paper.

EV-10. Optimal Design of Reducing Cogging Torque in the V-shape Interior Permanent Magnet Synchronous Motor Using Random Walk Method. *J. O*[1], M. Shin[1], K. Shin[1], T. Bang[1], J. Choi[1] and H. Cho[1]
1. Chungnam National University, Daejeon, The Republic of Korea

Interior Permanent Magnet Synchronous Motors (IPMSMs) with V-shape permanent magnets have advantages of high torque and high output in comparison with a flat-type permanent magnet because the pole magnetic flux increases as the permanent magnet cross-sectional area increases [1][2]. However, not only IPMSMs with a flat-type permanent magnet but V-shape-IPMSM can also easily generates a cogging torque that causes vibration and noise due to change in magnetic circuit by the interaction between the permanent magnet rotor and the stator slots [1]. On the other hand, the random walk method is one of the useful optimization techniques for finding the minimum or maximum value of the objective function, and can be applied to cases where the objective function is discontinuous at some points or cannot be differentiated [3]. In this study, we proposed optimum design technique of the V-Shape IPMSMs for reducing cogging torque by using the random walk method. Fig. 1 shows the basic model and design variables of the V-shape IPMSM. The two design variables are the chamfering angle of the stator teeth and the angle between the V-shape permanent magnets. chamfering angle and V-shape angle set constraint as follows. 0 < chamfering angle < 6.5 (deg.), 45 < V-shape angle <160 (deg.). Fig. 2 shows a comparison of the cogging torque waveforms according to the rotation degree(mechanical) for the basic model versus the optimum model. It can be seen that the peak to peak cogging torque of the optimum model is reduced by 96.63 [%] of the cogging torque from the basic model. In the full paper, the optimal design model of V-shape IPMSM with improved operating characteristics regarding the magnetic flux density and back EMF-THD will be presented. In addition, optimum design technique in electro-magnetic machines by using random walk method will be confirmed.

EV-11. Studies of Magnetic and Thermodynamic Characteristics Iron Core Under High Frequencies for Traction Motors. *R. Pei[1] 1. InnMag New Energy Ltd., Suzhou, China*

This paper mainly presents numerical modeling and experimental measurement of core loss and thermodynamic characteristics of an iron core in Permanent Magnet Synchronous Machine(PMSM) at various frequencies among 50Hz, 200Hz and 400Hz. Electrical Steel is of paramount importance as the EV traction motors. Thin-gage Non-Grain Oriented (NGO) silicon steel has been increasingly popular in high-speed and large-torque PMSM. A novel design strategy of PMSM will be described. The motor designed by authors is mounted on the vehicle and has 8 poles and 48 slots. The peak torque is 240 N.m. Three kinds of high-grade and thin NGO Silicon Steel sheets with 0.15mm, 0.30mm and 0.35mm are used in the stator and rotor, respectively. At first, the hysteric and eddy current loss of single electrical steel will be calculated, followed by measurement at different frequencies among 50Hz up to 400Hz. Then, the dynamic hysteresis loop and high-frequency harmonic losses will be accurately calculated with power loss and dimension of single sheet, which plays a key role in the total loss calculation, especially at high flux densities and high frequencies. The final section shows the numerical modeling and experimental results of (1) power losses of single sheet of non-grain oriented electrical steel, and (2) high-frequency iron core losses at 50Hz, 100Hz, 200Hz and 400Hz, which verify numerical algorithm. It is clarified that the numerical model and experimental iron core losses in each experiment are showed to be in good agreement. The numerical model for iron core losses and experimental results for single electrical steel sheet are especially useful to estimate power losses of electric machines running at higher frequency of 1000Hz~2000Hz. For different frequencies, the distribution of the thermodynamic model can be described by the iron core and the whole machine. Through the analysis and calculation, eddy-current loss is the main source that affects the thermodynamic characteristics of the motor. The speed-torque characteristic of electric motor made by these lamination electrical steels will be presented and discussed., which provides the direction for optimizing the cooling system of the motor.

EV-13. A Study on De-icing for Railway Turnouts Using 250kHz-200W-Class Induction Heating System. *H. Oh[1], C. Park[1], J. Lee[1], T. Kim[2], I. Jo[1], J. Lim[1], K. Seo[1] and H. Lee[1] 1. Korea National University of Transportation (KNUT), Uiwang-si, The Republic of Korea; 2. University of Michigan-Dearborn, Dearborn, MI, United States*

The railway turnout is one of the most important equipment in railway infrastructure [1]. Currently, an electric-heating wire is used as a heating device for a railway turnout. However, there are many drawbacks with the old technology, one of which is that the heating element requires a lot of power consumption [2]. Thus, the Induction Heating (IH) system is proposed that will replace the existing system. IH is a high-efficiency energy transfer system that transfers energy from the primary to the secondary without a medium [3]. In addition, since the use of high frequency reduces the skin depth of the secondary, a lot of heat can be generated on the surface of the secondary [4]. There are many limitations to be considered for the IH system in the turnouts. It should consume less power than the existing system and be designed to fit into the narrow space between the tongue rail and the main rail (see Fig. 1). Therefore, it is to design the heating system considering these limitations and introduced the Multi-physics method of the circuit, electromagnetic field, and thermal for the analysis of the IH system (see Fig. 2). The heating plate of the heating device needs to be heated only to the temperature at which the snow and ice melt. So, it was calculated by simulation that the heating plate requires about 200W loss to reach about 20°C.

The E-type core is reflected to shield the magnetic flux, and each inductance of the primary and secondary and the mutual inductance are calculated from the formula and designed to generate a loss of 200W on the heating plate. Also, IH devices should be installed within a narrow space, so the area is designed within 15×5 mm^2 size. To minimize the power, a resonant circuit was designed and analyzed in conjunction with an electromagnetic field model. In conclusion, the induction heating system which overcomes the limitation of the heating system for the railway turnout was designed, and the performance of the IH system was verified through introduced the Multi-physics method of the circuit, electromagnetic field, and thermal for the analysis.

EV-14. Design and application of the magnetic driven device in the microwave filtering tunable phase shifter. *F. Meng*[1], C. Ding[1] and S. Xu[2] *1. Harbin Institute of Technology, Harbin, China; 2. Emergency Department, First Hospital of Harbin City, Harbin, China*

In this paper, a novel magnetic driven device is designed and applied in the microwave filtering tunable phase shifter based on the liquid crystal (LC) technology. The proposed magnetic driven device composed of a pair of permanent magnets is utilized to generate the biased magnetic field which tunes the LC molecules of the filtering tunable liquid phase shifter (LCPS). This filtering tunable LCPS is based on the planar transmission line magnetically coupled with a series of split-ring resonators (SRRs). Under the action of the biased magnetic field induced by the magnetic driven device, the filtering tunable LCPS can simultaneously provide tunable phase shifts and self-embedded band-stop filtering function. Both the equivalent circuit model analysis and the transmission parameter characterization are afforded to comprehensively interpret the relationship between tunable phase shifts and stable filtering function. Then, the magnetic driven device and the filtering tunable LCPS are fabricated and tested, respectively. According to the measured results, the states of LC molecules are availably switched by the magnetic driven device. Thus, the filtering tunable LCPS not only achieves the stable stopband from 6.2 to 6.8 GHz but also realizes that the figure of merit (FoM) is more than 7.9 °/dB in the passband (from 4.0 to 6.1 GHz and from 6.9 to 10.0 GHz).

EV-16. Very Broad Bandwidth Permeability Measurement of Thin Film Using a Flexible Microstrip Line-Type Probe up to 67 GHz. *K. Nozawa*[1], L.T. Ton[1], K. Okita[1], S. Yabukami[1], Y. Endo[1], Y. Shimada[2], S. Saito[1] and R. Utsumi[2] *1. Tohoku University, Sendai, Japan; 2. Toei Scientific Industrial co.,Ltd., Natori, Japan*

High frequency permeability measurement of magnetic thin film is important as sensors and spintronic devices are fabricated from very thin films of less than 10 nm in thickness. However, almost all permeameters [1-2] can only measure samples with a width of no more than several millimeters and a thickness of more than 0.1 μm, and exceedingly few permeameters can measure thin films over 30 GHz continuously. In this study, we developed a flexible microstrip line-type probe, and using the probe we measured permeability up to 67 GHz without restriction on sample size (also applicable to wafer-sized samples). As shown in in Fig. 1, the probe was composed of a straight microstrip conductor (10 mm in length, 0.36 mm in width) on a flexible substrate (130 μm in thickness, ε_r =2.3), a ground plane, lead lines, and two connectors. The microstrip line sloped to meet the lead line at either end, and had slopes to maintain a characteristic impedance of around 50 Ω and to allow close contact of a large samples with the probe. A thin film was in contact with the microstrip conductor via a 0.1 mm thick PET film. In permeability measurement, firstly, S_{21} is calibrated by applying of a strong dc field (around 20 kOe) in the direction of the easy axis to saturate the magnetic film. Secondly, S_{21} is measured, and then the complex permeability is optimized using the Newton–Raphson method to take the skin effect of the magnetic film into account [3]. Fig. 2 (a) shows the hard–axis permeability of CoFeB film (45 mm x 25 mm, 0.5 μm in thickness) when bias fields of 14 kOe was applied along the easy axis, and (b) shows the ferromagnetic resonance (FMR) frequency as a function of dc field. The symbols show measured value, and the dotted lines and solid lines show the theoretical value on the LLG equation and eddy current generation. A damping factor of 0.02 and a *g* factor of 2.12 were used to calculate the theoretical permeability. The Results show that the measured permeability and FMR frequency agreed well with the theoretical value up to 67 GHz.

EV-17. Development of a spintronic vision system based on spin-torque diodes and its optimization for autonomous driving tasks. *G.D. Demin*[1,2], A. Buzdakov[2], N.A. Djuzhev[1], V.A. Bespalov[1] and K.A. Zvezdin[2] *1. R&D Center "MEMSEC", National Research University of Electronic Technology (MIET), Moscow, Russian Federation; 2. Laboratory of Physics of Magnetic Heterostructures and Spintronics for Energy-Efficient Information Technologies, Moscow Institute of Physics and Technology (MIPT), Dolgoprudny, Russian Federation*

Nowadays, development and searching for new solutions to the implementation of machine vision systems in vehicle control draw the attention of the scientific world. One of the crucial tasks is to ensure high accuracy in detecting road obstacles in the near vehicle zone in adverse conditions, such as bad weather, traffic overload, and poor lighting. One of the promising technologies capable of satisfying these requirements is the machine vision technology based on spin-torque diodes [1, 2]. A spin-torque diode is a magnetic tunnel junction, which demonstrates the effect of voltage rectification when microwave current flows through it. Spin-torque diodes have a sensitivity that substantially exceeds the sensitivity of semiconductor Schottky diodes [3]. Recently, it was shown that it is also possible to detect hidden objects located outside the line of sight by a microwave holography technique using spin-torque diode system [4]. Here we present a proposed spintronic machine vision system with a method of recording the amplitude of a reflected signal in the time domain by the array of spin-diode based microwave detectors. An experimental demonstration of this system was carried out using the setup consisting of the double-ridge horn antenna for transmission, several antipodal Vivaldi antenna elements for reception and a spin-diode based signal processing circuit (Fig. 1). Based on the experimental setup, we developed a finite-element model of microwave object detection system using an array of spin-torque diodes (CoFeB/MgO/CoFeB), the SPICE model of which was built by us earlier [5]. During the simulation, a frequency shift of the reflected signal on a spin-torque diode was detected when the object changed its position. The results show the effectiveness of using spintronic technologies to perform the tasks of near-field and far-field sensing of objects and can be used to improve the characteristics of the developed spintronic vision system for autonomous driving platforms. The work was performed using the equipment of R&D Center "MEMSEC" (MIET) and supported by the RF President Grant (No. 075-15-2019-1139).

EV-18. Magnetoelectric control of the microwave sensitivity of a spin-torque diode based on the magnetic tunnel junction with a ferromagnetic/ferroelectric bilayer by short THz electromagnetic pulse. *G.D. Demin*[1,2], A.V. Popov[1] and N.A. Djuzhev[1] *1. R&D Center "MEMSEC", National Research University of Electronic Technology (MIET), Moscow, Russian Federation; 2. Laboratory of Physics of Magnetic Heterostructures and spintronics for energy-efficient information technologies, Moscow Institute of Physics and Technology (State University), Dolgoprudny, Russian Federation*

Over the past decade, significant progress has been made in the development of spintronic microwave detectors based on spin-torque diode effect in magnetic tunnel junctions (MTJs), which demonstrate a microwave sensitivity of the resonant type up to 200 kV/W and higher [1]. This effect is due to the voltage rectification in MTJ as a result of microwave modulation of its resistance by input microwave current. However, to obtain such high sensitivity of spin-torque diodes, the presence of additional dc bias current (about 0.1-0.3 mA) is still necessary, which reduces the energy efficiency of such devices. In this regard, today an important task is to find alternative ways to control the sensitivity of spin-torque diodes in the absence of a bias current, which is associated with the consideration of new mechanisms providing low-energy manipulation of magnetization [2-4]. The ultrafast polarization switching of a ferroelectric layer by a short THz electromagnetic pulse seems very promising to solve this issue [5]. This phenomenon makes it possible to effectively control the magnetization state of the ferromagnet/ferroelectric bilayer as a part of MTJ via magnetoelectric coupling (Fig. 1). Moreover, the Joule heating of the MTJ with a microwave current may

provide an additional increase in the microwave sensitivity [6]. We consider this concept as applied to tune the sensitivity in spintronic microwave detectors in the absence of a bias current. The dynamics of ferroelectric domains in the MTJ ferroelectric layer under the action of THz electromagnetic pulse was studied, and a numerical analysis of the diode sensitivity as a function of the ferroelectric polarization state was carried out. The results obtained can be used in the development of low-power spin-torque diodes operating on a new magnetoelectric detection principle. The work was performed using the equipment of MIET Core Facilities Center "MEMSEC" and supported by the RF President Grant (No. 075-15-2019-1139).

EV-19. Theoretical Study on Lowering Loss of Skin Effect Suppressed Multi-layer Transmission Line with Positive/Negative (Cu/NiFe) Permeability Materials for High Data-Rate and Low Delay-Time I/O Interface Board. H. Nakayama[1], *Y. Aizawa*[2], K. Kubomura[2], R. Nakamura[1] and H. Tanaka[1] *1. Department of Electronics and Control Engineering, National Institute of Technology (KOSEN), Nagano College, Nagano, Japan; 2. Advanced Course of Production and Environment System, National Institute of Technology (KOSEN), Nagano College, Nagano, Japan*

INTRODUCTION - This paper proposes a new application of skin effect suppression technology [1]-[4] for long wiring on high-speed & low-delay I/O board. This proposal will overcome the difficulty of further reducing the transmission losses on the I/O board with >50 Gbps data rate. In previous research [5], it was demonstrated that suppression of the skin effect by electroplated conductor/magnetic multilayer, and estimated that the degree of transmission loss decrease at 16 GHz would be 5 %. A major challenge in this paper is to propose an electromagnetic field calculation theory for rectangular multilayer transmission line, verify it under the same conditions, clarify a lower loss structure by changing thickness of each layer. Also it is expanded to low loss design technology. *VERIFICATION* - Cu and NiFe were selected as metal conductor material and negative permeability magnetic material, respectively. The Cu and NiFe films are alternately stacked to form the multilayer, as shown in Fig. 1. The top and bottom surface layers are Cu layers. An electromagnetic field distribution, which considers of the skin effect in a rectangular multilayer transmission line, is derived based on Maxwell's equation. The current density of each layer and the total loss can be obtained by the equations (1) and (2) in Fig. 1. The loss suppression was compared under the following conditions. 1) Total number of layers is 33 and total thickness is 12.67 μm by a constant ratio, Cu t_N = 0.51 μm and NiFe t_F = 0.25 μm. 2) Optimal stacking determined by changing the thickness of each layer. *RESULTS AND DISCUSSION* - Fig. 2 shows the current density of multilayer transmission line. Compared to conventional thickness by a constant ratio, it was estimated that the loss is 90% in optimal thickness we proposed. By offsetting the phase change of current density, a lower loss structure could be determined. Compared with Cu conductor, the graph shows that the top and bottom surface current densities become low, and depth center current density becomes slightly high for the multilayer, showing the skin effect is suppressed.

Bioanalysis of a many samples in short times and at low cost is a challenge of modern times. It applies to health issues, but also to food safety, drug control, or environmental monitoring. One of the desired features of this technology is frequently that it can be used *in situ*. These requirements are fulfilled by the Lateral Flow Immunoassays (LFIA.) These are chromatographic tests based on nitrocellulose strips [1] on which the molecule of interest is immobilized by an immunoreaction and labelled to make it visible. This provides a presence/absence response. However, for many applications quantification of the analyte is needed. This must be addressed without compromising the advantages of the method regarding costs, duration, and portability [2], what leads us to the use of magnetic nanoparticles as labels. Their large magnetic permeability in the megahertz range can make them detectable. The sensor built in this work is based on three elements: (i) A conductive micro-track that is printed or sputtered on an insulating substrate and constitutes the sensing element [3], (ii) a 3D-printed polymer automatic positioner that slides the nitrocellulose strip on the sensing track, and (iii) a Colpitts oscillator that integrates the sensing track as inductor (Fig. 1). The active device in the Colpitts oscillator is a silicon Junction Field Effect Transistor (JFET) J310, and the capacitors are ceramic NP0 type, in order to minimize the frequency drift due to the temperature variations. A buffer stage is connected in cascade with the oscillator to reduce the influence of the frequency counter over the oscillator operation. The system has been tested with a series of LFIAs to detect neutravidin concentration (Fig. 2). The results were cross-checked and validated by reflectance measurements obtained with a commercial optical reader. The magnetic sensor proved better limit of detection and independence of the colour of the paper. This work was supported by the Asturian and Spanish Governments (MAT2017-84959-C2-1-R, MAT2016-81955-REDT and FC-GRUPIN-IDI-2018-000185) and IUTA-Gijon Council (SV-19-GIJÓN-1-25).

Ferrimagnet shows rich physics because two or more different sublattice spins interact with each other. In particular, if these two spins are coupled antiferromagnetically, not only the total magnetization but also the total angular momentum in ferrimagnet should be considered to explain the phenomena in dynamic properties. For ferrimagnet, which consists of transition metal and rare earth metal, the magnetization and angular momentum compensation points (T_M and T_A) are different because the g-factors of each spins are different[1]. Using Brillouin light scattering spectroscopy, we observed the inversion of Stokes-Antistokes intensities in surface spin wave mode at T_M and T_A, respectively, in Co_xGd_{1-x}(10)/Pt(5) system. This means that the mode in contact with the air and the mode in contact with the substrate is reversed at T_M and T_A, which leads to the conclusion that a left-handed spin wave exists between T_M and T_A. Moreover, we observed an increase of T_A in 0.83 Tesla magnetic field. Applying a magnetic field will change the total angular momentum of the system. To reach T_A, exchange fields should compensate the change of the total angular momentum. So, the interpretation of T_A in magnetic field supports the existence of left-handed spin wave. The reversal of the gyromagnetic ratio in $Ho_3Fe_5O_{12}$ at T_M and T_A, measured by macroscopic Barnett effect, also supports our experimental result[2].

EW-02. Controlling the Dzyaloshinkskii-Moriya interaction by varying the thickness of an oxide layer. *M. Arora*[1,2], J.M. Shaw[1] and H. Nembach[1,3] *1. National Institute of Standards and Technology, Boulder, CO, United States; 2. Physics, University of Colorado, Boulder, CO, United States; 3. JILA, University of Colorado, Boulder, CO, United States*

We demonstrate that both the magnitude and sign of Dzyaloshinskii Moriya interaction (DMI) can be tuned by varying the oxide layer at an interface adjacent to a ferromagnet. We studied Ti(3)/Cu(5)/$Co_{90}Fe_{10}$(1.5)/Ta(d_{ta})/Oxide/Ta(3) structures. The deposition of 0 - 3 nm of Ta was followed by an exposure to oxygen (thicknesses in nm). Here, "Oxide" can stand for TaO_x or $CoFeO_x$. Brillouin light scattering (BLS) is used to directly determine the asymmetric spin wave dispersion caused by an interfacial DMI in the relevant samples [1]. Since significant DMI at the bottom interface of Cu/CoFe is not expected and the Cu seed layer structure is kept constant for all samples, the variation in the measured DMI can be attributed to changes of the top interface between CoFe and the oxide layer. The observed volumetric DMI due to the CoFe /Oxide/Ta interface increased by a factor of six, accompanied by a sign reversal after first oxidizing the CoFe surface. The DMI showed further variation in sign and strength, with an increase of Ta thickness, which implies a thicker TaO_x at the interface. We attribute this change in DMI to the charge transfer between CoFe and oxide layer and the associated hybridization between 3d (CoFe) - 5d (Ta) electronic bands, that changes the 3d density of states at the Fermi level and hence the DMI [2]. Moreover, the changes in the magnetic anisotropy and the damping with the thickness of the Ta layer are related to the degree of oxidation of the CoFe interface. The initial formation of an oxide at the CoFe/Ta interfaces reduces the total damping, because any spin-pumping into Ta is suppressed. This study shows that in systems grown for applications, which are typically capped by Ta, the DMI interactions can be tuned by varying the thickness of the oxide layer. An understanding of the tunability of DMI at the interface may facilitate the development of next generation magnetic memory based on chiral magnetic structures. This research was supported by DARPA award No. R18-687-0004 and DOE award No. DE-SC0017643

EW-03. Manipulation of parametric spin wave mode in a Permalloy nanowire using Oersted field. *S. Hwang*[1], S. Han[2] and B. Cho[1] *1. School of Materials Science and Engineering, Gwangju Institute of Science and Technology, Gwangju, The Republic of Korea; 2. Division of Navigation Science, Mokpo National Maritime University, Mokpo, The Republic of Korea*

Manipulation of the parametric spin wave property of the Permalloy nanowire, controlled by electric current, has been intensively studied by micro-Brillouin light scattering (μ-BLS). Parametric pumping is a nonlinear wave phenomena and a promising technique for spin wave excitation, which shows threshold characteristics and high excitation efficiency for spin wave with large wave vector. Recent studies have shown that one can generate selectively the parametric spin wave mode in the microscopic waveguide by applying the external magnetic field, which enhances the applicability of the parametric process to magnonic devices [1]. Here, we demonstrate clear parametric pumping of quantized spin wave modes at five frequencies with low microwave power in a nanowire, characterized with width of 800 nm and length of 20 μm. From the electric current dependency of parametric threshold power, we have obtained the butterfly-shaped threshold characteristics at each frequencies, as shown in Fig.1. This indicates that the parametric mode can be selectivity excited by electric current instead of magnetic field. We also provide the direct evidence that the efficiency of parametric process decreases under the certain low field range at specific frequency when the hybridization of fundamental mode with exchange-dominant higher-order mode occurs. So, mode transition from hybrid one to single discrete one is found to be an important mechanism in the change of overall threshold characteristics in a sub-micro sized magnetic system. Figure 2 shows the mode crossing between the fundamental mode and higher-order ones at a specific frequency, f_2, in (a) analytic calculation and (b) experimental observation by μ-BLS.

Spin waves (SWs) are promising for highly efficient information processing and transmission at the nanoscale. The manipulation of propagating SWs quantized in nanostructured waveguides is a critical step toward the novel functionality. In this work we study the manipulation of quantized SWs propagating in YIG stripes by lateral proximate micromagnets. The SWs in YIG stripes are classified into two categories: the edge localized SWs (E-SWs) and the waveguide SWs (W-SWs). We use micromagnetic modelling to demonstrate a lateral proximate permalloy (Py) stripe along the YIG stripe (Fig. 1a) induces inhomogeneous static dipolar magnetic field ($H_{dip\text{-}Py}$) in width direction. The properties (wavelength λ, decay length δ and group velocity v_g) of the E-SWs can be manipulated (Fig. 1b) through a control of the $H_{dip\text{-}Py}$. In addition, the W-SWs contain a set of modes with integral quantization numbers interfered in the middle of the YIG stripe. We use a combination of micro-focused Brillouin light scattering (μ-BLS) and micromagnetic modelling to demonstrate the paths of the W-SWs are determined by the phase difference (Δφ) between the even and odd modes. The Δφ can be changed by the relative position of a proximate Py dot to the SWs excitation (Fig. 2a) and the external magnetic field (H_{ext}) in this magnetic structure (Fig. 2b)[1]. These results not only open new perspectives for the design of magnonic devices, but also provide ideal models in the fundamental physics of wave propagation.

EW-05. Spin wave modes in Permalloy nanowires detected by spin orbit torque induced ferromagnetic resonance. *J. Xu*[1], Y. Quessab[1] and A.D. Kent[1] *1. physics department, New York University, New York, NY, United States*

Spin torque ferromagnetic resonance (ST-FMR) is a convenient method to determine the magnetization, magnetic anisotropy and Gilbert damping of nanostructures. It also provides a way to extract both the field-like and damping-like spin torque. Here we study spin-wave excitations in permalloy nanowires to examine finite size effects on the spin-wave spectra. The basic questions we seek to address are the selection rules for exciting and detecting higher order spin-wave modes in nanowires. We studied trilayer heavy metal (HM) – ferromagnet – heavy metal heterostructure nanowires. Permalloy (Py) is used as the ferromagnetic layer due to its large anisotropic magnetoresistance (AMR) and low damping. Platinum (Pt) and tantalum (Ta) are used as heavy metal layer because they have large but opposite spin Hall angles. We used magnetron sputtering to deposit the films, and then the films are patterned into nanowires of various widths, from 150 to 1000 nm. A GHz frequency current is injected into the wire to generate an oscillating spin torque that drives magnetization precession. Due to AMR the resistance oscillates at the same frequency, such that a DC voltage is induced and can be used to detect the spin-wave excitations. In our measurements, we fix the frequency and sweep the external magnetic field, including a small field modulation to increase the signal-to-noise ratio. Figure 1 shows the spectrum of ST-FMR signal at different frequencies for wires of two different wire widths. The small difference between these spectra indicates that we are exciting the lowest frequency mode, the most spatially uniform mode in the width of the nanowire. In figure 2, a fit to the Kittel relation gives the magnetization (mu0 Ms = 1.11 T) and gyromagnetic ratio (gamma/2pi = 27.2 GHz/T). In this presentation, we will describe the conditions for exciting higher spin-wave order modes by ST-FMR.

EW-06. Spin-Wave Dynamics in Planar Connected Ferromagnetic Nanodot Arrays. S. Sahoo[1], S.N. Panda[1], *A. De*[1], Y. Otani[2] and A. Barman[1] *1. S. N. Bose National Centre for Basic Sciences, Kolkata, India; 2. University of Tokyo, Tokyo, Japan*

Two-dimensional (2D) nanodot arrays have long been interesting systems due to spin configuration, reversal properties, and spin dynamics as well as their potential applications in high density magnetic storage, memory, logic, transistor and communication devices. Several studies have reported the magnetization dynamics in 2D isolated nanodot arrays where the nanodots are magnetostatically coupled. Here, we investigate the spin-wave (SW) dynamics of square $Ni_{80}Fe_{20}$ nanodot arrays joined by rectangular nano-connectors of the same material which directly couple the dots via exchange interaction. The $Ni_{80}Fe_{20}$ nanodot arrays of thickness 20 nm are fabricated by using the combination of e-beam lithography and e-beam evaporation on Si (100) substrate. The nanodot width (connector length) varies as 900 (300), 600 (200) and 300 (100) nm, while the connector width is kept fixed at 300 nm. Custom build time-resolved magneto optical Kerr effect microscope is exploited to probe the precessional dynamics. The damped nonuniform oscillation shows multi-modal precession with high stability with bias magnetic field (H). The fast Fourier transform spectra of the time-resolved traces show the presence of four distinct SW modes for all three arrays. Further, the spatial profiles of the SW modes reveal that the lowest frequency mode forms an extended Damon-Eshbach(DE)-like mode. On the other hand, the two intermediate frequency modes from backward volume(B-V)-like standing wave modes whose quantization numbers increase with increasing frequency. Theses modes are coupled between the dots via the vertical connectors (VC), perpendicular to H. The highest frequency mode shows a mixed DE-BV-like behavior where the power of the mode is mainly concentrated inside the horizontal connector (HC) parallel to H. This mode is coupled between the dots via both HC and VC though the maximum power is concentrated inside HC. We have further numerically demonstrated the modulation of the highest frequency mode due to exchange coupling by varying the length of the connector. The observed modulation of SW dynamics in this new class of magnonic crystal opens the possibility of development of novel communication devices.

EW-07. Frequency Selective Spin-Wave Valve and Phase-Shifter in Damon-Eshbach Geometry. *K.G. Fripp*[1], F. Mushenok[1], V.D. Poimanov[2] and V.V. Kruglyak[1] *1. Physics and Astronomy, University of Exeter, Exeter, United Kingdom; 2. Donetsk National University, Donetsk, Ukraine*

The future of spin-wave logic devices requires us to excite spin waves with short wavelength and then to control their amplitude and / or phase at the nanoscale. Au et al demonstrated that a magnetic nano-element

formed above a longitudinally magnetised magnonic waveguide can act as an efficient spin-wave transducer, valve and phase shifter [1,2]. Here, we use micromagnetic simulations to extend this concept to the case of a an element magnetised orthogonal to the direction of spin-wave propagation, i.e. Damon-Eshbach geometry. This system is able to control the propagation of spin waves along the waveguide via magneto-dipolar coupling to the magnetic nano-element [1,2]. The direction of the magnetisation of the nano-element controls if spin waves are transmitted, reflected, or absorbed in the element. We explain our observations are explained in terms of the Fano resonance between the discrete spectrum of spin-wave modes of the nano-element and the spin-wave continuum in the waveguide, where a frequency dependent non-reciprocity in transmission is observed when the spin-wave wavelength becomes comparable to the width of the nano-element. Surprisingly, the switching of the confinement region of the magnetic field above or below the waveguide depending upon the direction of spin-wave propagation does not appear to explain the difference in coupling strength to the nano-element from the stray field. The research leading to these results has received funding from the EPSRC of the UK Project No. EP/L019876/1 and from the EU's Horizon 2020 research and innovation program under GA No. 644348 (MagIC).

EW-08. Unique Spin Wave Eigenmodes of Magnetic Domain Walls.

I. Purnama[1] and C. You[1] *1. DGIST, Daegu, The Republic of Korea*

Magnon, also known as spinwave (SW), have been investigated as a novel mean to drive both magnetic domain walls (DWs) and skyrmions in a patterned magnetic nanowire [1,2]. The mechanism of these SW-driven motions were then attributed to the transfer of linear momentum or angular momentum from the SW to the DW or the skyrmion. In application point of view, this method is attractive because it practically eliminates the Joule heating that normally happens when the DWs or skyrmions were driven by electrical current instead. In this work, we show that by calculating the transmission matrix of the SW, the presence of the DW in the nanowire alters the SW eigenmodes of the system. In the case of nanowire with in-plane magnetization anisotropy (IMA), the presence of transverse DW creates an asymmetrical defect in the shape of the SW eigenmodes. This asymmetry is also found to be related to the chirality of the transverse DW, with right-handed and left-handed DW having opposite defect in the SW eigenmodes. In the case of nanowire with perpendicular magnetization anisotropy (PMA), the SW eigenmodes of the PMA DW is found to differ depending on whether the DW receives linear or angular momentum from the SW. In the case where there is a linear momentum transfer from the SW to the DW (frequency of SW = 41 GHz), the transmission matrix shows us that the system has three distinct eigenmodes; while in the case of angular momentum transfer (frequency of SW = 45 GHz), the transmission matrix shows us that the DW only has two SW eigenmodes. The result is unexpected because in the case where no DW was present, higher SW frequency typically would excite more SW eigenmodes instead of suppress them. The study of unique SW eigenmodes in both IMA and PMA systems shall then further our understanding of the relation between SWs and topological defects such as DWs and skyrmions.

EW-09. The Realization of Spin-Wave Frequency Division Multiplexer via Laterally and Inhomogeneously Magnetized Microstripe.

Z. Zhang[1,2], M. Vogel[1], J. Pearson[1], R. Divan[3], A. Hoffmann[1], Y. Nie[2] and V. Novosad[1] *1. Materials Science Division, Argonne National Laboratory, Lemont, IL, United States; 2. School of Optical and Electronic Information, Huazhong University of Science and Technology, Wuhan, China; 3. Center for Nanoscale Materials, Argonne National Laboratory, Lemont, IL, United States*

Modern computation requires parallel data processing and transmission at different frequencies simultaneously in a single line, where the frequency division multiplexer (FDM) play an important role in the separation of mixed signal. In microwave engineering, one traditional idea to realize the FDM function is the application of a set of resonators with different center frequencies. The corresponding signals then propagate in various channels with the highest efficiencies and consequently the hybridized signals are distinguished. In magnonics, it has been similarly reported that the specific frequency spin waves (SWs) in the waveguide could reach the highest intensity near the ferromagnetic resonant (FMR) field[1]. In this work, we use micro Brillouin light scattering (μ-BLS) to demonstrate that the spin-wave FDM function can be realized in 3-μm wide yttrium iron garnet (YIG) microstripe laterally and inhomogeneously magnetized by proximate 2-μm wide permalloy (Py) stripe (Fig. 1). The results show the YIG stripe

supports the simultaneous propagation of 4 GHz and 4.4 GHz SWs (Fig. 2a). Meanwhile, images of the BLS intensities integrated around the excitation frequencies indicate the lower (higher) frequency SWs propagates in the region far away from (close to) Py stripe (Fig. 2b) due to the weaker (stronger) effective field. These results show a new method to divide the SWs with different frequencies hybridized in a signal waveguide. This paves a way toward the parallel processing and transmission of the SWs encoded data.

EW-10. Spin dynamics driven by optical spin-orbit torque. *R. Mondal*[1], A. Donges[1] and U. Nowak[1] *1. Department of Physics, Universität Konstanz, Konstanz, Germany*

The manipulation of spins by using light has become an intense research area due to its potential applications in future technological devices [1]. Here, we discuss a direct interaction of spins with the light by using the spin angular momentum of a laser pulse, an effect which is different from the Zeeman effect. It exerts a torque on the spins that is named "optical spin-orbit torque" (OSOT) which originates from relativistic spin-orbit effect [2]. Starting from the Dirac Hamiltonian, we derive a general spin-orbit coupling Hamiltonian that accounts for both, the internal and external fields (laser). Such a spin-orbit coupling term, between electron spins and the light's angular momentum, leads to OSOT on the magnetization. Our preceding analytical calculations show that the OSOT depends on the intensity, helicity, and frequency of the light. Depending upon the absorption and intensity of the light, the equivalent opto-magnetic field which is induced by OSOT can range from several mT to T. Finally, we investigate spin dynamics that is triggered by OSOT for magnetic model systems.

EW-11. Terahertz Spectrum in SHNO Driven by the Pure Spin Current. *B. Jiang*[1], W. Zhang[1], H. Zhong[1], Y. Zhang[1], S. Yu[1], G. Han[1], G. Liu[1], S. Yan[1], S. Xiao[1] and S. Kang[1] *1. school of physics, Shandong university, Jinan, China*

We studied the auto-oscillation spectrum of spin Hall nano-oscillators (SHNO) based on synthetic antiferromagnets (SAFs) by micromagnetic simulations. In our model, Py/Ru/Py is used as the synthetic antiferromagnet (see the inset of Fig. 1), and the typical heavy metal Pt is used to generate the pure spin current via spin Hall effect (SHE). The pure spin current perpendicularly flows into SAF and drive the magnetizations in SAF to precession. We found that the oscillation frequency of the nano-gap SHNO driven by the pure spin current can reach terahertz once the Ruderman-Kittel-Kasuya-Yosida (RKKY) intensity of SAF and current density are reasonably strong. This terahertz spectrum can be excited even without any external magnetic field. The competition between RKKY interaction and SHE definitely boost up the dynamics of magnetization in SAF. As illustrated in Fig. 1, the terahertz spectrum can be tuned by DC current and/or RKKY intensity. Moreover, we studied the influence of the thickness of SAF on terahertz spectrum. It is found that the thickness of bottom magnetic layer in SAF should be relatively thinner than that of top magnetic layer in SAF in order to obtain the terahertz spectrum. Finally, the nonreciprocity of generated terahertz spectrum is demonstrated by introducing DMI between HM and SAF. Our results suggest a possible way to exploit terahertz spintronics devices.

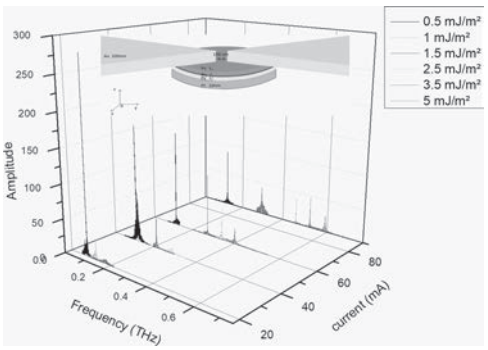

Fig.1: The FFT intensity of magnetization dynamics of the bottom magnetic layer in SAF for different RKKY intensity and DC current. The inset is the schematic drawing of SHNO.

EW-12. Spin Wave Spectra of 1D and 2D V[TCNE]$_{x\sim2}$ Magnonic Crystals. *K. Hu*[1] and M.E. Flatté[1,2] *1. Optical Science and Technology Center and Department of Physics, University of Iowa, Iowa city, IA, United States; 2. Pritzker School of Molecular Engineering, University of Chicago, Chicago, IL, United States*

The organic based ferrimagnet, vanadium tetracyanethylene (V[TCNE]$_{x\sim2}$) has received much attention recently as an attractive magnonic material. V[TCNE]$_{x\sim2}$ has ultra narrow ferromagnetic resonance, low Gilbert damping constant and high Q factor [1-3]. Furthermore, V[TCNE]$_{x\sim2}$ can be fabricated on various rigid and flexible substrates using low temperature chemical vapor deposition (CVD) [4]. These properties make V[TCNE]$_{x\sim2}$ a promising alternative to traditional magnonic crystals like yttrium iron garnet (YIG). Here, we present theoretical calculation of the band structures and linewidths of magnonic crystals of V[TCNE]$_{x\sim2}$. The calculation is based on Landau-Lifshitz-Gilbert (LLG) formalism [5]. We consider quasi one-dimensional and two-dimensional infinitely periodic heterostructures with other ferromagnets such as YIG and cobalt. First, we consier infinitely long cylinders of one magnetic material embedded in a second magnetic material forming a square lattice structure. Second, we study alternating finite slabs of magnetic materials as one-dimensional magnonic crystals. All calculations are done assuming an applied magnetic field of $\mu_0 H_0$=0.1T and a lattice constant of a=100nm. These results further the fundamental understanding of magnonic behavior in V[TCNE]$_{x\sim2}$ necessary for future application. We acknowledge support from NSF EFRI NewLAW under Award No. EFMA-1741666.

Periodically patterned metamaterials are known for exhibiting wave properties similar to the ones observed in electronic band structures in crystal lattices. In particular, periodic ferromagnetic materials, also known as magnonic crystals, are characterized by the presence of bands and bandgaps in their spin-wave spectrum at tunable GHz frequencies. Recently, the fabrication of magnets hosting Dzyaloshinskii-Moriya interactions has been pursued with high interest since properties such as the stabilization of chiral spin textures and nonreciprocal spin- wave propagation emerge from the antisymmetric exchange interaction. In this context, to further engineer the magnonic band structure, we propose the implementation of magnonic crystals with periodic Dzyaloshinskii- Moriya interactions, which can be obtained, for instance, via patterning of periodic arrays of heavy metals wires on top of an ultrathin magnetic film. We demonstrate through theoretical calculations and micromagnetic simulations that such systems show a unique evolution of the standing spin waves around the gaps in areas of the film that are in contact with the heavy metal wires. We also predict the emergence of flat magnonic bands and indirect gaps, demonstrating that these effects depend on the strength of the Dzyaloshinskii- Moriya interaction. This study opens further pathways towards engineered magnonics for spin- wave-based devices.

EW-14. Spin wave localization in a magnonic crystal with defects. *C.L. Ordonez Romero*[2], Z. Lazcano-Ortiz[1], G. Pirruccio[2], M. Urbánek[3], T. Hrncir[4], N. Qureshi[5], O. Kolokoltsev[5] and G. A broken translational symmetry in a magnonic crystal via the introduction of tailored defects can beneficially enhance or modify its properties leading to scenarios with outstanding capabilities to connect fundamental physics with applications at microwave frequencies. Their characteristics have inspired multiple studies where detailed results on the behavior of the frequency-amplitude characteristic as a function of different structural parameters have been demonstrated [1]. However, up to now, all the scientific reports deal exclusively with the resulting spin wave spectrum for the complete structure and little has been said about the behavior of the spin wave inside the defects. Here, we present a detailed study of the propagation of surface spin waves (MSSW) through a MC with broken translational symmetry, the influence of the defect in the spin wave propagation, the evolution of frequency bandgaps inside the MC, and the spatial energy distribution as a function of frequency and position. A time and space resolved magneto inductive probing system has been used to map the spin wave propagation in a magnonic crystal with tailored defects. The results show that the spin wave modes get trapped by the defect and the energy is localized in the space for specific frequencies.

While micro- and nanosized magnetic elements are widely used in various microwave applications, the analytical description of spin waves that govern their magnetodynamic response is a complicated problem. This is because of the inhomogeneity of the internal demagnetizing field limiting finding exact eigenfrequencies to only few cases of simplest symmetry – circular disks and infinite stripes. Here, we employ a dipole-exchange spin-wave dispersion equation from Ref. [1] to deduce magnetization and exchange

constant for individual Co-Fe nanodisks. The disks were directly written by focused electron beam-induced deposition [2] and studied by broadband ferromagnetic resonance spectroscopy with external magnetic field applied along the normal to sample plane. The finite disk radius leads to the quantization of the in-plane spin-wave vector and gives rise to resonance drum modes with circular Bessel-function profiles (Fig. 1). We were able to record spin-wave spectra with high signal/noise ratio (shapes of at least 8 peaks can be analyzed) from the individual Co-Fe disk with thickness L = 40 nm and radius R = 200 nm, but even for the disk with R = 100 nm the positions of 3 peaks were detected (Fig. 2). The analytical theory has been generalized for large aspect ratios $L/R \leq 0.5$ and found to agree well with numerical simulations. The proposed approach is especially valuable for the characterization of magnetic materials that are unavailable in large arrays or in bulk form.

FA-01. Hybrid Magnon Modes: Strong Coupling with Phonons and Photons. *G. Bauer*[1] *1. Institute for Materials Research, Tohoku University, Sendai, Japan*

The strong coupling of the magnetic order with the phonons and photons opens the vista of coherent control of the magnetic order by the lattice and electromagnetic fields, respectively. The dynamics of the electrically insulating ferrimagnet yttrium iron garnet (YIG) [1] has superior magnetic, acoustic, and optical quality factors and is therefore the material of choice to achieve this goal. In this symposium I will report the progress of several collaborations on the "spin cavitronics" of YIG with microwaves [2], infrared light [3], and lattice vibrations [4] with emphasis on theoretical/conceptual aspects.

Recently, magnon-based hybrid systems have attracted increasing interests as a new branch in spintronics research [1-3]. Due to diverse coupling mechanisms, magnons can be coupled to a wide variety of excitations including microwave photons, optical photons, phonons, and other magnons. In addition, the excitation frequency of magnons can be easily tuned by an external magnetic field, which is highly desired for controllable hybrid systems. Magnon-based hybrid systems exhibit many physical phenomena, such as mode anti-crossing, Rabi oscillation, and level attraction. They are promising for coherent information transfer between distinct physical platforms, which may ultimately be useful for quantum information science where information can be carried by both the quanta and the phase of the excitation states. One requirement for coherent information transfer is to reach a coupling strength that is larger than the damping rate. Up to date, most studies are based on low-damping yttrium ion garnet (YIG) spheres or thick films, which are beneficial for strong coupling strength but unfavorable for scalable on-chip-integrated applications. In this talk, we will explore the use of permalloy ($Ni_{80}Fe_{20}$) thin films in hybrid magnon systems. Permalloy is a classical metallic ferromagnet with well-known magnetic dynamic properties and is easy to grow and integrate into complex devices. In the first part, we demonstrate strong coupling of magnons in a permalloy thin-film device to the microwave photons in a coplanar superconducting resonator [4]. The coupling is introduced by the magnetic dipolar interaction. Owing to the small mode volume and high-quality factor of the superconducting resonator, a large coupling strength of 0.152 GHz and a cooperativity of 68 can be achieved for a 30 nm thick permalloy device, along with a coupling efficiency of 26.7 Hz for a single Bohr magneton. In the second part, we show strong coupling of permalloy magnons to the spatially nonuniform magnon modes of a YIG film in a permalloy/YIG bilayer structure. The two layers are coupled by interfacial exchange coupling as a field-like torque. In addition, we show evidence that spin pumping creates a damping-like coupling torque. This torque leads to an increase in line width for the out-of-phase hybrid mode and a reduction for the in-phase hybrid mode. Our results provide new pathways for implementing on-chip magnonic devices with efficient and coherent information transducers. This work was supported by the U.S. DOE, Office of Science, Materials Sciences and Engineering Division and as part of Quantum Materials for Energy Efficient Neuromorphic Computing, an Energy Frontier Research Center funded by the U.S. DOE, Office of Science.

FA-03. Strong Coupling between Microwave Photons and Nanomagnet Magnons. J.T. Hou[1] and *L. Liu*[1] *1. MIT, Cambridge, MA, United States*

Hybrid quantum systems have been extensively studied to harness advantages of distinct physical systems and realize functions that cannot be achieved with any individual sub-system alone. In particular, cavity and circuit quantum electrodynamics (Cavity/Circuit QED) provide promising platforms for realizing hybrid quantum systems using Josephson qubits, mechanical systems, atoms, quantum dots, as well as ensembles of spins. Recently, coupled microwave photon-magnon systems have received great attention as a potential approach to realize strong light-matter interactions. To overcome the weak coupling strength between a single spin and the

microwave field, millimeter size ferromagnetic metals or insulators with large spin numbers have been employed for reaching strong coupling. While great success has been demonstrated in achieving coherent sensing and control over the magnonic quantum state using this architecture, one important question remains unanswered: whether such a system is scalable for achieving integrable hybrid quantum systems. In this talk, we will show that by enhancing single spin coupling strength using lithographically defined superconducting resonators, we can reach high cooperativities between a resonator mode and a Kittel mode in nanometer thick Permalloy wires (Fig. 1), where the number of spins for reaching strong coupling is reduced by more than 3 orders of magnitude compared with previous studies [1]. Moreover, we confirm the scaling law of coupling strength by varying Py magnetic volume and extract the single spin coupling strength, which agrees well with the theoretical value derived from analytical model (Fig. 2). This highly engineerable device design and the large coupling strength with nanomagnets provides a direct avenue towards hybrid quantum systems which can benefit from various magnon physics, including nonlinearity, synchronized coupling, non-Hermitian physics, as well as current or voltage controlled magnetic dynamics.

FA-04. Cavity Optomagnonics: Lessons from Quantum Optics for Magnons. *S. Viola Kusminskiy*[1,2] *1. Max Planck Institute for the Science of Light, Erlangen, Germany; 2. Friedrich-Alexander University Erlangen-Nuremberg, Erlangen, Germany*

Optomagnonics studies the quantum-coherent coupling of light to collective magnetic excitations in solid state systems. The magnetic material hosting the magnetic excitations can be also used as an optical cavity if patterned appropriately. This not only enhances the magnon-photon coupling (making these systems promising for applications in quantum technologies) but also allows studying cavity-modified light-matter interaction in a novel platform. In my talk I will go over the basics of cavity optomagnonics and present results on recent theory developments in my group, including optomagnonics with magnetic textures, optical heralding of magnon Fock states, and antiferromagnetic cavity optomagnonics.

FA-05. Endowing Phonons with Spin via Coherent Coupling with Magnons. J. Holanda[1], D.S. Maior[1], *A. Azevedo*[1] and S. Rezende[1]
1. Department of Physics, Federal University of Pernambuco, Recife, Brazil

Spin waves (magnons) play a key role in many spintronics phenomena. For instance, they are responsible for the spin current flow in magnetic insulators and they can interact with other elementary excitations, such as phonons, photons, electrons, polarons, etc. In particular, magnons can strongly interact with phonons in materials with magnetostrictive interaction, creating hybrid magnon-phonon excitations (magnetoelastic waves). The interconversion between magnons and phonons was extensively investigated in the past in bulk samples of the ferrimagnetic insulator yttrium iron garnet (YIG) with the shape of rods and disks that have internal nonuniform magnetic fields. At that time, the research was mainly driven by applications in delay line technology. In this talk, we present an investigation of the conversion of magnons, generated by microwave fields, into phonons in a YIG film in the presence of a non-uniform magnetic field. We will present results obtained by means of two different experiments. First, we used pulsed microwave signals to launch spin-wave packets at one end of the YIG strip and use time resolved measurements to observe the delayed pulse at the other end of the film. Second, we used wave-vector resolved Brillouin light scattering (BLS) to measure the field dependence of the signal generated by continuous (CW) microwave driving, at various positions of the YIG film under a nonuniform field. Comparison of the measured time-delay vs field and wavevector vs field dependencies with calculations using the magnetoelastic wave dispersion shows that the magnon-phonon conversion occurs with constant energy and varying linear momentum. While it is well established that photons in circularly polarized light carry a spin, the spin of phonons has had little attention in the literature. With the BLS experiments we show that the light scattered by the phonons generated in the magnon-phonon conversion process is circularly polarized, thus demonstrating that the phonons carry angular moment [1].

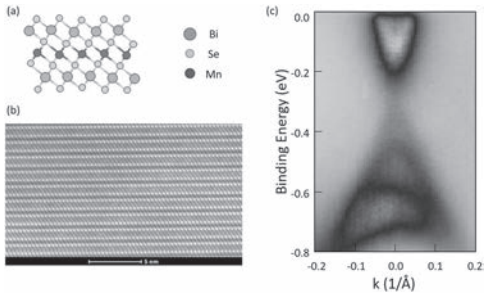
Peter Grünberg Institute (PGI-9), orschungszentrum Jülich, Jülich, Germany*



We present time-resolved Kerr rotation measurements in monolayer $MoSe_2$ showing spin lifetimes of over 100 ns at room temperature [1]. These long spin lifetimes are accompanied by an intriguing temperature dependence of the Kerr rotation amplitude, which increases with temperature up to 50 K and then abruptly switches sign. Using ab initio simulations we explain the latter behavior in terms of the intrinsic electron-phonon coupling and the activation of transitions to secondary valleys. The phonon-assisted scattering of the photo-excited electron-hole pairs prepares a valley spin polarization within the first few ps after laser excitation. The sign of the total valley magnetization, and thus the Kerr amplitude, switches as a function of temperature, as conduction and valence band states exhibit different phonon-mediated inter-valley scattering rates. However, the electron-phonon scattering on the ps time scale does not provide an explanation for the long spin lifetimes. Hence, we deduce that the initial spin polarization must be transferred into spin states which are protected from the intrinsic electron-phonon coupling, and are most likely resident charge carriers which are not part of the itinerant valence or conduction band states.

Intrinsic magnetic topological insulators are stoichiometric materials with both magnetic ordering and topological electronic states. Due to its inherent magnetism, this class of materials provides a new route in achieving various novel topological quantum effects that require breaking time-reversal symmetry, while maintaining good crystallinity and high purity of the material. We report the synthesis and characterization of an intrinsic magnetic topological insulator $MnBi_2Se_4$. The $MnBi_2Se_4$ thin films are deposited with alternating layer growth of Bi_2Se_3 and a-MnSe. The high quality of the material is shown with cross-sectional TEM. Dirac surface state is demonstrated with angle-resolved photoemission spectroscopy above its magnetic ordering temperature. SQUID magnetometry measurement on films with different thicknesses shows layered-antiferromagnetic ordering in this material. Low-field SQUID measurement also shows a hysteresis loop, with magnetic moments preferred to stay within the lattice plane. The ferromagnetic signal is attributed to uncompensated magnetic moments at the surface. Its magnetic characterization is also confirmed with XMCD measurement. Furthermore, preliminary magnetometry measurement also shows that the magnetic ordering in $MnBi_2Se_4$ persists down to the monolayer limit.

FB-03. Weak Antilocalization and Surface Quantum Oscillations in Topologically Nontrivial Half Heusler YPdBi Thin Films. *V. Bhardwaj*[1], A. Bhattacharya[2,1], L.K. Varga[3], A.K. Nigam[4] and R. Chatterjee[1]
1. Physics, IIT Delhi, New Delhi, India; 2. Mechanical Engineering, IIT Delhi, New Delhi, India; 3. Wigner research center for Physics Hungarian Academy of Sciences, Budapest, Hungary; 4. Tata Institute of Fundamental Research, Homi Bhabha Road, Mumbai, India

The topological insulator (TI) is a new quantum state of matter which carries metallic surface/edge states along with insulating bulk states[1]. Rare-earth(R) based RPdBi single and poly-crystalline Half-Heusler(HH) alloys are proposed to harbor topological nontrivial states based on first principle calculations[2-3]. In this work, we study the observation of topological non trivial properties in [110] oriented YPdBi(YPB) thin films grown on MgO (100) substrates. First, polycrystalline bulk sample of YPB is prepared in a specially designed RF induction melting set-up. XRD analysis reveal single phase with MgAgAs-type cubic crystal (lattice constant~ 6.68Å) structure. The thin films of YPB is prepared from the same target by pulsed laser deposition technique under the optimized conditions, which showed a textured structure with (110) planes parallel to the (100) plane of MgO[4]. The topological nontrivial properties of sample is studied using magnetotransport measurements. The longitudinal resistance R_{xx} vs temperature (T) data shows a typical semi metallic behavior from $4K \leq T \leq 350K$ but abrupt metallic transition is observed for $T \leq 4K$ (see Fig.1). Effect of external magnetic field (H=0 to 9T) is studied on this anomaly and it can be seen in the inset of Fig.1, that for $H \geq 5T$ this anomaly disappeared completely. This implies that the anomaly in R_{xx} data at 3.8K can be attributed to the dominance of metallic surface state below this temperature and degeneracy of surface states is lifted in presence of magnetic field due to breaking of time reversal symmetry. The low magnetic field magnetoresistance data follows the Hikami-Larkin-Nagaoka (HLN) model and confirms 2D WAL effect. The extracted values of phase coherence length (l_{Φ}) and α indicate the presence of the 2D surface states in YPB. The Dirac nature of the surface states is further confirmed by Landau level fan diagram analysis to extract finite Berry Phase from SdH oscillations data. Sheet Carrier density calculated from the SdH oscillations and Hall measurements agree well with each other. These findings show that thin films of the HH YPB can be used for studying the novel quantum transport properties of surface Dirac fermions

FB-04. Dimension Transcendence and Anomalous Charge Transport in Magnets with Moving Multiple-Q Spin Textures. *Y. Su*[1], S. Hayami[2] and S. Lin[1] *1. Los Alamos National Lab, Los Alamos, NM, United States; 2. Hokkaido University, Sapporo, Japan*

Multiple-Q spin textures, such as magnetic bubble and skyrmion lattices, have been observed in a large family of magnets [1]. These spin textures can be driven into motion by external stimuli [2]. The motion of spin textures affects the electronic states. Here we show that to describe correctly the electronic dynamics, the momentum space needs to be transcended to higher dimensions by including the ancillary dimensions associated with phason modes of the translational motion of the spin textures [3]. The electronic states have non-trivial topology characterized by the first and second Chern numbers in the high dimensional hybrid momentum space [4]. This gives rise to an anomalous electric charge transport due to the motion of spin textures. By deforming the spin textures, a nonlinear response associated with the second Chern number can be induced. The charge transport is derived from the semi-classical equation of motion of electrons that depends on the Berry curvature in the hybrid momentum space. Our results suggest that the motion of multiple-Q spin textures has significant effects on the electronic dynamics and provides a new platform to explore high dimensional topological physics.

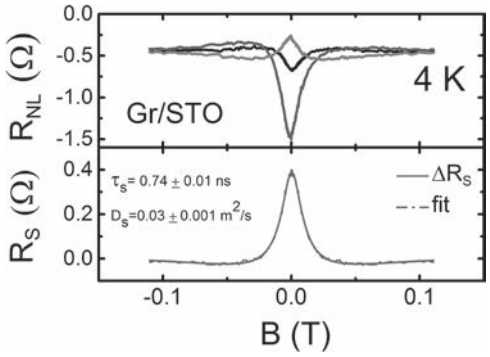
FB-05. Interaction of 2D materials and π-electron systems with magnetic surfaces. *N. Atodiresei*[1], V. Caciuc[1] and S. Bluegel[1]
1. Peter Grünberg Institut and Institute for Advanced Simulation, Forschungszentrum Jülich GmbH, Jülich, Germany



The density functional theory provides a framework with predictive power that can be used to describe hybrid systems incorporating 2D-materials, π-electron systems and metal substrates. In this respect, *ab initio* studies elucidate how the subtle interplay between the electrostatic, the weak van der Waals and the strong chemical interactions determine the geometric, electronic and magnetic structure of hybrid interfaces. More precisely, the interaction between 2D-materials and π-electron systems with the magnetic states of a metal influences the (i) spin-polarization, (ii) magnetic exchange coupling, (iii) magnetic moments and (iv) their orientation at such hybrid interfaces. In this talk I will briefly summarize how first-principles calculations (i) provide the basic insights needed to interpret surface-science experiments and (ii) are a key tool to design novel materials with tailored properties that can be integrated in 2D-materials and carbon-based spintronic devices.

FB-06. Temperature and Electric Field Dependence of Spin Relaxation in Graphene due to Surface Electric Dipoles on $SrTiO_3$. *S. Chen*[1], R. Ruiter[1], V. Mathkar[1], B. van Wees[1] and T. Banerjee[1] *1. University of Groningen, Groningen, Netherlands*

The theoretically predicted intrinsic spin relaxation time of up to 1 μs in graphene along with extremely high mobility makes it a promising material in spintronics. Novel functionalities can be introduced in graphene via proximity effect with different underlying substrates. In this work, we use the electronically rich platform of $SrTiO_3$ (STO) with broken inversion symmetry and study spin transport in graphene in the presence of surface electric fields. We find spin relaxation time and length as large as 0.96 ± 0.03 ns and 4.1 ± 0.1 μm respectively at 290 K in graphene, using non-local spin valve studies and find a non-monotonous dependence with temperature, unlike that observed on other substrates. Analysis of the temperature dependence indicates the role of surface electric dipoles and electric field driven electronic and structural phase transitions, unique to STO, to spin transport and spin relaxation in graphene. We have further investigated the influence of breaking inversion symmetry at the surface of STO by introducing an 8 nm thick hBN layer. On the same STO substrate, we identically fabricate two different devices: graphene/STO and graphene/hBN/STO. Hanle measurements show a lower spin relaxation time in graphene/hBN/STO. Furthermore, we observe notable differences in the Hanle lineshapes for the graphene/hBN/STO device as compared to the graphene/STO device. A pronounced upturn in the Hanle lineshape, reminiscent of tunneling anisotropic magneto-resistance, is observed at high magnetic fields for the former device and that disappears at RT. Our study provides a new direction to understanding the role of spin-orbit interaction on spin transport in graphene.

FB-07. Magnetic properties of micrometer sized YIG/FGT heterostructure revealed by local ferromagnetic resonance. *B. Arkook*[1], M. Al ghamdi[1], V.H. Ortiz[1], J. Shi[1] and I. Barsukov[1] *1. Physics and Astronomy, UC Riverside, Riverside, CA, United States*

Multilayer heterostructures consisting of magnetic insulator and 2D spin system offer a versatile, promising platform for next-generation spintronics and quantum computation applications. Understanding interfacial spin coupling and transport in such heterostructures requires a local microwave spectroscopy technique, since the flakes of 2D materials obtained by exfoliation are limited to micrometers in size. Here, we fabricate disks of 20μm diameter from epitaxial ferrimagnetic insulator, yttrium iron garnet (YIG), thin film using pulsed laser deposition, e-beam lithography, and lift-off. We place few-nm thick flakes of van-der-Waals material Fe_3GeTe_2 (FGT) on the pre-patterned YIG disks and transfer them onto a planar microwave resonator. Employing angle-dependent ferromagnetic resonance, we observe low-energy spin wave modes in YIG at several microwave frequencies, allowing for evaluation of magnetic anisotropy and damping. Using cryogenic measurements, we find an anomalous temperature dependence of effective magnetic anisotropy. The results shed light on spin phenomena at YIG/FGT interfaces and present an experimental approach for studies of micro-scale magnetic insulator/2D heterostructures. FB-08. Giant Spin Galvanic Effects in Topological Material Heterostructures. *S.P. Dash*[1] *1. Microtechnology and Nanoscience, Chalmers University of Technology, Gothenburg, Sweden*

Engineering 2D materials heterostructures by combining the best of different materials in one ultimate unit can offer a plethora of opportunities in condensed matter physics. Among the 2D materials, while large area CVD graphene is shown to be an excellent medium for long distance spin communication and fabrication of spin circuits [1,2], the insulating CVD h-BN has shown a very large tunnel spin polarization up to 65% at room temperature [3]. Furthermore, by inducing SOC and spin absorption effects, we demonstrated an electrical gate control of spin-polarization and spin lifetime in graphene/MoS_2 heterostructures at room temperature [4]. Recently,

we combined graphene with topological insulators in van der Waals heterostructures to demonstrate the emergence of a strong and tunable proximity-induced spin-orbit coupling in graphene [5], consequently giving rise to a giant spin galvanic effects at room temperature. Furthermore, using Weyl semimetals, we observed a giant spin to charge conversion [6] and efficient spin injection effects at room temperature. These findings demonstrate all-electrical spintronic devices at room temperature in van der Waals heterostructure, which can be key building blocks in future device architectures.

For years graphene has been considered as the most potential material which paves the way to advanced high-performance spintronic devices due to its extraordinary electrical and physical properties. In those reported graphene-spintronic devices, conventional ferromagnets such as NiFe etc of low spin polarization have been often used due to the well-established synthesis method of graphene on them. However, the spin signal reported in those systems are far from being considered satisfactory for spintronic device applications [1,2]. Adopting highly spin-polarized material can be the most effective way to improve the performance of graphene spintronic devices, the experimental demonstration, however, is still lacking. Here we report the demonstration of a novel heterostructure consisting of graphene and full Heusler alloy $Co_2Fe(Ge_{0.5}Ga_{0.5})$ (CFGG), in which half-metallicity has been confirmed experimentally [3]. Single layer graphene was prepared by in situ chemical vapor deposition on a magnetron sputtered CFGG thin film grown on single crystalline MgO(001) substrate. As shown by the RHEED images in Fig. 1, the sharp streaky patterns from both graphene and CFGG indicate an atomic flatness of the SLG/CFGG interface. The high quality of graphene was further confirmed by Raman spectroscopy. A depth-resolved XMCD study reveals that the CFGG surface adjacent to graphene possesses a robust magnetic moment comparable to the bulk CFGG (Fig. 2) in association with the weak interfacial interaction. This finding is in sharp contrast to the large reduction of the magnetic moment reported in other graphene/ferromagnets heterostructures. DFT calculations show that the inherent properties such as half-metallicity of CFGG and the linear Dirac band of graphene are preserved at the interface. These findings are highly promising for realizing effective transport of highly spin-polarized electrons in graphene-based spintronic devices.

FB-10. Extrinsic Spin-Orbit Coupling Induced Interfacial Dzyaloshinskii-Moriya Interaction in MoS_2/NiFe/Ta Heterostructures. *A. Kumar*[1], A. Chaurasiya[2], N. Chowdhury[1], A. Mondal[2], A. Barman[2] and P.K. Muduli[1] *1. Physics, Indian Institute of Technology Delhi, New Delhi, India; 2. S. N. Bose National Centre for Basic Sciences, Kolkata, India*

Dzyaloshinskii-Moriya interaction (DMI) leads to canted spins which gives an extra stability to skyrmions and other chiral structures [1, 2]. Investigation of 2D transition metal dichalcogenide (TMDs) materials have received increasing attention as they possess interesting properties like direct band gap, strong spin-orbit coupling [3], and lack of inversion centre in crystal structure [4] in their monolayer form. These properties of 2D TMDs with novel magnetic properties arising due to DMI may open up new avenues for spintronic devices. Therefore, in this work we explore the possibility of interfacial DMI (iDMI) in MoS_2/Py heterostructures. Two series of samples were prepared by varying the thickness of the Py layer from 0-10 nm on large area 2L and 3~4L MoS_2 layers. Photoluminescence (PL) and Raman mapping shows the presence of defects (Sulphur vacancies) at 3~4L MoS_2 [5]. DMI measurements were performed using Brillouin-light-scattering (BLS) spectroscopy in Damon-Eshbach (DE) geometry [6]. Fig. 1 (a) and (b) shows the asymmetry in the spin-wave frequency (Δf) in BLS measurements for 2L and 3-4L MoS_2/Py (5 nm), respectively. A linear increase in DMI constant (D) with inverse of Py thickness (t_{Py}) was observed for both 2L and 3-4L MoS_2/Py series. These observations indicate the presence of iDMI in these samples which arises due to MoS_2/Py interface. Interestingly our analysis shows ~58% enhancement of iDMI in 3-4L MoS_2/Py system as compared to 2L-MoS_2/Py. This observation is counterintuitive as strength DMI depends on spin-orbit coupling and hence should decrease with increase in number of MoS_2 layers. Therefore, we explain our results based on presence of higher defect density in 3-4L MoS_2 which leads to extrinsic spin-orbit coupling at 3-4L MoS_2/Py interface. This results in higher iDMI in 3-4L MoS_2/Py as compared to 2L-MoS_2/Py. Our results indicates the possibility of utilizing the defects at interface of 2D TMD/FM heterostructures for tailoring the chiral structures for spintronic devices.

2D ferromagnetism is an emerging field in spintronics applications. The use of generic 2D ferromagnetic materials, however, suffers of the so-called 'superparamagnetic limit', which imposes restrictions on the size and dimension of the ferromagnetic component used in spintronics devices. The recent discovery of the Chiral-Induced Spin Selectivity (CISS) effect offers a possibility to generate spin angular momentum by replacing the ferromagnetic component with chiral systems, e.g., chiral (left- or right-handed) molecules and their assemblies lacking inversion symmetry. As a result of the CISS effect, the chiral materials can produce an effective magnetic field at room temperature, whose direction is determined by the left or right chirality, circumventing the 'superparamagnetic limit'. Here, we report the observation of a large chiral-induced magnetic field in solution-processed, 2D-layered, organic-inorganic hybrid perovskites incorporating chiral molecule ligands. Such chiral-induced magnetic field is probed by measuring the resistance through an attached platinum layer, analogous with the spin-Hall magnetoresistance (SMR). We found a substantial angular dependent chirality-induced SMR that agrees well with theoretical models. By sweeping the magnetic field, the SMR reveals a clear hysteresis depending upon the chirality of 2D perovskites, which could be used to quantify the effective magnetic field strength produced via the CISS effect. Incorporating the chiral molecules into a 2D layered hybrid perovskite framework offers a versatile platform for designing 2D ferromagnetic materials at room temperature. FC-01. Resistance-area product effects on spin torque switching in perpendicular STT-MRAM. *G. Mihajlovic*[1], N. Smith[1], T. Santos[1], J. Li[1], M. Tran[1], M. Carey[1], B. Terris[1] and J. Katine[1] *1. Western Digital Research Center, Western Digital Corporation, San Jose, CA, United States*

In a perpendicular STT-MRAM cell, the critical switching current density J_{c0} is not expected to depend on the resistance-area product RA. Experimentally, however, an RA dependence has been observed by several groups and attributed to an RA-dependent spin pumping contribution to the damping parameter of the free layer FL [1, 2]. In this talk we will present an experimental study of field and current-induced switching in perpendicular STT MRAM cells with variable RA = 5, 10, 15 and 20 Ωmm^2. We will show that the RA dependence of J_{c0} is influenced by phenomena other than spin pumping. Instead, the RA dependence is due to the current-induced self-heating of an MRAM cell (which reduces the effective H_k of the FL), and, to a smaller extent, the RA dependence is due to the voltage-controlled magnetic anisotropy effect (VCMA). As the temperature rise of the FL is proportional to the dissipated power density (RA)J^2, higher RA devices result in lower J_{c0}. In addition, as the VCMA effect is proportional to the bias voltage V_b across the MRAM cell, for a given J, VCMA effects are stronger with higher RA. We will present a simple quantitative model to include self-heating and VCMA contributions to the STT, which quantitatively explains all of our experimental findings, in particular the much stronger RA dependence of J_c for P→AP compared to AP→P switching. We will also show that the RA dependence of STT efficiency E_b/I_{c0} obtained from pulse width t_p dependent measurements of switching voltage V_c in the thermally assisted regime (E_b is the energy barrier for magnetization reversal of the FL and I_{c0} is the critical switching current) is due to an error when fitting the data assuming that only STT is responsible for switching, without including contributions from VCMA and self-heating effects. When the latter two contributions are properly included the RA dependence of STT efficiency disappears, as expected for STT switching.

FC-02. Importance of self-heating in perpendicular MRAM: modeling and experimental evidence. *D. Apalkov*[1], A. Khvalkovskiy[1,2], V. Voznyuk[1] and V. Nikitin[1] *1. New Memory Technology, Samsung Semiconductor Inc., San Jose, CA, United States; 2. Crocus Nanoelectronics LLC, Moscow, Russian Federation*

In the last few years, there were a number of breakthroughs in understanding the complex behavior of a free layer in perpendicular MRAM [1-4]. Despite that, there are still some experimental observations that cannot be adequately explained. One such example includes the dependence of switching current on the resistance-area product (RA)[5,6]. In this work, we present a comprehensive picture based on modeling and experimental measurements that demonstrates that a number of unsolved effects can be quantitatively explained by the presence of Joule heating during the current pulse application. Our 3D modeling of resistive (Joule) heating of a realistic perpendicular MRAM structure predicts large and very fast (1-3 ns) temperature increase with an applied voltage pulse of amplitude comparable to switching voltages of MRAM cells. Simulation results suggest that depending on the assumed thermal conductivity of the materials surrounding MTJ stack, temperature increase varies between ΔT_{min} and ΔT_{max} as shown in Fig. 1. For experimental verification, we have developed a novel technique [7] to directly measure temperature increase as a function of applied voltage (Fig. 1). This method relies on the temperature sensitivity of the switching field of the reference layer, and unlike a similar technique using the coercivity change of the free layer [8] avoids the unwanted contribution of the spin transfer effect. To understand the implications of the Joule heating on device behavior, we have included temperature increase and associated effects into a micromagnetic model and show that it can explain many phenomena that were previously observed experimentally. As an example, we compare the modeled dependence of switching current on RA with experimental measurements in Fig. 2. In conclusion, we will discuss some other important and not obvious implications of Joule heating on free layer behavior.

FC-03. Enhancement of Thermal Spin Transfer Torque via Superlattice Design. *P. Priyadarshi*[1] and B. Muralidharan[1] *1. Electrical Engineering, Indian Institute of Technology Bombaay, Mumbai, India*

Apart from current induced spin transfer torque (STT), there is also a possibility to generate STT and consequently, magentization switching via thermal means [1]. In this work, we propose to harness the optical analog of anti-reflective (AR) coats [2,3] in a heterostructure MTJ device, as sketched in Fig. 1, as a means to improve the thermal spin transfer torque (TSTT). Using the spin-resolved non-equilibrium Green's function formalism, we propose the use of an energy bandpass filtering approach in the MTJ superlattice configurations that reports a large spin torque in the linear regime of temperature bias. The use of SL in the device leads to the formation of passbands and forbidden bands in energy for coherent electron transport. We note from Fig. 1(b, c), that the area under T(E) curve in the AR-SL configuration is maximum than the normal SL (NSL) configuration. The adjustment of passband with respect to the Fermi level enables to capture the full positive swing of current distribution due to the contacts. We plot the parallel component of the spin transfer torque due to temperature bias as a function of the number of barriers in the SL structures in Fig. 1(d) and note that the TSTT first increases up to 3 barriers and then almost saturates afterward in both the configurations. The thermally excited spin transfer torque is enhanced by almost five times more with our (AR-SL) device design. Although the thermally driven spin torque is much smaller than the potential driven torque, this technique provides an energy efficient way to switch the magnetization. This opens up a new viable area for spintronics applications. With the existing advanced thin-film growth technology, the optimized superlattice configurations can be achieved.

FC-04. The magneto-optical Kerr effect for efficient characterization of thermal stability in dense arrays of pMTJs. *S. Van Beek*[1], R. Carpenter[1], S. Kundu[1], S. Couet[1], J. Swerts[1], S. Rao[1], W. Kim[1], Y. Wu[2,1], S.H. Sharifi[1], F. Yasin[1], B.F. Vermeulen[2,1] and G.S. Kar[1] *1. imec, Leuven, Belgium; 2. KU Leuven, Leuven, Belgium*

Magnetic Random Access Memory (MRAM) targets high density arrays of perpendicular Magnetic Tunnel Junctions (p-MTJs) [1]. MRAM is a non-volatile memory, therefore the MTJs require sufficient data retention, which is described by the thermal stability factor Δ, i.e. the ratio between the activation energy needed to switch states and the available thermal energy. We produced arrays with MTJs of 20 nm diameter and spaced at a dense pitch of only 50 nm, see Fig. 1. Evaluating the functionality of these arrays is time consuming and generally based on electric read out of the pillars. In this contribution, we show that magneto-optical Kerr effect (MOKE) measurements enable efficient and in-line characterization of both the magnetic properties and the data retention. We demonstrate this by studying the impact of engineering the stack and etch process. Furthermore, pillar-to-pillar variability is obtained by including various distributions of the Neel-Brown model parameters Δ and anisotropy field B_k. With MOKE, it is possible to distinguish the reversal of the free layer, reference layer and hard layer of the p-MTJ and gain insight in the magnetic properties of the MTJ stack. In this experiment, we use MOKE to characterize the thermal stability factor Δ by performing waiting time experiments [2]. After sweeping the magnetic field from negative saturation up to a positive waiting field, the magnetization is monitored as a function of time (see Fig. 2). The time-dependent switching of the magnetization during the sweep and at the waiting field contains a vast amount of information concerning the Neel-Brown model parameters. Finally, we compare the results with the thermal stability characterization based on electrical read out of the pillars.

National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan*

Heat controlled magnetic anisotropy in nano-magnet is efficient technology for spin control [1]. Generally, while a nano-scale heat engine is inefficient because of huge heat dissipation, the heat dissipation can be suppressed by interfacial thermal resistance at MgO|ferromagnetic metal interface even in the nano-scale [2]. In the MgO|FeB|MgO system, the temperature increase in FeB is enhanced, which provides the giant magnetic anisotropy change. Figure 1 shows the bias voltage dependence of perpendicular anisotropy constant in the CoFeB|MgO|FeB|MgO magnetic tunnel junctions (MTJs). The magnitude of magnetic anisotropy change characterized by the slope of the curve is corresponding to the voltage controlled magnetic anisotropy (VCMA) of 300 fJ/Vm. This value is close to the maximum value of conventional VCMA effect (320 fJ/Vm) which shows rapid anisotropy change [3]. The rapid and large anisotropy change exerts the spin torque on magnetization, which induce the large microwave property, microwave amplification effect. The microwave amplification effect had been studied using dc-biased MTJs [4-5]. However, the microwave was not amplified because the spin-torque was not efficient. We tried the microwave amplification using heat-induced spin torque and succeeded in observing amplification gain of more than 20% as shown in Fig. 2. This value is consistent with the theoretical result using macro-spin calculation. This result opens the way to develop new microwave devices. Also, the heat controlled magnetic anisotropy becomes the efficient spin control technology in nano-scale devices. This research was supported by Bilateral Programs (MEXT), MIC, ImPACT program of the Council for Science, Technology, and Innovation (Cabinet Office, Government of Japan), and JSPS KAKENHI (Grant No. JP16H03850).

FC-06. Magneto-Optical Control of Heat Current. *K. Uchida*[1], J. Wang[1] and Y. Takahashi[1] *1. National Institute for Materials Science, Tsukuba, Japan*

Active control of heat flow is crucial for the thermal management of increasingly complex electronic and spintronic devices. In addition to conventional phonon heat transport engineering, spin caloritronics has received extensive attention as a novel heat control principle owing to its high controllability and unique thermoelectric conversion symmetry [1,2]. Here, we demonstrate that the direction of heat currents generated by spin-caloritronic phenomena can be changed simply by illuminating magnetic materials with visible light [3]. The optical control of heat currents is realized through a combination of the spin-driven thermoelectric conversion called an anomalous Ettingshausen effect [4,5] and all-optical helicity-dependent switching of magnetization [6]. This approach enables not only pinpoint manipulation and flexible design of the heat current distribution by patterning the illuminating light but also on/off control of the resulting temperature modulation by tuning the light polarization. These versatile heat control functionalities will open up a new pathway for nanoscale thermal energy engineering.

STT-MRAMs have attracted a considerable attention because they offer the zero standby power required for low power consumption IoT and AI systems. Development of interface-perpendicular-anisotropy type CoFeB/MgO MTJs (p-MTJs) has led to mass production of STT-MRAMs [1-7]. The MgO cap layer (CL) on a free layer (FL) which enhances a perpendicular magnetic anisotropy (PMA) plays a crucial role in determining the performances of p-MTJs. Although we achieved high thermal tolerance in the MTJ with double CoFeB/MgO with MgO-CL by controlling boron composition in the FL [8,9], further improvement of deposition process with lower damage is required for further development of STT-MRAMs [10,11]. Because a CL on the MgO-CL also plays an important role for PMA [12], we investigated the effect of the CL on the MgO-CL on magnetic properties of the FL as well as underlying mechanism for it. First, we investigated the magnetic properties in the MTJ stacks with different CL materials on the MgO-CL. Fig. 1 shows the areal perpendicular anisotropy energy density $K_{\mathrm{eff}}t$ as a function of FL thickness t for MTJs with Ta, Ru and CoFeB CLs after annealing at 400°C. In the studied entire t range, the largest PMA is achieved for the MTJ stack with CoFeB CL. To gain insight into a reason for the behavior, we performed EDX line analysis of the MTJs after annealing at 400°C. In case of the Ta-CL, Ta penetrates the MgO-CL and the oxygen in MgO-CL diffuses into the Ta-CL (Fig.2(a)). Both of them are harmful for the interfacial anisotropy at CoFeB (FL)/MgO-CL, as the PMA of the structure originates from the Fe-O bond [1,13]. In contrast, in case of Ru and CoFeB CLs, oxygen stayed in around MgO-CL (Fig.2(b)-(c)), results in the higher PMA than that of Ta CL. However, in case of the Ru-CL, Ru diffuses into FL, which results in degradation of PMA, resulting in that the FL with CoFeB-CL shows highest PMA among the three structures. FC-08. Independence between spin and momentum relaxation characteristic times in Pt, revealed by spin pumping measurements. *C.A. Gonzalez-Fuentes*[1], R.K. Dumas[2], B. Bozzo[3], A. Pomar[3], M. Abellan[1] and C. Garcia[1] *1. Physics, UTFSM, Valparaiso, Chile; 2. Quantum Design, San Diego, CA, United States; 3. ICMAB, Bellaterra, Spain*

We present a broadband Ferromagnetic Resonance study of the Gilbert's damping (α) enhancement due to spin pumping in NiFe/Pt bilayers, with variable thickness of the Pt layer, performed at temperatures from 100 to 300 K. Our samples were fabricated with improved interfacial spin-current transparency by means of a post-annealing (500K) procedure. In the framework of diffusive spin pumping theory [1], we demonstrate that Dyakonov-Perel

(DP) or Elliot-Yaffet (EY) spin relaxation mechanisms acting by alone are incompatible with our observations. Instead, if we assume that the spin relaxation characteristic time (τ_{SF}) is independent of the momentum relaxation characteristic time (τ_p), the qualitative and quantitative agreement with our results is excellent. This is in conflict with the theoretically expected absence of DP mechanism in Pt [2], however, is in concordance with recent observations on similar systems in which was shown that τ_{SF} is nearly constant for the range of temperatures we work with, but interpreted as a compensation between DP and EY mechanisms [3].

FC-09. Measurement of the Spin Relaxation Anisotropy in 3d Ferromagnets. *M. Cosset-Chéneau*[1,2], L. Vila[1], D. Gusakova[1], X. Waintal[1], A. Marty[1] and J. Attané[1] *1. Univ. Grenoble Alpes, CNRS, CEA, Grenoble INP, IRIG-SPINTEC, Grenoble, France; 2. Département de Physique, Ecole Normale Supérieure de Lyon, Lyon, France*

The relaxation of a spin current into a ferromagnetic material occurs through different processes depending on the spin currents' polarization orientation. For a polarization collinear with the material magnetization, the relaxation occurs through diffusive processes controlled by the spin diffusion length [1]. When the polarization is transverse with the magnetization, the relaxation is driven by ballistic processes due to band structure mismatch and non-coherent spin precession [2]. Despite being a key ingredient for the understanding of phenomena like Spin Transfer Torque, this anisotropy has never been directly observed so far. In this presentation, we report the observation of the spin relaxation anisotropy on a single device by using a spin absorption method in Lateral Spin Valves (LSVs) [3]. Using a magnetic field, we control the relative orientation between the spin current polarization and the magnetization of a nanodisk-shaped ferromagnetic absorber (fig. 1). We observed that the efficiency of the spin current absorption increases when this polarization and the absorber magnetization have transverse directions. We will present a device that allows the study of spin transport in a LSV with non-collinear ferromagnetic component. By demonstrating a good control over its magnetic states, we will show that we indeed observed the spin current relaxation anisotropy in a single device. We carried out an analysis by introducing bulk characteristic lengths of the transverse spin relaxation, and the spin mixing conductance describing transverse interfacial spin relaxation processes. This data analysis points out the role of both interfacial and bulk contribution in the non-collinear spin current relaxation.

FC-10. Spin transport and conflicting values of spin diffusion length in FM/HM systems. *C. Swindells*[1], A. Hindmarch[1], A. Gallant[2] and D. Atkinson[1] *1. Department of Physics, Durham University, Durham, United Kingdom; 2. Department of Engineering, Durham University, Durham, United Kingdom*

Understanding interfacial spin transport is fundamental for modern spintronic devices. To fully exploit related interface phenomena, such as spin-orbit torques or spin-pumping, the dependence of the structure and properties of the interface on key transport parameters must be quantified. Our previous work has shown the enhancement in interfacial transport with improved structural matching between FM and NM materials [1], as well as the dependence of spin transport on the thickness of the NM layer [2]. The nature of the parameters governing this transport however remains a subject of debate with the reported values seemingly affected by the different experimental methods and analyses. In particular, experimental values for the spin-diffusion length of the NM layer are inconsistent; for Pt, spin diffusion lengths have been reported from 1 nm up to 10 nm [3,4] depending on the method used. The role of the interface structure and its influence on the effective spin-diffusion length are also unclear. Here we present results and new analysis of a recently published study (Swindells et al, Phys. Rev. B (2019)) [5] of spin transport in a variety of crystalline and amorphous HM/FM and FM/HM systems that fully quantifies spin transport across the interface. Building upon the proposed linkage of resistivity and the spin diffusion length [6] our new analysis of experimental FMR data takes into account the dependence of the damping on both the NM and FM thickness (see figure 1) and resolves the differences in previously reported values for the spin diffusion length of Pt, see table 1. This analysis demonstrates that larger values for the spin diffusion length are correct, and lower values obtained from dynamic spin-pumping studies are limited by an incomplete understanding of the role of the interface. This new understanding provides a more complete account of interfacial spin transport phenomena.

FC-11. Reversible tuning of Cu spin relaxation length by ionic gating at room temperature. *X. Shen*[1], Y. Cai[1], Y. Wu[2] and Y. Ji[1] *1. Department of Physics and Astronomy, University of Delaware, Newark, DE, United States; 2. Department of Physics, State Key Laboratory of Surface Physics, Fudan University, Shanghai, China*

Electric control of spin current is long-sought-after, because of the prospect of enabling a spintronic version of the field effect transistors. [1] An injected spin current in a material decays over distance because of the ubiquitous process of spin relaxation, characterized by the spin relaxation length (λ_s). Therefore, one can control the spin current by tuning λ_s. In this work, we demonstrate electrical tuning of λ_s in mesoscopic Cu channels via ionic gating. Mesoscopic nonlocal spin valves (NLSV), each consisting of a Cu channel and a pair of Permalloy (Py) electrodes, are fabricated by using E-beam lithography. A gate electrode is placed 5 μm away from the Cu channel. A drop of electrolyte ($PEO/LiClO_4$) is applied onto the sample, covering the entire area including the NLSV and the gate. Cations (anions) accumulate on the surface of Cu channel when a positive (negative) gate voltage is applied while the channel is grounded. An intense electric field is generated at the Cu/electrolyte interface, due to the formation of an electric double layer. The measured nonlocal spin signals at 295 K show a clear dependence on the gate voltages. Figure 1 (a) and (b) show spin signals of 2.17 mΩ under +1.2 V and 0.98 mΩ under -1.5 V respectively, differing by 120%. Figure 1 (c) shows that the spin signals are tuned reversibly and reproducibly as the gate voltage cycles through +1.2 V, 0 V, and – 1.5 V. Figure 1 (d) demonstrates that the resistivity of the Cu channel is also tuned by the gate voltages with a tuning range of 5%. In a comparison experiment, we fabricate NLSVs with Al channels instead. No tuning is observed up to gate voltages of ± 3.0 V. This demonstrates that the tuning effects originate from the Cu channel rather than the Py electrodes. With the assumption of 10% injection and detection spin polarizations at 295 K, we estimate that the Cu spin relaxation length is tuned between 300 nm and 380 nm.

FD-01. Exploiting Hysteresis in a Multicaloric Cooling Cycle.
T. Gottschall[1], A. Gràcia-Condal[2], A. Taubel[3], M. Fries[3], L. Pfeuffer[3], L. Mañosa[2], A. Planes[2], K. Skokov[3] and O. Gutfleisch[3] *1. Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany; 2. University of Barcelona, Barcelona, Spain; 3. TU Darmstadt, Darmstadt, Germany*

Although there have been improvements in efficiency, the working principle for conventional cooling - vapor-compression - has remained largely unchanged for more than 100 years. However, with the world's increasingly affluent population demanding more comfortable living and working conditions, it is vital that we address the development of much more efficient cooling technologies as an urgent priority. Most research is focused on solid-state refrigeration and one of the caloric effects – electrocaloric, magnetocaloric, barocaloric or elastocaloric - where the material's entropy is forced to change under the application of an electrical, magnetic, or mechanical field [1]. The magnetocaloric effect, the most studied of the three, manifests itself as a change in the material's temperature as it is exposed to a magnetic field [2]. However, more than 20 years of research into materials exhibiting the giant magnetocaloric effect did not lead to the introduction of commercial products yet. In this work, we report on the novel approach that the thermal hysteresis, which is inherent in first-order magnetostructural transformations in magnetocaloric materials need not be the obstacle as it is always assumed. On the contrary, we demonstrate here that the thermal hysteresis of Heusler alloys is actually useful and can be exploited [3]. The hysteresis of the transition allows us to lock-in the ferromagnetic phase as the magnetizing field is removed and so the magnetic field is only required for a very short time. A second stimulus, uniaxial load, then causes the multicaloric material to transform back into its paramagnetic phase. This hysteresis-positive approach drastically reduces the costs of the magnetic field source made of expensive Nd–Fe–B permanent magnets because, in this case, the volume over which the magnetic field needs to be generated and maintained is very small. At the same time, focusing the magnetic field means we can double the magnetic field strength up to 2 T. In addition, the mass ratio between the magnetocaloric material and the permanent magnet can be increased, which allows scaling of the cooling power of a device simply by increasing the refrigerant body. The technical feasibility of this hysteresis-positive approach is demonstrated using Ni–Mn–In Heusler alloys. This novel solid-state refrigeration cycle could lead to an enhanced usage of the giant magnetocaloric effect in commercial applications.

FD-02. Tunable first order transition in La(Fe,Cr,Si)$_{13}$ compounds: retaining magnetocaloric response despite a magnetic moment reduction.
L.M. Moreno-Ramirez[1], C. Romero-Muñiz[2], J. Law[1], *V. Franco*[1], A. Conde[1], I.A. Radulov[3], F. Maccari[3], K. Skokov[3] and O. Gutfleisch[3] *1. Sevilla University, Sevilla, Spain; 2. Autonomous University of Madrid, Madrid, Spain; 3. TU Darmstadt, Darmstadt, Germany*

One usual method to seek for improved magnetocaloric effect in series of alloys and compounds is to increase their magnetic moment. In this work we demonstrate that even for doping elements that decrease the magnetic moment, the magnetocaloric response can be retained, in connection with the details of the phase transition that the material undergoes. To identify first order phase transition (FOPT), a recently proposed criterion based on the field dependence of magnetocaloric effect ($\Delta s_T(T,\Delta H)=a(T)\ \Delta H^{n(T,H)}$) has been used [1], whereby the field exponent n yields an overshoot above 2. In addition, n at transition temperature ($n(T_{trans})$) can further reveal the critical composition of the crossover of FOPT to second order phase transition (SOPT) as $n(T_{trans})<0.4$ indicates FOPT, $n(T_{trans})>0.4$ for SOPT and $n(T_{trans})=0.4$ as the crossover [2]. In this work, we report Cr-doped La(Fe,Si)$_{13}$ compounds (for $x \leq 0.6$ in $LaFe_{11.6-x}Cr_xSi_{1.4}$) can exhibit a maintained magnetocaloric response despite the dopant diluting the overall magnetic moment [3]. Unlike other transition metal dopants (e.g. Co or Mn), Cr occupies 8b sites and antiferromagnetically couples to Fe in the $NaZn_{13}$-type structure. Despite the reduction in overall magnetic moment, the magnetocaloric response is retained up to $x\approx0.3$ due to the increment of the FOPT-character (which is characterized by the reduction of $n(T_{trans})$ values). For higher Cr content, the series exhibit a crossover from FOPT to SOPT. These features are presented in Figure 1. Moreover, a direct relation between the first order character and thermal hysteresis is observed. Results from both experimental and first principle calculations are found in good agreement, indicating that they illustrate the importance of the nature of phase transition in both magnetocaloric response as well as its compositional dependence.

FD-03. Effect of martensite modulation on magnetocaloric properties of Ni-Mn-In, Ni-Mn-Sn and Ni-Fe-Ga melt-spun ribbons. *G. R*[1] and K. Srikanti[1] *1. International Advanced Research Centre for Powder Metallurgy and New Materials (ARCI), Chennai, India*

Ni-Mn-*X* (*X* = Ga, In, Sn) Heusler alloys have enormous potential for technological applications due to a rich variety of properties ranging from shape memory effect, magnetocaloric effect, magnetoresistance, exchange bias behavior [1-6]. These technologically important properties mainly arise due to the martensitic transition, which in many cases is coupled with the magnetic transition, giving rise to a first order magnetostructural transition from an ordered austenite (cubic) phase to a less ordered martensite (tetragonal or orthorhombic) phase on cooling. In this work we investigate the structure of the martensite twin boundaries in melt-spun samples through Transmission Electron Microscopy and discuss the microstructure in conjunction with the magnetocaloric properties. We have chosen three alloys *viz*. Ni Mn Sn, Ni Mn In and Ni Fe Ga for processing the ribbons by melt-spinning technique. Among several compositions investigated in the present study, $Ni_{50}Mn_{36.5}Sn_{13.5}$, $Ni_{50}Mn_{36.5}In_{13.5}$ and $Ni_{50}Fe_{44}Ga_6$ ribbons have shown the martensite and magneto structural transformations to occur close to 300 K. It is observed that among all the above-mentioned systems under study, Ni-Mn-In melt-spun ribbons exhibit huge magnetic entropy of 26 J/kg-K at 5 T. Figure 1 shows the Selected Area Electron Diffraction (SAED) pattern of Melt-spun (a) Ni-Mn-In, (b) Ni-Mn-Sn and (c) Ni-Fe-Ga. It is found that Ni-Mn-In sample has martensite structure with low modulation (< 5M) as compared to Ni-Mn-Sn (5M) and Ni-Fe-Ga (14M). A large positive magnetic entropy change at 2 T was obtained in Ni-Mn-In (7.5 J/kg-K) as compared to Ni-Mn-Sn (6 J/kg-K) and Ni-Fe-Ga (1.1 J/kg-K) (Fig. 1 (d-f)). The correlation between the order of modulation and magnetic entropy would be discussed in detail in terms of magnetic domains and twin planes. Apart from this we would be also presenting on the enhancement in magnetocaloric properties of Ni-Mn-Sn alloys with doping such as B.

FD-04. Magneto-transport and magnetocaloric properties of bulk and rapidly solidified nanostructured Ni-Co-Mn-Ti based shape memory alloys. *A.K. Pathak*[1], X. Liu[1], H. Bez[1], Y. Mudryk[1] and V.K. Pecharsky[1] *1. Materials Science and Enginering, Ames Laboratory, Ames, IA, United States*

Ferromagnetic shape memory alloys, which upon heating undergo magneto-structural transitions (MST) from antiferromagnetic/paramagnetic martensite to ferromagnetic austenite followed by second-order transformation to the paramagnetic austenite phase, are of considerable interest due to their potential applications in multi-calorics and sensors. Here we report the investigation of electrical and thermal conductivities in rapidly solidified nanostructured $Ni_{37.5}Co_{12.5}Mn_{35}Ti_{15}$ ribbons that exhibit giant magnetocaloric effect near room temperature [1]. We observed an anomaly in thermal conductivity in the vicinity of the MST, and the thermal conductivity was found to be 9.7 W m^{-1} K^{-1} at T = 300K. The magnetoresistance of the ribbons was found to be -15% at T = 289 K and H = 20 kOe. Thermomagnetic and electrical transport measurements indicate the Ni-Co-Mn-Ti bulk- and melt-spun-alloys show similar thermal hysteresis (~20 K). Temperature-dependent x-ray powder diffraction shows the sluggish MST from the high-temperature B2 (CsCl-type) phase to the low-temperature modulated M5 phase with thermal hysteresis of about 20-30 K, in agreement with the transport and magnetic measurement results. The effect of microstructure on hysteresis was studied as well. Our results indicate that the thermal hysteresis is not sensitive to microstructure of alloy, but is intimately related to the lattice misfit between the austenitic and martensitic phases. Work was funded through CaloriCool® – the Caloric Materials Consortium – which is a part of the Energy Materials Network. The Consortium is funded by the Advanced Manufacturing Office and is managed jointly by the Advanced Manufacturing Office and Building Technologies Office of the Office of Energy Efficiency and Renewable Energy of the United States Department of Energy. The research was performed at the Ames Laboratory. Ames Laboratory is operated for the U.S. Department of Energy by Iowa State University under contract No. DE-AC02-07CH11358.

FD-05. Impact of atomic disorder on the thermodynamic properties of ferromagnetic Fe_2MnSi – a computational study. H.G. Trigo[1], J.N. Gonçalves[1], B.M. Pimentel[2], D.L. Rocco[2], M.S. Reis[2] and *J.S. Amaral*[1] *1. Physics and CICECO, Universidade de Aveiro, Aveiro, Portugal; 2. Instituto de Física, Universidade Federal Fluminense, Rio de Janeiro, Brazil*

Heusler alloys are intermetallic compounds which exhibit many technologically relevant properties, including semi-metallic behavior, and strong magneto volume coupling [1]. The richness in the properties of this family of alloys lies in the wide range of possible doping compositions of magnetic and non-magnetic ions. In terms of applications in magnetic refrigeration, Heusler alloys (such as NiMnInCo) can show a giant magnetocaloric effect (MCE) [2], which demonstrates how tuning the thermodynamic properties of these alloys can lead to the discovery of new high-performance refrigerants. Fe2MnSi is a well-known ferromagnetic alloy, typically referred to as having a L21 structure. Still, in earlier works, a small degree (~12%) of DO3 disorder was observed via neutron scattering experiments [3]. This disorder corresponds to an exchange of atomic positions between Fe (A, C positions) and Mn (B position). Recently, it was shown through a combined Density Functional Theory (DFT) and Monte-Carlo (MC) approach that this 12% amount of DO3 disorder would lead to a remarkable increase of the Curie temperature (TC) from 160 K of the pure system to 200 K of the disordered one [4]. In this work, we computationally explore the impact of DO3 disorder on the magnetic and magnetocaloric properties of the Fe2MnSi alloy. Our detailed simulations show how the disorder at the atomic level strongly impacts the MCE properties of the alloy. To obtain an agreeable computational estimate of the MCE of this material compared to experimental results, the DO3 disorder needs to be considered not only as an average value, but as a distribution of disorder, which has a strong impact on the estimated MCE and Tc values, as shown in Fig. 1. The work here presented opens the way to explore the effects of atomic disorder on the magnetic and magnetocaloric properties of other Heusler alloys and of other families of materials where atomic disorder can easily occur.

Taming first order phase transitions and mastering the associated thermal hysteresis [1, 2] are the main objectives when studying the integration of caloric materials into energy conversion devices. The suppression of irreversible phenomena preserving the key properties of the phase transition (i.e their critical temperature T_c and the caloric effects) are the key issues in order to achieve energy efficient, high throughput devices. Hysteresis reduction has been achieved varying the material composition, the microstructure design, and tuning the phase change using an external control parameter [3–5]. We recently reported hysteresis suppression in manganese arsenide films (MnAs) after ion bombardment [6]; this result represents a potentially relevant tool to investigate the role of quenched disorder on phase transitions, a fundamental problem studied since four decades [7, 8]. Ion bombardment is often used to tailor material properties but the mechanism underlying their change is seldom understood. Here we show that in MnAs *150* nm thick films irradiated under different conditions (fluence, ion kinetic energy and mass), hysteresis reduction under weak fluence, and phase transition rounding after a stronger one, are both directly related to the number of atom-atom effective collisions, whereas they do not depend on the implanted ion density. This allows to tune defect density in order to study the interplay between pre-transition phenomena (i.e. precursors) and hysteresis reduction (i.e. metastable states decay). Our analysis suggests a weak T_c dependence on the average induced defect density, making local density fluctuations the leading mechanism responsible for the reduction of the critical nucleation barrier (i.e. hysteresis suppression), and of the transition rounding observed after a certain density threshold.

FD-07. Magnetofunctional response of FeRh nanoparticles obtained by novel processing routes. V. Sharmar[1], S. Gupta[2], A. Biswas[2], H. Fu[3], R.L. Hadimani[1], V.K. Pecharsky[2] and *R. Barua*[1] *1. Department of Mechanical & Nuclear Engineering, Virginia Commonwealth University, Richmond, VA, United States; 2. Division of Materials Sciences and Engineering, Ames Laboratory, Ames, IA, United States; 3. School of Physics, University of Electronic Science and Technology, Chengdu, China*

Materials that exhibit coupled magnetic and structural (magnetostructural) phase transitions can realize strong responses to perturbations in magnetic field, temperature, and strain. Nanostructuring of such materials offers a route to tailor both the transitions and functional responses by modifying the balance between surface and volume free energies of finite systems, potentially enabling emerging applications. To this end, near-equiatomic compositions of the B2 phase of FeRh is of interest in this study. Synthesis of FeRh nanoparticles (NPs) using traditional sol-gel wet-chemistry methods is fraught with challenges associated with phase purity, chemical inhomogeneity, and poor functional response [1,2]. Hence, here we focus on Fe_xRh_{1-x} NPs ($0.40 \leq x \leq 0.50$; dia = 40–100 nm) synthesized via two novel approaches - (i) Thermal decomposition method using precursor $FeCl_3$ and $RhCl_3$ solutions; (ii) Solvent-free mechanochemical co-reduction of $FeCl_2$ and $RhCl_3$. X-ray diffraction reveals that the as-made NPs exhibit an *fcc* structure, which can be converted into the ordered B2 structure upon annealing. Magnetothermal measurements indicate that depending upon particle size and composition, the magnetostructural transition temperatures (T_t) of the NPs can be tuned between 350 K and 415 K. The overall magnetization of the mechanochemically-processed NPs is significantly larger than the particles produced by thermal decomposition (see Fig 1). All samples show the presence of a secondary ferromagnetic phase below T_t – a feature attributed to chemical inhomogeneity due to presence of off-stoichiometric $Fe_{1-x}Rh_x$ ($x > 0.55$) phase. Last, the magnetocaloric response of promising nanoparticle compositions was evaluated and a maximum magnetic entropy change of ΔS_{mag} ~9 J/kgK at 2 T was noted (see inset). It is anticipated that the magnetocaloric FeRh NPs will be useful for biomedical aplications, mainly thermal magnetic resonance imaging and magnetic hyperthermia therapy. Acknowledgements: NSF (1726617) and U.S. Department of Energy (DE-AC02-07CH11358).

FD-08. Investigation of the Magnetic Anisotropy in Sputtered Ga-rich Fe-Ga Thin Films. A. Muñoz-Noval[1], E. Salas-Colera[3,4], S. Fin[2], A. Begué[5], I. Hontecillas[1], D. Bisero[2], M. Ciria[5] and *R. Ranchal*[1] *1. Complutense University, Madrid, Spain; 2. Ferrara University, Ferrara, Italy; 3. BM25-Spline, ESRF., Grenoble, France; 4. Instituto de Ciencia de Materiales de Madrid-CSIC, Madrid, Spain; 5. ICMA-Universidad de Zaragoza, CSIC, Zaragoza, Spain*

Fe-Ga alloys are promising materials for magneto-elastic (ME) applications [1-2] since they are rare-earth free systems with large magnetostriction and low coercivity. The magnetostriction shows two maxima around 20 at.% and 28 at.%, respectively, being higher in the Ga-rich range. The reported strong influence of processing on the magnetostrictive properties of bulk alloys has pointed out the necessity of a precise control of the growth method when trying to develop FeGa nanosystems [2]. In our recent investigations about Ga-rich Fe-Ga thin films, we have explored how the flow regime of the sputtering technique can be used to tune the in-plane magnetic anisotropy [3]. Furthermore, we have also studied how anisotropy is also dependent on the layer thickness [4]. Our structural investigation combining x-ray diffractometry (XRD) and x-ray absorption near the edge spectroscopy (XANES) together with the magnetic characterization done by vibrating sample magnetometry (VSM) and magneto-optical Kerr effect (MOKE) indicate that both growth parameters and thickness have an influence on the structural phases present in the Fe-Ga films. The increase of B2 phase together with a preferential alignment of Ga-pairs that tetragonally distort the lattice seem to play a role on the enhancement of the magnetic anisotropy (fig. 1-2). When modifying the growth power for the sputtering deposition similar conclusions can be reached [5]. The effective ME coefficient is around -7.6 MPa for 250 nm films with both isotropic and preferential alignment of the Ga-pairs. This result suggests that the ME stress is barely affected by a non-homogeneous Ga pair distribution, although it is a fundamental parameter to explain de magnetic anisotropy in these films.

Ferromagnetic Shape Memory Alloys (FSMAs) are a group of active materials that undergo martensitic transformations induced by temperature, stress and/or magnetic fields, which result in large recoverable mechanical deformations [1]. Their fast response and high energy density make them ideal candidates for implementation in sensors and actuators. The magnetic properties of FSMAs depend on the interactions between the magnetic moments of atoms that, in turn, depend on the atomic positions within the lattice [2, 3]. Here we present a combination of powder neutron diffraction experiments in a series of polycrystalline samples of 6-element FSMAs with varied Fe content, where the alloys present actuation at temperatures around 370 K. Their atomic site occupancies, the ratio c/a and, therefore, the maximum achievable deformation ε, are calculated for each alloy [4]. Based on the atomic site occupancies and additional measurements of the saturation magnetization in each sample, the influence of the structure and atomic site occupancies on the magnetism in these samples is presented. This study is complemented by the single crystal polarized and non-polarized neutron diffraction experiments in one of the samples used for the powder neutron diffraction measurements, from which a single crystal was grown. Together with the atomic site occupancies in the single crystal, the analysis of the polarized neutron diffraction measurements provides us with information about the magnetic moment distribution in each atomic position present in the unit cell of the single crystal. Finally, the element-specific magnetic

moments contribution to the magnetism of the alloy are depicted via X-ray magnetic circular dichroism (XMCD) measurements. The combination of the polarized neutron diffraction and XMCD measurements allows us to unravel element and site-specific magnetic moment distributions in the alloy.

Magnetorheological elastomers (MREs) are composite materials consisting of elastomer matrix with embedded micro- or nano- sized ferromagnetic entities. Ultra-soft polydimethylsiloxane (PDMS) based MREs are promising candidates for dynamic cell culture substrata [1-2]. The behavior of cells cultured on the surface of such MREs can be modified through tuning the mechanical and surface properties using an applied magnetic field. In this work, we report the fabrication and magnetic characterization of PDMS-based MREs. Sylgard 527 and carbonyl iron powder were mixed together at various ratios and cured at 60°C for 1 hour with applied magnetic fields ranging from 0 to 400 Oe. Magnetic hysteresis loops and first order reversal curves (FORC) [3-4] of the MREs were measured using a vibrating sample magnetometer. The MREs that were cured with no applied magnetic field show no angular dependence in the major hysteresis loop, consistent with the isotropic distribution of iron particles in the MREs. The hysteresis loops for MREs that were cured in a magnetic field, however, clearly display anisotropy. The applied field leads to alignment of the iron particles during the curing process and the alignment leads to the observed anisotropy. The difference in the FORC distribution characteristics of the isotropic and anisotropic MREs are also consistent with expectations based on the structural difference of these two types of MREs. Micromagnetic simulations give insight into the underlying mechanisms behind the magnetization reversal behavior. *This work is supported by the Center for Engineering MechanoBiology (CEMB), an NSF Science and Technology Center, under grant agreement CMMI: 15-48571. FD-11. Frequency Dependence of Magnetic and Magnetoelastic Properties of Magnetostrictive Materials for Multiferroic Antennae. *P. Finkel*[1], M. Staruch[1] and N.J. Jones[2] *1. Naval Research Laboratory, Washington, DC, United States; 2. NSWC, Bethesda, MD, United States*

Magnetoelectric (ME) resonators are of significant interest for pure mechanically driven antennae targeting the ULF/VLF radio frequency range. Direct coupling of magnetostrictive and piezoelectric phases in the ME composites enables time variable magnetic field generation with exceptionally low operational power requirements. A dynamic stress loading of the magnetoelastic/magnetostrictive material by piezoelectric element results in a fluctuating magnetic field. In this work we fully characterize magnetostrictive materials $Fe_{81.6}Ga_{18.4}$ and Terfenol-D at high frequencies up to several kHz and studied the effect of eddy current losses that potentially curtail the magnetic response of the material. We evaluated the dynamic response of Galfenol rod up to 1000 Hz comparing both its sensing response (changing dynamic stresses) to its actuation response (changing dynamic magnetic fields) in both solid and laminated rods.

FD-12. Nonreciprocal Surface-Acoustic-Wave Phase Shifter Based on Magnetoelastic Coupling. *R.V. Verba*[1], V. Tiberkevich[2] and A.N. Slavin[2] *1. Institute of Magnetism, Kyiv, Ukraine; 2. Oakland University, Rochester, MI, United States*

Absence of nonreciprocity of pure linear acoustic waves is one of the major challenges in the surface acoustic wave (SAW) technology. This challenge can be met by using magnetoelastic coupling of SAWs with spin waves (SWs) propagating in ferromagnetic media, where wave nonreciprocity can be easily realized. Usually, for the development of magnetoelastic isolators the nonreciprocity of propagation losses is used [1,2], but other important nonreciprocal devices, such as circulators, use, instead, the nonreciprocity of phase accumulation [3]. This phase effect is hard to achieve in standard magnetoelastic devices, as in the ranges of effective magnetoelastic coupling damping of coupled waves becomes prohibitively large. In this work we propose a new method to realize nonreciprocal phase accumulation of SAW which is based on the coupling of SAW with a *strongly nonreciprocal* SW. It turns out, that in such a case magnetoelastic bandgaps for positive and negative propagation directions, which occur near the crossing of the dispersion lines, are situated at substantially different frequencies (Fig. 1). The strong magnetoelastic nonreciprocity can be achieved, e.g., by using ferromagnetic bilayers having antiparallel magnetization configuration, placed on a top of an acoustic crystal. In this case one can position the "working band"(see Fig.1) at the "tails"of the magnetoacoustic bandgaps, where the influences of magnetoelastic coupling on both the SAW dispersion and losses are weak, but still nonzero. The weak shift of dispersion leads to a nonreciprocal phase accumulation $\Delta\varphi=(|k_+|-|k_-|)L$, and the value of $\Delta\varphi=\pi$ required for applications can be achieved for the phase shifter length of L~100-300 μm, as shown in Fig. 2 for an example of a $LiNbO_3$/Co(16nm)/Ru(0.9)/Co(14) structure. Note also, that in the "working band"of 4.4-4.8 GHz the propagation losses remain small (3-4 dB) and, importantly, similar for both propagation directions.

FD-13. Magnetic and Magnetostrictive Performance of $Fe_{1-x}Co_x$ Additively Manufactured Pillars. *N.J. Jones*[1], G. Petculescu[2], P.K. Lambert[1], J.M. Healy[1], R.T. Ott[3] and E. Simsek[3] *1. Physical Metallurgy and Fire Performance Branch, Naval Surface Warfare Center, Carderock Division, Bethesda, MD, United States; 2. Physics Department, University of Louisiana, Lafayette, LA, United States; 3. Division of Materials Science and Engineering, Ames Laboratory, Ames, IA, United States*

Traditional, slow crystal growth techniques can be very useful for fabricating highly textured magnetic and magnetostrictive materials. Additive manufacturing (AM) of metals, on the other hand, is composed of a large number of rapidly solidified regions that may provide textured growth, if configured correctly. If the growth parameters are not configured appropriately, however, poor crystal growth may result along with chemical inhomogeneity, which can also allow for multiple crystallographic phases. Therefore, if metal AM techniques are going to be used for magnetic materials and applications, their overall performance needs to be evaluated and linked to their crystallography, chemistry, and post-print material processing. Fifteen $Fe_{1-x}Co_x$ pillars (X = 0 – 20 at%) have been fabricated using the laser engineered net shaping (LENS^{TM}) technique, with various compositions of Co. Pillars were cut in half horizontally to evaluate variations in performance between the substrate and free ends. Magnetization and magnetostrictive strain has been measured as a function of composition and temperature. The room temperature magnetization values stay within 3% of the literature values, exhibiting 1 – 2% spread from sample to sample. The polycrystalline magnetostriction values ($3/2\ \lambda_s$) are isotropic in the plane, ranging from 3 – 50 ppm. Elastic constants have also been measured, along with crystal grain size, phase, orientation and composition.

ORNL, Oak Ridge, TN, United States*

In the quantum critical regime of a 3D Heisenberg antiferromagnet, the spins are nearly polarized, leading to a very small entropy change across the phase boundary. By contrast, an isolated 1D chain of such spins exhibits a large entropy change at its quantum critical point. Here we study an intermediate case, spin chains coupled to form a 3D ordered state, in the molecular salt $K_2PbCu(NO_2)_6$. We show that at the 3D quantum critical point, the system exhibits behavior characteristic of the constituent chains, with a specific heat comparable in magnitude to the spinon contribution[1]. We will also show that such behavior is generic to quasi-2D systems, opening up a new way to create highly fluctuating quantum magnetism.

FE-02. Quantum spin liquid in 1T-TaS_2. *D. Arcon*[2,1], M. Klanjšek[1], N. Jansa[1], I. Benedicic[1], D. Mihailovic[1] and P. Prelovsek[1] *1. Jozef Stefan Institute, Ljubljana, Slovenia; 2. University of Ljubljana, Faculty of Mathematics and Physics, Ljubljana, Slovenia*

The original Anderson's proposal of a resonating valence bond state [1] was put forward to account for the unusual magnetic properties of a triangular atomic lattice of Ta atoms in the layered transition metal dichalcogenide 1T-TaS_2. Compared to some recent candidates for quantum spin liquids (QSL) on triangular lattice, e.g., $YbMgGaO_4$ [2] or κ-$(ET)_2Cu_2(CN)_3$ [3], layered dichalcogenides have perfect triangular lattice geometry and a weaker effective spin-orbit coupling, offering a possibility for obtaining a unique insight into the competition between antagonistic QSL and Néel states. Here we report [4] on QSL that appears to be realized by atomic-cluster spins on the triangular lattice of a charge-density wave (CDW) state of 1T-TaS_2. In this system, nuclear magnetic quadrupole resonance and muon spin relaxation experiments reveal that the spins show gapless quantum spin liquid dynamics and no long range magnetic order down to 70 mK. Canonical T^2 power-law temperature dependence of the spin relaxation dynamics characteristic of a QSL is observed from 200 K to T_f = 55 K. Below this temperature we observe a new gapless state with reduced density of spin excitations and high degree of local disorder signifying new quantum spin order emerging from the QSL. The observed QSL is at first robust against applying chemical pressure in Se-doped samples before giving a way to superconducting state.

FE-03. Reestablishment of Spin-Density-Wave Magnetic Order in Epitaxial Chromium Films Following Photoexcitation. *S.K. Patel*[1,2], A. Singer[2], M. Chollet[3], J.M. Glownia[3], O.G. Shpyrko[2] and E. Fullerton[1] *1. Center for Memory and Recording Research, University of California, San Diego, La Jolla, CA, United States; 2. Physics Department, University of California, San Diego, La Jolla, CA, United States; 3. Linac Coherent Light Source, SLAC National Accelerator Laboratory, Stanford, CA, United States*

The emergence of order in complex systems such as itinerant antiferromagnets results in intriguing phenomena like spin density waves (SDW). Tuning material properties to extend magnetic control may offer new applications in spintronic devices. Here we discuss the response of the antiferromagnetic order of Cr films to photoexcitation. Epitaxial Cr (001) thin films exhibit a SDW and an associated charge density wave (CDW) normal to their surface. The number of periods of the SDW and CDW is quantized and changes hysteretically with temperature. The CDW can be measured in X-ray diffraction as satellite peaks centered on a specific Laue fringe around the (002) peak (see Fig. 1). Here, we study the CDW response in an X-ray pump probe experiment at the free electron laser LCLS where we excite a 28-nm Cr film with an optical pulse (800 nm, 40 fs) and probe with an X-ray pulse (8.9 keV, 50 fs). After photoexcitation, the static CDW is initially converted into a damped coherent dynamic phonon that is fully suppressed by 10 ps with sufficiently strong optical excitations. As the system cools, we measure how the magnetic order in the system is reestablished. The recovery to the initial ground state of the system is usually on the order of 1-10 ns, consistent with the cooling time for the lattice. However, near the hysteretic region where the number SDW and CDW periods discretely changes, the recovery of the lattice ordering stalls in a super-cooled metastable state which persists at least to the limit of measurement, 400 ns (see Fig. 2). Work at UCSD supported by the BES Award DE-SC0018237.

FE-04. Optical evidence of an electronic nematic phase in FeSe driven by spin fluctuations. *L. Degiorgi*[1] *1. Physics, ETHZ, Zurich, Switzerland*

We have evinced, within one single experiment, all relevant ingredients determining the anisotropy in the charge dynamics as well as in the dc transport properties of FeSe, a prominent iron-based superconductor. It is established that the scattering by spin fluctuations turns out to be the most decisive effect with respect to the anisotropic nematic properties. FeSe lately acquired a prominent role within the panorama of superconducting materials, since it harbors a tetragonal-to-orthorhombic structural phase transition at T_s=90 K, where the lattice breaks a discrete rotational symmetry, in the absence of any subsequent, ambient pressure long-range magnetic order, prior the onset of superconductivity at 8 K. This is associated to an electronic nematic phase, the relevance of which in shaping the phase diagram of high temperature superconductors is certainly one of the most debated issues nowadays. This work describes novel results of reflectivity measurements from the far-infrared up to the ultraviolet that probe the optical response as a function of the tunable symmetry breaking field (stress) at any T < or > T_s. The data provide evidence that the low-energy excitation spectrum in the nematic phase is shaped by an important interplay of the anisotropic spectral (Drude) weight and scattering rate. In the zero-frequency limit though, the charge scattering rather than the Fermi surface parameters seems to determine the nematic anisotropy. In a broader context, these findings may support theoretical proposals advocating a close connection between spin fluctuations, nematicity (i.e., orbital order) and superconductivity [1,2].

FE-05. Dynamic, disordered ground state in the fluorite, $Dy_2Zr_2O_7$. *J.S. Gardner*[1], C. Wang[3], J. Ramon[2], L. Ishida[2], P.L. Bernardo[2], M.M. Leite[4], F.M. Vichi[4] and R.S. Freitas[2] *1. Songshan Lake Materials Laboratory, Dongguang, China; 2. Physics, Universidade de São Paulo, São Paulo, Brazil; 3. Neutron Group, National Synchrotron Radiation Research Center, Hsinchu, Taiwan; 4. Instituto de Química, Universidade de São Paulo, São Paulo, Brazil*

Neutron scattering, a.c. magnetic susceptibility and specific heat studies have been carried out on polycrystalline $Dy_2Zr_2O_7$ [1]. Unlike the pyrochlore spin ice $Dy_2Ti_2O_7$ [2,3], $Dy_2Zr_2O_7$ crystallizes into the fluorite structure and the magnetic Dy^{3+}moments randomly reside on the corner-sharing tetrahedral sublattice with non-magnetic Zr ions. Also unlike the Spin Ice compounds, antiferromagnetic spin correlations, not ferromagnetic ones, develop below 10 K. A.C. magnetic susceptibility suggests the magnetic Dy^{3+}moments remain dynamic down to 40 mK, with a significant amount of magnetic susceptibility. The spatial correlations extend over the length of two tetrahedra edges in zero magnetic field. We propose that the longer nearest neighbor distances promotes antiferromagnetic correlations and precludes the development of spin ice correlations. $Dy_2Zr_2O_7$ possesses fluctuating spins in a disordered, liquid-like state (albeit slow) and which do not freeze into a canonical spin glass state that one might intuitively expect. The application of a magnetic field to the polycrystalline sample results in extended correlations up to 6 nearest neighbors with the application of a 20 kOe magnetic field. Concomitantly, a subset of the spins enters a long-range ordered state, and resolution limited Bragg peaks are observed in neutron scattering experiments.

FE-06. Probing the Antiferromagnetic-Ferromagnetic Transition in Artificial Spin Ice. *M. Massouras*[1], D. Lacour[1], M. Hehn[1] and F. Montaigne[1] *1. Institut Jean Lamour, Nancy, France*

Artificial spin ice, two-dimensional arrays of nanomagnets in close interaction, provide a playground to directly observe magnetic frustration [1–3]. By the use of shape anisotropy, mesoscopic Ising-like spins could be patterned with various spatial distributions. In this study, we experimentally examine

a tuned artificial spin ice system composed of nine tilted networks in which every bar is rotated around its central point. Rotating the elements of an angle ranging from 0° to 45° by 5° steps tunes the coupling strength inducing a transition from a antiferromagnetic phase for the square system to ferromagnetic phase for the 45°-tilted network or pinwheel system [3]. The as-grown state was observed [2] using Magnetic Force Microscopy (MFM) thus right after lift-off, the image obtained for the 35°-tilted network is shown in Fig.1. We characterize our system using vertex population, spin configurations, magnetic structure factor and dipolar energy to probe the phase exhibited by each array. We show that from the square up to the 25°-tilted array, the antiferromagnetic phase is clearly dominating although an increased number of excitations whereas the 40° and 45°-tilted networks exhibit a ferromagnetic phase arranged in domains. This transition is clearly demonstrated by their specific Bragg peaks on magnetic structure factor in Fig.2. This behavior is consistent with dipolar computations and Monte Carlo simulations for this tuned system. However in between, 30° and 35°-tilted arrays exhibit both phases on magnetic structure factor but their spin configurations show an arrangement in domains rather that a disorder state. Dipolar energy of our experimental system show deviations from the expected ground state that are described by an effective temperature determined by Monte Carlo simulations consistent with previous theoretical studies [3].

FE-07. Tunable Frustration in Antiferromagnetic Artificial Kagome Spin Ice. *Y. Li*[1], F.P. Barrows[2,1], A. Petford-Long[1,3] and C.M. Phatak[1]
1. Materials Science Division, Argonne National Laboratory, Lemont, IL, United States; 2. Northwestern University, Evanston, IL, United States; 3. Materials Science and Engineering, Northwestern University, Avanston, IL, United States

Artificial spin ices (ASI) are patterned nanomagnetic arrays in which the inter-play between the moment orientations of Ising-like elements and their coupling strength leads to the emergence of exotic phenomena such as magnetic frustration[1,2]. Here we report a novel ASI geometry – an antiferromagnetic (AFM) Kagome ASI, in which each element in the Kagome lattice is formed from a pair of islands. Such a geometry provides us with an additional degree of freedom to tune magnetic frustration by changing the inter-island distance, *s*, between the paired islands. Micromagnetic simulations were performed using Mumax[3] to predict the energies of all possible magnetic configurations for different lattice spacings, *a*, and inter-island spacing *s*, in the proposed antiferromagnetic Kagome ASI. With the distance between the paired islands being sufficiently small, the number of energy levels in the landscape is primarily determined by the number of possible combinations of the AFM- and ferromagnetic- (FM) aligned magnetization states between each pair at the vertices or the Kagome lattice. It is found that an increase in *s* decreases the energy difference between different magnetic configurations, leading to a more frustrated system. We also found that the degeneracy increases when the lattice constant *a* is reduced, thus leading to an increase in frustration. Guided by simulation results, we lithographically fabricated the antiferromagnetic Kagome ASI arrays from a Permalloy ($Ni_{80}Fe_{20}$) film, where each island has dimensions of 300 nm × 100 nm and approximately 3 nm thickness. The geometric parameters *a* and *s* of the lattice are varied from 350 to 550 nm and from 130 nm to 250 nm, respectively. Direct images of the magnetization configurations in the antiferromagnetic Kagome ASI arrays were obtained by use of the Lorentz transmission electron microscopy (LTEM). We will show how the magnetization state of the ASI sample is affected by the interaction strength determined by *a* and *s*.

FE-08. Characterization of noncollinear spin textures in spin ice materials using capacitive torque magnetometry. *C. Beekman*[1,2]
1. Physics, Florida State University, Tallahassee, FL, United States; 2. National High Magnetic Field Laboratory, Tallahassee, FL, United States

Geometrically frustrated systems have received a lot of attention because incompatibility between the lattice geometry and the magnetic interactions results in macroscopically degenerate ground-state manifolds, and numerous unusual cooperative spin states [1]. In pyrochlore titanates ($A_2Ti_2O_7$ with A = Ho, Dy), large single ion anisotropy leads to a highly degenerate two-in/two-out spin ice state. Degeneracy is lifted when magnetic fields are applied, leading to magnetic transitions between various spin textures that depend on the direction of the field (see Fig. 1 [2,3]), and to emergent quasiparticle

excitations equivalent to magnetic monopoles. There is an enticing potential of harnessing these monopoles, as information carriers; to realize this thin films are required. The go-to tools for spin ice characterization, such as neutron scattering, are very challenging on thin films (due to the small amount of material present). We show that capacitive torque magnetometry can be used to perform magnetic crystallography on highly anisotropic systems such as spin ices, and more importantly, that the technique is sensitive enough to perform the same characterization on thin film samples. The technique involves a sample mounted on a flexible Cu-Be cantilever that serves as a top plate of a parallel plate capacitor. Changes in capacitance as a function of applied field strength, field direction, and temperature, are directly proportional to the torque, i.e., changes in the magnetic properties of the sample. Using capacitive torque magnetometry we can distinguish between the various noncollinear spin textures of the spin ice state shown in Fig. 1. Furthermore, transient states away from equilibrium, i.e., spin flips (monopoles), result in measurable changes in torque and can also be observed. We have performed torque measurements for a variety of rotation planes in a $Ho_2Ti_2O_7$ single crystal and we will show that a simple model suffices to explain the observed torque behavior. Hence, we can chart the respective phases of the spin ice state as a function of field strength and direction, and we can extract information on the transitions between them. This very sensitive technique is highly suitable for thin film characterization; hence, this paves the way to compilation of phase diagrams detailing spin ice physics in thin films as a function of temperature, film thickness, and strain. We will show data on thin films that indicate that spin ice physics in thin films grown on yttria-stabilized zirconia substrates [4] is modified compared to bulk spin ice behavior.

Magnetic monopoles, proposed as elementary particles that act as isolated magnetic south- and north poles as an explanation of the quantization of the electric charge [1] have long been the subject of intense research efforts. In solid state physics, a classical analogue to these elusive particles has been shown to emerge as topological excitations out of the ground state manifold of magnetic systems generally known as pyrochlore spin ices [2,3]. In our work, we introduce extensively degenerate artificial spin ice systems exhibiting thermally induced moment reorientations [4]. We not only directly visualize magnetic configurations achieved following thermal annealing, but also perform real-time observations and characterization of thermal fluctuations and motion of emergent magnetic monopole defects, allowing us to perform a first-time real-space characterization of emergent magnetic monopoles within the framework of the Debye-Hückel theory. Our work marks a starting point for a whole new line of research aiming at real-space investigations on the nature of macroscopic degeneracy, spin freezing phenomena and verification of magnetic analogues to electrolyte models [3,5].

Frustration refers to the inability of a system for simultaneously minimize its interactions, as a consequence, its ground state is degenerate. Geometric frustration in materials known as spin ices [1], which have magnetic moments in the net obeying the ice rule (a rule similar to that of water molecules), has attracted great attention of researchers in the last decade, due to emergence of quasi-particles like monopoles [2]. Studies of magnetic monopoles have also being directed to arrays of magnetic nanobars, known as artificial spin ices (ASI). In the ASI system magnetic monopoles can also be observed [3], with the advantage over natural spin ices of monopoles observation with magnetic microscopy techniques and manipulation of these monopoles at room temperature. In this work, we present a study on ASI emergent excitations for different lattice geometries and spacing during a magnetization reversal process through analysis of magnetic force microscopy images, as presented in Figure 1. Our results are well fitted by a theoretical model that describes the emergent excitations in the ASI with coulomb and dipolar interaction among monopoles and dipoles [4]. With our results we could investigate the density of monopoles and its response to the external magnetic field and map its highest mobility in function of lattice parameters. FE-11. Domain Wall Propagation in Magnetic Galton Board.

M. Massouras[1], D. Lacour[1], M. Hehn[1] and F. Montaigne[1] *1. Institut Jean Lamour, Nancy, France*

A wide range of devices based on domain wall (DW) propagation has been proposed and investigated. Magnetic storage is obviously the key application either in the form of single bit or multi-level devices or in "racetrack" devices. But other applications are also targeted like magnetic logic devices, multiturn position sensors, memresistors… Many aspects are involved in this propagation: DW topology, pinning/depinning phenomena, temperature effects, driving force (magnetic field, charge currents, spin currents, light…), dynamic aspects and particularly Walker breakdown…. Reproducible and controllable domain wall propagation is therefore a challenge for most of the evocated devices that require a precise control of the DW propagation. On the other hand, other devices might benefit from random or pseudo-random propagation for random number generation[1], cryptography or neuromorphic structures. This aspect will be investigated in this presentation with the demonstration of the magnetic analog to the Galton board. We developed an artificial spin ice system arranged in honeycomb lattice to observe one-dimensional propagation of a DW[2]. The study of a classical design of a 3-output Galton board with connected nanomagnets demonstrated the successful injection of a DW with an ellipsoidal pad (Fig. 1) and its propagation throughout the structure by applying an in-plane field. Activated outputs show a stochastic behavior with a Gaussian distribution. The 8 outputs board highlighted the limitations of such a design: higher fields are needed to propagate the DW than to nucleate one at outter outputs as shown in Fig. 2. Thus, we elaborated a novel structure with smooth vertices in a funnel shape and sharp ends to decrease the pinning field increase the nucleation field at the outputs respectively as shown in Fig. 1. The corresponding activated outputs exhibit a better Gaussian distribution yet biased probably due to field misalignment but more acceptable number of activated outputs on the sides.

FF-01. Magnetism, Hidden Order and Emergent Collective Behavior in a Bacterial Suspension. *R. Sooryakumar[1] 1. Department of Physics, The Ohio State University, Columbus, OH, United States*

One of the most fascinating aspects of living matter is their ability to form exotic structures emerging from large numbers of individual disordered components. Moreover, these structures span a staggering range of length scales ranging from, for example, bird flocks and ant colonies to microscopic cells that come together to form tissues. While bacteria are often thought of as solitary organisms, we have recently identified [1] a new form of collective behavior of bacteria in species which are not only abundant in nature but also *synthesize their own magnetic nanoparticle arrays.* In addition to their inherent magnetism, the species is motile where the chemically powered flagellum (a thin helical appendage responsible for cellular propulsion) provides the source of activity. When magnetically guided to orient near a surface, the hydrodynamic wake produced by these swimming bacteria draws in nearby cells, resulting in dense clusters and networks, reminiscent of large scale galactic structures. As these shapes grow larger, the process slows down, as the innate magnetic forces push the clusters apart leading to stable, long-lived cluster structures. To quantify the self-organization, a Lempel-Ziv compression algorithm [2] is applied to each recorded image. As recently demonstrated [3], this approach, which is widely used in file compression applications, yields the computable information density, which bounds the Shannon entropy. It also provides a generic measure of the order in the system without knowledge of the particular nature of the ordering and reveals the phase boundary defining the onset of self-organization. The high degree of experimental control offered through their magnetism and theoretical tractability offered by this bacterial system enables broad questions in active matter self-organization to be addressed. The ensuing mathematical description of order in a nonequilibrium living, many-body system provides a new framework to understand how microscopic active swimmers can be magnetically guided for diverse applications as in robotics and nano-medicine. The understanding gained from such complex, far-from-equilibrium systems are relevant to broader phenomena in biomagnetism, statistical mechanics and condensed matter physics.

FF-02. Mechanical resonator to measure magnetic susceptibility of structurally intact bone samples. L.R. Moore[1], M. Midura[1], R. Royer III[1], C. Androjna[1], E.I. Waldorff[2], N. Zhang[2], J.T. Ryaby[2], R.J. Midura[1] and *M. Zborowski[1] 1. Cleveland Clinic, Cleveland, OH, United States; 2. Orthofix Inc., Lewisville, TX, United States*

Low frequency, low field pulsed electromagnetic field (LF PEMF, below 10 kHz and 10 mT amplitude) is an FDA-approved treatment of fracture non-unions and an adjunct to cervical fusion surgery. LF PEMF exerts measurable magnetic force on bone [1] and the combined effect of the local B field vector and the bone susceptibility tensor determine the local force magnitude, a potentially important factor for treatment efficacy. We compared magnetic susceptibility measured by commercial susceptometer (MSB Auto, Sherwood Scientific) with that measured by a custom built mechanical resonator comprising a diametrically-polarized NeFeB permanent dipole magnet cylinder (25.4 x 25.4 mm, height by diameter) rotated about its axis by a stepper motor at even intervals from 53 – 63 RPM, acting on an intact bone sample (rat lumbar vertebrae) suspended 26.0 mm from magnet axis on a thin line of 71.0 mm effective length. The sample was exposed to a local oscillating mean field of 250 mT, gradient of 50 T/m, and its motion was captured by a video camera and resolved into 2D space coordinates versus time by ImagePro® and Excel® macros (Figure). The MSB Auto susceptometry required bone pulverization resulting in the loss of information about bone magnetic anisotropy, unlike that measured by mechanical resonator at three different spatial bone orientations. The amplitude of bone oscillations at twice the angular frequency of the rotating magnet yielded maximum displacement that agrees with the forced, damped simple pendulum model and the local diamagnetic Maxwell stress as the driving force. The mean volume magnetic susceptibility (SI) of -8.75 $x10^{-6}$ ± 2% (n=7 vertebrae) agreed with that calculated from the mechanical resonator traces showing the strongest field-tissue interaction for the vertebra axis orientation normal to the local field vector. The results point to site-specific aspect of LF PEMF therapy and provide novel, rational methods of designing next generation of effective LF PEMF therapies.

Lawrence Berkeley National Lab, Berkeley, CA, United States; 4. University of Massachusetts, Amherst, Amherst, MA, United States*

Solid ferromagnetic materials are rigid in shape and cannot be reconfigured. Ferrofluids, while reconfigurable, are paramagnetic at room temperature and lose their magnetization when the applied magnetic field is removed. Here, we show a reversible paramagnetic to the ferromagnetic transformation of ferrofluid droplets by the jamming of a monolayer of magnetic nanoparticles assembled at the water-oil interface. These ferromagnetic liquid droplets exhibit a finite coercivity and remanent magnetization. The ferromagnetic response is striking since the separation distance between the dispersed nanoparticles is much larger than characteristic distances of ferromagnetic dipolar coupling. They can be easily reconfigured into different shapes while preserving the magnetic properties of solid ferromagnets with classic north-south dipole interactions. Their translational and rotational motions can be actuated remotely and precisely by an external magnetic field, inspiring studies on the active matter, energy-dissipative assemblies and programmable liquid constructs.

FF-04. Magnetism as an Efficient Tool for Malaria Detection. Y. Kumar[1], *A. Rathi*[1], A. Singh[1], G. Sumana[1], B. Gahtori[1], R. Pant[1] and G. Basheed[1] *1. AcSIR, CSIR-National Physical Laboratory (NPL) campus, New Delhi, India*

Malaria is an extremely devastating mosquito-borne blood disease caused by Plasmodium parasites (mainly falciparum, 99.7 %), resulting in approximately five million deaths every year around the world, according to world malaria report 2018 [1]. This situation is despite of malaria being easily preventable and curable. In this connection, the major challenge remains accurate and early stage (efficiency) detection of malaria on affordable prices. The present day moderate-cost rapid diagnostic tests (RDTs) are limited by sensitivity (detection only above 100-200 parasites/μl blood), and a more rapid, sensitive and affordable alternatives are need to be developed [2]. Here, we, in lab, chemically produced β-hematin, which is a synthetic analogous of malaria pigment hemozoin, resulted from hemoglobin detoxifcation by the Plasmodium parasite [3]. The analogy of β-hematin to hemozoin is confirmed by Fourier-transform infrared spectroscopy (FTIR) spectroscopy. The β-hematin is formed in shape of nano-sized needles with diameter of 50-100 nm, and length of 200-600 nm, as revealed by High-Resolution transmission electron microscopy (HRTEM) study. The X-ray diffraction and HRTEM study reveal a high crystalline nature of β-hematin (in similar to hemozoin). Importantly, Vibrating-sample magnetometer (VSM) shows that β-hematin nanoneedles are magnetic in nature with (technical) saturation field of 2 kOe. This highly sensitive magnetic and more importantly, highly anisotropic nature (due to needle shape) of β-hematin (hemozoin) enables us to develop an easy, cost-effective and highly efficient detection technique for malaria. We are in process to develop a compact magneto-optical setup using a set of diode red laser, polarizer, quartz cuvette (for sample mounting), NdFeB permanent magnets and highly sensitive photodiode (determining the efficiency for malaria detection) for highly efficient and cost-effective malaria detection.

FF-05. Interaction of Two Magnetic Micro-Chains in Rotating Field. *J. Cheng*[1], C. Lin[1] and C. Chen[1] *1. Mechanical Engineering, National Chiao Tung University, Hsinchu City, Taiwan*

Magneto-microfluidics have been popular research subjects because of their effective manipulability by an external magnetic field. One particular branch of these studies focuses on microchains consisted of magnetic

particles and driven by a rotating field. Under such a condition, the microchains are induced to perform two distinct modes of rotational motion: individual rotation and global revolution. Because of the magnetic torque induced by the phase lag between the external field and the individual microchain, the microchain rotates synchronously with the field. On the other hand, the magnetic attraction/repulsion between the microchains drives the microchains undergoing tangential motion similar to planetary revolution. To elucidate the dual rotational motion, experiments of two microchains, consisted of several 5-micrometer magnetic beads, are conducted. Two possible modes of the magnetic interactions between the chains are identified, referred to as chaining and lock-on, respectively. In more common situations, the two chains, subjected an overall magnetic attraction to each other while undergoing global revolution, would approach to connect, and form a longer rotating chain. Temporal evolution of the chaining mode is shown in Fig. 1. Nevertheless, an interesting mode of lock-on may occur, in which the two chain appear nearly parallel, and revolute along a certain origin, whose orbits mimic the system of binary stars as shown in Fig. 2. To understand the dynamics of these two distinct modes, the forces involves in the system, such as magnetic forces and hydrodynamic drags, are evaluated. The criterion forming the lock-on mode is analyzed based on the balance of these two forces.

FF-06. Auditory Evoked Fields (AEFs) Measurements via Peak to Peak Voltage Detector Type MI Gradiometer. *J. Ma*[1] and T. Uchiyama[1]
1. Department of Electrical Engineering, Graduate School of Engineering, Nagoya University, Nagoya, Japan

1. Introduction As one of the most prominent responses in AEF, N100 surfaces as a negative deflection with a latency of roughly 80 to 120 ms after the onset of a stimulus. In this study, we have developed a peak to peak voltage detector type MI sensor system for auditory evoked fields measurements. 2. Pk-pk VD-type MI sensor system For measuring extremely weak magnetic fields, we have developed Pk-pk VD-type MI sensor system based on the new MI magnetometer reported recently [1]. We have achieved a high sensitivity of 1.4×10^7 V/T with good linearity, which is 1.3 higher than that of previous MI sensor. The noise floor of new MI sensor system is lower than 1 pT/Hz$^{1/2}$ in the frequency range from 1 Hz to 100 Hz. It is 1/10 of noise level of previous MI gradiometer [2]. 3. N100 measurements We record MEG signals by Pk-pk VD-type MI sensor system, with a 1-20 Hz bandpass filter. Fig. 1 illustrates averaged N100 brain activity waveforms evoked by 1 kHz auditory stimuli, on the left and right sides of the temporal region. As shown in Fig. 1(a), there is a positive deflection with latency about 120 ms obviously elicited by auditory stimuli. In Fig. 1(b), there is a negative deflection. The polarity of deflections on the left and right temporal regions is opposite. The amplitudes of the N100 deflections are approximately 4 pT. We have also demonstrated N100 measurements in different stimuli conditions with different frequency of auditory stimuli. Fig. 2 illustrates the averaged N100 signals evoked by auditory stimuli with 1 kHz, 2 kHz, 4 kHz, 6 kHz and 8 kHz frequency. For all stimuli conditions, we have successfully observed positive deflections with a latency about 100 ms. Fig. 2(b) illustrates amplitudes and latency of N100 signals depending on frequency of stimuli. N100 amplitudes of all subjects have a tendency to decrease with frequency of auditory stimuli. According to the results, these characteristics coincides well with previous studies [3].

FF-07. Green Synthesis of Magnetic Nanoferrites (Fe, Co, Ni) from Aloe Vera Extract and Its Biomedical Potential. *G.C. Hermosa*[1], H. Wu[1], C. Liao[1], S. Wang[2], Y. Chen[1,3] and A. Sun[1] *1. Chemical Engineering and Materials Science, Yuan Ze University, Taoyuan, Taiwan; 2. Department of Materials and Mineral Resources Engineering, National Taipei of Technology, Taipei, Taiwan; 3. Surgery, Far Eastern Memorial Hospital, New Taipei, Taiwan*

The synthesis of magnetic nanoferrites is an active area of academic and, more importantly, "application research" in nanotechnology for potential biomedical use. A variety of chemical and physical procedures could be used for synthesis of nanoferrites. However, these methods are fraught with many problems with the use of toxic solvents, generation of hazardous by-products, and high energy consumption. Accordingly, there is a vital need to develop environmentally benign procedures for the synthesis of nanoferrites. A promising approach to achieve this objective is to exploit the array of biological resources in nature. Indeed, over the past several years, plants, have been used for production of low-cost, energy-efficient, and nontoxic metallic nanoferrites. Plant-mediated synthesis of nanoparticles is a green chemistry approach that connects nanotechnology with plants. This innovation is particularly compensating as far as decreasing the poisonous quality caused by the conventionally integrated NPs. Aloe Vera leaf extract is a medicinal agent with multiple properties including an antibacterial effect. Moreover, the constituents of Aloe Vera leaves include lignin, hemicellulose, and pectins which can be used in the reduction of nanoferrites. The magnetic nanoferrites (Fe, Co, Ni) were prepared by an eco-friendly hydrothermal method using an Aloe Vera plant extract solution as both a reducing and stabilizing agent. Magnetic nanoferrites were characterized using FTIR, XRD, VSM and SEM. Cytotoxicity were obtained using the MTT assay. X-ray diffraction analysis also demonstrated that the size range of the nanoferrites exhibited average diameters of 7- 19 nm. Results showed that all the metallic nanoparticles are magnetic with values Fe= 52 emu/g, Co= 33 emu/g and Ni=7.1 emu/g. The magnetic nanoferrites exhibited high cell viability rate at high concentrations signifying their non-toxic property. The magnetic nanoferrites produced in this study by green synthesis methodology from leaf extract of *Aloe Vera* needs to be further evaluated and could find greater biomedical application.

FF-08. Magnetic Characteristics of Magnetic Markers for Localized Tumor Excision with a Handheld Magnetic Probe. *Y. Xiao*[1], O. Bhowmik Debnath[1], S. Chikaki[1], A. Kuwahata[1], M. Peek[1], I. Saito[2], S. Maeda[3], M. Kusakabe[4,1] and M. Sekino[1] *1. University of Tokyo, Tokyo, Japan; 2. iMed Japan Inc, Tokyo, Japan; 3. Kyoshin Co., Ltd, Nasu Shiobara, Japan; 4. Matrix Cell Research Institute Inc., Ushiku, Japan*

To excise the primary tumor on patient with a non-palpable breast cancer, surgeons estimate the excision margin by naked eyes subjectively with the help of a localization tool such as a hook wire(1). By introducing a magnetic detection system, location of the magnetic marker injected intratumorally can be identified with a handheld magnetic probe(2). Detection ranges of existing magnetic markers are up to 30 mm(3), limiting application in tumors located deeper down the skin. In this study, materials and designs of magnetic markers are evaluated to achieve an extended detection range. Todetermine the material that generates strong magnetic signal, magnetic properties of marker samples in selected materials including SUS (stainless steel) 304, SUS 316 and permalloy are analyzed. Samples are fabricated with wire with a diameter of 0.8 mm into the hook shape shown in Fig. 1(a). Measured magnetic signal strength is shown in Fig. 2(a). Amongst the three, SUS 304 generates the strongest signal, therefore is determined as the material for the marker. Three marker designs are evaluated. The first design is a hook shape, similar to the tip of a hook wire, as shown in Fig. 1(a). The second design is a 'Y' shape where one wire is folded and twisted as shown in Fig. 1(b). The third design is an 'X' shape where two wires are twisted together at the middle, as shown in Fig. 1(c). Three markers are made of SUS 304 wire with a diameter of 0.4 mm. Signals from these three markers are shown in Fig. 2(b). Results show that all three designs generate magnetic signals greater than 1μT, which can be detected by the magnetic probe, at distance of 42 mm, while the 'X' shape marker achieves the longest detection range of over 50 mm, which exceeds the detection range of 30 mm of existing magnetic markers. Application range of the marker is widened, including tumors at all depths and in all breast sizes. As a next step, magnetic properties of the marker in three dimensions will be evaluated.

Department of Electrical and Electronic Engineering, Tokyo Institute of Technology, Tokyo, Japan; 4. Institute of Quantum Optics, Ulm University, Ulm, Germany; 5. Matrix Cell Research Institute Inc., Ibaraki, Japan*

Magnetic nanoparticles (MNPs) have been widely employed in biomedical applications, such as diagnosis and therapy of various diseases [1]. Advanced clinical studies have demonstrated the feasibility of the detection of MNPs using the magnetometer, as a promising technique alternative to harmful radioactive particles, to diagnose cancer metastasis in breast cancer patients [2,3]. To further expand the applicable clinical regime, there is a need to develop highly sensitive magnetic detection. The negatively charged nitrogen-vacancy (NV-) color center in a diamond provide immensely a remarkable quantum magnetic sensing, which enables us to detect sub-pico-Tesla at room temperature [4,5]. In this study, we have developed the novel magnetometer with NV- center in a bulk diamond for detecting MNPs (Fig. 1). The optical fiber-based system is employed to fabricate the compact probe system compared with a confocal-based optical system, and the alternating current (AC) magnetic fields (~1 mT) of the excitation coil system to magnetize MNPs yields the highly sensitive detection of MNPs. Figure 2(a) shows the magnetic sensitivity of the developed probe in the Lock-in detection system. The minimum detectable AC magnetic field is approximately 60 nT. The sensitivity of the MNPs detection with the developed probe strongly depends on the remnant excitation fields. We thus produced the magnetic null point at the NV- center location by using an additional cancellation coil for eliminating the remnant fields, and achieved the detectable distances with respect to MNPs of 40 and 5 mL are 9 and 5 mm, respectively, as shown in Fig. 2(b). These results indicate the developed probe can detect the tiny amount of MNPs. We will pursue the further highly sensitive detection by the enhancement of a light collecting efficiency and optimization of the excitation coil system.

FF-10. Development of an automatic magnetic immunostaining system for rapid diagnosis of cancer metastasis. *M. Sekino*[1], A. Kuwahata[1], A. Yoshibe[1], K. Imai[1], M. Kaneko[1], S. Chikaki[1], I. Saito[1], A. Tsuruma[2], S. Sakamoto[2], H. Handa[3], S. Matsuda[4] and M. Kusakabe[5] *1. The University of Tokyo, Tokyo, Japan; 2. Tokyo Institute of Technology, Tokyo, Japan; 3. Tokyo Medical University, Tokyo, Japan; 4. Keio University School of Medicine, Tokyo, Japan; 5. Matrix Cell Research Institute Inc., Tokyo, Japan*

Magnetically-promoted rapid immunofluorescence staining – using the functionalized fluorescent ferrite beads (FF beads of ~200 nm with diameter) [1] and permanent magnets – is a novel technique providing us with the intraoperative diagnosis of cancer metastasis. The magnetic force of the magnets promotes the binding between the objects and FF beads, resulting in the reduction of the immunostaining time. Recent clinical studies have demonstrated the feasibility of this technique with experts' hand-operations [2]. There is a clinical need for the automation of this magnetic staining technique to diagnose without experts in medical institutions. In this paper, we established the specifications of an automatic system, such as the shape of a permanent magnet, the iron concentration of the FF beads, and the condition of immunoreaction, based on the hand-operated experimental results, and fabricated an automatic device. Figure 1(a) shows a magnetic immunostaining device to stain automatically five frozen sections of biomedical tissues, such as lymph nodes. The five sections are stained effectively by the reciprocating motion of the five magnets (the magnetic force: ~10^{-15} N for each nanoparticle). The automatic procedures are completed within 10 minutes, realizing the intraoperative diagnosis of cancer metastasis. Figure 1(b) shows five frozen sections of mouse xenograft samples stained simultaneously by the prototype device. While red fluorescence of cancer cells expressing EGFR (epidermal growth factor receptor) on the frozen section was clearly observed, there is no fluorescence on the section without EGFR.

The results indicate that we succeeded to demonstrate the feasibility of the automatic immunofluorescence staining. Further clinical studies with human lymph nodes are needed to develop as a medical device.

FF-11. Development of an optimized dome-shaped magnet in magnetically-promoted rapid immunofluorescence staining for cancer diagnoses. *M. Sekino*[1], A. Kuwahata[1], S. Fujita[1], S. Matsuda[2], M. Kaneko[1], S. Chikaki[1], S. Sakamoto[3], I. Saito[4], H. Handa[5] and M. Kusakabe[6] *1. The University of Tokyo, Tokyo, Japan; 2. Keio University School of Medicine, Tokyo, Japan; 3. Tokyo Institute of Technology, Tokyo, Japan; 4. iMed Japan Inc., Tokyo, Japan; 5. Tokyo Medical University, Tokyo, Japan; 6. Matrix Cell Research Institute Inc., Ibaraki, Japan*

To accelerate the diagnosis speed of cancer cells, magnetically-promoted rapid immunofluorescence staining has been devised by the applications of the functionalized fluorescent ferrite beads (FF beads of ~200 nm with diameter) and the magnetic force generated by a permanent magnet [1,2]. This novel magnetic staining method enables us to diagnose cancer metastasis intraoperatively. To realize the spatial uniformity of magnetic immunostaining for enhancing the sensitivity of the diagnoses, the optimization of the magnetic shape that can generate the uniform/strong magnetic force is required. In this study, we developed the dome-shaped magnet optimized by numerical simulations and experimentally evaluated the uniformity of the immunostaining by using the optimized magnet. To promote the immunoreaction, the magnetic force (~10^{-13} N for each particle) is applied to the FF beads solution above the frozen section of cancer cells on the slide grass as shown in Fig. 1(a). Our numerical calculations show the magnetic force, particle trajectory of FF beads, and optimization of the magnet shape. Figure 1(b) shows the uniform distribution of the magnetic force and FF beads attracted on the frozen section compared with conventional column-shaped magnets. In Fig 2(a), red fluorescence color represents the cancer cell with EGFR (epidermal growth factor receptor) stained by the dome-shaped magnet. The spatial distribution of red fluorescence intensity of the dome-shaped magnet is uniform as same as numerical evaluations, as shown in Fig. 2(b). These results indicate the optimized dome-shaped magnet is effective for the uniform immunostaining. In the future, we will perform the clinical trial using human tissue, such as lymph nodes, to demonstrate the feasibility of this technique using the proposed magnet.

FF-12. Capillary Hysteresis Effects in Magnetic Hyperthermia Cancer Treatment. *M. Pavel*[1], R. Tanasa[2], D. Constantinescu[1], C. Cianga[1], P. Cianga[1] and A. Stancu[1,2] *1. Department of Immunology, "Grigore T. Popa" University of Medicine and Pharmacy of Iasi, Iasi, Romania; 2. Department of Physics, Alexandru Ioan Cuza University of Iasi, Iasi, Romania*

As magnetic hyperthermia is gradually evolving towards an accepted technique for cancer treatment one observes the need for modeling the entire process with sufficient accuracy in order to avoid unnecessary destruction of healthy tissue during the treatment. The computation of the right doses of magnetic material for a concrete case includes not only the proper calculus of the heat produced by the magnetization a.c. process [1-3] but also the right distribution of the particles in the tissue with the proper consideration of the real physical properties of the tissue. This includes the initial process in which the magnetic fluid is inserted in the biological tissue by the means of a syringe. The most difficult part of this simulation is to take into account correctly how the fluid is flowing into the porous biological tissue. Recently, we have analyzed the case of homogenous porous media [4]. However the real media are non-homogenous and in order to correctly find the right distribution of particles in the porous material one should take into account the capillary hysteresis of the flow of the magnetic fluid. In this work we have simulated the flow of a magnetic fluid in a porous material with a known structure. We have evidenced a complex hysteretic behavior and identified the shape of a fundamental hysteron for the given structure (see Figs. 1-2). This type of hysteresis shows a number of similarities with the ferromagnetic hysteresis and potentially can be analyzed using the first-order reversal curves (FORC) technique, well known in magnetism. In the presentation we will show the properties of the hysteretic flow of the magnetic fluid in a real biological structure and evaluate the effect in the temperature field due to this fact.

FG-01. The origin of the athermal training effect in exchange bias multilayers. *S. Jenkins*[1], R.W. Chantrell[1] and R.F. Evans[1] *1. Physics, University of York, York, United Kingdom*

The exchange bias effect occurs when a FM is coupled to an AFM, causing a shift of the magnetic hysteresis loop. The shift is caused by pinned interfacial spins, these cause a unidirectional field pinning the exchange coupling of atomic spins at the interface. The training effect causes a large drop in the measured exchange bias after the first measured hysteresis loop[1]. This has two main causes: thermal training and athermal training[1]. Thermal training is due to well understood thermal instabilities in the AFM\cite{training}. The origin of athermal training however is still a widely disputed problem due to the difficulty in experimentally probing the rearrangement of AFM spins at the interface. It has been proposed to be due to the degree of order of the AFM at the interface. Here we uncover the origin of training in a CoFe/$IrMn_3$ ferromagnet/antiferromagnet (FM/AFM) bilayer using an atomistic spin model. To model the properties of the CoFe/ $IrMn_3$ bilayer we have developed an atomistic spin model[2]. The properties of the disordered $IrMn_3$ AFM are modelled using the Heisenberg form of the exchange interaction and the anisotropy is calculated using the Neel pair anisotropy model. These reproduce key experimental results including the Neel temperature and magnetic ground state. It was found that for an atomically flat interface, after field cooling and equilibration, a simulated hysteresis loop gave an exchange bias field of less than 0.25T and the training effect was non existent. As the width of the interface mixing is increased the training effect becomes stronger as shown in Fig. 1. The exchange bias was observed to increase with interface mixing for the initial hysteresis loop but the training effect causes a much larger reduction for subsequent hysteresis loops when the interface is mixed. We will present further simulations of the temperature dependence of the exchange bias with thermal training and a statistical study of polygranular exchange biased systems.

FG-02. Observation of a Chirality Created Exchange Bias Effect. *D. Lott*[3], K. Chen[1], A. Philippi-Kobs[2] and V. Lauter[4] *1. Helmholtz-Zentrum Berlin, Berlin, Germany; 2. Deutsches Elektronen-Synchrotron, Hamburg, Germany; 3. WPD, Helmholtz-Zentrum Geesthacht, Geesthacht, Germany; 4. Neutron Scattering Directorate, Oak Ridge National Laboratory, Oak Ridge, TN, United States*

The exchange bias effect refers to the unidirectional shift of the hysteresis loop of a magnetization curve, conventionally that of a ferromagnet in direct contact to an antiferromagnet. Chiral magnetism, on the other hand, that manifests in the existence of skyrmions or chiral domain walls, offers an alternative way for creating anisotropies in magnetic materials that might have large potential for being used in future spintronic devices. Alloys of rare-earth elements and 3d transition metals (RE-TM) became recently in the focus of attention due their rich variety of magnetic effects owed to the different anisotropies of both material classes [1-4]. Here we show experimental evidence for a new type of in-plane exchange bias effect present at room temperature that is created from a chiral 90 domain wall at the interface of a ferrimagnetic RE-TM (DyCo) layer in contact to a ferromagnetic (NiFe) layer. We found that the chiral interfacial domain wall is formed due to the presence of macroscopic Dzyaloshinskii-Moriya interaction in the ferrimagnetic layer and its orthogonal exchange coupling to the ferromagnetic layer at the interface. As a consequence of the fixed chirality of the interfacial domain wall, the sign of the shift of the hysteresis loop can be reversed by changing the direction of the out-of-plane magnetization of the ferrimagnetic layer (see Figure 1). The chirality created tunable exchange bias is very robust against high in-plane magnetic fields and does not show any damping effects after multiple reversal of the exchange bias direction, therefore, it overcomes the limitations of conventional exchange bias systems. Such chirality based EB systems may be of crucial importance for the development of future applications in the field of magnetic sensors and data storage devices.

The interfacial Dzyaloshinskii-Moriya interaction (DMI) is of great interest as it can stabilize chiral spin structures in thin film systems [1,2]. Usually in thin film systems with perpendicular magnetic anisotropy, the interfacial DMI vectors responsible for the type of magnetic chirality are expected to be parallel to the film plane [3], which has been experimentally demonstrated in many systems [4]. Measuring the rotation sense of in-plane Néel wall in in-plane magnetized systems may allow one to explore possible DMI vectors that are normal to the surface. In this work, we have measured the domain structures in magnetic films grown on fcc(001), fcc(110) and fcc(111) surfaces respectively. We find perpendicular magnetic anisotropy in Fe/Ni/Cu(001) and $[Co/Ni]_n$/Pt(111) systems where the interfacial DMI is sufficiently strong to stabilize chiral spin structures. By tailoring the effective anisotropy of the films, we observe achiral in-plane Néel walls in the in-plane magnetized regime in slightly thicker films with the same interfacial DMI interface. On the other hand, neither a perpendicularly magnetized regime nor in-plane Néel walls can be observed in Co/Pt(110) due to the presence of strong in-plane uniaxial magnetic anisotropy. These findings indicate that a substantial normal vector of the DMI is neither present in fcc(001) and fcc(111) oriented interfaces nor induced by atomic roughness. Supports by the NSF (DMR-1610060 and DMR- 1905468), UCOP (MRP-17-454963), and DOE (DE-AC02-05CH11231) are gratefully acknowledged.

FG-04. Modulation vector dependence of a second helical phase pocket in FeGe. *D. Burn*[1], S. Zhang[2,3], S. Wang[4], H. Du[4], G. van der Laan[1] and T. Hesjedal[2] *1. Diamond Light Source, Oxford, United Kingdom; 2. Department of Physics, University of Oxford, Oxford, United Kingdom; 3. School of Physical Science and Technology, ShanghaiTech University, Shanghai, China; 4. High Magnetic Field Laboratory, Chinese Academy of Sciences, Hefei, China*

FeGe is a noncentrosymmetric helimagnet in which non-collinear spin textures result from a competition between the exchange interaction and the spin-orbit-induced Dzyaloshinskii-Moriya interaction. Below the ordering temperature, T_c, bulk FeGe has a well-established and rich magnetic phase diagram showing helical, conical, and skyrmion states [1]. The skyrmion pocket has a wide temperature-field window extending up to room temperature [2,3] which can be manipulated through changes to the sample thickness [2,4]. These features make FeGe of great interest due to the potential for novel room-temperature technological devices based on the manipulation of topological magnetic states. In this work, we characterize the magnetic states in a thin slab of FeGe with smallangle soft x-ray scattering on beamline I10 at the Diamond Light Source as a function of both temperature and magnetic field applied out-of-plane. In addition to the helical, conical, and skyrmion phases, we observe an additional helical phase which coexists beneath the skyrmion phase towards the higher field boundary of the helical phase. In contrast to the other phases this additional helical phase shows strong uniaxial preferential alignment of the modulation vector. We have also explored the variation in the magnitude of the modulation vector when traversing each of the magnetic phase pockets. For the helical and conical phases, this shows a field-dependent but temperature-independent variation, whereas for the skyrmion phase both a field and temperature variation is observed. Furthermore, the two helical phases show significantly different coefficients for the field-dependent modulation vector contraction. Our findings build on other work for FeGe, strengthening the case that the room-temperature topological magnetic properties are of great interest for the development of novel technological devices. Our work shows how multiple coexistent phases can be simultaneously and uniquely identified which will provide further opportunities for potential information processing and storage methodologies.

FG-05. Interlayer exchange coupling in Fe/MgO/$Co_xFe_{3-x}O_4$(001) trilayers. *H. Koizumi*[1], M. Hagihara[1], S. Kobayashi[1] and H. Yanagihara[1,2] *1. Department of Applied Physics, University of Tsukuba, Tsukuba, Japan; 2. Tsukuba Research Center for Energy Materials Science, Tsukuba, Japan*

Interlayer exchange coupling (IEC) is a phenomenon in which two ferromagnetic (FM) layers are magnetically coupled and is understood within the framework of the spin-dependent quantum well model [1]. IEC is often found in trilayer systems with various different metallic layers. Besides the metallic trilayer systems, IEC through an insulating layer has also been reported for Fe/MgO/Fe [2], Fe/MgO/γ-Fe_2O_3(001) [3] and so on. Since thin films of $(Co,Fe)_3O_4$(CFO)(001) grown on MgO(001) exhibit large perpendicular magnetic anisotropy [4], we can expect that the trilayer of Fe/ MgO(t_{MgO})/CFO(001) shows IEC between a perpendicular FM insulator and an in-plane FM metal films. The multilayered structure of Fe/MgO/CFO was deposited on a MgO(001) substrate by the RF magnetron sputtering method. The thickness of the MgO(t_{MgO}) layer was formed with a wedged shape by using a continuously moving mask. We used two alloy targets

of Co_xFe_{3-x} with the composition ratio of x=0.75 and 0.125. Since both MgO and CFO are good insulators, anomalous Hall effect (AHE) measurements of the trilayer system solely reflect the magnetization processes of the Fe layer, and therefore the change of the saturation field($\Delta\mu_0 H_A$) determined from the Hall curves indicates the variation of IEC as a function of t_{MgO}. Because of the low $\mu_0 H_A$ and positive remanence, the evaluated exchange coupling at the interface of the bilayer system of Fe/CFO with x=0.125 is ferromagnetic. While the bilayer with x=0.75 was antiferromagnetic because of negative remanence. The trilayer systems of Fe/MgO/CFO with t_{MgO} ranging from 0.5 to 1 nm showed antiferromagnetic coupling for both x=0.125 and x=0.75, as shown in Fig.1. The overall t_{MgO} dependent IEC can be understood as the combination of both the *direct* coupling component that simply decreases with t_{MgO} and the MgO-mediated *indirect* antiferromagnetic coupling that exhibits a maximum at 0.5 to 1 nm. This result suggests that the composition ratio of the ferromagnetic material can control the strength of the IEC.

FG-06. Ab initio calculation of interlayer exchange coupling in synthetic antiferromagnetic pinned layer. *R. Takashima*[1], T. Tsukagoshi[1], T. Ishihara[1] and T. Kai[1] *1. Institute of Memory Technology Research & Development, Toshiba Memory Corporation, Kawasaki, Japan*

Interlayer exchange coupling (IEC)[1,2], coupling between two magnetic layers separated by a non-magnetic spacer layer, plays a crucial role in MRAM. Antiferromagnetic IEC is commonly used in the pinned layer in magnetic tunneling junctions (MTJ); the stray field can be reduced with the use of synthetic antiferromagnets (SAF), where magnetic layers have anti-parallel spin configuration via IEC [3]. In previous works, Co/Ru/Co or Co/Ir/Co, which shows strong antiferromagnetic IEC, has been considered as a promising material for SAF pinned layers [4]. However, it is recently pointed out that even stronger IEC is required in SAF pinned layers to increase the reliability of the operation in high density MRAM [5]. Therefore, it is necessary to find materials that show stronger IEC. In this work, we theoretically investigate IEC in cobalt-based multilayers by first principles calculations based on density functional theory (DFT) (Fig. 1), and find that several alloy spacers exhibit much stronger IEC compared to previously known spacers such as Ru and Ir. We show that IEC in $Co/Ru_{1-x}Fe_x/Co$ ($0 \leqq x \leqq 0.5$) increases as x increases (left panel in Fig.2), which qualitatively agrees with a recent experiment [6]. Furthermore, we show that several binary alloy spacers composed of a group 8 element and a group 9 element have stronger IEC compared to a single element spacer. In particular, we find that IEC in $Co/Ru_{0.5}Ir_{0.5}/Co$ is 1.4 times as stronger as one in Co/Ru/Co (right panel in Fig. 2). We expect that our study opens up new perspectives for the development of high density MRAM.

FG-07. Enhanced Exchange Interaction between Fe and FeO in Fe/FeO/CoO(NiO) due to the Antiferromagnetic Proximity Effect. *A. Koziol-Rachwal*[1], M. Slezak[1], P. Drozdz[1], W. Janus[1], K. Matlak[1], M. Szpytma[1], J. Korecki[1,2] and T. Slezak[1] *1. Solid State Physics, AGH University of Science and Technology, Krakow, Poland; 2. Jerzy Haber Institute of Catalysis and Surface Chemistry Polish Academy of Science, Krakow, Poland*

Antiferromagnets are promising candidates for future spintronic materials. However, due to the low ordering temperature a wide group of antiferromagnetic (AFM) materials seems to be useless for application. A new route towards formation of AFMs with a high ordering temperature and tunable spin configuration is to use magnetic proximity effect in AFM/AFM bi/multi-layered

structures.[1,2] In our study we examine the influence of proximity of antiferromagnetic layer with a higher ordering temperature on the magnetic properties of FeO in Fe/FeO/NiO(CoO). The layers were grown by molecular beam epitaxy on MgO(001) substrate. First, wedged shaped CoO(NiO) layers were prepared by reactive deposition of metal in an oxygen atmosphere on Cr buffer layer. After NiO(CoO) deposition FeO layer with a thickness of 1.9nm was prepared following the procedure described in [3]. Finally, 1-nm thick Fe layer was grown and capped with 3nm of MgO. The antiferromagnetic proximity effect was evaluated via examination of exchange interaction between Fe and FeO in Fe/FeO/NiO(CoO). Figure 1 presents temperature dependence of exchange bias field (H_{EB}) determined for Fe/FeO/NiO(CoO) systems from the hysteresis loops measured with longitudinal magnetooptic Kerr effect (LMOKE). While for Fe/FeO bilayer we noted H_{EB}=100Oe the exchange interaction between Fe and FeO was strongly enhanced when the Fe/FeO bilayer was grown on NiO(CoO). In particular for Fe/FeO/CoO(0.5nm) we noted a maximum of H_{EB} of about 600Oe. Moreover, with increasing CoO thickness significant enhancement of blocking temperature T_B was observed. For CoO thickness $t_{CoO} \geq$ 2nm T_B=290K can be estimated from MOKE data, which is much higher than a blocking temperature of Fe/FeO bilayer (140K). Similar enhancement of exchange interaction and increase of blocking temperature (T_B) was observed for Fe/FeO/NiO in comparison with Fe/FeO. In this case T_B was estimated to be 230K. Our study demonstrate the feasibility of tailoring the magnetic properties of AFM layer with a proximity of other AFM. FG-08. Fabrication and characterization of IrMn/PtMn/PtCr/PtMn antiferromagnets in terms of the role of each layer. *M. Saito*[1] and F. Koike[1] *1. Alps-Engineering Headquarters, Alps Alpine Co., Ltd., Nagaoka, Japan*

Antiferromagnet (AF) films of PtCr/Mn (0.5 nm), PtCr/FeMn (0.5 nm), and PtCr/PtMn (2 nm) exhibit a large unidirectional anisotropy constant (J_k) and high blocking temperature (T_b) [1], [2]. The $L1_0$ ordering temperature for PtCr (30 nm) was reduced by inserting PtMn (2 nm) at the CoFe/PtCr interface [2]. The AF layer structure was extended to $Ir_{80}Mn_{20}/Pt_{50}Mn_{50}/Pt_{50}Cr_{50}/Pt_{50}Mn_{50}$. Fig. 1 shows magnetization loops obtained for Si/alumina/NiFeCr/Cu/Ru/$Fe_{60}Co_{40}$(10 nm)/AF(30 nm)/Ru/Ta, where the AFs were PtMn(2 nm)/PtCr(28 nm) and IrMn(0.8 nm)/PtMn(1.2 nm)/PtCr(25 nm)/PtMn(3 nm), annealed at 350 °C for 20 h in a 10-kOe static field. Coercivity (H_c) was nearly halved while the exchange bias field (H_{ex}) remained almost unchanged, resulting in H_{ex}/H_c ratio > 1 for the later AF. Fig. 2 shows J_k plotted against total AF thickness, where the AFs were PtCr, PtMn, PtMn(2 nm)/PtCr, IrMn(0.8 nm)/PtMn(1.2 nm)/PtCr, and IrMn(0.8 nm)/PtMn(1.2 nm)/PtCr/PtMn(3 nm). The PtCr sandwiched by thin PtMn with ultrathin IrMn inserted at the FeCo layer interface showed J_k > 0.4 erg/cm^2, though total AF thickness was reduced to 18 nm. Effects of the PtMn layers are presumably the same as the reported effects of decreasing the $L1_0$ transformation temperature for FePt by AuCu [3] and PtMn [4] underlayers, and assisting PtMn ordering by the AuCu underlayer [5]. In other words, the typical annealing temperature to achieve ordered PtMn was much lower than that of PtCr, and the c/a ratio of bulk $L1_0$ PtMn was 0.92, lower than that of PtCr (0.99). The a-axis lattice constants of bulk $L1_0$ PtMn and PtCr were 0.400 nm and 0.382 nm, respectively. The larger lattice constants and lattice deformation during $L1_0$ transformation of PtMn may promote PtCr ordering, though the PtCr thickness was reduced to 11 nm. The dependence of each AF layer thickness on exchange bias properties and T_b will be shown at the conference to further discussed the role of each AF layer. GMR/TMR films utilizing the PtCr-based AF should achieve robust and thermally stable pin layers.

MnN as an antiferromagnet has a very large exchange bias and is known to have a large bulk Neel temperature of 600K [1] and is quite stable [2]. In this study we investigated Ta (10 nm)/MnN (30 nm)/CoFeB (t_{CoFeB})/Ta (0.5 nm)/Ta_2O_5 (2 nm) exchange bias system with CoFeB film thicknesses ranging from 5 to 20 nm. Using broadband and in-plane angle dependent ferromagnetic resonance measurements, we find a strong unidirectional anisotropy accompanied by a strong uniaxial in-plane anisotropy and a small interfacial perpendicular anisotropy $K_{\perp,i}$ = 0.043 ± 0.001 erg/cm^2. The strength of the interfacial exchange bias coupling in this system $\Delta\sigma_{eb}$ = 0.193 ± 0.005 erg/cm^2 is about 2.5 times larger than the interfacial uniaxial coupling strength $\Delta\sigma_u$= 0.076 ± 0.003 erg/cm^2 [3]. Exchange bias systems have shown a unidirectional contribution to relaxation [4,5]. For this system, we see a strong unidirectional and uniaxial in-plane anisotropy contribution to relaxation as shown in Fig 1 [3]. Our observations are consistent with the models of exchange bias that predict a square root dependence of the macroscopic coupling energies and on the corresponding local coupling energies [6]. In addition to that, the uniaxial anisotropy of the relaxation follows t_{CoFeB}^{-2} dependence (interfacial two-magnon scattering contribution). However, we find the uniaxial anisotropy of the relaxation does not strictly follow a t_{CoFeB}^{-2} dependence. Acknowledgements: MINT Center summer program & NSF-CAREER #1452670

FG-10. Interface Engineering towards Enhanced Exchange Interaction between Fe and FeO in Fe/MgO/FeO Epitaxial Heterostructures. *A. Koziol-Rachwal*[1], W. Janus[1], M. Szpytma[1], P. Drozdz[1], M. Slezak[1], K. Matlak[1], T. Slezak[1] and J. Korecki[1,2] *1. Solid State Physics, AGH University of Science and Technology, Krakow, Poland; 2. Jerzy Haber Institute of Catalysis and Surface Chemistry Polish Academy of Science, Krakow, Poland*

Interface structure plays a decisive role in determining the properties of ultrathin multi- layer structures. For ferromagnetic(FM)/antiferromagnetic(AFM) bi-layers ability to grow controllable, well-defined interface is crucial for interface driven phenomena such as exchange coupling between FM and AFM. [1] Recently, we succeeded in stabilization of an epitaxial wüstite (FeO) film on MgO(001) by reactive deposition of Fe in oxygen atmosphere[2] and we showed that proximity of a metallic Fe layer deposited on FeO(001) modifies the chemical and magnetic properties of oxide in the Fe/FeO stack. In present study we examined chemical and magnetic properties of FeO in an epitaxial Fe/MgO(d_{MgO})/FeO trilayers for different MgO thicknesses, d_{MgO}. Analysis of the chemical structure revealed a stoichiometry improvement of the FeO layer in Fe/MgO/FeO in comparison with a Fe/FeO bilayer. Interestingly, in Fe/MgO/FeO system, despite the separation of Fe and FeO films, enhancement of the exchange bias was observed as compared with the Fe/FeO bilayers owing to the superior structural and magnetic structure quality of FeO. For d_{MgO}=1.4Å we noted a 200% enhancement of exchange bias in Fe/MgO/FeO as compared with Fe/FeO. Acknowledgment *This work was supported by the "Antiferromagnetic proximity effect and development of epitaxial bimetallic antiferromagnets – two routes towards next-generation spintronics" project which is carried out within the Homing programme of the Foundation for Polish Science co-financed by the European Union under the European Regional Development Fund.*

FG-11. Magnetic Properties of Multilayers That Include GdFeCo Thin Films. *J. Bello*[1], M. Hehn[1] and S. Mangin[1] *1. Spintronics and Nanomagnetism group, Institut Jean Lamour, Nancy, France*

Amorphous rare-earth transition-metal (RE-TM) GdFeCo thin films are well-known to exhibit many interesting magnetic properties. Among those properties, perpendicular to film plane magnetization could be stabilized with weak anisotropies and total moment compensation depends on concentration and temperature. In addition to magnetic fields, its magnetic moment has been shown to be switched either by single femtosecond laser pulse [1] or spin orbit torque [2]. Since this material appears to be promising for future spintronics applications, we focused on the study of the magnetic

properties of multilayers that include this material. We first report the dependence of magnetic properties in $Gd_x(Fe_{90}Co_{10})_{1-x}$ ferrimagnetic alloys single layers on the composition and on the nature of the interfaces. 5nm thick $Gd_x(Fe_{90}Co_{10})_{1-x}$ layers were integrated in different multilayers, all grown by magnetron sputtering. For x between 22 and 33, we show that the composition at which the magnetic compensation occurs changes depending on the layers under and over the TE-RM layer. We studied different interfaces M/GdFeCo/N with M or N = Cu, Pt, Ta, Ir. We will detail which multilayer shows out of plane magnetization and for which compositions. Then, for GdFeCo layers having out of plane magnetization, more complex structures have been grown associating two GdFeCo layers. Especially, we grew GdFeCo/Ir/GdFeCo with varying Ir thickness. We show that it is possible to have an antiferromagnetic coupling (Fig. 1). As for ferromagnetic layers, the coupling depends on the thickness of the Ir layer and varies following the typical oscillation of the RKKY interaction. Those synthetic antiferromagnetics will be used in the future to extend the Walker breakdown limit for domain wall motion as predicted [3]. Domain wall motion at compensation of the SAF or of each layer will be measured. Furthermore, magnetization reversal using laser pulses or spin orbit torques will be tested in the near future on the same structures.

FG-12. Broad Tunability of Interfacial Magnetic Anisotropy by Rashba Spin-orbit Coupling in Metal/Ferrimagnetic-Insulator Bilayers. *A.J. Lee*[1], A.S. Ahmed[1], B. McCullian[1], S. Guo[1], M. Zhu[2], S. Yu[1], P. Balachandran[3], J. Hwang[2], P.C. Hammel[1] and F. Yang[1] *1. Physics, The Ohio State University, Columbus, OH, United States; 2. Center for Electron Microscopy and Analysis, The Ohio State University, Columbus, OH, United States; 3. Materials Science and Engineering, University of Virginia, Charlottesville, VA, United States*

It has been widely studied and accepted that the interface of a magnetic thin film can play a crucial role in the film's overall magnetism and therefore can be manipulated to alter magnetic properties. Specifically, interfacial magnetic anisotropy research has focused on metallic ferromagnets where specific seed and capping layers can be used to change the film's anisotropy. However, less attention has been dedicated to insulating ferrimagnets, which are advantageous for spintronic applications as they typically have low damping and are not susceptible to current shunting and Joule heating. In this work we studied how various capping layers can significantly change the interfacial magnetic anisotropy of high-quality, epitaxial thin films of $Tm_3Fe_5O_{12}$ (TmIG), an insulating ferrimagnet that is perpendicularly magnetized when under tensile strain. TmIG thin films were capped with a wide range of elemental metals spanning a significant portion of the periodic table to illuminate trends in interfacial magnetic anisotropy caused by Rashba spin-orbit coupling. The angular dependence of the ferromagnetic resonance fields (H_{res}) was utilized to extract the effective saturation magnetization ($4\pi M_{eff} = 4\pi M_s - H_\perp$) before and after the capping layers were grown. Figure 1a – h shows this angular dependence before and after capping TmIG as well as the extracted change in the effective saturation magnetization, $\Delta(4\pi M_{eff})$, for a subset of the capping layers tested. Depending on the capping material, $4\pi M_{eff}$ can vary from no change at all to as large as ~2000 G. Figure 2 shows $\Delta(4\pi M_{eff})$ for the fifteen capping layers that were tested as a function of the group number in the periodic table. This large survey of different capping layers in contact with a ferrimagnetic oxide will aid in the understanding of Rashba spin-orbit coupling that causes this large change in interfacial magnetism.

FG-13. Epitaxial Ferrimagnetic Mn_4N Grown on MgO and GaN: A Comparative Study. *Z. Zhang*[1], J. Singhal[1], Y. Cho[1], P. Dang[1], H. Lee[1], Y. Tang[1], D. Ralph[1], H.G. Xing[1] and D. Jena[1] *1. Cornell University, Ithaca, NY, United States*

Epitaxial growth of ferromagnetic thin films on semiconductors is attracting much interest for devices that exploit spin-orbit torques, and aim to merge logic, memory and communication components. Among them, the rare-earth-free ferrimagnet Mn_4N (Fig.1(a)) is promising because of a high Neel temperature of 738K, perpendicular magnetic anisotropy, a large anomalous Hall resistance (AHR), as well as large domain size and high domain wall velocities [1-5]. Furthermore, GaN based RF and power electronics platforms can benefit tremendously if magnetic materials could be integrated seamlessly with the GaN material system [6]. However, properties of epitaxial Mn_4N films on GaN have not been reported. Here we report the successful growth of Mn_4N on both MgO substrates and GaN templates using plasma assisted molecular beam epitaxy (Fig.1(b)). Xray diffraction (XRD) on films grown on both substrates show no peaks from other manganese nitride phases (Fig.1(c)). The Mn_4N films on MgO are single crystal with roughness less than 8 Angstrom (Fig.1(d)). The films on GaN are polycrystalline with a rougher surface. For films on MgO, we observe negative AHR with rapid magnetization switching and full remanence at zero field, as shown in Fig.2(a). In sharp contrast, on GaN the AHR (Fig.2(b)) shows a positive sign with a much smaller Hall angle. In addition, we also observe humps in AHR especially at low temperatures for film on GaN. Both the coercive field and saturation moment are found to decrease much faster with temperature when grown on GaN (Fig.2(c)&(d)). The magnetic hysteresis loop of the Mn_4N film on GaN is more rounded with half remanence at zero field. Finally, a shift of the M vs H hysteresis loop as well as an increase in coercive field are observed when field cooling to 5K for Mn_4N on GaN. The underlying reason for these differences will be discussed in detail.

FG-14. Impact of magnetic moment and anisotropy of $Co_{1-x}Fe_x$ thin films on the magnetic proximity effect of Pt. *T. Kuschel*[1] *1. Bielefeld University, Bielefeld, Germany*

We have investigated the magnetic proximity effect in Pt depending on the magnetic moment and anisotropy of adjacent metallic ferromagnetic films by x-ray resonant magnetic reflectivity (XRMR) at the Pt absorption edge (11565 eV) [1]. Thus, XRMR is element-selective and allows to obtain the spin depth profile of a chemical element, in our case Pt, by detecting x-ray reflectivity curves under opposite x-ray helicity and magnetic field directions, while varying the adjacent ferromagnetic support layers below from sample to sample. For Pt on ferromagnetic 3d metal alloys such as $Ni_{1-x}Fe_x$ [2] and $Co_{1-x}Fe_x$ [3], we observe a linear dependence between the Pt magnetic moment and the moment of the adjacent ferromagnet. The largest Pt magnetic moment of $(0.72\pm0.03)\ \mu_B$ per spin-polarized Pt atom has been detected in $Pt/Co_{0.33}Fe_{0.67}$ [3], while the number of affected Pt layers is independent from the magnetic moment of the ferromagnetic support. In addition, the Pt magnetic moment clearly follows the magnetic anisotropy of the ferromagnet below. This has been studied for Pt on Fe(001) and on $Co_{0.5}Fe_{0.5}$(001) with 45° rotated fourfold magnetocrystalline anisotropy as checked by magnetooptic Kerr effect [3], and substantiates the strong coupling between the moments of Pt and the ones of the ferromagnet. Our findings will support future investigations of the interplay of spin caloritronic and thermoelectric effects in these all-metallic bilayers.

FG-15. Large Perpendicular Magnetic Anisotropy in Single Crystalline Fe/MgO Heterostructures via Optimized Rf-Sputtering Processes. *Y. Iida*[1,2], J. Okabayashi[3], H. Sukegawa[2] and S. Mitani[2,1] *1. Graduate School of Pure and Applied Sciences, University of Tsukuba, Tsukuba, Japan; 2. Research Center for Magnetic and Spintronic Materials, National Institute for Materials Science, Tsukuba, Japan; 3. Research Center for Spectrochemistry, The University of Tokyo, Bunkyo, Japan*

Controlling interface perpendicular magnetic anisotropy (PMA) is important to develop high performance perpendicular magnetic tunnel junctions (p-MTJs). Many efforts have been made to obtain strong PMA, particularly in stacks with a CoFeB/MgO interface [1], which can be easily grown on a Si/SiO_2 substrate using sputtering. Recently epitaxial Fe/MgO grown by

molecular beam epitaxy (MBE) achieved larger PMA than CoFeB/MgO [2,3]. However, it is difficult to obtain sizable PMA in sputter-deposited boron-free Fe/MgO structures [4,5]. These PMA at polycrystalline Fe/MgO in Ref. [4,5] are smaller than that in CoFeB/MgO, although boron is not included. Therefore, Fe/MgO has been used only for basic researches in the PMA. It is also difficult to incorporate heavy metals, e.g. W and Ir, into the stack to enhance PMA. In this study, we aimed to achieve large PMA in sputter-deposited Fe/MgO on an MgO substrate. MgO(5 nm)/Cr(40 nm)/Fe(t_{Fe})/MgO(2 nm) stacks were grown by rf sputtering at room temperature. The MgO substrates and Cr layer were annealed at 500°C for 1 h, and post annealing was performed at T_{ann} = 300, 400, and 500°C. Fig. 1 shows *M-H* curves of the epitaxial Fe(0.7 nm)/MgO annealed at 300 and 500°C. When T_{ann} exceeds 400°C, Fe/MgO exhibited PMA. A large PMA energy K_{eff} of 0.77 MJ/m^3 was obtained at T_{ann} = 500°C, which is comparable to a value of an MBE grown Fe/MgO [3]. Also, the saturation magnetization drastically increases with increasing T_{ann}. Therefore, oxygen impurities remaining in the Fe layer may move to the MgO side during the high temperature annealing process, leading to large PMA. To evaluate an interface PMA energy K_i and areal PMA energy $K_{eff} \times t_{Fe}$ for T_{ann} = 500°C was plotted as a function of t_{Fe} in Fig. 2. Considering a 0.142 nm thick magnetic dead layer, K_i was deduced to be 1.55 mJ/m^2. These results suggest that a well-controlled sputter/annealing process can provide Fe/MgO stacks with sufficiently large PMA, which exceeds values in polycrystalline Fe/MgO and CoFeB/MgO.

Magnetic properties of Nd-Fe alloys are subject of intense studies owing to an important role of the Nd-rich intergranular phases in the sintered Nd-Fe-B-based permanent magnets. Analysis of macroscopic magnetization curves is difficult due to the presence of several magnetic phases observed by electron microscopy studies: primary Nd crystals, Nd as part of metastable eutectic, primary Nd_2Fe_{17} and a poorly known so-called A_1 regions. These regions as identified by high resolution transmission electron microscopy are composed of nanocrystals embedded in an amorphous phase. To elucidate a relationship between local structural and magnetic properties of various magnetic phases we have exploited an element selective technique – x-ray magnetic circular dichroism (XMCD). We have studied XMCD spectra at the $L_{2,3}$-edges of Nd and at the K-edge of Fe in hypereutectic $Fe_{14}Nd_{86}$ alloy prepared by mold casting and melt spinning in temperature range from 5 to 300K and under a magnetic field of up to 17T. The spectra are compared with those measured on pure Nd metal and nanocrystalline $Nd_2Fe_{14}B$ samples. Analysis of XMCD spectra allowed to separate contributions from Nd and Fe-containing phases. To get a deeper insight into magnetic behavior of different phases we have recorded element-selective magnetization curves by monitoring intensity of Nd and Fe XMCD signals as a function of applied magnetic field. Analysis of Nd magnetization curve in as-cast sample revealed that it is a sum of three contributions: the primary pamagnetic Nd phase (*dhcp)*, a soft magnetic Nd-based phase (*fcc*) and a Fe-Nd phase with high coercivity contained in A_1 region, with chemical composition close to $NbFe_5$. In the rapidly quenched alloy, presence of only two magnetic phases paramagnetic Nd and a metastable hard magnetic Nd_2Fe phase has been evidenced. Obtained results are important for understanding microscopic origin of high-coercivity phase in Nd-rich Fe-Nd alloys.

Sm-Co alloys are the best-performing high temperature permanent magnets as a result of their cellular microstructure, which comprises a Sm_2Co_{17} matrix and $SmCo_5$ cells, intersected by Zr-rich platelets [1]. A dense network of strongly-pinned domain walls forms in this microstructure, giving the material remarkable magnetic hardness. Despite extensive research on the connection between microstructure and magnetic properties [2], theoretical predictions and experimental results are still not in good agreement. Here, we combine high-resolution magnetic imaging by means of Lorentz transmission electron microscopy and off-axis electron holography with micromagnetic simulations to analyze how magnetic texture and magnetization reversal in this material are affected by its microstructure [3]. We find that magnetization reversal starts by the nucleation of domain walls at interfaces between Zr-rich platelets and the Sm_2Co_{17} matrix. Despite strong pinning at $SmCo_5$ cells, curling instabilities form at the intersections of all three phases and magnetization reversal propagates through the $SmCo_5$ cells *via* the Zr-rich platelets. Surprisingly, topologically non-trivial structures, such as 2π and 3π domain wall windings, are involved in domain wall pinning, significantly affecting the reversal mechanism. Our results demonstrate the important connection between microstructure and magnetic properties in Sm-Co alloys. Based on our observations, we propose a way to modify the microstructure of the alloy to increase its coercivity and remanence.

FH-03. The Effect of Zr in Progress toward the Development of High-Performance $SmFe_{12}$-based Magnet. *P. Tozman*[1], S. Hossein[1], Y. Takahashi[1], D. Ogawa[1], S. Hirosawa[1] and K. Hono[1] *1. National Institute for Materials Science, Tsukuba, Japan*

Permanent magnets are essential components for energy conversion and mobility applications where there is an increasing demand for new hard magnets, which has superior magnetic properties than that of $Nd_2Fe_{14}B$, at elevated temperatures over 140°C. $SmFe_{11}Ti_1$ has a large uniaxial anisotropy (K_1 = 4.87 MJ/m^3), high Curie temperature (T_c = 584 K) which are comparable those $Nd_2Fe_{14}B$ (K_1 = 4.9 MJ/m^3, T_c = 598 K) [1,2]. On the other hand, its saturation magnetization, ($\mu_0 M_s$ = 1.14 T) is lower than $Nd_2Fe_{14}B$ ($\mu_0 M_s$ = 1.14 T). Saturation magnetization can be increased with an optimum substitution of Co for Fe or by reducing non-magnetic Ti content. The latter can reduce the phase stability of $ThMn_{12}$ phase. This can be overcome by Zr substitution for Sm. Using this approaches, promising intrinsic hard magnetic properties have been reported; $\mu_0 H_a$, $\mu_0 M_s$ and T_c to be 10.9 T, 1.43 T, 800 K respectively for bulk $Sm(Fe_{0.8}Co_{0.2})_{11}Ti_1$ and 8.4 T, 1.53 T, 830 K, respectively for bulk $(Sm_{0.8}Zr_{0.2})(Fe_{0.8}Co_{0.2})_{11.5}Ti_{0.5}$ at 300 K [3]. However, the sole effect of Zr on the intrinsic magnetic properties cannot be investigated directly from bulk samples since $ThMn_{12}$-type structure without Ti cannot be stabilized in the absence of Zr. Hence, we developed highly textured $(Sm_{1-x}Zr_x)(Fe_{0.8}Co_{0.2})_{12}$ films for x = 0.18, 0.26 using an ultra-high vacuum co-sputtering system. The increment of Zr substitution from x = 0 to 0.26 for $(Sm_{1-x}Zr_x)(Fe_{0.8}Co_{0.2})_{12}$ increases $\mu_0 M_s$ from 1.78 T to 1.90 T, which is the *largest value* reported for hard magnetic compounds. The anisotropy field decreases by Zr substitution from 12 T for x = 0 to 9.8 T for x = 0.18 and 8.9 T for x = 0.26 at 300 K [4]. These values are still superior to those for $Nd_2Fe_{14}B$ ($\mu_0 H_a$ =6.2 T). Figure 1 compares $\mu_0 H_a$ and $\mu_0 M_s$ of $Nd_2Fe_{14}B$ with several compounds. This figure clearly shows the potential of $Sm(Fe_{0.8}Co_{0.2})_{12}$ compounds for practical applications as they have superior intrinsic magnetic properties at elevated temperature, 200°C where magnet application depends on. How to realize coercivity in the film by defect engineering will be discussed at the end of the talk.

FH-04. Achievement of both high coercivity and maximum energy product for 2:17-type Sm-Co sintered magnets via microstructural adjustment. S. Wang[1], *Y. Fang*[1], K. Song[1], X. Zhu[1], L. Wang[1], W. Sun[2], W. Pan[1], M. Zhu[1,2] and W. Li[1,2] *1. Central Iron and Steel Research Institute, Beijing, China; 2. National Engineering Research Center for Magnetic Materials, Beijing, China*

2:17-type Sm-Co sintered magnet performs well for high temperature applications as its excellent magnetic properties and high Curie temperature [1-5]. To meet application at relatively high temperature for Sm-Co sintered magnet, high intrinsic coercivity (H_{cj}) is also prerequisite besides maximum energy product ($(BH)_{max}$), improving temperature stability. In this work, high $(BH)_{max}$ (>264 kJ/m^3) as well as high H_{cj} (>1800 kA/m) were simultaneously obtained in $Sm(Co_{bal}Cu_{0.062}Fe_{0.285}Zr_x)_{7.6}$ sintered magnets. More importantly, the magnet compacts were made from powders fabricated by jet milling process, not a traditional technique, i.e., ball milling. The optimal magnetic properties obtained is remanence B_r = 1.186 T, $(BH)_{max}$=264.8kJ/m^3, H_{cj}=1848 kA/m when x=0.021, and the magnet also shows good squareness of demagnetization curve, as shown in Fig.1. The comprehensive magnetic properties are impressive due to both high $(BH)_{max}$ and H_{cj}. The origin of the good magnetic performance and influence of Zr content on the microstructure and magnetic properties have been studied for the $Sm(Co_{bal}Cu_{0.062}Fe_{0.285}Zr_x)_{7.6}$ magnets (x=0.016, 0.019, 0.021, 0.023). With the decreasing of Zr content the B_r enhances from 1.174 T to 1.207 T, and H_{cj} decreases from 2314 kA/m to 131 kA/m. It is found that the average cell size and density of lamellar phase are strongly influenced by the Zr content. With the x decreasing from 0.023 to 0.016, the average cell size increase slightly from 100.4nm to 113nm, while the density of lamellar structure decrease dramatically from 0.043nm^{-1} to 0.008nm^{-1}. For high Zr content magnet (x=0.023), the Cu concentration average and peak values in the cell boundary are measured to be ~10.77at.% and ~21.58at.%, respectively. However, the two above values are only ~6 at.% and ~7.95 at.% for the lower Zr content magnet (x=0.016). It is experimentally confirmed that the relatively more Zr content results in the increase of the density of lamellar phase, promoting the segregation of Cu in the cell boundary, giving rise to the well comprehensive magnetic performance for 2:17-type Sm-Co sintered magnet.

FH-05. High Temperature Properties Improvement and Microstructure Regulation of Sm_2Co_{17}-based Permanent Magnet.
C. Wang[1], M. Zhu[1], Y. Fang[1], S. Wang[1] and W. Li[1] *1. Central Iron and Steel Research Institute, Beijing, China*

In order to further improve the magnetic properties and the maximum operating temperatures of Sm_2Co_{17}-based permanent magnets, the effects of Sm content on the magnetic properties and microstructure of the $Sm(Co_{bal}Fe_{0.1}Cu_{0.09}Zr_{0.03})_z$(z=7-7.3) magnets were studied in this article. Then the solid solution process of $Sm(Co_{bal}Fe_{0.1}Cu_{0.09}Zr_{0.03})_{7.2}$ magnet was optimized from the perspective of high temperature magnetic properties. To acquire lower coercivity coefficient (β) for $Sm(Co_{bal}Fe_{0.1}Cu_{0.09}Zr_{0.03})_{7.2}$ magnet, the effects of the quenching temperature (T_q) on the magnetic properties and microstructure of the $Sm(Co_{bal}Fe_{0.1}Cu_{0.09}Zr_{0.03})_{7.2}$ magnet were also studied. The Sm content has no significant on phase composition, microstructure and cell size of magnets expect cell boundary. Higher Sm content will lead to wider cell boundary phase of magnet. The $Sm(Co_{bal}Fe_{0.1}Cu_{0.09}Zr_{0.03})_{7.2}$ magnet shows the optimal magnetic properties as: B_r=9.65kG, H_{cj}=28.3kOe, $(BH)_{max}$=22.5MGOe at room temperature (RT). After optimizing solution temperature and time, it is found that the $Sm(Co_{bal}Fe_{0.1}Cu_{0.09}Zr_{0.03})_{7.2}$ magnet solution-treated at 1195°C for 4h exhibits the best magnetic properties as B_r=7.22kG, H_{cj}=7.6kOe $(BH)_{max}$=11.6MGOe at 500°C. The variant T_q apparently affects the coercivity temperature dependent of $Sm(Co_{bal}Fe_{0.1}Cu_{0.09}Zr_{0.03})_{7.2}$ magnet. With T_q decreasing from 830°C to 420°C, the H_{cj} of the magnets increases from 1.406 kOe to 21.7kOe, while the β(RT-500°C) changes from +0.1113 %/°C of the T_q=830°C magnet to -0.134 %/°C of the T_q=420°C magnet. Analysis of the microstructure of the magnets with T_q=830°C and 420°C indicates that T_q has a great influence on the Cu distribution of the cell boundary phase. The difference of the Cu content and its distribution was ascribed to be the main reason for the different H_{cj} and its temperature dependence behavior of the T_q=830°C and 420°C magnets.

TEM, SEAD and HRTEM images of cellular structure of the $Sm(Co_{bal}Fe_{0.1}Cu_{0.09}Zr_{0.03})_z$ magnets with z=7.0(a, c, e) and 7.2(b, d, f)

FH-06. Theoretical study on the electronic states and finite temperature magnetic properties of $Sm_2Fe_{17}N_x$.
S. Yamashita[1], D. Suzuki[1], T. Yoshioka[1,2], H. Tsuchiura[1,2] and P. Novak[3] *1. Department of Applied Physics, Tohoku University, Sendai, Japan; 2. Center for Spintronics Research Network, Tohoku University, Sendai, Japan; 3. Institute of Physics of ASCR, Prague, Czechia*

The $Sm_2Fe_{17}N_x$ nitrides have unusual anisotropic magnetic properties. It is well known that the system at x=3 exhibits strong uniaxial magnetocrystalline anisotropy, which is higher than that of $Nd_2Fe_{14}B$. On the other hand, the system at x=0, that is binary Sm_2Fe_{17}, has weak planar anisotropy. A first-principles study in early days showed that the Sm local anisotropy in Sm_2Fe_{17} is weak but strong enough to overcome that of the Fe sublattice when the Sm is treated as a trivalent ion in the calculations [1]. Another recent ab-initio study based on the KKR method has claimed that the Sm ions may have a divalent electronic configuration [2]. Motivated by these backgrounds, in this contribution, we examine the magnetocrystalline anisotropy of the $Sm_2Fe_{17}N_x$ systems assuming the Sm^{3+} or Sm^{2+} configuration based on first-principles calculations. Furthermore, we construct an effective spin model to describe the finite temperature magnetic properties of these systems based on the information such as crystal field parameters obtained in the first-principles way. First of all, we calculate the crystal field parameters, the leading term of which is $A_2^0\langle r^2\rangle$=-171 K (-8.85 K) and -554 K (-686 K) for Sm^{3+} (Sm^{2+}) ion in Sm_2Fe_{17} and $Sm_2Fe_{17}N_3$, respectively. These values are all negative, which indicates that the Sm ions has local uniaxial anisotropy. However, its amplitude is very small when we assume the divalent configuration for the Sm ions in Sm_2Fe_{17}. Fig. 1 and 2 show the temperature dependence of the magnetization curves along the c-axis and (100) direction of these systems obtained by using the effective spin model. We can see that the experimental result is well described for $Sm_2Fe_{17}N_3$ but not even qualitatively for Sm_2Fe_{17} when we assume the Sm^{3+} configuration for the Sm. Instead, we find that the spin model based on the Sm^{2+} ions can give a qualitatively consistent result with the experimental one. These results imply that the valency of the Sm ions in $Sm_2Fe_{17}N_x$ systems can be strongly affected by nitrogenation processes.

FH-07. Magnetic properties and microstructures of high heat-resistance Sm-Co magnets with high Fe and low Zr content.
H. Machida[1], T. Fujiwara[1], C. Fujimoto[1], Y. Kanamori[1], K. Sakakura[2] and M. Takezawa[2] *1. TOKIN Corporation, Sendai, Japan; 2. Kyushu Institute of Technology, Kitakyushu, Japan*

Sm-Co magnets have high Curie temperature and appropriate to devices working under high temperature. As a way of enhancing magnetic properties, increasing Fe content has been conducted. However, this leads to poor squareness and deterioration of heat resistance due to decrease of Co content [1]. We tackled these problems by decreasing Zr content to maintain Co content as much as possible and employing slow cooling between sintering and solid solution treatment to homogenize microstructure. Although Zr is known as making Fe magnetically stable, there seems to be no reports discussing magnetic properties and heat resistance with increasing Fe and decreasing Zr content [2]. Magnetic properties were evaluated with a B-H tracer, then $(BH)_m$ of 34.5 MGOe were obtained at 25°C and 30.5 MGOe at 150°C. Temperature coefficients of B_r and H_{cj} were 0.034 %/K and 0.28 %/K respectively, which were almost as same as conventional Sm-Co magnets. Moreover, B-H loop at 150°C was linear, which means irreversible demagnetization doesn't occur at 150°C (Fig. 1). Cell structure observation and its composition analysis were conducted with TEM-EDX. Cell size was 200~500 nm with Fe and Cu separated and concentrated to 2-17 and 1-5 phase respectively. This size was larger than conventional Sm-Co magnets and Fe and Cu concentration led to high squareness [3]. Degree of orientation was examined with EBSD, then *c*-axis orientation which is preferable for Sm-Co was obtained. From XRD results, *a*-axis was increased but *c*-axis was decreased with increasing Zr content. Considering atomic radius, it was suggested that Zr was incorporated in Co dumbbell site. This means Zr was preferentially substituted by Co dumbbell. Therefore, interaction between Co stronger, this led to high heat resistance. We have been observing magnetic domain structures with a Kerr effect microscope with a magnetic field applied. From our past studies, magnetic domains are expected to be generated evenly from grain boundaries and propagated to inside grains. Result details of magnetic domain structures will be given a presentation.

FH-08. Magnetic properties of $Sm(Fe,Ti,V)_{12}$ magnets.
T. Saito[1], F. Watanabe[1] and D. Nishio-Hamane[2] *1. Chiba Institute of Technology, Narashino, Japan; 2. Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan*

RFe_{12} (R = rare earth) intermetallic compounds with a $ThMn_{12}$ structure have long been of interest in the production of high-performance permanent magnets [1]. Because binary RFe_{12} compounds are metastable, production of the RFe_{12} phase is difficult. However, it has been found that the small substitution of T (T = Cr, Mo, V, Ti) for Fe in the RFe_{12} compound results in the formation of the $R(Fe,T)_{12}$ compound [2–6]. In this study, $Sm(Fe,Ti,V)_{12}$ magnets were produced by the spark plasma sintering (SPS) method from $Sm(Fe,Ti,V)_{12}$ melt-spun ribbons. The structures and magnetic properties of the $Sm(Fe,Ti,V)_{12}$ magnets are discussed here. $Sm(Fe,Ti,V)_{12}$ alloy ingots were prepared by induction melting in an argon atmosphere. The alloy ingots were induction melted and then ejected through an orifice with argon onto a copper wheel rotating at a surface velocity of 50 ms^{-1}. The melt-spun ribbons were comminuted into powders and then hot-pressed in a vacuum at 873–1073 K for 300 s under a pressure of 100 MPa by the SPS method. The $Sm(Fe,Ti,V)_{12}$ melt-spun ribbons were successfully consolidated into bulk $Sm(Fe,Ti,V)_{12}$ magnets. The resultant $Sm(Fe,Ti,V)_{12}$ magnets consisted of the $Sm(Fe, Ti,V)_{12}$ phase. It was found that the magnetic properties of the $Sm(Fe,Ti,V)_{12}$ magnets were deeply dependent on the composition and consolidating temperature. Figure 1 shows the hysteresis loop of the $SmFe_{10}Ti_{0.5}V_{1.5}$ magnets consolidated at 973 K by the SPS method. This magnet achieved a coercivity of 9.2 kOe, the highest among all of the magnets produced.

FH-09. Nanoparticle-based synthesis and magnetic properties of $Sm(Fe_{1-x}Co_x)_{11}Ti$ ($0 \le x \le 0.3$) particle. *J. Kim*[1], T. Trinh[1], R. Sato[1] and T. Teranishi[1] *1. Advanced Inorganic Synthesis, Division of Synthetic Chemistry, Institute for Chemical Research Kyoto University, Uji-shi, Japan*

Recently, the $Sm(Fe_{1-x}Co_x)_{12}$ films with excellent intrinsic hard magnetic properties (M_s: 1.78 T, H_A: 12 T, T_C: 859 K) were successfully synthesized [1]. On the other hand, in case of the RFe_{12} isolated particles, we need a nonmagnetic stabilizer, *i.e.*, $R(Fe,M)_{12}$ (M: Ti, V, Cr, Mn, Mo, etc.), to maintain the $ThMn_{12}$ structure due to the thermodynamic instability. Element Ti can stabilize the $ThMn_{12}$ structure with the smallest amount [2] and can minimize the decrease of saturation magnetization by substitution with Fe sites. A reduction-diffusion (RD) process, which is one of the synthesis methods for $Sm_2Fe_{17}N_3$ particles [3-5], was used because this process can produce the equiaxed-shape particles with the lower temperature than metal melting method. In this study, we focus on the synthesis of a single-phase $Sm(Fe_{1-x}Co_x)_{11}Ti$ particles and the investigation on the magnetic properties depending on RD conditions. First, the mixture of Sm, Fe, and Co acetates and Ti isopropoxide was reacted in the organic solvent and calcined to remove organic ligands. Then, the H_2 and Ca reductions (RD process) were conducted for reducing the metal ions. Finally, the products were washed with N_2-purged mQH_2O to remove CaO. Figure 1 shows the XRD patterns of $Sm(Fe_{1-x}Co_x)_{11}Ti$ particles with different RD temperatures. The intermediate Sm-Fe-(Ti) phase can be observed at 1113 K (indicated by arrows in Fig.1) because the RD reaction did not finish due to the lower temperature than the Ca melting point (~1115 K). Nearly single-phase $Sm(Fe_{1-x}Co_x)_{11}Ti$ with <1wt% $(Fe\text{-}Co)_2Ti$ subphase was produced at above 1173 K. Table 1 shows the H_c of $Sm(Fe_{1-x}Co_x)_{11}Ti$ particles depending on the conditions of the RD process. The $Sm(Fe_{1-x}Co_x)_{11}Ti$ particles synthesized at above 1173 K for 2 h shows the H_c of around 237 kA/m. Meanwhile, the H_c increased with shorter RD time because the particle size and agglomeration were suppressed to maintain the equiaxed-shape of particles.

FH-10. Evolution of microstructure and magnetic properties in annealed high energy ball milled $Sm(Fe, Co, Ti)_{12}$ compounds doped with Zr. *M. Gjoka*[1,2], C. Sarafidis[3], D. Niarchos[1] and G.C. Hadjipanayis[2] *1. Department of Materials Science, INN, NCSR Demokritos, Athens, Greece; 2. Department of Physics and Astronomy, University of Delaware, Newark, DE, United States; 3. Department of Physics, Aristotle University of Thessaloniki, Thessaloniki, Greece*

The tetragonal $R_{1-x}Zr_x$ $(FeCo)_{11}Ti$ alloys, where R is a rare earth and T is a transition metal, are promising candidates for permanent magnets [1, 2]. $Sm_{1-x}Zr_x(Fe_{0.8}Co_{0.2})_{11-y}Ti_y$ (x=0 and 0.25; y=1 and 0.7)) master alloys were prepared by arc-melting under argon atmosphere. According to the Rietveld analysis, all as-cast samples were almost single-phase 1:12 compounds with a small amount of a-Fe. The as-cast ingots were milled using high-energy ball milling (HEBM) for different times (4 and 8 hours) in an argon atmosphere keeping a weight ratio of balls to powder 10:1. All samples after milling exhibit an amorphous/disordered phase. After annealing at 700 °C-900 °C at different interval times (15-90 min), the amorphous powders were re-crystallized into a majority 1:12 phase. However the SEM images show that the grain size of annealed sample depends strongly on the milling time of precursor material. The powder milled for 4 h after annealing contains a large variation of grain size from 2-4 μ to 20 μ or larger. While the respective sample milled for 8 h exhibits a grain size mainly in the range of 2-6 μ after annealing. This is reflected in the fact that the coercivity is higher in the last case reaching a maximum value of 5.5 kOe for $SmFe_9Co_2Ti$ annealed at 850 °C for 15 min. Representative demagnetization curves of $Sm_{0.75}Zr_{0.25}Fe_{9.04}Co_{2.26}Ti_{0.7}$ annealed for 15 and 30 min are shown in figure 1 and the respective SEM image of the annealed sample at 850 °C is shown in figure 2. The $SmFe_9Co_2Ti$ samples annealed at 900 °C exhibit a higher amount of a-Fe than when annealed at 800 °C, and this can explain the moderate value of coercivity, reaching the maximum value of 4.04 kOe (annealing for 30 min). Samples annealed at 700 °C for 15, 30 ad 60 min, exhibit a relatively low coercivity ~1.5 kOe. The microstructure evolution with emphasis on the particles size during annealing and their correlation with coercivity will be discussed. FH-11. Effect of Ingot Cooling Rate on Cu Distribution and Magnetic Properties of $Sm(Co_{bal}Fe_{0.28}Cu_{0.07}Zr_{0.03})_{7.6}$ Magnet. *Z. Shang*[1], D. Zhang[1], Y. Li[1], Z. Ma[1], X. Xu[1], H. Zhang[1], W. Liu[1], Q. Lu[1], Q. Wu[1] and M. Yue[1]
1. College of Materials Science and Engineering, Beijing University of Technology, Beijing, China

Cast process has obvious effect on magnetic properties of Sm_2Co_{17}-type magnets[1]. By changing the shape of metal mold, ingots with different cooling rates can be obtained. In this work, cast alloys with a nominal composition of $Sm(Co_{bal}Fe_{0.28}Cu_{0.07}Zr_{0.03})_{7.6}$ were prepared by induction melting. The alloy solution was casted into bullet type of copper mold (BM) and plate type of copper mold (PM) with water-cooling. The microstructure and corresponding Cu distributions of the magnets are shown in Fig. 1. A small amount of black phase in the BM magnet are observed and shown in Fig. 1 (a), while the content of the black phase in the PM magnet is very low, shown in Fig. 1 (d). According to the corresponding of Zr mapping in Fig. 1 (c) and (f), the Zr element enriches in the black phase, and it might be $Zr_6(Co, Fe)_{23}$ phase. The results are in agreement with the XRD results. Fig. 1 (a) and (b) show that for the BM magnet, the Cu element enriches in the regions near to Sm_2O_3 phase and grain boundaries. For the PM magnet, the Cu element distributes homogeneously in the magnet, as shown in Fig. 1 (e). The demagnetization curves of the magnets indicate that the coercivity and squareness of the PM magnet are significantly higher than that of the BM magnet. The faster cooling rate is helpful for the uniformity of the Cu element distribution in the ingots and magnets. The uneven Cu distribution leads to the loss of cell boundary phase, and the coercivity and squareness of the BM magnet is poor. For the PM sample, the Cu element diffuse evenly during homogenization and the cellular structure is well developed, therefore the PM magnet has more excellent magnetic properties.

FH-12. Strain-Induced Magnetic Properties in RCo_5 (R=rare earth) Magnets. *R. Choudhary*[1] and D. Paudyal[1] *1. U.S. Department of Energy, ISU, Ames Laboratory, Ames, IA, United States*

RCo_5 (R= rare earth metals) magnets have attracted the attention of researchers because of their large magnetocrystalline anisotropies [1-3]. RCo_5 with space group P6/mmm form with the three non-equivalent sites: R (1a), Co (2c), and Co (3g). R atom lies in the middle of the hexagonal layer of Co (2c) atoms, shown in Fig. 1(a). This layer is sandwiched by the hexagonal layers of Co (3g) atoms. This unique structural environment creates a crystal field that splits localized 4f states and partially quenches the R 4f orbital moment giving rise to the large part of the magnetic anisotropy and net 4f moment especially, in $SmCo_5$. First-principles calculations are performed to study the effect of strain on RCo_5 (R = La, Ce, Sm) magnets. R-Co exchange field is different for different rare earth R-atoms which affects the rare earth contribution to the magnetic anisotropy in RCo_5[4, 5] Therefore, the response of all three magnets here, RCo_5 for R = La, Ce, and Sm, to the strain will be different because of R-atoms. $LaCo_5$ and $SmCo_5$ have a borderline lattice constants ratio (c/a) to separate the planar and the uniaxial anisotropy. In contrast, magnetic anisotropy remains uniaxial in a wide range of c/a-ratio in $CeCo_5$ in which the 4f mixed valence states play a key role. Anisotropy variation of CeCo5 as a function of c/a ratio is shown in Fig. 1(b). Our calculations pinpoint $CeCo_5$ as a potential candidate model material for manipulating the uniaxial anisotropy. The underlying electronic structure of RCo_5 for different R-atoms plays an important role in optimizing and tailoring the uniaxial magnetic anisotropy. The projected outlook provides a path forward for the synthesis and characterization of the predicted materials with optimal strain and uniaxial magnetic anisotropy. FH-13. Torque Magnetometry Study of Magnetocrystalline Anisotropy in the Permanent Magnet $NdCo_5$. *S. Kumar*[1], C.E. Patrick[1], R.S. Edwards[1], G. Balakrishnan[1], M.R. Lees[1] and J.B. Staunton[1]
1. Department of Physics, University of Warwick, Coventry, United Kingdom

The permanent magnet $NdCo_5$ has attracted considerable attention owing to the observation of a giant rotating magnetocaloric effect close to room temperature [1] associated with a spin reorientation transition (SRT) [2]. To study the magnetic anisotropy and the SRT in this compound, we have carried out detailed torque and magnetization measurements on a single crystal of $NdCo_5$ grown using the optical floating zone technique. The SRT is reflected in a change in the polarity of the torque curves, $\tau(\gamma)$, measured as the direction of the applied field is varied in the *ac* plane. We compared our experimental results with the calculated torque data and found a good agreement above the transition (see Fig. 1). Torque measurements in magnetic fields as high as 6 T have allowed us to extract the temperature dependence of the anisotropy constants, K_1 and K_2, for $NdCo_5$. The observed behaviour has been compared with previous reports [2-4]. We have also calculated the finite temperature magnetocrystalline anisotropy of $NdCo_5$ from first principles using a recently developed framework, which combines density-functional theory based on the disordered local moment picture with crystal field theory. The calculations provide a good account of the temperature dependence of the spin reorientation and give a microscopic insight into the SRT, which occurs due to the competing perpendicular and uniaxial anisotropies of the Nd and Co sublattices. The current work is a part of the PRETAMAG project www.warwick.ac.uk/pretamag funded by the UK Engineering and Physical Sciences Research Council, Grant no. EP/M028941/1 and EP/M028771/1.

FH-14. Magnetization Enhancement and Phase Stability of Mn Doped $SmCo_5$ System. *B. Song*[1], H. Zhang[1], Q. Lu[1], W. Liu[1], Y. Li[1], Z. Altounian[2] and M. Yue[1] *1. College of Materials Science and Engineering, Beijing University of Technology, Beijing, China; 2. Center for the Physics of Materials, Department of Physics, McGill University, Montreal, QC, Canada*

$SmCo_5$ permanent magnet has many advantages such as promising high temperature magnetic properties and easy preparation, comparing with Nd-Fe-B and other Sm-Co systems.[1] However, its permanent-magnet performance is limited by low saturation magnetization (M_S). In this work, we successively enhanced the M_S by introducing Mn on Co sites in $SmCo_5$. The method to get pure $Sm(Co, Mn)_5$ phase and the mechanism of phase stability in this system were also addressed. The BSE images in Fig.(a) show the coexistence of $SmCo_5$, Sm_2Co_7 and Sm_2Co_{17} in the annealed $Sm(Co, Mn)_5$ ingots, indicating the deterioration of phase stability with Mn doping. This is attributed to the increase of system energy based on the theoretical calculation. We thus adopted rapid solidification and subsequent annealing to obtain pure $SmCo_5$ phase, as shown in Fig.(b). With the increase of Mn content, the cell volume and c/a ratio increase monotonously, while the grain size increases from 1 to 60 mm after annealing. More importantly, M_S is enhanced for 13% by Mn doping, which is comparable with that of the Pr doping. Theoretical calculation also indicates that Mn doping has greater potential in the enhancement of M_S than Fe doping, which makes $Sm(Co, Mn)_5$ system a promising candidate for the application of permanent magnet.

FH-15. Optimizing the microtructure and magnetic properties of $SmCo_5$/α-Fe nanocomposite magnets by adjusting the morphology of Fe. *X. Xu*[1], Y. Li[1], Z. Shang[1], M. Yue[1], D. Zhang[1], Q. Lu[1], H. Zhang[1], W. Liu[1], Q. Wu[1] and Z. Altounian[2] *1. Beijing University of Technology, Beijing, China; 2. McGill University, Montreal, QC, Canada*

In recent years, nanocomposite magnets based on exchange coupling have become a research hotspot in the permanent magnetic material field. Compared with traditional single-phase coarse-grained permanent magnets, nanocomposite magnets have higher theoretical magnetic energy product, and become a powerful competitor for the new generation of permanent magnets [1]. Moreover, the addition of soft phase greatly reduces the content and rare earth and raw material cost of products. In this work, Fe nanoflakes

and Fe nanopowders were mixed with $SmCo_5$ ribbons, respectively. Subsequently, amorphous $SmCo_5$/Fe powders were obtained by high energy ball milling. Then the isotropic $SmCo_5$/Fe magnets were obtained by the same hot pressing process. The addition amount of Fe is 10wt.%, 15wt.%, 20wt.% and 25wt.%. Fig. 1 shows the hysteresis loops of $SmCo_5$/Fe HP magnets added with different Fe nanoflakes and Fe nanopowders. For Fe nanoflake-doped magnets, the magnetic properties show that the saturation magnetization and remanence increase gradually, and the coercivity decreases gradually with the increase of Fe content. The hp magnet with 15 wt.% has the best magnetic energy product. The product of magnetic energy is 13.8 MGOe. Moreover, all the remanence ratios of the magnets are above 0.75 indicating significant remanence enhancement effect. By contrast, Fe nanopowder-doped magnets show lower coercivity, remanence and squareness than those of the Fe nanoflake-doped magnets with the same Fe addition. The microstructure observation reveals that the soft phase Fe grains distributed more dispersed in the magnets with the addition of Fe nanoflakes. Moreover, based on experimental observations, micromagnetism model is established and the micromagnetic simulation is carried out to analyze the relation between microstructure and magnetization reversal.

FI-01. Learning Magnetization Dynamics. *T. Schrefl*[1], A. Kovacs[1], J. Fischbacher[1], H. Oezelt[1] and M. Gusenbauer[1] *1. Danube University Krems, Wiener Neustadt, Austria*

A deep neural network is trained to predict the magnetization dynamics of thin film elements. The model is tested by solving the micromagnetic standard problem 4 [1]. Neural network models for magnetization dynamics can be useful for applications where computing time is important. The basic idea is to learn the magnetic state at time $t+\Delta t$ from the magnetic state at time t. A model trained for such updates in time will then be able to predict the time evolution of the magnetization. However, the high total number of unknowns to describe the magnetic state of the thin film element makes learning expensive and data intensive. A successful neural network model would require a very large set of training data. Therefore, we first compress the magnetization and then learn time stepping in a low-dimensional latent space. We train a convolutional autoencoder to learn a low-dimensional representation whereby we achieve a compression of 1024:1. Learning the updates in time now involves magnetic states that are represented only with 16 variables. We use a dense seven-layer feed-forward network to learn magnetization dynamics in low-dimensional space. The application of the decoder to the predicted compressed states gives the magnetic states along the trajectory. We train the neural networks with the magnetic states of 200 trajectories computed for different applied fields using a finite difference solver [2]. We find that the predictions of the neural network model agree well with the solution of the Landau-Lifshitz-Gilbert equation obtained with the micromagnetic solver. Figure 1 shows the time evolution of the averaged magnetization components. Figure 2 shows the ground truth and the predicted magnetic states at different times. Please note that the external field used here was not part of the training data which was used to learn the low-dimensional representation and to learn time stepping.

Micromagnetics is extensively used today in the area of magnetic nanotechnology and it has been demonstrated to be reasonably accurate in the analysis of magnetic systems up to the submicron spatial scale. In such systems, fluctuations cannot be neglected and micromagnetic theory has to be formulated in terms of a suitable statistical approach. In this work, we investigate and discuss the application of Stochastic Thermodynamics [1] to micromagnetics of small magnetic systems. Stochastic thermodynamics is an emergent field in statistical mechanics in which state variables of the system are assumed to be stochastic. The theory is formulated in terms of quantities, such as free energy, entropy, average magnetization, etc., associated with the ensemble of all possible realizations of the stochastic processes due to the noise mechanisms in the system. Stochastic thermodynamics is applied to a nanomagnet by using stochastic Landau Lifshitz equation to generate the realizations of the stochastic process. In this respect, we consider that the various heat/particle reservoirs in contact with the system, can be modeled in terms of a jump-noise stochastic process [2]. This enables to analyze the statistical properties of the system in terms of a Boltzmann equation. In the first part of the talk, we introduce and discuss the assumptions at the basis of the used formalism. The effect of each reservoir is included by an appropriate term in the kernel of the collision integral of the Boltzmann equation.

The form of these terms is specialized by imposing a generalized version of the detailed balance condition [3]. The stochastic termodynamics approach is then applied in the case when the magnetic nanoparticle under investigation is in contact with heat reservoirs and particle reservoirs. In this situation, it is possible to derive a suitable fluctuation theorem governing the statistics of the entropy production associated with the realizations of the stochastic magnetization dynamics [4]. In addition, the formalism enables to derive reciprocity (Onsager-type) relations associated to the presence of heat and particle fluxes [3]-[4].

FI-03. Models of Advanced Recording Systems (MARS) - a multi-timescale micromagnetic code for granular film simulations.

S.E. Rannala[1], A. Meo[2], S. Ruta[1], R.W. Chantrell[1], P. Chureemart[2] and J. Chureemart[2] *1. Physics, University of York, York, United Kingdom; 2. Physics, Mahasrakham University, Mahasarakham, Thailand*

Micromagnetic modelling provides the ability to simulate large magnetic systems accurately without the computational cost limitation of atomistic modelling. Through this modelling it is possible to simulate thousands of grains over a time range of nanoseconds to years. Here we present an open-source multi-timescale micromagnetic code, called MARS, consisting of the key solvers: Landau-Lifshitz-Gilbert, Landau-Lifshitz-Bloch and Kinetic Monte Carlo. Extensive tests of the solvers has been performed and are included with the code to allow for quick verification after user desired changes have been made. Fig.1 shows a comparison between simulated data and analytical solutions for the magnetisation distribution at temperatures below and above the Curie point. MARS has been developed to allow for the simple addition of custom simulations, which can utilise any of the solvers separately or in a combined multi-timescale manner. MARS generates Voronoi films comprising of different layers, which can be specified separately. Input parameters such as Curie temperature and temperature dependent magnetisation and anisotropy are required and can be obtained via atomistic simulation [1,2]. MARS is capable of simulating the writing process of HAMR (heat assisted magnetic recording) for multiple tracks and bits with user configurable laser and field profiles. The writing process occurs in the short timescale and requires description of magnetisation at temperatures near the Curie temperature, this is done using the LLB solver. Fig.2 is a snapshot of the writing process for a single track consisting of five bits. These simulated bits are then read back at any time, ranging from nanoseconds to years after the writing process, via the KMC. This read back of the written data enables investigations into the success rate of HAMR writing and also the data longevity obtained by the recording medium.

FI-04. Macroscopic effects due to atomistic colored noise in magnetization dynamics.

O. Chubykalo-Fesenko[1] and U. Atxitia[2] *1. Instituto de Ciencia de Materiales de Madrid, Madrid, Spain; 2. Freie Universitat Berlin, Berlin, Germany*

The atomistic spin dynamics has recommended itself as a valuable tool for modeling magnetization dynamics in the ultrafast timescale of exchange interactions in the presence of high excitations which lead to electronic temperatures higher than the Curie temperature [1]. This approach is based on the Langevin dynamics simulations with the assumption of a white (uncorrelated) noise [2]. However, the time and length scales in ultrafast magnetization dynamics are approaching limits where the memory effects in the spin-bath dynamics will play an important role. The correct atomistic spin dynamics with colored noise has been shown to be based on the Landau-Lifshitz-Miyasaki-Seki (LL-MS) approach [3]. Here we investigate the macroscopic effects arising from the assumption that at the atomic level the noise is colored. By using the same derivation as for the Landau-Lifshitz-Bloch (LLB) equation [4], we arrive at the modified LLB equation in the presence of colored noise. This allows us to discuss its macrosopic manifestations, namely that it (i) introduces a red shift in the precessional frequency which is temperature and correlation time dependent (ii) changes the susceptibility of an ensemble of non-interacting particles which may become negative at large exciting frequencies due to the memory effects [5] (iii) slows down both transverse and longitudinal relaxation times. To prove the viability of the macroscopic equation we compare the results with direct atomistic Langevin dynamics simulations using the LL-MS colored noise approach, see Fig.1. For the transverse dynamics the effect of the colored noise becomes significant for the correlation times larger than 1ps while for the longitudinal relaxation - for correlation times of the order of several femtoseconds (timescale of the precession in the exchange field). The new LLB equation constitutes a novel micromagnetic approach where the atomistic correlation times are already incorporates into the macroscopic equation and it may be useful for large-scale modeling at ultrafast timescales.

FI-05. Thermal fluctiations in the Landau-Lifshitz-Bloch equation.
M. Menarini[1] and V. Lomakin[1] *1. Electrical and Computer Engineering, University of California San Diego, La Jolla, CA, United States*

The Landau-Lifshitz-Bloch (LLB) equation allows micromagnetic simulations of the magnetization dynamics at low and high temperatures, including near Curie temperature. The LLB model is derived via thermal averaging of exchange-coupled spins and the magnetization length is a dynamic variable of the system, representing the thermal average obtained from atomistic models [1]. For high temperature application, such as heat assisted magnetic recording or laser induced demagnetization, having a correct description of the thermal fluctuations is essential to describe phenomena of interest, including signal to noise ratio, jitter, and optical reversal. Several stochastic LLB formulations have been proposed to incorporate the fluctuations into the deterministic formulation. However, these models either produce an average magnetization that differs from the expected value [2,3], making the formulation unsuited for multiscale atomistic-micromagnetic modeling techniques, or they ignore the fluctuations of the magnetization length [4]. In this paper, we introduced a formulation of the thermal fluctuations based on the Fokker-Plank (FP) equation following a procedure similar to the one used in Ref. [5] and [6] for the Landau-Lifshitz-Gilbert model. The thermal fields are introduced as 3 fluctuators applied to the precessional, longitudinal and perpendicular damping part of the LLB equation. The thermal fields are assumed to be (i) stationary, (ii) Gaussian stochastic processes with zero mean, and (iii) uncorrelated in time. No assumption is made on the probability distribution of the FP equation. We support out derivation with numerical results. We show that our formulation reproduces the Gaussian distribution at low temperature, while maintaining the value of the average magnetization at high temperatures (Fig.1).

FI-06. Pseudospectral method for the solution of the Fokker-Planck equation associated to stochastic magnetization dynamics.
V. Scalera[1], M. d'Aquino[2], S. Perna[1], M. Hoang-Ngoc[3] and C. Serpico[1] *1. Department of Electrical Engineering and ICT, University of Naples Federico II, Naples, Italy; 2. Engineering Department, University of Naples "Parthenope", Naples, Italy; 3. Physics, Université Paris-Saclay, Orsay, France*

In magnetic memories high density of data is obtained by reducing the size of the single bit cell. For a sufficiently small particle, in the submicrometer scale, the effect of thermal agitation is not negligible anymore and the magnetization dynamics is not deterministic [1]. One possible approach to study this situation consists in adding to the Landau-Lifshitz-Gilbert (LLG) equation a stochastic term in the effective field which models thermal fluctuations. In order to determine the statistics of thermal switching, LLG equation has to be numerically integrated for a large number of realization of the stochastic process. Alternatively, one can describe the stochastic magnetization dynamics by analyzing the probability density function (p.d.f.) of the magnetization. Assuming a spatially uniform magnetization for the specimen, the p.d.f. time evolution is described by the Fokker-Planck (FP) equation on the unit sphere. In the general case, it is not possible to derive an analytical solution for the FP equation and numerical methods must be employed. In this work, we present a numerical scheme to efficiently solve FP equation on the unit sphere based on the pseudospectral method. This method consist in choosing a grid of points and expanding the solution using a set of basis function, which are smooth, defined in the whole domain and equal to zero in all the grid points except one. The grid on the unit sphere is constructed by using as coordinates the component of magnetization along a given axis z and the azimuthal angle associated to rotation around axis z. Grid points are equispaced in the azimuth angle and are distributed as Chebyshev nodes in the z variable. The basis function are given by the product of Lagrange polynomials in the variable z and periodic sinc functions in the azimuth angle. We check the method accuracy by comparing the slowest thermal relaxation time constant numerically evaluated from the FP equation, Langevin dynamics of an ensemble of magnetic particles [2] and the approximated analytical expression given by Brown in [1], as shown in fig. 1.

FI-07. Large-scale computation of magnetization eigenmodes in complex micromagnetic systems. *M. d'Aquino*[1], S. Perna[2] and C. Serpico[2] *1. Department of Engineering, University of Naples "Parthenope", Naples, Italy; 2. DIETI, University of Naples Federico II, Naples, Italy*

The study of normal oscillation modes of magnetic nanosystems is fundamental for analyzing magnetization dynamics under microwave applied fields[1,2], thermal fluctuations[3] and magnonic structures[4]. The normal oscillation problem was originally tackled with analytical techniques[1,5] limited to spherical/ellipsoidal particles for saturated equilibria. Recently, considerable research has been focused on normal modes for structures with generic shapes[4,6] and spatially non uniform magnetization equilibria such as vortices[3] or skyrmions[7]. In this work, normal modes around generic equilibria in arbitrarily-shaped micromagnetic systems are evaluated in the frequency domain by using a special formulation[8] of the linearized Landau-Lifshitz-Gilbert equation, which is recast as generalized eigenvalue problem for self-adjoint operators related to the micromagnetic effective field. This formulation has several advantages over time-domain or dynamical matrix approaches: 1) it naturally preserves the physical properties implied by magnetization amplitude conservation. 2) The discrete eigenvalue problem obtained by either finite difference or finite element methods preserves relevant properties of the continuum formulation. 3) This approach leads to a matrix-free eigenmode solver, in that it does not require assembling the effective field operator, which would result in unpractical $O(N^2)$ storage and computational cost (N is the number of cells), but rather it exploits classical exchange and magnetostatic field computational routines implemented within micromagnetic codes. This allows to perform large-scale computations of magnetization eigenmodes in systems composed of hundred thousand cells in reasonably short time (e.g. 200 modes for a system of $N=4\times10^5$ cells computed in 17 hours on single CPU, equivalent matrix eigenvalue problem size would be $(8\times10^5)^2$). Figure 1 reports examples of normal modes for complexly shaped structures with several microns size.

FI-08. Computing resonant modes and excitation states in micromagnetic systems with finite element based solvers. *Z. Lin*[1,2] and V. Lomakin[1] *1. Electrical and Computer Engineering, University of California, San Diego, La Jolla, CA, United States; 2. Materials Science and Engineering, University of California, San Diego, La Jolla, CA, United States*

Solvers for excitation states and resonant modes serve as a powerful tool applicable to various micromagnetic systems. Linearized time domain Landau-Lifshitz-Gilbert (LLG) equation can be used to study situations with weak excitations but has limitations when the solution at a particular frequency is of interest. We present a finite element method (FEM) based eigen-value solver for computing normal oscillation frequencies and modes in micromagnetic systems. The solver can find resonant modes for both conservative (zero-damping) and non-conservative (non-zero damping) cases. This is achieved by directly using an eigen-value solver on a transformed linearized LLG. This approach does not use any perturbation theory [1] and allows handling zero-, small-, and large-damping cases, and can be accelerated by preconditioner. We also address the orthogonality properties between different resonant modes. Such a solver is useful for a set of applications, e.g. calculating noise in magnetic devices, such as magnetic sensors, or studying spin wave excitations. We also develop an FEM-based linear solver in frequency domain. The solver can compute excitation states with an iterative procedure and is accelerated by preconditioners. Specifically, we use a preconditioner based on keeping only exchange related terms, which itself is preconditioned with ILU preconditioner and a special block inverse precondioner. This approach can be used for modeling linear phenomena, such as spin waves. The solvers are integrated with the FastMag simulator framework and are accelerated by Graphics Processing Unit (GPU) and multi-core CPU computing. We carried out numerical experiments to study various systems.

FI-09. Implementation of high-performance effective-field-calculation algorithm for ultra-large-scale micromagnetic simulation on multi-GPUs. *H. Tsukahara*[1] and K. Ono[1] *1. High Energy Accelerator Research Organization, Tsukuba, Japan*

Micromagnetic simulations have been revealing magnetization dynamics for various magnetic materials. A supercomputing system is indispensable to perform ultra-large-scale simulation over 0.1 billion calculation cells. In principle, a graphics processing unit (GPU) can execute massively parallel computing at high speed with low energy consumption. However, due to the slow data transfer between GPUs and between GPUs and CPUs, using GPUs for large-scale simulations tends to be difficult. We implement the high-performance demagnetization-field-calculation algorithm on our simulator for an ultra-large-scale micromagnetic simulation on multi-GPUs. Our simulator solves Landau–Lifshitz–Gilbert equation and with MPI and SMP parallelization. Figure 1(a) shows the algorithm of an effective field calculation. Basically, the calculations are performed on GPU, except for the data transfer. The most serious problem in demagnetization field calculation is MPI communications. We employ the heterogeneous computing algorithm to overlap data transfer and computing. We use three streams in which the computing is performed asynchronously. We performed calculations of other magnetic fields, such as the exchange field, during the MPI communication with CPU. Additionally, we can calculate three components of magnetic field vectors simultaneously. Figure 1(b) shows the elapsed time of one step with 2563 and 5123 cells. In these calculations, we use Cray XC50-LC and Cray CS-Storm 500GT supercomputer at Tohoku University in Japan. The elapsed times using multi-GPU and 512 CPU cores are almost the same, even we use only 4 GPUs (Tesla-V100). The calculation speed reaches 84.0 times faster compared to that with 32 CPU cores (Xeon E5-2699v3). This study shows the world largest simulation of about 0.1 billion cells can be performed single work-station with a few GPUs.

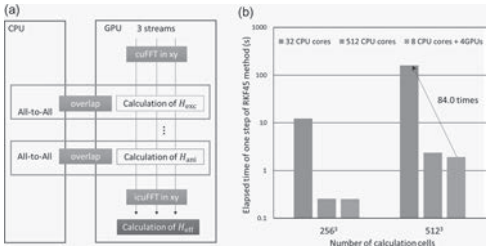

Fig. 1: (a) Schematic of the implemented algorithm. (b) Elapsed times of one step of RKF45 method. Blue, orange and gray colors represent the elapsed times using 32 CPU cores, 512 CPU cores, and 8 CPU cores + 4GPUs, respectively.

FI-10. Advancement in high-performance FEM-based micromagnetic codes on GPUs. X. Wang[1], S. Fu[1], R. Chang[1], M. Kuteifan[1], I. Volvach[1] and *V. Lomakin*[1] *1. CMRR, University of California, San Diego, La Jolla, CA, United States*

We present recent advancements in the development of high-performance finite element method (FEM) based micromagnetic framework FastMag. FastMag solves the Landau Lifshitz Gilbert (LLG) equation for modeling the magnetization dynamics and can handle multiscale problems, such as coupling the LLG equation with Maxwell's equations. It also implements the Nudged Elastic Band method for computing the energy barriers in complex systems. The simulator derives its high performance from efficient methods for evaluating the effective field and from implementations on massively parallel graphics processing unit (GPU) architectures and on multi-core CPU systems. FastMag uses tetrahedral geometrical discretization and thus it is highly flexible for general problems. For the magnetostatic fields, FastMag uses superposition principle for both volume and surface parts of the computational domain and uses a fast method for computing the related integrals in O(N log N) operations for N mesh elements. The time integration is accomplished via implicit time integrator, which is automatically adaptive in choosing the time step and order. We discuss various aspects of the implementation on GPUs and multi-core CPUs of all the code components, including all effective field computations, time integration, linear (GMRES) solver with preconditioners, and Jacobian operations. All these components are implemented in house and we show that it is important to make each one of them of high-performance to allow for high efficiency robust modeling of complex magnetic materials and devices. Table 1 shows computational time scaling versus the problem size. We chose to model the dynamics on standard micromagnetic problem 4, where we discretized the structure into a mesh with the edge length from 1nm to 7 nm for a dynamic simulation for 1 ns. Table 1 shows the performance statistics for the computations on CPU and nVidia RTX2080 GPU. It is evident that both CPU and GPU computation times exhibit a nearly linear scaling with the respect to the problem size, the time stepping is robust. Both CPU and GPU code components operate efficiently, and the GPU-CPU speed ups are around 30-fold for larger problems.

Mesh size, [nm]	# of nodes	#of elements	# of steps	# of linear iterations	Time on CPU	Time on GPU

FI-11. A fast algorithm to reconstruct 3D object in CXDI based on massively parallel processing. *F. Ai*[1], A. Shabalin[3], O.G. Shpyrko[3] and V. Lomakin[1,2] *1. ECE, UCSD, La Jolla, CA, United States; 2. CMRR, UCSD, La Jolla, CA, United States; 3. Physics, UCSD, La Jolla, CA, United States*

Coherent X-ray Diffraction Imaging (CXDI) is a computational method used for the reconstruction of images at nanoscale resolution. CXDI allows reconstructing magnetization states, such as magnetic domains, based on a series of images taken from synchrotron experiments. CXDI relies on an iterative procedure based on forward and backward FFTs allowing extracting the phase information from intensity measurements, which leads to a high-resolution reconstruction. CXDI for reconstructing 3D objects becomes computationally expensive and the computations can take significant time, which does not allow using it in real time while performing measurements. The long computational time is due to the need to do many 3D FFTs, which, for large systems, become slow and occupy large memory. We present a new algorithm to reconstruct 3D object using CXDI. This algorithm is based on the Fourier slice theorem and shrinkwrap iterative algorithm. Instead of performing phase reconstructions iterations using 3D FFTs we reconstruct a set of 2D images, each for a slice taking for a specific measured angle. Once this set of 2D reconstructed images is accomplished, we perform a 3D reconstruction step, which is rapidly converging since the 2D images already contain both intensity and phase information. In order to allow for efficient reconstruction of the 2D images, we developed an approach, allowing using a reconstruction for one of the images as a guess of the close in angle images. The benefits of the proposed algorithm include the reduction of the iterations needed for convergence, the ability to process a large number of images in parallel, a large reduction of the memory consumption, increased accuracy, and improved robustness of the reconstruction. Due to the reductions of the memory consumption and the ability to process sets of images independently, the proposed algorithm is well-suited for implementations on massively parallel graphics processing units (GPUs) with major speed

improvements. Figure 1 shows an example of running CXDI on a simulated particle. This result as an average of 60 independent reconstructions shows high quality while only taking 1 hour.

Institute of Theoretical Physics, University of Warsaw, Warszawa, Poland; 4. International Research Centre MagTop, Polish Academy of Sciences, Warszawa, Poland; 5. WPI-Advanced Institute for Materials Research, Tohoku University, Sendai, Japan*

The interplay between magnetic and electric properties of magnetic layers is of considerable interest owing to the perspective of exploiting the underlying mechanisms for the next generation of devices for information storage and processing. Recently we observed an electric field-induced decrease of coercivity, and a non-reversible magnetization switching at $T \geq 2$ K for magnetic fields close to the coercive field in molecular beam epitaxy grown (Ga,Mn)N layers. The data are interpreted within the theory of the precessional magnetization switching adapted to (Ga,Mn)N by allowing for the control of the magnitude of trigonal deformation along the wurtzite *c* axis by the applied electric field [1]. Here we show that experimental data can be reproduced by theoretical results obtained from the Landau-Lifshitz-Gilbert (LLG) equation that describes how the magnetization direction evolves towards its new equilibrium orientation after a change of an effective magnetic field. We use atomistic spin model simulations [2], applied for ensembles of near ten thousands Mn spins randomly distributed on GaN lattice, with ferromagnetic superexchange included up to 14th neighbour. In general, the parallelization of the code has been applied. As shown in the Fig. 1 an experimentally established magnetization curve can be adequately reproduced within our approach. Elaboration of such numerical tool allows to theoretically investigate these factors which determine the probability of the precessional magnetization switching induced by electric field. The calculations are supplemented by density functional theory simulations.

The work is supported by the National Science Centre, Poland, through projects DEC-2018/31/B/ST3/03438, DEC-2011/02/A/ST3/00125, DEC-2016/23/B/ST3/03575 and DEC-2014/12/S/ST3/00549. FI-13. Modelling of heating efficiency in magnetic hyperthermia: effect of non-harmonic driving field. *P. Tiberto*[1], P. Allia[2,1] and G. Barrera[1] *1. Advanced materials and life sciences, INRIM, Torino, Italy; 2. DISAT, Politecnico di Torino, Torino, Italy*

Rate equations are a useful tool to study high-frequency hysteresis loops of magnetic nanoparticles (MNPs) in the weak interaction limit and in the uniaxial anisotropy approximation [1]. The response of superparamagnetic nanoparticles described as double-well systems with randomly distributed easy axes is studied by a rate-equation approach in the typical range of frequencies and temperature adopted in magnetic hyperthermia. Hysteresis loops obtained applying non-harmonic driving field waveforms with various frequencies and vertex fields show that sawtooth (AT) and square (SQ) field waveforms substantially enhance the Specific Loss Power (SLP) with respect to a harmonic excitation (ST) of same frequency and amplitude. This improvement is related to the presence of fast, quasi-adiabatic transformations where the occupancy numbers in the two potential wells are virtually frozen, resulting in largely off-equilibrium magnetization states and in hysteresis loops with a greater area. In addition, the square driving field waveform is particularly promising for magnetic hyperthermia because the range of nanoparticle sizes useful to produce an optimal SLP becomes much wider respect to sawtooth harmonic waveform (Figure 1a). The observed temperature dependence of hysteresis power losses during hyperthermia can be taken into account considering the variation of MNP saturation magnetization and anisotropy in the studied temperature range. The calculated power loss evolution is included in a numerical model describing the Fourier's law of heat conduction to obtain the steady state and transient temperature profile in cancer tissue containing MNPs with selected size and concentrations excited by a radiofrequency field (frequency = 100 kHz, amplitude = 7.96 kA/m) (Figure 1b). The heat conduction model includes also terms describing the heat exchange between cancer tissues and blood flow.

FI-14. Model for xyFORC vectorial characterization technique of multi-phase magnetic systems. *A. Stancu*[1] and L. Stoleriu[1] *1. Department of Physics, Alexandru Ioan Cuza University of Iasi, Iasi, Romania*

The most notable development in the use of magnetic characterization of materials is to use the second set of detection coils which many modern VSMs already have [1]. The classical measurement of first-order reversal curves (FORC) is giving the value of the magnetic moment of the sample along the direction of the applied field. If we call this set xFORC, the measurement made by the other set of detection coils could be named yFORC. We have named this type of measurement xyFORC and the main idea of this vectorial technique is to use the two sets of data to add information concerning the magnetic sample measured. This method has the clear advantage that it uses existent equipment in many laboratories and it is not significantly more complicated compared to the classical scalar one in which one uses only the xFORC data. The xyFORC technique could be a more attractive version of vectorial FORC characterization compared to the ones already used, which are more difficult to implement [2]. It could also provide the opportunity to clarify the problem of the reversible component in the FORC experiment [3]. In the figures we show typical xyFORCs for a system with two magnetic phases with perpendicular easy axes. One can observe in this example the typical problems in the understanding the yFORCs compared with the better known xFORCs. We see, for example, that the yFORCs show a non-monotonic behavior as a function of the reversal field. In the presentation we shall show how this property can be explained and how the yFORC diagram can provide supplementary information about the mixture of phases.

FI-15. A Vector Hysteresis Model of Silicon Steel Based on Rotational Magnetization. *C. Zhang*[1,2], Y. Chen[1], Z. Zhang[2], Y. Li[1] and Q. Yang[3,1] *1. Hebei university of technology, Tianjin, China; 2. Ohio state university, Columbus, OH, United States; 3. Tianjin university of technology, Tianjin, China*

In the core of rotating machines, the trajectory of magnetic flux density can be very complex, including high order harmonics and rotational magnetization, especially in the tip region of stator teeth and slots. Due to strong magnetic anisotropy of the oriented silicon steel, it can be found that the core loss caused by rotational flux far exceeds that caused by alternating flux at low magnetic induction [1]. Among the research topics related to the analysis of rotational core loss, there are two types of calculation methods: Empirical loss model based on Steinmetz formula and vector hysteresis model [2]. The scalar hysteresis model such as Preisach model is more accurate and effective to estimate the core losses with several minor hysteresis loops, but relies on measurement results to identify the model and consume much more calculation resources [3]. This paper presents a novel core loss of silicon steel sheet based on rotational magnetization. The vectorial hysteresis loss is decomposed into the tangential and radial components which are defined based on rotational and alternating loss. Then, based on the pattern of rotational magnetization loci, the different regions in the stator core of induction motor are defined and classified. Rotational magnetization region produces much more core loss than the alternating core loss at low magnetic induction, but less core loss at high magnetic induction. The spatial angle difference α between vector H and vector B varies with the direction and magnitude of B. To simplify the loss model, the integral average of α is taken as the characteristic parameters as shown Fig. 1 based on rotational magnetization at different frequency. Fig. 2 illustrates the B-P curve of B35A210 specimen at 50 Hz with alternating and circular rotational excitation. Finally, the core loss of silicon steel calculated by the traditional Steinmetz formula and the modified hysteresis model are compared. It shows that the proposed model gives more precise result prediction than the traditional Steinmetz method.

FP-01. Optical Control of Diamagnetically Levitated Pyrolytic Graphite.

J. Young[1], S. Yee[1] and H. ElBidweihy[1] *1. Electrical and Computer Engineering, United States Naval Academy, Annapolis, MD, United States*

Pyrolytic graphite (PyG), when levitated above an array of alternating-pole permanent magnets, can be displaced by a localized increase in temperature due to the temperature dependence of its magnetic susceptibility. The increase in local temperature decreases the local diamagnetic forces, inducing a tilt and displacing the PyG sample in the plane of the permanent magnet array. Previous work has verified and demonstrated the optomechanical actuation of PyG using experiments and simulations [1]. Small-scale assembly methods can be extraordinarily complex processes because of the mediums in which they operate [2, 3]. This work proposes a milli-scale assembly system based on optical control of levitating diamagnetic milli-robots in air that minimizes undesirable effects such as stiction prevalent in systems with denser mediums [4]. Additionally, optical control allows accurate addressable control of multiple milli-robots able to move in close proximity to each other throughout the working surface with no work surface segmentation, a limitation of other diamagnetic control schemes [5]. A laser diode mounted on a 2-axis motorized translational stage and coupled to a controller accurately irradiates and actuates the PyG sample, which acts as a milli-robot with variable speed and acceleration. An infrared camera provides vision feedback to a MATLAB-based controller and user interface, permitting open loop or closed loop control. Figure 1 shows overlaid images providing an overview of an example trajectory of a PyG milli-robot levitating and actuated on top of an array of 6.35mm-diameter cylindrical NdFeB permanent magnets. The *x* and *y* pixel coordinates and yellow outline shown are MATLAB-generated computations of the milli-robot centroid and boundary, respectively. Figure 2 tracks the displacement of the PyG sample according to the same open loop input trajectory over a 23-second period.

FP-02. Magnetic Levitation of a Ferrofluid Droplet in Mid-Air.

T. Ohji[1], *S. Yamaguchi*[1], K. Amei[1] and K. Kiyota[1] *1. University of Toyama, Toyama, Japan*

This paper reports that the levitation of a ferrofluid droplet in the air at room temperature was realized using our magnetic levitation (maglev) device fabricated for non-contacting gripping and transport of ferrofluid droplets. The ferrofluid in a DC magnetic field theoretically deforms into an elongated spheroid in the direction of the magnetic field, as long as the surface tension of the droplet is higher than the tensile stress due to the magnetic field [1, 2]. Magnetic levitation system is suitable for experimentally verifying the

droplet deformation. Rhee et al. have reported on active magnetic levitation experiments of encapsulated ferrofluid in silicone oil [3]. The ferrofluid in the capsule floated at the steady position, but the viscous drag and buoyancy from the immiscible silicone oil slowed the capsule movement. Besides, the capsule filled with ferrofluid itself did not allow the deformation of the ferrofluid. We fabricated a new maglev system to observe the deformation and behavior of ferrofluid in an external DC magnetic field in mid-air. The maglev setup consists of an I-shaped electromagnet with a tapered magnetic pole tip, a laser displacement sensor, AD/DA, DSP, and power amplifier. The apex of a ferrofluid droplet (Base liquid: poly-alpha-olefin, viscosity: 5,000 mPa.sec, mass: 15 mg) placed on an oil-repellent film (Toyo Aluminium Inc., Toyal Ultra Lotus) was detected using the displacement sensor and actively stabilized by a PID controller. Figure 1 is a photograph of a magnetically levitated ferrofluid droplet. Figure 2 shows continuous shooting immediately before and after the levitation start with a high-speed camera (Photron Ltd., FASTCAM mini AX-50). The droplet extended upward just before leaving the oil-repellent film. After levitation, the droplet's apex fluctuated up and down for 2.5 seconds with deformation of the droplet. Finally, after 2.5 seconds, the droplet was stably levitated while keeping an oval shape of 3.4 mm height and 2.1 mm symmetrical axis length. Details of this research will appear at the conference.

FP-03. The Interaction between Two Permanent Magnets with Significantly Different Permeance Coefficients. *H. Meng*[1], Q. Wei[1], G. Tang[2], L. Cheng[3], G. Mizzell[4] and C.H. Chen[5] *1. Hangzhou Foresee Group Holding Co., LTD., Hangzhou, China; 2. Hangzhou Quadrant Technology Co. LTD, Hangzhou, China; 3. Hangzhou Magmax Technology Co., LTD., Hangzhou, China; 4. SuperMagnetMan, Pelham, AL, United States; 5. Quadrant Solutions, Louisville, KY, United States*

Even though Gauss' law for magnetic flux density (B-field) indicates there is no free magnetic charge, we can still define the effective bound magnetic charges from the magnetization of magnetic material [1]. The positive magnetic charge is what we usually called the "north pole", and correspondingly, the negative magnetic charge is what we usually called the "south pole". The interaction between the magnetic charges is governed by Coulomb's law so that like poles repel and unlike poles attract [2]. However, experiment shows that when two permanent magnets with significantly different permeance coefficients Pc (say, a small one with dimension of D4mm*4mm and Pc of 3.46, and a big one with dimension of D24mm*2mm and Pc of 0.18) were put together, with their directions of magnetization (DOM) pointing against each other, instead of repelling, they will attract to each other, especially when the coercivity of the big magnet is relatively low. This phenomenon may lead people to think that Coulomb's law for magnetic charges is not always right, and in some cases, like poles attract. In this work, we show that the above bizarre phenomenon is caused by the partial demagnetization in the low Pc magnet, rather than violation of Coulomb's law. When the experiment is carried out using sintered NdFeB magnet of N50 grade, the working point for the stand-alone low Pc magnet is very near to the knee of its demagnetizing curve, so it's very vulnerable to the external and its self-demagnetizing field. Finite Element Analysis (FEA) shows that demagnetization happens obviously in the central region of the magnet with low Pc, but the magnetization remains in the same direction all over the magnet. FEA also gives an attractive force when the above low Pc and high Pc magnets are close to each other and with opposite DOMs. Based on the magnetic charge model and Coulomb's law, the numerical integration of Coulomb's force is carried out, which gives almost the same attractive force as FEA.

FP-04. Reprogrammable Nanomagnets for Shape-morphing Micromachines. *J. Cui*[1,3], T. Huang[2], Z. Luo[1,3], P. Testa[1,3], H. Gu[2], X. Chen[2], B. Nelson[2] and L. Heyderman[1,3] *1. Laboratory for Mesoscopic Systems, ETH Zurich, Zurich, Switzerland; 2. Institute of Robotics and Intelligent Systems, ETH Zurich, Zurich, Switzerland; 3. Laboratory for Multiscale Materials Experiments, Paul Scherrer Institute, Villigen, Switzerland*

Shape-morphing micromachines have demonstrated significant potential in drug delivery, minimally invasive surgery, cell manipulation, and stenting applications [1]. With current fabrication methods, most micromachines are limited to a single type of transformation determined by their geometric design, which cannot be altered once fabricated [2]. In this work, we have developed a strategy to encode multiple shape-morphing information into transformable micromachines making use of the magnetic configurations of single-domain nanomagnet arrays. Inspired by origami, our micromachines consist of rigid panels carrying the arrays of nanomagnets separated by structured soft creases. The nanomagnets have tailored magnetic switching fields and, by applying a sequence of magnetizing fields, the arrays can be set into a particular magnetic configuration. By customizing the micromachine designs, we can obtain micromachines that perform specific shape transformations in an applied magnetic field (see Figure 1). Based on this strategy, we have built a simple four-pad micromachine with 2^4 possible magnetic configurations, demonstrating four distinct conformations when actuated by a magnetic field. Further, multicomponent micromachines were constructed by assembling modular units and, by customizing each individual unit, we have engineered a micromachine that can transform between two alphabet letters. We have also created complex folding behaviors, such as bending and twisting, and have implemented these folding modes in a microscale 'origami bird' capable of several different flapping modes. This work paves the way for the development of future intelligent microsystems that are reconfigurable and reprogrammable, which is required for biomedical applications and is also of interest for 3D magnetic and optical metamaterials. FP-05. Magnetic Control of Flexible Thermoelectric Devices Based on Macroscopic 3D Interconnected Nanowire Networks. *N. Marchal*[1], T. da Câmara Santa Clara Gomes[1], F. Abreu Araujo[1] and L. Piraux[1] *1. IMCN, Université catholique de Louvain, Louvain-la-Neuve, Belgium*

The emerging field of spin-caloritronics combines heat-driven transport with spintronics[1] and allows promising applications, such as magnetic heat valves or magnetically switchable cooling. However, dimensions in magnetic nanostructures lead to major experimental issues such as insufficient power generation capability and lack of reliable methods to obtain key spin-caloritronic parameters[2-3]. In contrast, more efficient macroscopic spin-caloritronics devices built from 3D interconnected multilayered nanowire (NW) networks (see Fig. 1) allow direct extraction of accurate key spin-caloritronics parameters[4]. They are fabricated by pulsed electrodeposition into 3D nanoporous polymer host membranes with no sample size limitation[5-7]. The branched structure of the network provides an excellent electrical connectivity, good mechanical robustness, while the pore-filled membranes show flexibility. The local removal of the gold layer serving as a cathode in the electrodeposition process yields a two-probe design suitable for magneto-transport measurements (see Fig. 2a). We studied Permalloy/copper (Py/Cu) multilayered NW networks showing giant magneto-transport (electrical, thermal and thermoelectric) properties (see Fig 2b-c), with room-temperature (RT) CPP-GMR up to 20%, and power factors comparable to that of bismuth telluride and that are magnetically modulated with magneto-power factor ratios up to 90% at RT. We observed large RT spin-dependent Seebeck coefficients of -12 μV/K. Those observations hold promise for magnetically modulated energy conversion using light and flexible thermoelectric generators and could lead to advances in future spin-caloritronic devices.

FP-06. Magnetic navigation system with a triangularly positioned triple coil set for the 2D manipulation of biomedical magnetic robots. *H. Lee*[1] and S. Jeon[1] *1. Mechanical and Automotive Engineering, Kongju National University, Cheonan, The Republic of Korea*

For 2D manipulation of biomedical small-scale magnetic robots such as in a fluid surface or a horizontal plane, conventional magnetic navigation systems (MNSs) were generally constructed with multiple numbers of 1D electromagnetic coils (Helmholtz coil, Maxwell coil, etc). However, conventional MNSs suffered from the ineffectively large overall structure, power consumption, asymmetric frequency response effect, etc [3, 4]. We propose a novel MNS simply composed of three circular coils (triple coil set, TCS), as shown in Fig.1a. Since it can be constructed with triangularly positioned identical coils, the MNS occupies minimal space to obtain a robot's working space within the system. Therefore, the corresponding power consumption and frequency response effect of the MNS can be effectively minimized during manipulation. We derived a general expression of a magnetic field generated by multiple numbers of arbitrarily positioned circular coils by using Jacobian and transformation matrices. From this expression, we could establish several constraint equations by which the proposed MNS with the TCS can selectively generate a uniform field or a gradient field near the geometric center of the coil set. Figs. 1c and 2 show several examples of the TCS's ability to generate a uniform magnetic field. Fig. 1c shows the variations of the field's uniformity and states that a TCS with a sufficiently large value of the aspect ratio can generate a more uniform field. Fig. 2 shows several cases of the uniform field generated along with the directions of 0, 45, and 90 degrees from x-axis, respectively (R/d = 1.3). We then constructed the proposed MNS, a magnetic robot, and a 2D robot manipulation environment and showed the validity of the proposed structure and manipulation method.

FP-07. Separation of Diamagnetic and Weak Paramagnetic Solid Particles Realized by a Small Nd-Fe-B Magnetic Circuit. *C. Ueda*[1] *1. Science, Earth and Space Science, Osaka, Japan*

Most solid particles that are studied in industrial and/or basic researches are composed of diamagnetic or weak paramagnetic materials; possibilities of field-induced dynamical motions were not expected in these materials unless an ultra-strong field were applied to these particles. We were able to separate a mixture of heterogeous particles into groups of different materials for the first time using a pair of Nb-Fe-B magnetic plates, and the materials of the separated groups were immediately determined from their translating velocities; this was realized by comparing the value experimental susceptibility obtained from velocity with a list of published values [1][2]. The separation is based on a recent finding that acceleration *a* of particle induced by a magnetic volume force is independent to its mass [3]; it is deduced from an energy conservation law that *a* is uniquely determined by intrinsic susceptibility of the material. In performing a refined analysis on a mixture of heterogeneous particles, it is desirable to thoroughly separate the particles into groups of different materials before putting them to the analyses. In future, the proposed technique can realize the above task of pre-treatment, and then it may play a role of a chromatography technique, a conventional technique of pre-treatment. Extraction of rare-metal(i.e. Au, In, Ag) from the heterogeneous mixture is also possible because the susceptibilities of these materials are considerably small compared to other materials [2], A methodo separate mixture of weak magnetic particles by its concentration of paramagnetic Fe ion is newly proposed [4].

FP-08. Optimal Design and Experimental Verification of a Linear Magnetic Gear. *S. Seo*[1], K. Shin[1], G. Jang[1], S. Kim[1] and J. Choi[1] *1. Dept. of Electrical Engineering, Chungnam National University, Daejeon, The Republic of Korea*

Electrical equipment typically cannot be driven without power transmission. For this reason, gears are used in a variety of mechanical systems [1–2]. However, mechanical gears cause mechanical losses when transmitting power. This problem has motivated various studies on magnetic gears, which can effectively compensate for the disadvantages of conventional gears [3–4]. In particular, in linear motion systems such as those used for wave power generation, utilizing a linear gear is inevitable. Thus, research on magnetic gears with tubular structures has recently been conducted.

Major limitations identified for this type of gear are manufacturing difficulties and high costs. Similar results are obtained when simplifying the tubular structure to a linear structure [5]. However, few studies related to linear magnetic gears have been conducted thus far. Therefore, this is a very relevant topic. In this study, we present an optimal design and verification of a linear magnetic gear (LMG). First, we choose a basic model that considers limitation specifications and then select an optimal model through parametric analysis. Next, an optimal model is presented considering mechanical characteristics through stress analysis. Finally, the reliability of the analysis is verified through experiments on an actual manufactured model. Fig. 1 present the structure and experimental system of the LMG. More specifically, Fig. 1(a)–(c) show the basic and two optimal shapes, respectively, of the flux-modulation poles (FMPs). Fig. 2(a) and (b) present comparisons of analytical and experimental results, and Fig. 2(c) shows stress analysis results of the optimal FMP shape. All results reveal the superiority of the optimal model design process. The final manuscript will provide more details on the design method and verification.

FP-09. A Novel Five-Degree-of-Freedom AC-DC Hybrid Magnetic Bearing. *W. Zhu*[1] and Q. Le[1] *1. Huaiyin Institute of Technology, Huai'an, China*

High-speed motors have the advantages of high efficiency and power density. The high-speed motor directly drives the load, which eliminates the transmission mechanism, reduces the volume and weight of the drive system, and has no transmission loss and noise. It has broad application prospects in many fields such as aerospace, flywheel energy storage and high-speed CNC machine tools. HMB is a high-performance bearing which uses electromagnetic force to support high-speed rotor. The high-speed motor supported by HMB has many excellent qualities, such as no friction, no wear, no lubrication and sealing, no oil pollution, high speed, high precision, low noise, long life and adjustable dynamic characteristics [1]-[2]. The HMB realizes the development of the motor towards higher speed and power, and provides a new solution for the high-speed transmission system. A novel five degrees of freedom (DOFs) AC-DC HMB is proposed in this paper, whose structure is compact. Stable suspension performance can be implemented in one unit. The radial four DOFs are completely controlled by two three-phase power inverters. The axial one DOF is driven by a DC amplifier.Firstly, the structure and suspension force production mechanism are introduced. The magnetic circuits are calculated by equivalent magnetic circuit method. The mathematical models of suspension force are deduced. The main parameters of the five DOFs HMB is designed. The magnetic circuits are analyzed by the three-dimensional finite element method, and the suspension mechanism of the five DOFs is verified. The relationships between suspension forces and currents are calculated. The research results have shown that the structure of five DOFs AC-DC HMB is reasonable, and the suspension mechanism and mathematical models are correct. The 3D structure of the five-DOF AC-DC HMB is shown in Fig. 1(a). Fig. 1(b) shows the operating principle of the proposed HMB.Fig.2(a) shows the magnetic density distribution. The curve of the suspension force in the x, y and z- direction are calculated by the parametric method as shown in Fig. 2(b). The results of FEA are agree with the theoretical values.

FP-10. Eddy Current Braking Force Analysis of an Ironless Linear Synchronous Motor with Cooling System. *L. Zhang*[1] *1. Harbin Institute of Technology, Harbin, China*

As the permanent magnet linear synchronous motor (LSM) have many advantages such as high force density, rapid dynamic response, low thermal losses, and simple structure, the linear motor drive technology is used

more and more widely in ultra-precision positioning and processing areas. However, the thrust ripple, which is the main disadvantage of permanent magnet linear synchronous motor, results in a periodic force oscillation with respect to the mover position. For the linear synchronous motor with cooling system, the eddy current braking force introduced in the cooling system is a main reason for thrust ripple. In this paper, analysis and calculation of the eddy current braking force of an ironless LSM is investigated. Fig. 1 shows the side-view of the ironless LSM which is investigated in this paper. This LSM consisting of a mover with ironless winding and a yoke with double layer Halbach magnet array mounted on it. The primary winding is divided into two layers, and the cooling system is located between the two layers. Water flowing through the cooling system and carrying the heat away. The vector magnetic potential is used to solve the magnetic system, and the differential equations are solved by the separation of variables method according to the boundary conditions. By solving the equations of the vector magnetic potential, the flux density distribution can be obtained and the expression of the eddy current density can be got furtherly. Then, the eddy current braking force introduced in the cooling system can be drived. The finite element model of the ironless LSM with cooling system is established by using Ansoft. The eddy current braking force introduced in the cooling system is calculated and compared with the analytical results. Based on the above investigation, an ironless LSM with cooling system is designed and established in laboratory as shown in Fig.2. Performance of the ironless LSM such as the detent force, eddy current braking force are measured with the prototype. And the experiment results are validated by finite element analyzed results.

FP-11. A New HTS Traveling Magnetic Electromagnetic Halbach Array for Electromagnetic Launch System. *W. Qin*[1] *1. School of Electrical Engineering, Beijing Jiaotong University, Beijing, China*

Electromagnetic launch (EML) systems need the driving sources featuring great thrust, high speed [1]. High Temperature Superconducting (HTS) has a bright future in the electromagnetic aircraft launch system for its high performance [2]–[3]. HTS windings with slotted iron core primary is the popular choices of LIM for the applications of EML[4]. The motor with slotted has a high efficiency, but its thrust ripple is high too and the core becomes saturated easily for large current carrying capacity of HTS. In this paper, a novel HTS Traveling Magnetic Electromagnetic Halbach Array (TMEHA) shown as in Fig.1 was proposed as the primary windings of the motor, of which are self-shielding, have ability for creating magnetic flux enhanced on one side (strong side) of the array while the flux cancelled on the other side (weak side) as Fig.1. The primary section for installing and fixing HTS coils is made of non-magnetic and non-conductive material, which is different from conventional iron core. HTS TMEHA successfully alleviates the saturation of the iron core and take full use of the advantages of the superconductors. The structure and the operation principle of the proposed array are described, and the major design parameters are optimized for maximum thrust force. Moreover, electromagnetic performances of different type array are compared by 3-D analytical and finite-element method. Theoretical and simulation analysis shows that the proposed array has a higher thrust and eliminates the cogging effect for heavy load EML. Finally, a 3-D modeling LIM with Electromagnetic Halbach array is built for a global observation of motor structure and further verification of the 3-D analysis. The results prove that the proposed motors can effectively satisfy the requirements of EML.

The conventional railway uses the adhesive driving system and generates noise, vibration, dust, and abrasion due to mechanical contact, and because it travels in the air, the maximum speed is limited due to air resistance. To solve these problems, magnetic levitation trains such as hyperloop have been developed[1]. Because the Hyperloop is no mechanical friction, there requires propulsion, levitation, and guiding force for driving, and a device for generating each force is necessary. For these reasons, several countries

have used more than two devices to generate propulsion, levitation, and guidance forces of Hyperloop. However, if there are too many such devices, there is a disadvantage that maintenance and manufacturing costs increase and control is difficult. To solve these problems, recently, research of All-In-One system using NSDLIM (Non-Symmetry Double-sided Linear Induction Motor), which generates a force of propulsion, levitation, guidance in one interface has been carried out. In the study, the initial NSDLIM which travels at 1000km/h speed was designed and FEM analysis was carried out, and detailed design was carried out to achieve the required performance. In addition, the analysis of the change in the conductivity of the secondary material was carried out[2]. However, 1% conductivity of Aluminum model selected as the final performance improvement model is impossible in actual manufacturing and since the performance characteristics of the motor can not be predicted due to the repulsive magnetic field of the secondary material in high speed, Therefore, research on optimal design considering these problems is necessary and is being studied in many countries[3]. This paper is a follow-up study of the All-In-One system. The optimal design parameters of primary and secondary were selected through the FEM analysis using the reaction surface method (RSM) and the final performance improvement model was proposed. In addition, the design feasibility for the proposed final performance improvement model was verified through the performance test after manufacturing the small-scale rotary type test machine.

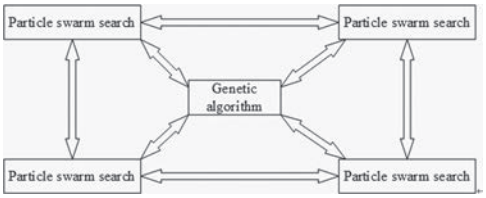
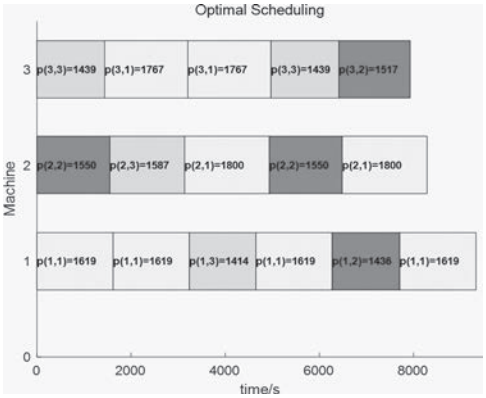
FP-13. Feasibility Study on Combined Piezoelectric (Solid) and Ferrofluid (Liquid) Vibration Energy Harvester. *N. Anand*[1] and R. Gould[1] *1. Mechanical & Aerospace Engineering, North Carolina State University, Raleigh, NC, United States*

In this paper we have introduced and studied the feasibility of a hybrid solid-liquid vibration energy harvester. The energy harvester consists of a ferrofluid partially filled in a tank and a piezoelectric beam fixed at one of the tank walls. External to tank lies two powerful electromagnets which magnetize the ferrofluid non-uniformly in space, and hence creates a potential for energy harvesting due to changing magnetic field when subject to external oscillations. We used different piezoelectric beam configurations along with different oscillation loads to study and characterize this 2-D multi-scale, multiphysics and multiphase fluid structure interaction. The tank is subjected to an external oscillatory motion, which sloshes the ferrofluid and oscillates the beam by means of two modes, one due to beam's inertia and second due to the impact of the ferrofluid on the beam. An external circuit is also modelled which has a load resistor to measure the voltage generated from the piezo and from the ferrofluid sloshing. The parameters varied are the piezo beam length, beam thickness, piezo materials, ferrofluid fill height, oscillation frequency and the oscillation amplitude. The natural frequency modes for the piezoelectric beam are very important, since at those modes the beam harvests the highest power. We have observed that when the fluid motion vibrates the beam such that it is near its first natural frequency, the power harvested naturally increases. Finally, we have proposed design rules for such a system to obtain the highest performance.



System Configuration



FP-14. Research on Multi-objective Task Scheduling Algorithm for Electromagnetic Cloud Computing. *L. Jin*[1], J. Wang[1], X. Liu[1] and W. Feng[1] *1. Tianjin Polytechnic University, Tianjin, Tianjin, China*

With the development of cloud computing in the field of high-performance computing, large-scale electromagnetic finite element and multi-sample computing are gradually completed by cloud computing. Therefore, cloud platform task scheduling has become an important issue to be solved. In this paper, a cloud resource scheduling model is constructed. Aiming at the indivisibility of electromagnetic finite element single sample computation, a multi-group hybrid genetic algorithm with particle swarm search is proposed. The approach is tested on instances taken from the literature and practical data. The computation results validate the effectiveness of the proposed algorithm. The finite element efficient calculation and the full utilization of resources are realized on the cloud platform. I. INTRODUCTION How to allocate cloud computing resources to the users of electromagnetic finite element computation under constrained conditions and achieve efficient scheduling to reduce the computing time of tasks and improve the efficient utilization of cloud computing resources has become a practical problem in the field of cloud computing[1,2]. II.Scheduling in cloud In the environment of cloud computing, different types of virtual machines with different performance characteristics are abstracted from a large number of physical resources by virtualization technology, and tasks are calculated by scheduling virtual machine resources. III.Cloud Platform Scheduling Algorithms A hybrid multi-population algorithm based on cloud platform is proposed by combining particle swarm optimization and genetic algorithm, as shown in Fig.1. IV.Conclusion Three-dimensional motors, three-dimensional inductors and TEAM Problem 7 were tested on cloud platform, and the optimal CPU core number and memory allocation in computing time and resource consumption were obtained. The sample numbers of three finite element calculation cases were 8, 4 and 4, respectively. The most satisfactory task scheduling scheme was obtained, as shown in Fig.2.

FP-15. Application of Grain-Oriented Electrical Steel Used in Super-High Speed Electric Machines. *R. Pei*[1] and L. Zeng[1] *1. InnMag New Energy Ltd., Suzhou, China*

Abstract — Electrical steel is one of the core magnetic materials in Electrical Vehicle(EV) traction motor. In terms of high power density and torque density for the EV traction motors. Traditional Non Grain-Oriented (NGO) silicon steel is difficult to satisfy these requirements because of limited saturation flux density and magnetic permeability. This paper mainly presents that a novel thin anisotropic Grain-Oriented (GO) silicon steel is used in high-speed (up to 14000rpm)traction motors after deeply analysing magnetic saturation, power loss, thermal conductivity and mechanical property of a traction motor with high-frequency (50Hz-400Hz) and high-torque running status. It applies a combination design between NGO and GO steel in order to avoid the low magnetic permeability in the transverse direction. The noise and magnetostriction of the electric machine can be reduced by applying a self-stick punching technique between GO steel sheets in a stator. The research on numerical modeling and experimental results has been done. The new prototype is being fabricated and it can be produced in mass production in next few years. The measured B-H curve states the difference between NGO and GO silicon steel in the direction of magnetization can be shown in Figures. The novel prototype of high-speed traction motor has been designed with 12 slots and 8 poles. The rating/peak power is 15/30kW. According to the relationship of flux density, iron loss and offset angle of the rolling direction for GO and NGO steel, we should use the magnetic property of GO steel in the range of 0^o and 30^o of the rolling direction to design a stator. The new design can be shown in the Figures. The new design shows the power loss of the stator remarkably decrease by using GO steel. Moreover, the saturation flux density and magnetic permeability will rise. After the motor teeth adopt the grain-oriented silicon steel sheet, the efficiency of the motor rated condition increases from 96.6% to 97.8%, an increase of 1.2%.

FQ-01. Differential Effect of Magnetic Alignment on Magnetocaloric Effect during Additive Manufacturing of Magnetocaloric Particles.
K. Al Milaji[1], S. Gupta[2], V.K. Pecharsky[2,3], H. Zhao[1], R. Barua[1] and *R.L. Hadimani*[1,4] *1. Mechanical and Nuclear Engineering, Virginia Commonwealth University, Richmond, VA, United States; 2. Materials Science and Engineering, Ames Laboratory, Ames, IA, United States; 3. Materials Science and Engineering, Iowa State University, Ames, IA, United States; 4. Biomedical Engineering, Virginia Commonwealth University, Richmond, VA, United States*

Thin films of ball-milled Gd_5Si_4 particles [2] were deposited using inkjet printing process in the presence of an external magnetic field. During the printing, NdFeB permanent magnet arrays were used to align the particles along the axis of the printing plane, normal to the printing plane and without the alignment. The external magnetic field aligns the magnetic particles along their magnetic easy axis. The combined effect of all the particles enhances the magnetization of the film by aligning the particle's magnetocrystalline easy axis with the direction of the magnetic field of the permanent magnet. We demonstrate the ability to print thin magnetic films with a defined anisotropy in any chosen direction which could lead to the enhancement of magnetic properties approaching those of single crystal materials. Fig.1 (a) shows hysteresis graphs measured at 300K along long axis of films printed with no applied field (random), field applied in parallel orientation to the plane and along long axis (parallel), field applied in parallel orientation to the plane and along short axis (random 90 deg.), field applied normal to the plane (normal) and photo paper without the Gd_5Si_4 particles. It can be seen that the when films are printed with a field applied parallel to the long axis the magnetization is highest and the lowest magnetization is seen for particles printed with field applied normal to the paper. Fig. 1 (b) shows SEM images of random and parallel films. Entropy change was calculated from Maxwell's equations for random, parallel and normal films. The entropy change for an applied field of 3T at 310K showed an increase of 440% for parallel films compared to normal films (2.3 J/kgK, 3.4 J/kgK and 10.2 J/kgK for normal, random and parallel films respectively). FQ-02. Magnetocaloric effect in rare-earth based oxynitrides.
Y. Jin[1], *A. Biswas*[1], A.K. Pathak[1], Y. Mudryk[1], S. Gupta[1] and V.K. Pecharsky[1] *1. Division of Materials Science and enigineerig, Ames Laboratory, Ames, IA, United States*

The magnetocaloric effect (MCE) is extensively studied in rare-earth (RE) based compounds, including alloys, intermetallics, and salts. Among these materials, RE-oxides, and other oxide-based salts such as carbonates, oxalates etc, are the most stable compounds and are easily obtained. However, their magnetic transition temperatures, if any, are often too low. There is hardly any study regarding MCE of rare-earth based oxynitride compounds of the type $RE^{2+}RE^{3+}ON$. In this work, we focus on the study of magnetic and magnetocaloric properties of a fully stoichiometric compound, GdEuON that crystallizes in the NaCl-type structure. Polycrystalline samples of GdEuON were prepared via mechanochemical reaction of EuO and GdN. As-reacted powders were annealed at 600 °C under Ar. The study of the temperature dependence of magnetization reveals that the sample exhibits a second order magnetic transition between paramagnetic and ferromagnetic state at $T_C \sim 60$ K. It also shows glassy behavior at low temperature, which may be due to the interplay between the magnetic Gd^{3+} and Eu^{2+} ions. Consistent with magnetization study, electrical resistivity measurement shows a clear phase transition near T_C for the sample and it exhibits semiconducting behavior above T_C The magnetic entropy change (DS_M), one of the important parameters characterizing magnetocaloric properties of materials, was estimated from the magnetization data. A large DS_M (-9 J/Kg K near T_C for a 2 T magnetic field change) has been observed over a broad temperature range (full width at half maximum of DS_M vs. T is ~80 K). The broad peak of large $-DS_M(T)$ is beneficial for application in magnetic refrigeration as it can provide high refrigeration capacity. Fig.1 The MCE of GdEuON as the magnetic entropy change from magnetization data. The Ames Laboratory is operated for the U. S. Department of Energy by Iowa State University of Science and Technology under contract No. DE-AC02-07CH11358. This work was supported by the Department of Energy, Office of Basic Energy Sciences, Materials Sciences Division.

FQ-03. 3D checker board pattern formation of martensite/austenite domains in NiCoMnAl magnetic shape memory alloys. *A. Becker*[1], D. Ramerman[1], M. Gottschalk[1], I. Ennen[1], T. Matalla-Wagner[1], G. Reiss[1] and A. Hütten[1] *1. Physics, Bielefeld University, Bielefeld, Germany*

NiMnX (X=Al,Ga,Sn,In) magnetic shape memory Heusler alloys are considered as promising materials for magnetocaloric cooling applications due to their magnetoelastic coupling near room temperature [1]. However, most of them show a very large thermal hysteresis, which can span over several hundreds of Kelvin, limiting their potential in future applications. Therefore, efficient mechanisms to change the martensitic transformation behavior have to be identified. Our research showed that rigid substrates increase hysteresis width due to residual austenite at the interface in NiCoMnAl thin films [2],[3]. We conclude that thin martensite intercalations in those films should be beneficial for transforming films, because the formation energy during martensite nucleation is reduced. Our aim is to decrease the thermal hysteresis in off-stoichiometric NiCoMnAl thin films, grown by sputter deposition, by preparing multilayer systems, which consist of alternatively grown martensite intercalations and active transforming austenitic layers. The stoichiometry of these two layers is chosen in such a way that their individual thermal hysteresis do not overlap. In these intercalated multilayer systems we find from temperature dependent magnetization measurements that the thermal hysteresis of the active layer is decreased in comparison to the non-intercalated system. Furthermore, if the thickness of the active and fixed layer becomes comparable, the strain in these systems induces a long range order of martensite and austenite regions, which resembles a 3d checker board pattern in TEM cross-section images. However, the formation process of this system is still under investigation. High resolution XRD measurements, in combination with TEM analysis, allow us to visualize the microstructure and micro strain in this multilayer system. The results can be directly compared to molecular dynamics [4] and phase field model simulations [5]. This would enable us to refine martensitic intercalations in terms of crystallographic growth direction, thicknesses and transition temperatures to achieve a multilayer system with very low thermal hysteresis.

FQ-04. Controllable magnetic transitions and magnetocaloric effect of $Ho_{1-x}Tm_xNi$ ($0 \le x \le 0.8$) compounds. *J. Xu*[1], X. Zheng[1], S. Shao[1], S. Yang[1], J. Zhang[1], S. Wang[1], J. Liu[2], Y. Zhang[2], Y. Liu[2], Z. Xu[3], L. Wang[4] and B. Shen[2] *1. School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China; 2. State key laboratory for Magnetism, Institute of Physics, Chinese Academy of Sciences & University of Chinese Academy of Sciences, Beijing, China; 3. National Institute of Metrology, Beijing, China; 4. Department of Physics, Capital Normal University, Beijing, China*

As a potential alternative technology for traditional refrigeration, magnetic refrigeration has received extensive attention. In the past few decades, some materials with large/giant magnetocaloric effect (MCE) have been reported near room temperature, such as La-Fe-Si[1] and Gd-Si-Ge. [2] Low-temperature MCE materials used for liquefaction of gas have also become a research hotspot recently. Rare earth based RNi compounds (R=Gd-Tm) have orthorhombic crystal structure and the basic magnetic properties and heat transport properties have been studied. [3-7] In this work, the magnetic transitions of HoNi compound were adjusted by introducing Tm with small spin quantum number to replace Ho atoms. The magnetic properties and MCEs of $Ho_{1-x}Tm_xNi$ ($0 \le x \le 0.8$) compounds have been investigated in detail. Both ZFC (zero-filed-cooling) and FCC (field-cooled-cooling) curves were measured for $Ho_{1-x}Tm_xNi$ ($0 \le x \le 0.8$) compounds and magnetic phase diagram is shown in Fig.1 (a). As Tm content increases, the transition temperature for spin reorientation (T_{SR}) changes little around 10 K and Curie temperature (T_C) decreases monotonously from 35.5 K to 9.3 K. When x=0.8, T_{SR} and T_C get

closer and only one phase transition can be observed. On basis of magnetic measurements, magnetic entropy change ($-\Delta S_M$) was calculated and the temperature dependences of $-\Delta S_M$ curves for field change of 0-5 T were shown in Fig. 1 (b). The maximum value of $-\Delta S_M$ is 16.6, 15.8, 17.4 and 22.4 J/kg K for x=0, 0.3, 0.5 and 0.8 respectively. It is worth noting that a platform was observed on ΔS_M curves for $Ho_{0.7}Tm_{0.3}Ni$ compound. The value of $-\Delta S_M$ is relatively stable over a temperature range as wide as 35.0 K, which is beneficial to practical applications. In summary, $Ho_{1-x}Tm_xNi$ ($0 \le x \le 0.8$) compounds has potential applications for low temperature magnetic refrigeration.

FQ-05. The Use of Magnetically Hard Materials in Thermomagnetic Power Generation Cycles. *A.N. Tantillo*[1,2], N. Dempsey[3], L. Ranno[3] and K.G. Sandeman[2,1] *1. Physics, CUNY Graduate Center, Brooklyn, NY, United States; 2. Physics, Brooklyn College, Brooklyn, NY, United States; 3. Universite Grenoble Alpes, CNRS, Institut Neel, Grenoble, France*

Thermomagnetic power generation (TMG) is the process by which magnetic flux, which comes from a temperature-driven change of magnetization, is converted into usable energy. Generally, TMG functional materials are magnetically soft, meaning they have little to no remnant magnetization and magnetize in the direction of the applied field, limiting TMG loops to the first quadrant of the *M-H* plane. This work investigates the ways in which magnetically hard materials, which have strong magnetic anisotropy and non-zero magnetic remanence, can be incorporated into TMG cycles in order to expand the area of *M-H* plane available for energy conversion. Three cases are considered: (i) hard ferrite magnets as the functional material for a two-quadrant TMG cycle; (ii) a hard magnet applying a bias field to a soft functional material, thus opening the second quadrant of the *M-H* plane; and (iii) spin-reorientation transition (SRT) TMG, in which a change of the direction of the magnetization vector (instead of a decrease in the magnitude of the magnetization) drives the observed magnetic flux. The literature shows that SRT TMG yields work outputs an order of magnitude greater than pyromagnetic TMG, with roughly equal relative efficiencies, without driving a Curie-point transition [1]. Experiments on commercially available hard ferrites reveal that these materials are not yet good TMG candidates, but hard magnets with higher thermal conductivity and a greater change of magnetization with temperature could outperform existing TMG materials. Computational results using *RADIA* [2] indicate that biasing a soft magnet with a hard magnet is essentially equivalent to shifting the *M-H* loop by an amount proportional to the field of the biasing magnet. In the case of polycrystalline gadolinium, the work output increases from 13.6 J/kg [3] without a bias field to 33.6 J/kg with a bias field for the same temperature range, but experimental verification is needed. Concerning the case of SRT TMG, the literature describes promising avenues of future investigation in single-material embodiments using $NdCo_5$ [1] as well as artificial spin-reorientation composites [4].

FQ-06. Magnetocaloric Gadolinium thick films for energy harvesting applications. *D. Nguyen Ba*[1,2], L. Becerra[2], N. Casaretto[2], J. Duvauchelle[2], M. Marangolo[2] and M. LoBue[1] *1. SATIE, CNRS, ENS Paris-Saclay, Université Paris-Saclay, Cachan, France; 2. Sorbonne Université, CNRS, Institut des NanoSciences de Paris, UMR7588, Paris, France*

Improving energy efficiency and cutting greenhouse emissions have been the main motivation of the last two decades intense research activity in the field of caloric materials [1]. The research of new solid state cooling devices have been focused on bulk magnetocalorics (MC) with a particular emphasis on efficiency [2]. Recently a growing interest in energy harvesting applications with some emphasis on the micro and nano scales has triggered a paradigm shift towards the research of higher power output [3,4]. Gadolinium has been the benchmark material for bulk cooling devices and its study will be extremely relevant as well for development of micro-scale harvesting devices where the comparison between first and second order MC performance is still an open issue [5]. Unfortunately the use and characterization of Gd films are still rather preliminary with some controversial results concerning substrate role in modifying magnetic moment, and Curie temperature [6]. High thoroughput thermo-generation at the microscale requires relatively thick films (between 5 and 10 μm) and a reduced thermal influence from the substrate. Therefore, a detailed characterization of magnetic and MC properties as a function of thickness and substrate is in order. Here we study Gd films deposited with thicknesses ranging from nanometer to micrometer using a sputtering machine deposited on (i) different silicon substrates: with and without SiO_2, (ii) various buffer layers such as tungsten, tantalum, (iii) various growth conditions. Magnetic properties including magnetization as a function of temperature and magnetic field, and entropy change are investigated using a SQUID or VSM-PPMS. Crystal structure has been characterized using a high precision XRD machine. Results show a change of crystal structure as a function of both growth temperature and thickness. We observed that the magnetic phase transtion depends on thickness, growth condition, substrate and buffer layer. Growth at high temperature also sharpens the transition.

FQ-07. Enhanced Magnetocaloric Effect via Halide Substitution in the Tunable Molecular Magnet, $Cu_9Br_2(cpa)_6$. *S.F. Skinner*[1] and L.W. Ter Haar[1] *1. Chemistry, University of West Florida, Pensacola, FL, United States*

The magnetothermodynamic properties [1-4] of the low-dimensional 2-D metal organic framework (MOF) halide series, $Cu_9X_2(cpa)_6$ (X = F, Cl, Br; cpa = anion of 2-carboxypentonic acid), abbreviated as CPA, has been the subject of experimental studies suggesting the tunability of magnetic properties via halide and guest-host chemistry [1,3]. CPA is best described as a topologically spin frustrated triangles-in-triangles or triangulated-Kagome-lattice on a layered MOF. CPA consists of microporous channels (oriented transverse to the layers) available for chemical manipulation, which support tunability of properties and further expansion of this class of materials. While the spin frustrated topology of $Cu_9Cl_2(cpa)_6$ has been shown to exhibit a magnetocaloric effect at temperatures less than 10 K [5], we report here new temperature- and field-dependent magnetization data for the bromine derivative of CPA, $Cu_9Br_2(cpa)_6$. As shown in earlier studies [1], exchanging the halide in this material can enhance the magnetic properties of this system. In this study, we estimate the effect of halide interchangeability on the magnetocaloric effect produced by this system in low field and at cryogenic temperatures. Magnetic entropy change (ΔS_{mag}), relative cooling power (RCP), and refrigerant capacity (RC) are calculated for this material and the effects of halide interchangeability on the MCE are discussed. CPA, as a tunable molecular magnet that may also serve as a candidate for quantum spin liquid (QSL) studies [5], invites numerous opportunities for manipulations of its chemistry, and therefore variations in the magnetic properties, including the magnetocaloric effect. The limits of chemical variability in the molecular structure and the extent of channel guest host chemistry is the focus of future studies to support the need for application-specific, tunable, magnetic refrigerants. FQ-08. The first-order magnetoelastic transition in Eu_2In: A ^{151}Eu Mössbauer study. *D. Ryan*[1], D. Paudyal[2], F. Guillou[2], A.K. Pathak[2], Y. Mudryk[2] and V.K. Pecharsky[2] *1. Physics, McGill University, Montreal, QC, Canada; 2. Ames Laboratory, Ames, IA, United States*

First-order magnetic transitions (FOMTs) with large differences in magnetization are important in the development of advanced functional magnetic materials, *e.g.* magnetocalorics. Eu_2In exhibits a particularly sharp, isosymmetric ferromagnetic (FM) to paramagnetic (PM) transition at T_C = 55K (FWHM<1K) with a remarkable combination of large latent heat and magnetocaloric response, small volume discontinuity, and negligible hysteresis[1]. By contrast, the isostructural Eu_2Sn is a conventional second-order antiferromagnet with T_N = 31K. Here we study the difference in magnetic behaviour between Eu_2In and Eu_2Sn using ^{151}Eu Mössbauer spectroscopy and band structure calculations. The Mössbauer data in Fig. 1 shows the remarkable differences between these two materials. Eu_2Sn has a single Eu component with a rather small (13 T) hyperfine field (B_{hf}) at 5K that evolves normally as it is warmed through T_N (Fig. 2). By contrast, Eu_2In shows two, distinct, equal-area components with much larger hyperfine fields (17 T and 27 T) that decline by about 25% on warming towards the FOMT at T_C where both vanish abruptly. The very different, and larger, hyperfine fields observed at the two Eu sites in Eu_2In are particularly surprising given that the two sites in the isostructural Eu_2Sn are indistinguishable, and that DFT calculations indicate that the Eu moments at the two sites are essentially the same[1]. Calculations indicate that the Eu-5d states hybridize with the In-5p states, resulting in a large exchange splitting. While the Mössbauer behavior of each compound taken in isolation may appear as conventional examples of first-order (Eu_2In) and second-order (Eu_2Sn) transitions, the striking differences between the physical properties of these two structurally similar compounds demand an in-depth investigation of their underlying magnetism by neutron diffraction. Work at Ames Laboratory is supported by the Office of Basic Energy Sciences of the U.S. Department of Energy, Division of Materials Sciences and Engineering under contract No. DE-AC02-07CH11358 with Iowa State University.

FQ-09. Magnetic field dependence of the martensitic transition and magnetocaloric effects in $Ni_{49}BiMn_{35}In_{15}$. *A. Aryal*[1], I. Dubenko[1], S. Talapatra[1], S. Stadler[2] and N. Ali[1] *1. Physics, Southern Illinois University, Carbondale, IL, United States; 2. Physics and Astronomy, Louisiana State University, Baton Rouge, LA, United States*

The structural, magnetic, and magnetocaloric properties of Bi doped Heusler alloy $Ni_{49}BiMn_{35}In_{15}$ have been investigated using room temperature X-ray diffraction (XRD) and magnetization measurements in a temperature interval of 5-400 K and for magnetic field changes ($\mu_o\Delta H$) up to 5T. The magnetization measurements were carried out during heating and after the samples were cooled from 400 K to 10 K at zero magnetic field (ZFC), and in the presence of a magnetic field (FC). The alloy at room temperature was found to be in a mixture of a high temperature austenite phase (AP) and a low temperature martensite phase (MP). Two ground states characterized by different magnetization values of (40 and 110 emu/g) were found to stabilize at 5 K and $\mu_o\Delta H$ = 5T depending on the cooling protocol. Based on the magnetization data, the states were identified as ferromagnetic AP (110 emu/g, FC) and MP (40 emu/g, ZFC), respectively. A shift in the martensitic transition temperature (T_M) from 195 K to lower temperatures with applied magnetic field at the rate of 15 K/T was observed in the ZFC $M(T)$ curves. Metamagnetic behavior characterized by a jump in magnetization in the isothermal $M(H)$ curves near T_M was observed in the ZFC measurement. Maximum value of the magnetic entropy change and refrigerant capacity in the vicinity of the magnetostructural transition temperature was found to be 5.0 $Jkg^{-1}K^{-1}$ and 225 Jkg^{-1} for $\mu_o\Delta H$ = 5T. Acknowledgment: This work was supported by the U.S. Department of Energy (DOE), Office of Science, Basic Energy Sciences (BES) under Award No. DE-FG02-06ER46291 (SIU) and DE-FG02-13ER46946 (LSU).

FQ-10. Coupled Phase Transitions and Associated Magnetocaloric Effects in $Ni_2Mn_{0.70}Cu_{0.30}Ga$. *S.A. Agbo*[1], S. Bhatt[1] and M. Khan[1] *1. Physics, Miami University, Oxford, OH, United States*

In the last few decades, the Ni-Mn-Ga based Heusler alloys have been extensively studied for their multifunctional properties that are primarily associated with the first order martensitic phase transformation. It has been shown that the first and second order phase transitions in these materials can be precisely controlled by varying their stoichiometry and by atomic doping. For example, when Mn is partially replaced by Cu in $Ni_2Mn_{1-x}Cu_xGa$, the martensitic transition shifts from ~220 K to higher temperatures while the second order ferromagnetic transition shifts from ~380 K towards lower temperatures [1, 2]. For x = 0.25, the two transitions occur nearly at the same temperature resulting in a coupled first order phase transition. The structural and magnetic properties of $Ni_2Mn_{1-x}Cu_xGa$ with x > 0.25 have not yet been reported. Since a first order phase transition exhibits a thermal hysteresis while a second order phase transition does not, it is interesting to study the phase transitions in $Ni_2Mn_{1-x}Cu_xGa$ with x slightly larger than 0.25. Exciting coupling and decoupling effects may be expected in such a material. Keeping this discussion in mind, we have investigated the structural, electronic, magnetic, and magnetocaloric properties of $Ni_2Mn_{0.70}Cu_{0.30}Ga$. Upon heating, a first order coupled magnetostructural phase transformation was observed in the material near 345 K. A partial decoupling of the phase transitions occurred during cooling. The decoupling effect resulted in a large variation in the magnetocaloric properties of the material when the measurements were done while heating and cooling. For a field change of 5 T, the peak magnetic entropy change obtained while heating was -17 J $kg^{-1}K^{-1}$. Interestingly, the peak value was -33 $Jkg^{-1}K^{-1}$ when the measurements were done while cooling from 400 K to lower temperatures. The electrical resistivity data also exhibit interesting behavior. The results of this experimental study will be presented and discussed.

Physics, Brooklyn College, Brooklyn, NY, United States*

We present Pair Distribution Function (PDF) analysis of x-ray diffraction measurements of $AlFe_2B_2$ in order to quantify local disorder. $AlFe_2B_2$ is a second-order magnetocaloric material that has considerable promise for potential magnetic refrigeration applications, as it exhibits moderate room-temperature magnetocaloric effect (MCE) in the vicinity of a highly tunable Curie temperature near room temperature. Previous thermodynamic studies have shown a substantial dependence of both its Tc and MCE properties (magnetic entropy change and adiabatic temperature change) on compositional parameters such as stoichiometric ratio of the constituent elements and elemental substitution (Fig. 1, Ref. [1]) With this in mind, total scattering measurements with hard x-rays were made on a selection of different compositional variants of $AlFe_2B_2$, including both polycrystalline samples and crushed single crystals (see Fig. 2 for example). In doing so, we aim to provide a template for next-generation characterization of caloric materials, by obtaining a real space map of local (e.g. anti-site) disorder that can used in *ab initio* materials models to predict the thermomagnetic properties of materials with phase transitions at finite temperature.

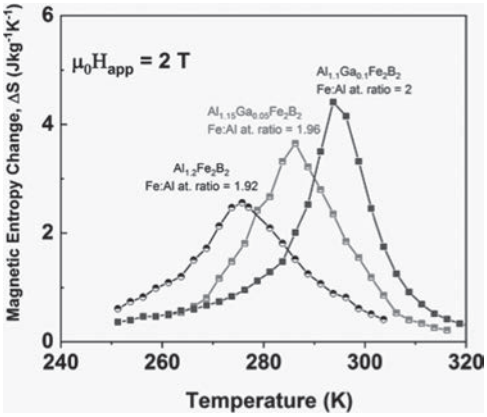

Fig. 1: The isothermal entropy change, observed in a 2 Tesla field, for three compositions of the $Al_{1.2-x}Ga_xFe_2B_2$ system (x=0, 0.05 and 0.1). The Fe:Al atomic ratio within the $AlFe_2B_2$ phase in this set of samples increases from 1.96 to 2.04 as the atomic % of Ga increases from 0 to 0.1. Up to a two fold increase in ΔS is observed upon addition of Ga. A similar increase in the adiabatic temperature change is observed, as determined from heat capacity measurements (taken from Ref. 1).

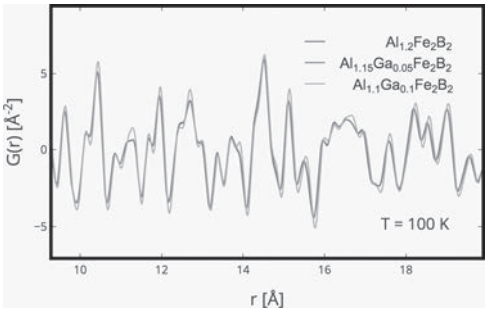

Fig. 2: A comparison of the pair distribution functions for polycrystalline samples of the same three compositions of the $Al_{1.2-x}Ga_xFe_2B_2$ system (x=0, 0.05 and 0.1) taken from x-ray diffraction measurements at 100 K.

FQ-12. Magnetocaloric effect in a cluster-glass system $Ho_5Pd_{2-x}Ag_x$ for hydrogen liquefaction. *H. Kitazawa*[1], S. Toyoizumi[2], K. Kujirai[2], H. Mamiya[3], R. Tamura[4], K. Morita[5] and A. Tamaki[2] *1. Center for Green Research on Energy and Environmental Materials, National Institute for Materials Science (NIMS), Tsukuba, Japan; 2. The magnetic refrigeration based on magnetocaloric effect (MCE) of magnetic materials has attracted attention due to its potential application in energy-efficient environment-friendly refrigeration technology. T. Samanta *et al*. discovered that the rare-earth compound Ho_5Pd_2 which crystallizes in the cubic Dy_5Pd_2 structure has a large relative cooling power 6.32 J/cm^3 at around 30 K [1]. This material is expected to be a good candidate for hydrogen liquefaction by magnetic refrigeration because the boiling temperature 20 K of hydrogen gas is near the maximum temperature 30 K. Our neutron experiments clarified that Ho_5Pd_2 belongs to a cluster-glass specified by a short-range ordering with a long wavelength [2]. A. F. Gubkin *et al*. reported their spin-glass behaviors by DC and AC magnetization measurements with results of neutron experiments [3]. These glass-like behaviors should be originated from partial occupancies at Ho and Pd sites. In order to investigate of the relationship between large MCE and the cluster glass, we have shown the magnetic entropy change depends on number of vacancies at Ho sites [4] and substitution amount of Ni for Pd [5]. In this study, we examined magnetic and thermal properties of a solid solution system $Ho_5Pd_{2-x}Ag_x$ ($0 \leqq x \leqq 0.4$) by the measurements of magnetization and heat capacity to investigate substitutional effect of Ho_5Pd_2. We have obtained polycrystalline samples with a single phase for $Ho_5Pd_{2-x}Ag_x$ from $x = 0$ to $x = 0.2$. However, the volume fraction of a foreign phase Ho_2O_3 starts to increase with increase of x above $x = 0.4$. The lattice parameter a lineally increases with increase of x. The paramagnetic Curie-Weiss temperature θ_p gradually decreases with increase of x. However, the magnetic entropy change $-\Delta S_m$ for $Ho_5Pd_{2-x}Ag_x$ in a magnetic field of 5 T demonstrates anomalous x-dependence as shown in Figure 1. The maximum value of $-\Delta S_m$ suddenly drops from $x = 0$ to $x = 0.03$, gradually decreases from $x = 0.03$ to $x = 0.2$ and drops again from 0.2 to 0.4. We will discuss the vacancy and Ni substitutional effects of Ho_5Pd_2 with other magnetic and thermal properties.

FQ-13. Interstitial effects on the magnetic phase transition and magnetocaloric effects in (Hf, Ta)Fe_2 kagome phase. S. Li[1], T. Chen[2], *J. Chen*[3], X. Zhou[1], P. Jia[1], W. Cui[1,2] and Q. Wang[1] *1. Northeastern Unversity, Shenyang, China; 2. Lanzhou University of Technology, Lanzhou, China; 3. Institute Of Electronics, CAS, Beijing, China*

(Hf,Ta)Fe_2 phase crystallizes in the hexagonal Laves Kagome-like lattice in the whole Ta concentration [1]. With increasing temperature, the system abnormally undergoes a first-order magnetic phase transition from FM ground state to AFM state and then PM state without change in the crystal symmetry. Its interesting magnetic and electronic properties have caused lots of research attentions. The $Hf_{1-x}Ta_xFe_2C_y$(x=0.15, 0.165, 0.18, y=0, 0.015) ingots were prepared by arc-melting and annealed at 1273 K for 10 days. The phase constituent and magnetic properties have been examined by X-ray powder diffraction (XRD) and cryogenic VSM. The XRD patterns shows that the single-phase has been obtained in the $Hf_{1-x}Ta_xFe_2$(x=0.15, 0.165, 0.18, y=0, 0.015) alloys. More Ta substitution leads into the increased lattice parameter *a* but decreased *c*. Due to C addition, a is decreased but c is increased compared with C-free benchmark alloy. The first-order FM-AFM phase transition is confirmed with thermal hysteresis as shown in Fig.1. More Ta substitution reduces the Tc from 222 K at x = 0.15 to 153 K at x = 0.18 without widening the thermal hysteresis. By C addition, transition temperature is not affected in $Hf_{0.85}Ta_{0.15}Fe_2$ alloy. But the influence of C addition becomes obvious with more Ta additions not only in the reduced transition temperature but also the widened thermal hysteresis. Near their respective transition temperature, the typical step-like metamagnetic curves are observed, indicating the field-induced phase transition from AFM to FM state. The magnetic entropy changes are calculated by Maxwell relationship. For a field change of 7 T, the maximum of entropy change, delta S^{max}(7T), is 3.7 Jkg^{-1}K^{-1} in $Hf_{0.85}Ta_{0.15}Fe_2$ alloy and slightly increased to 4 Jkg^{-1}K^{-1} in $Hf_{0.835}Ta_{0.165}Fe_2$ alloy. While, the delta S^{max} is not influenced by C addition.

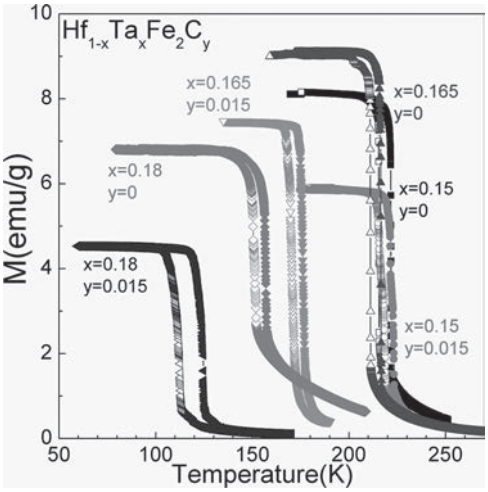

Fig.1 The M-T curves of $Hf_{1-x}Ta_xFe_2$(x=0.15, 0.165, 0.18, y=0, 0.015) alloys measured under 0.05 T.

FQ-14. Electric field controlled magnetocaloric effect in FeRh/PMN-PT heterostructure. *K. Qiao*[1], J. Li[1], C. Zhang[1], F. Hu[1], J. Wang[1], J. Sun[1] and B. Shen[1] *1. Institute of Physics, Chinese Academy of Scienes, Beijing, China*

With the increasing of high energy consumption and environmental problems in conventional cooling technology, magnetic refrigeration technology stands out as an alternative due to its energy-saving and environment-friendly characteristics. As typical magnetic refrigeration materials, first-order phase transition materials are limited by the narrow cooling temperature region. To solve this problem, FeRh films were successfully grown onto (011)-PMN-PT substrates with typical AFM-FM first order phase transition, as indicated by the *M-T* curves in Fig. 1a. Interestingly, two peaks occurs in d*M*/d*T-T* curves as shown inset of Fig.1a, indicating the AFM-FM phase transition of FeRh film was split in two successive parts. The reason is ascribed to the different strains of FeRh film grown on different ferroelectric domains in rhombohedral(R) phase PMN-PT substrates induced by lattice mismatch. However, two peaks merge into one peak at 6kV/cm and the peak position move to a higher temperature, which is attribute to electric field induced phase transition from multi-domain R phase to single domain orthorhombic(O) phase in PMN-PT[1]. There are also two peaks in Δ*S-T* curves at 0kV/cm in Fig.1b and one peak at 6kV/cm, coinciding with d*M*/d*T-T* curves. Actually, with electric field applied, not only the peak value of Δ*S-T* curves at 5T increased from 142 mJ/cm^{3}K to 153 mJ/cm^{3}K, but also the cooling temperature region expands from 25K to 33K as shown in shadow area in Fig.1b. With the help of electric field, the operating temperature region extends remarkably from 25K to 43K as shown in shadow area in Fig.1b and the value of Δ*S* at different temperature region is adjustable. This study lays a foundation for realizing a tunable magnetic entropy change by electric field in a broad cooling temperature region of first-order phase transition materials and promoting the application of magnetic refrigeration.

FQ-15. Influence of a magnetic field in $[Fe(pzt)_6](PF_6)_2$ (pzt=1-propyltetrazole), a spin-crossover material. *B.d. Alho*[1], P.d. Alho[1], R.M. Ribas[1], V.R. de Sousa[1], E.P. Nóbrega[1] and P. von Ranke[1] *1. Rio de Janeiro State University, Rio de Janeiro, Brazil*

Nowadays, there is a strong necessity of saving energy consumption in cooling processes as well as finding new environmental friendly materials to act as refrigerant, in the so called solid-state refrigeration. Those materials are used as an alternative to the actual gas-compression refrigeration systems, which have low efficiency and negative environmental effects. The caloric effects are described by two thermodynamic quantities: isothermal entropy change (ΔS_T) and adiabatic temperature change (ΔT_{ad}). The spin-crossover (SCO) phenomena is a switching between a high spin (HS) and low spin (LS) state when the system is submitted to an external parameter variation such as pressure and temperature [1-4]. Recently, SCO materials have been pointed as good candidates for caloric refrigeration due to their giant barocaloric potentials. However, other caloric effects are yet to be investigated in those compounds. In this work we studied the magnetic and magnetocaloric effects on the $[Fe(pzt)_6](PF_6)_2$ (pzt=1-propyltetrazole) spin-crossover compound [4]. Our theoretical microscopic model results in a total entropy with includes the magnetic, lattice, electronic and configurational contributions. We obtained, as expected, a small magnetocaloric effect in comparison with the giant barocaloric effect on the same compound. However, this results points out that a larger magnetocaloric effect may be obtained in SCO compounds which includes a ferromagnetic phase.

FQ-16. Computational Discovery of Novel Iron-Based Amorphous Magnetocaloric Alloys. *A.M. Krajewski*[1,2], B. Dong[1], P. Wang[1] and M.A. Willard[1] *1. Department of Materials Science and Engineering, Case Western Reserve Univeristy, Cleveland, OH, United States; 2. Department of Materials Science and Engineering, The Pennsylvania State University, University Park, PA, United States*

In this study, we created a framework of machine learning and search algorithms to design novel high-performance magnetocaloric alloys. The framework operates by maximizing the magnitude of peak magnetic entropy change $|-\Delta S_M^{peak}|$ and tuning the Curie temperature T_C to the desired value (i.e. 320±10 K), while keeping the composition relatively close to known alloys. We have first collected data (e.g. $|-\Delta S_M^{peak}|$ and T_C) on magnetocaloric effect in 194 distinct alloys reported in 41 publications. These alloys lay in the 18-dimensional composition space: $Fe_{100-\Sigma}$ $Ni_{0–38}$ $Co_{0–40}$ Cu_{0-1} Zr_{0-11} $B_{0–29}$ $Cr_{0–10}$ $Nb_{0–10}$ $Gd_{0–4}$ $Y_{0–22}$ $Mo_{0–10}$ $Si_{0–10}$ $Nd_{0–15}$ $Ce_{0–13}$ $Sm_{0–3}$ $Mn_{0–24}$ $Ti_{0–8}$ $V_{0–14}$. All essential properties were normalized to their values at an applied induction of 1.5 T, using V. Franco's universal curve method.[1] Using our tool, we have selected known high-performing alloys, then predicted modifications to these alloys with varying degrees of deviation (with larger deviations deemed riskier but resulting in larger predicted magnetic entropy). Starting with a known alloy with $Fe_{80}Zr_{10}B_{10}$ composition, reported to have $|-\Delta S_M^{peak}|$ of 1.47 J/(kg K) at H=1 T (1.95 J/(kg K) at H=1.5 T) and T_C of 365K,[3] our tool predicted three new alloys based on it: $Fe_{79}Zr_{10}B_{10}Ce_1$, $Fe_{76}Cu_1Zr_{10}B_{10}Ce_2Ti_1$ and $Fe_{74}Cu_1Zr_{10}B_{10}Nd_1Ce_2Ti_2$. Each step was predicted to increase $|-\Delta S_M^{peak}|$ by roughly 0.05 J/(kg K) at H=1.5 T relative to each other, and lower T_C by 15, 25, 25 K relative to the base alloy. We measured that $Fe_{80}Zr_{10}B_{10}$ had $|-\Delta S_M^{peak}|$ of 0.91 J/(kg K) at H=0.9T (1.31 J/(kg K) at H=1.5T) and T_C of 343K. The first new alloy with composition $Fe_{79}Zr_{10}B_{10}Ce_{1,}$ was found to increase the $|-\Delta S_M^{peak}|$ by 0.09 J/(kg K) at H=1.5 T and lower T_C by 10 K. In this contribution, we will discuss details of the model methodology, further validation experiments, and availability of this tool to other researchers.

A long-standing barrier to using magnetocalorics (MCs) in industrial applications is the requirement of high magnetic fields[1]. Recently intense research efforts have been undertaken to try to optimize MCs response to magnetic field and to increase the cooling power achievable close to room temperature. To further these goals various doping schemes of bulk materials have been extensively studied, however recently focus has shifted to optimizing synthesis techniques and structural engineering[2]. In order to develop advanced nano-structured MC materials, a fundamental understanding of how to produce high quality MC thin films will be required. We have used pulsed laser deposition to grow thin films, between 50nm and 150nm thick, on thermally oxidised Si substrates from a single LaFeCoSi target. Samples have been studied using SQUID magnetometry, AFM, XRR and PNR. Figure 1 presents XRR data for a 140nm thick film grown with a substrate temperature of 250°C and a laser pulse power of 200mJ with 18Hz repetition rate in a 20mTorr Ar atmosphere. The data clearly show the presence of Kiessig fringes out to a 2Θ angle of 6°, indicating low surface and interface roughness. Fits to the data indicate roughness of 3.52Å and 1.35Å at the surface and interface respectfully. Measurements of the magnetization as a function of temperature show a distinct change in gradient, characteristic of a magnetocaloric material near its Curie temperature. The change in gradient is close to 285K expected from previous measurements of bulk materials and corresponds to the structural phase transition. Hysteresis loops show a transition from ferromagnetic to paramagnetic behaviour as the temperature increases and approaches the gradient change seen in magnetization data. From these measurements the entropy change has been calculated (see figure 2) and shows a large negative magnetocaloric effect with a peak close to that expected for the bulk. A maximum peak of 20J/K in a 3T field is calculated for our LaFeCoSi thin films. For comparison we have also grown the more commonly studied material GdSiGe as thin films and have measured a peak entropy change of 4J/K at 3T[3, 4].

Spherical powder is key for achieving good heat transfer and maintaining low pressure drop for heat transfer fluid in magnetocaloric regenerator. Obtaining relatively large spherical powder of rare earth metals that are extremely sensitive to oxygen is challenging. Comparing to gas atomization and plasma rotating electrode methods, rotating disk atomization (RDA) method is more robust for obtaining a small amount of powder with a short turn-around time, thereby, more suitable for research and development of new magnetocaloric materials. In this work, commercially bulk gadolinium was successfully atomized to produce spherical powder in the targeted 150-250 μm range. The obtained powder exhibited the expected magnetocaloric performance with a maximum change of magnetic entropy of 12.1 J/kg K and a maximum adiabatic temperature change of 12.8 K with an applied magnetic field of 7 T.

In this paper, we mainly focus on the magnetic and magnetocaloric features of $La_{2-x}Dy_xNiMnO_6$ double perovskites. Their magnetocaloric properties are investigated in terms of both entropy and adiabatic temperature changes. In contrast to early works, it was found that the Dy_2NiMnO_6 compound unveils

dominant antiferromagnetic interactions under very low magnetic fields. The ordering of its Dy^{3+} magnetic moments is associated with a giant magnetocaloric effect at very low temperatures, while the established ferromagnetic Ni-O-Mn super-exchange interactions close to 100 K give rise to moderate magnetocaloric levels. On the other hand, the doping of Dy_2NiMnO_6 with high amounts of large-size rare earth elements such as La would enable us to cover an unusually wide magnetocaloric temperature range going from the liquid helium temperature up to room-temperature. More interestingly, the presence of both ordered and disordered ferromagnetic phases in $La_{1.5}Dy_{0.5}NiMnO_6$ maintains constant its magnetocaloric effect over a temperature span of about 200 K (Fig.1), being a favorable situation from a practical point of view [1, 2]. However, the $La_{2-x}Dy_xNiMnO_6$ family cannot be directly implemented in functional devices because of its moderate thermal effects. The latter can be markedly enhanced by increasing the grains size of its polycrystalline forms using optimum annealing conditions. Additionally, the entropy change exhibited by $La_{1.5}Dy_{0.5}NiMnO_6$ under 7 T (for example) in the temperature range between 50 and 255 K is only 2.5 % of the theoretical limit. This opens the way to further fundamental and experimental investigations of R_2NiMnO_6 double perovskites (R = rare earth element) with the aim to fully taking advantage of their magnetocaloric potential. Also, some of the R_2NiMnO_6 double perovskites exhibit additional degrees of freedom such as electrical polarization enabling potential supplemental caloric effects under electric fields.

FR-01. Influence of Current Harmonics and Rotor Structure on Electromagnetic Losses of High Speed Permanent Magnet Synchronous Motor. *K. Shin*[1], J. Lee[1], G. Jang[1] and J. Choi[1] *1. Chungnam National University, Daejeon, The Republic of Korea*

High-speed permanent magnet synchronous motors (HPMSMs) are developed in direct-drive applications such as centrifugal compressor and vacuum pump because of the advantages of compact size and high efficiency [1]. However, due to the small size, it has a high loss density and a limited heat dissipation surface, which causes difficulties in cooling [2]. Therefore, the accurate prediction of electromagnetic losses is very important in the design stage of HPMSM. In this study, electromagnetic analysis considering pulse width modulation (PWM) inverter and effective three-dimensional (3D) electromagnetic structure is proposed for predicting accurate electromagnetic losses of stator and rotor of HPMSM. Fig. 1 shows the 3D structure and side view of the HPMSM and the evaluation system of the prototype. In order to improve the analysis time, an effective 3D analysis model has been defined based on physical properties. In addition, the phase current with carrier harmonics from PWM inverter was estimated by dynamic simulation model, and it was used for electromagnetic losses analysis. Figs. 2(a) and (b) show the predicted and measured current waveforms and FFT analysis results of currents. From the comparison of the analysis results with experiments, it can be confirmed that the modeling of the control system is valid. As shown in Fig.2(c), mechanical loss were measured from finite element analysis and open circuit test of prototype. Using effective 3D model and current harmonics, electromagnetic analysis deals with calculation of copper loss, core loss, and rotor loss, respectively. When the mechanical loss is added to the electromagnetic loss analysis result, the error between the proposed electromagnetic loss analysis and the experiment is within 3% according to the operating condition as shown in Fig. 2 (d). The analysis, discussions and measurements of HPMSM will be explained in more detail in the full paper.

FR-02. Magnet Selection in Permanent Magnet Synchronous Traction Motor for Electric Vehicles. *H. Won*[1], Y. Hong[1] and M. Choi[1] *1. Department of Electrical and Computer Engineering and Center for Advanced Vehicle Technologies, The University of Alabama, Tuscaloosa, AL, United States*

This paper has investigated the coercivity (H_c) and remanent flux density (B_r) of permanent magnet (PM), that meet the traction motor specifications set by US Department of Energy for electric vehicle (EV) application [1]. To identify the required values of H_c and B_r, five PM traction motors, which are fractional-slot concentrated wounded surface PM motor (FSCW-SPM), FSCW flux-switching PM motor (FSCW-FSPM), FSCW spoke interior PM motor (FSCW-SIPM), integer-slot distributed wounded SIPM (ISDW-SIPM), and ISDW V-shape interior PM motor (ISDW-VIPM) [1-5], were considered and simulated for motor performance using ANSYS Maxwell 2D under rated and peak conditions. Table I shows the motor specifications and performance of five optimized motors. The B_r and H_c of PM are swept from 0.6 to 1 T in steps of 0.1 T and 600 to 900 kA/m in steps of 100 kA/m, respectively. Fig. 1 shows the maximum torque in solid line and demagnetization rate (D_{rate}) in dashed line of the five motors. The D_{rate} is calculated by dividing the area where flux density of PM is lower than 0.1 T and/or magnetization direction (M_{dir}) is opposite to the initial M_{dir} to the space occupied by the whole magnet when the input current is 2.5x of rated current. To meet the DOE requirements with PM demanding low H_c and D_{rate} below 2 %, the required B_r needs to be 0.9, 0.7, 0.8, 0.7, and 0.9 T with H_c of 700, 900, 750, 600, and 700 kA/m for FSCW-SPM, FSCW-FSPM, FSCW-SIPM, ISDW-SIPM, and ISDW-VIPM, respectively. For PM requiring low B_r and D_{rate} below 2 %, the B_r of 0.85, 0.72, 0.75, 0.6, and 0.7 T for listed motors with H_c of 900, 900, 900, 700, and 900 kA/m, respectively, are required. The motors employing PM with low H_c are investigated further for rated and maximum speed using ANSYS motor toolkit. It was found that all motors meet the DOE requirements, as listed in Table I. Our results provide the

motor designers with some guidelines for PM selection for EV application. This work was supported in part by the NSF-I/UCRC for EV-STS under Grant number 1650564.

FR-03. Sensorless PMSM Drive Based on Modified MRAS Parameter Estimation with GWO Algorithm. J. Cao[1], *X. Sun*[1], G. Lei[2], J. Zhu[3] and Y. Guo[2] *1. Automotive Engineering Research Institute, Jiangsu University, Zhenjiang, China; 2. School of Electrical, Mechanical, and Mechatronic Systems, University of Technology Sydney, Sydney, NSW, Australia; 3. School of Electrical and Information Engineering, University of Sydney, Sydney, NSW, Australia*

Abstract-This paper proposes a modified model reference adaptive system (MRAS) method for sensorless control of permanent magnet synchronous motor (PMSM). To reduce the adverse effect of parameters variation, the stator resistance and magnet flux linkage are estimated and continuously updated. Besides, controller parameters of adaptive law are optimized by grey wolf optimization (GWO) algorithm. 1.Introduction Conventional MRAS takes rotor speed as adjustable parameter to obtain speed adaptive law [1], and ignores the adverse effect caused by parameters variation [2]. While the modified MRAS can improve control performance by estimating the parameters. Augmented with GWO algorithm, the performance of the control system can be improved greatly. 2.The proposed method The dynamic model of SPMSM in *dq*-axis reference frame can be described as $d(i_d+\Psi_f/L_s)/dt=-R/L_s(i_d+\Psi_f/L_s)+\omega_e i_q+(u_d+R\Psi_f/L_s)$ $d(i_q)/dt=-Ri_q/L_s-\omega_e(i_d+\Psi_f/L_s)+u_q/L_s$ where u_d, u_q, i_d, and i_q are stator voltages and currents. R, L_s, Ψ_f and ω_e are stator resistance, inductance, magnetic flux linkage, and electrical angular velocity, respectively. The currents are taken as variables to obtain adjustable model. According to Popov's inequality criteria, the adaptive law can be obtained as $\omega_e=-(k_p+k_i/s)(i_d\hat{i}_q-i_q\hat{i}_d-\Psi_f(i_q-\hat{i}_q)/L_s)$ The estimated parameters are substituted to obtain the modified model. Adaptation laws for R_s and Ψ_f are given respectively as $R'=-(k_{pres}+k_{ires}/s)(i_d\hat{i}_d+i_q\hat{i}_q-i_di_d-i_qi_q+\Psi_f(i_d-\hat{i}_d)/L_s)+R(0)$ $\Psi'f=-(k_{pflux}+k_{iflux}/s)(i_q-\hat{i}_q)\omega_e/L_s+\Psi_f(0)$ To reduce speed error and suppress overshoot, GWO is used to optimize controller parameters and cost function is given as $f=T_s/N\sum(k|\omega(k)-\omega^*|+k|i_d(k)-i^*\ d|+k\lambda(\omega(k)-\omega^*))$ whereT_s is the sampling period, λ is penalty factor, k is sample time index. 3.Results In this section, experiments are used to verify the performance of the modified MRAS and GWO is used to optimize the controller parameters. The experimental setup and results are shown in Fig.1 and Fig.2, respectively. 4.Conclusion In this paper, a sensorless PMSM drive scheme based on modified MRAS with GWO algorithm is proposed and verified by simulations and experiments.

FR-04. Dynamic Characteristic Analysis and Experimental Verification of IPMSM according to Operating Range. *G. Jang*[1], C. Kim[1], H. Lee[1], H. Shin[1], J. Gu[1] and J. Choi[1] *1. Chungnam National University, Daejeon, The Republic of Korea*

The interior permanent magnet synchronous motor (IPMSM) is a structure resistant to scattering due to centrifugal force by embedding a permanent magnet in a barrier inside a rotor core. The rotor core has a salient pole, and in addition to magnetic torque, reluctance torque can be generated. Therefore, when the flux weakening control is properly performed, high-speed operation and wide constant output operation can be achieved due to the influence of the reluctance torque. In particular, there is little impact on price, high performance, high output, and high reliability [1]. Many studies have focused on the design and performance evaluation of such an IPMSM. However, there is little detailed performance analysis considering the pulse width modulation (PWM) controller of the motor. In general, the FEM cannot accurately depict the torque ripple and loss because the PWM current harmonics cannot be considered. Therefore, when the motor is actually driven, the result of the experiment is different from that of the analysis [2]. In this paper, we propose a dynamic characteristics analysis method of

IPMSM to provide high-accuracy analysis of the motor controller. Fig. 1 (a) shows the shape of the IPMSM described in this paper. It comprises six poles and nine slots, and the magnet is embedded in a V shape. Fig. 1(b) shows the comparison of torque analysis results using the finite element method (FEM), the calculated value and the experiment according to the current magnitude and phase angle. Fig. 1 (c) is a block diagram describing the dynamic characteristics analysis of the IPMSM. Fig. 2 (a) and (b) show the d-axis and q-axis inductance values according to the current magnitude and phase angle of IPMSM. Fig. 2 (c) shows a comparison of the performance of the motor analyzed using the FEM and the dynamic characteristics. Detailed analysis methods, experimental methods and results are presented in the full paper.

FR-05. A Study of the Number of Axial Segments of Permanent Magnet in SPMSM for Ultra-High Speed Applications. *H. Lee*[1] *1. Electrical Engineering, Busan Institute of Science & Technology, Busan, The Republic of Korea*

This paper describes the analysis on the Number of Axial Segments of Permanent Magnet in SPMSM for Ultra-High-Speed Application; Electric-Turbo Compound System(E-TCS) for Construction Equipment. E-TCS is a device that combines a turbocharger, which is a regenerative device through exhaust gas, and a compressor to improve the turbo lag. As a result, E-TCS must be able to drive at least 80,000 rpm and require a large torque at low speeds. And because of scattering problem of permanent magnets, so limit to increase the rotor size and shaft length is realatively long. To increase performace of motor, difficulties of permanent magnetization and reduce permanent magnet loss, the segment must be applied in the axial direction on permanent magnet. Design criteria and power loss analysis of the ultra-high-speed motor are described by analytical method, and the results are validated by 3D-finite element method. And then, the prototype motor has been fabricated 3 cases and tested. The experimental results confrimed the validity of the proposed design and alalysis scheme of the ultra-high-speed SPMSM(Surfaced Permanent Magnet Synchronous Motor).

FR-06. Hybrid membrane computing and evolutionary algorithm for permanent magnet synchronous motor parameter design. X. Liu[1] and *W. Fu*[2] *1. Chongqing University, Chongqing, China; 2. The Hong Kong Polytechnic University, Hong Kong, Hong Kong*

I. Introduction To overcome the parameter design problem of a motor, optimization tools have been considered [1]. Genetic algorithm (GA) is a search algorithm simulates the natural selection mechanism. It has the ability of self-organization, self-adaptation and self-learning. Gheorghe Paun proposed the concept of membrane computing (MC) systems which are also known as P systems. In this paper, the optimization problem of a permanent magnet synchronous motor (PMSM) is solved by the proposed novel hybrid MC based GA (HMCGA). The HMCGA takes advantage of the MC model and GA, which can obtain satisfying searching efficiency and a good balance between exploration and exploitation. The simulations are conducted and comparative results are given in this work and show that the HMCGA is feasible. II. Hybrid MC based GA In order to fully use the advantages of GA, the HMCGA model is formulated in this section. The procedure can be described as follows: 1. Initialize parameters of HMCGA. 2. Initialize positions and velocities randomly. Evaluate their fitness values and generate the best individuals. 3. Implement the *R* operator and the landmark operator for membranes as Fig. 2(c). 4. Calculate the fitness value. 5. Go to 3 for the next iteration if needed and output the optimal solution. III. HMCGA To test and validate the proposed algorithm, functions in Fig. 2(a) are examined [2]. Then a dual-PM-excited synchronous motor, as shown in Fig. 1(b), is optimized. The main specification and the design variables of the motor are listed in Fig. 1(c). The Convergence curves conducted by proposed algorithm, GA and PSO are shown as Fig. 2(b). IV. Conclusion In this paper, a novel HMCGA is proposed for optimization problem of a PMSM. The MC model has the advantages of simplicity and efficiency and the GA is introduced into the framework of MC model. Finally, the performance of HMCGA for optimization of PMSM is evaluated. Comparative results show that the proposed HMCGA is more efficient than the basic GA and PSO algorithms.

FR-07. Study on the Process for Improving the Design Precision of Working Bar of Double Cage Induction Motor. *D. Kim*[1], K. Kim[2], I. Yang[1], S. Song[1], S. Lee[1] and W. Kim[1] *1. Energy IT, Gachon University, Seungnam-si, The Republic of Korea; 2. Mechatronics Engineering, Halla University, Wonju-Si, The Republic of Korea*

Induction motors are the most commonly used energy consuming equipment and are highly effective in high efficiency design. Therefore, in order to satisfy both high efficiency and starting torque, an induction motor uses a double cage type rotor. In the case of the working bar of the double cage bar, most of the cases use an experience constant. However, these cases are applied to high voltage and large capacity induction motors (over 100kW), In case of medium and low capacity induction motors, errors are generated, resulting in lower results than the actual efficiency. This is because the resistance and impedance of the rotor at the time of design can not be accurately predicted. In this paper, we proposed a novel design process for improving precision on performance prediction in the design of rotor working bar of high efficiency double cage induction motor. The proposed process includes the process of determining the area of the rotor working bar and the process of determining the shape. The process for calculating the area of the rotor working bar sets the target value of current density and teeth flux density. The current density by obtaining the current and area of the working bar is calculated using the resistance. Regression of the efficiency constant until the target is collected, and find the optimal area of the working bar. This allows accurate rotor resistance to be predicted. Once the area is determined, a working bar shape determination process is performed that involves changing the shape of the working bar and calculating the rotor tooth flux density. The working bar is assumed to be rectangular, divide the height by dividing the width by the top, middle, and bottom. Change the width and repeatedly calculate the rotor tooth flux density until it converges to the target value using a magnetic equivalent circuit. Based on a model of 15 kw-class induction motor, the finite element analysis results of the design model using the existing experience constant and the proposed design process were compared. Finally, the validity of the process is verified by prototype performance test.

FR-08. Analyzing Position Detection by the Frozen Permeability of a Single-Phase BLDC Motor for Cordless Vacuum Applications. *H. Hwang*[1], Y. Choo[1], J. Cho[1], C. Kim[1], J. Choi[2], S. Hwang[3] and C. Lee[1] *1. Pusan National University, Busan, The Republic of Korea; 2. Kyungsung University, Busan, The Republic of Korea; 3. Kyungnam University, Changwon, The Republic of Korea*

This paper discusses the detection of rotor position in a single-phase blushless DC motor (BLDCM) without a sensor. Fig. 1(a) shows the direction of flux generated by permanent magnets (PMs) and coils, respectively. By injecting high-frequency voltage, relative permeability is changed in the core according to the interaction of PMs with coils. As a result, this permeability causes current offset by which the sensorless detection of rotor position has been implemented. To analyze permeability swing, it is mandatory to set the relative permeability of silicon steel in case of considering both coil and PM flux at the same time, and then total flux has to be decomposed into each flux. This is called frozen permeability method (FPM) and Fig. 1(b) shows B-H curve for explanation of the method. It is seen that a summation of flux densities of coil and PM is not the same as total flux density because of nonlinear permeability. The FPM should be used to avoid problem of the nonlinear permeability. Fig. 2(a) shows current offset and each flux linkage from coil and PM by the FPM. A direction of flux by coil and PM when negative current flows is the same as Fig. 1(a), and magnetic saturation occurs at this point. The magnetic saturation makes flux linkage from PM reduce and current offset as shown in Fig. 2(a). Fig. 2(b) shows experimental results on prototype of a single-phase BLDCM, and it is seen that negative current offset is occurred at the point of magnetic saturation. By detecting this current offset, rotor position of a single-phase BLDCM can be estimated without a sensor. In the final paper, we will discuss the experiment verification with detailed explanation through equations using FPM.

FR-09. Analytical and Experimental Verification for Electromagnetic Performances of Permanent Magnet Linear Synchronous Machines with Horizontally Magnetized Permanent Magnets. *K. Shin*[1], S. Seo[1], J. Woo[1] and J. Choi[1] *1. Chungnam National University, Daejeon, The Republic of Korea*

Permanent magnet linear synchronous machines (PMLSMs) are able to provide thrust force directly to the load without mechanical gears and transmission; therefore, they have significant advantages over rotary machines, such as simplicity and high efficiency [1]. A study on the performance comparison of PMLSM with magnet arrays showed that horizontal magnetization is better than vertical magnetization in terms of efficiency and weight in PMLSMs [2]. To develop design techniques for PMLSM with horizontal magnetization, this paper deals with the analytical modeling and experimental study for electromagnetic analysis of PMLSMs with horizontally magnetized permanent magnets (PMs) as shown in Fig. 1(a). The subdomains are divided into six regions: air gap (I, III), mover end (II), PMs (i), stator slots (j), and stator end (IV) as shown in Fig. 1 (b). The analytical solutions in all subdomains can be obtained by applying the boundary conditions to the interfaces between the subdomains. The validity of the proposed boundary condition was verified by comparing the air gap flux density as shown in Fig.1 (c) and (d). The analytical solutions allow for the prediction of the back-EMF, inductance, and generating characteristic in closed forms. The magnetic field and electromagnetic performances obtained by the analytical method were compared with those obtained by the finite element (FE) and experimental results. Fig. 2 (a) is a prototype and experiment set for verifying the reliability of the analytical results of the proposed analytical model. The generating characteristic analysis according to the load resistance connected to each phase are shown in Fig. 2 (b) and (c), and the results of the analytical method agreed well with the FE and experimental results. The analytical modeling, analysis results, and measurements will be presented in more detail in the full paper.

FR-10. Performance Verification of DR-PMSM for Traction System according to Permanent Magnet Shape. *C. Park*[1], H. Lee[1], G. Jeong[2], I. Jo[1], J. Lee[1] and T. Kim[3] *1. Korea National University of Transportation, Uiwang-si, The Republic of Korea; 2. Hanyang University, Seoul, The Republic of Korea; 3. University of Michigan-Dearbon, Dearbon, MI, United States*

Conventional driving systems of railway vehicle are composed of traction motor, mechanical reduction gear, and wheel sets, so that the structure of the driving systems is complicated and there is a limit in reducing the size and weight of them. In addition, the conventional driving systems have large maintenance cost problem due to transmission oil leakage and tooth wear of the ruction gear, and low efficiency problem due to additional power loss by the mechanical gear. Therefore, it is necessary to develop a new technology that can increase the output power density and maintainability of the conventional topology in driving system. Dual rotor permanent magnet synchronous motor (DR-PMSM) can be a good alternative to the conventional driving systems. DR-PMSM is structurally integrated with magnetic gear and PMSM, and it is directly mounted on the wheel without mechanical reduction gear. Currently, research on magnetic gears to replace mechanical reduction gears is being carried out variously all over the world [1]-[3]. However, the researches of DR-PMSM as a driving system for rail vehicle traction is now the beginning [4]. In this paper, the design study of the inner rotor including the permanent magnet is carried out in the application of the DR-PMSM. In designing the DR-PMSM models, Surface permanent

magnet (SPM) type and interior permanent magnet (IPM) type are considered according to the permanent magnet type of rotor, and IPM type is designed by dividing into bar type and V type. A comparative analysis of the three 1kW-class DR-PMSM models, in terms of electromagnetic properties, is performed to assess their general performance. The overall electromagnetic properties of the three designed models are similarly derived. But, the cogging torque and the rated torque characteristics of the IPM (V) type model are the best in comparison with the other models. In addition, the 1kW-class DR-PMSM prototype with V type magnet is fabricated to verify the validity of the analytical model and performance verification is performed.

FR-11. A Study on Position Control of Electro-mechanical Fin Actuator Using a New Position/Velocity Measurement Method Based Linear Type Hall-effect Sensor of BLDC Motor. J. Gu[2,1], *C. Kim*[1] and J. Choi[1]
1. Electrical engineering, Chungnam National University, Daejeon, The Republic of Korea; 2. Agency for Defense Development, Daejeion, The Republic of Korea

Electro-mechanical fin actuator system consists of a servo controller and an actuator. The electro-mechanical fin actuator for guided weapons requires robust controllers with position control algorithms to ensure robustness against uncertain disturbances such as aerodynamic loads and parameter variations. In order to design such robust controller, position and velocity of actuator are required. In general, position sensor(Potentiometer) and velocity sensor(Tachometer) are used shown in Fig.1(a). However, the use of such a sensor causes problems such as an increase in cost, an additional space for mounting, and a decrease in system reliability due to a sensor failure. To overcome this problem, we tried to implement the position and velocity signals by replacing the conventional latch type Hall-effect sensor of the BLDC motor with the linear type Hall-effect sensor as shown in Fig.1(b). The conventional position sensor and the velocity sensor were removed through a position and velocity implementation algorithm using the analog output of the linear type Hall-effect sensor while generating a commutation signal for driving the BLDC motor through a comparator having a hysteresis characteristic. Fig.2(a) shows the results of the 3/5deg step response test performed by applying the existing position/velocity sensor to the robust position controller, MFSMC(MFSMC : Model Following Sliding Mode Controller). Fig.2(b) shows the result of applying the newly proposed position/velocity signal by the linear type Hall-effect sensor to the robust position controller, MFSMC. As a result of the test, it is experimentally confirmed that the proposed method in this paper enables the position control through the robust position controller design without using the existing position/velocity sensor. In conclusion, it is confirmed that the proposed system can contribute to the miniaturization, cost reduction and system reliability improvement of the electro-mechanical fin actuator.

FS-01. Exploring magnetic resonance with a compass. *D. Nelson*[1], E. Cookson[1], M. Anderson[1], D. McKinney[2] and I. Barsukov[1] *1. Physics and Astronomy, UC Riverside, Riverside, CA, United States; 2. Santa Rosa Academy, Menifee, CA, United States*

Magnetic resonance plays an important role in today's science, engineering, and medical diagnostics. Learning and teaching magnetic resonance is challenging since it requires advanced knowledge of condensed matter physics and quantum mechanics. Driven by the need to popularize this technologically impactful phenomenon, we develop an inexpensive table-top demonstration experiment. It unveils the magnetic resonance of a hand-held compass in the magnetic fields of a permanent magnet. The setup provides an immediate visualization of the underlying physical concepts and allows for their translation to broad student audiences. This work was supported by the National Science Foundation under Grant No. ECCS-1810541.

FS-02. Magnetic Fields Web Series: Engaging Middle School Students in STEM. *P. Pena Martin*[1], J. Isberg[1], E. Ertekin[1,3], V. Lorenz[1,2] and N. Mason[1,2] *1. Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 2. Department of Physics, University of Illinois at Urbana-Champaign, Urbana, IL, United States; 3. Department of Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, United States*

Web based media can make scientific content accessible to audiences far beyond the scientific community. We created a web series called "Magnetic Fields" that aims to introduce materials science, particularly concepts related to magnetism, and promote themes more general to STEM fields, such as persistence and the scientific process, through use of characters and a story geared towards a middle school audience. The goal is to build and maintain interest in science at an age where this tends to drop off. The four-episode arc follows a group of high school characters as they encounter a strange new material during a class field trip to a laboratory. The series is directed by John Isberg, with professional actors making up most of the cast. The series was initiated by scientists in the Illinois MRSEC, and the storyline was developed in collaboration with MRSEC students and faculty. The episodes were released in May 2019 through Youtube. We report on the process of creating this series, response to it upon release, and discussion of its use as an educational tool. The authors acknowledge primary support of the NSF through the University of Illinois at Urbana-Champaign Materials Research Science and Engineering Center DMR-1720633.

FS-03. In-class experiments with smart phones for teaching upper-level electricity and magnetism. A. Davidson[1], A. Ranjan[2] and *X. Fan*[1] *1. Physics and Astronomy, University of Denver, Denver, CO, United States; 2. Cherry Creek High School, Greenwood Village, CO, United States*

Interactive-engagement method such as studio physics [1, 2], has demonstrated higher learning gains than traditional lecturing in intro-level physics classes. However, there have been limited applications in upper-level classes, such as Electricity and Magnetism (E&M), possibly because experiments on E&M topics can be too costly and sophisticated to be carried out in the classroom. Smart phone, which is equipped with magnetic field sensors, radio signal detectors and light sensors, provides a convenient platform for carrying out E&M-related experiments. In this poster, we will present three examples of the implementation of smart-phone-based studio physics in an E&M class for Physics majors: (1) Detection of earth magnetic field inclination; (2) quantifying skin depth of aluminum foil with cellphone tower signals; and (3) Measurement of Brewster's angle. Besides sensitive sensors, smart phone also has computational power, which can be explored to further expand the breadth and depth of the smart-phone-based studio physics. Due to the wide accessibility of smart phones and the simplicity of experimental setup, we expect this teaching technique can be easily transferred to other institutes in the world.

Electronic and Computer Engineering, Oakland University, Rochester, MI, United States; 4. Physics Department, Wayne State University, Detroit, MI, United States*

Lab sessions in physics education connect the fundamental concepts to practical examples and are effective measures of the students' understanding and reasoning through ultimate real-world tests. Many topics in condensed

matter physics are known to be challenging to convey in both lectures and labs. In addition, these topics are usually resource demanding, which has been one of the challenging issues. Here, we introduce and demonstrate the use of virtue lab modules for teaching physics labs and for effectively integrating research and education. Experiments that are relevant to magnetism and spintronics include, but not limited to, spin current detecting, microwave energy harvesting, and spin-based thermoelectric effects. An important highlight of these modules is the highly-interactive laboratory learning platform. In the class, each piece of experimental hardware (e.g. electrometers, oscilloscopes, etc) will be paired with a computer-based virtual module. The individual modules mimic the hardware, which the students can use to become familiar with the hardware, acquire real-time feedback, and visualize the data acquisition dynamics, on-demand and risk-free. The virtual component is also helpful for demonstrating delicate, shared hardware in class, without risk of damaging the actual instrumentation. These individual components are connected to a central operating system and the experiment can be re-programmed by simple coding and user-interfaced commands [1]. Work at Oakland University is supported by NSF DMR-1808892.

FT-01. The Co thickness dependence of the Dzyaloshinskii-Moriya interaction and magnetic anisotropy in Pt/Co/W trilayers. *Y. Park*[1,2], J. Kim[1], Y. Nam[1], S. Jeon[1], J. Park[1], K. Kim[2], H. Lee[3], B. Min[2] and S. Choe[1] *1. Seoul National University, Seoul, The Republic of Korea; 2. Korea Institute of Science and Technology, Seoul, The Republic of Korea; 3. Pohang University of Science and Technology, Pohang, The Republic of Korea*

In nanostructures, physical properties are heavily influenced by the interface condition, requiring more comprehensive understanding of interfaces. The Dzyaloshinskii-Moriya interaction (DMI), one of interesting interfacial phenomena, has been extensively studied due to academic interests and technological opportunity for generating chiral spin structures in systems with broken inversion symmetry [1]. Here, we show the Co thickness tendency of the DMI. We fabricate 3-nm Pt/Co/5-nm W trilayers with different Co thickness t_{Co} and measure the DMI, D, and effective magnetic anisotropy, K_U^{eff}. The K_U^{eff} is known to have volume contribution K_V^{eff} and surface contribution K_S phenomenologically, with the relation $K_U^{eff}t_{Co}=K_U^{eff}t_{Co}+K_S$ [2]. Both contributions have structural dependence [2]. Since the DMI is sensitive to the interface condition, the D may be linked to the structural condition. In that point, we compare the tendency of K_U^{eff} and D with respect to the $t_{Co}^{eff}(\equiv t_{Co}\text{-}t^{d})$, where t^{d} is the dead layer. Like K_U^{eff}, the D may also be presented by the relation $Dt_{Co}^{eff}=D_V t_{Co}^{eff}+D_S$, to decompose the volume contribution D_V and surface contribution D_S. In fig.1(a), the deviate from the linear dependence when the t_{Co}^{eff} is thinner than ~ 1 nm, indicating interface condition begin to change. The Dt_{Co}^{eff} have saturated value in relatively thick t_{Co}^{eff} in fig.1(b), indicating $D_V\approx 0$ and the surface contribution is mostly responsible. Since the tendency of K_U^{eff} and D are not coincident, there may be another magnetic factors affecting the DMI as well as structural factor. Moreover, it is remarkable that the D deviate from the inverse proportionality to the t_{Co}^{eff} in relatively thin t_{Co}^{eff}. This peculiar behaviour of D will be discussed. The t_{Co}^{eff} tendencies of the DMI and SOT, and change of magnetic properties when very thin Cu layer is inserted at Co/W interface will also be discussed. The present observations provide physical understanding for the DMI and a guideline to maximize the DMI for spintronic applications. Figure 1. The $K_U^{eff}t_{Co}^{eff}$ and Dt_{Co}^{eff} with respect to t_{Co}^{eff}. The blue line in (a) is the linear fitting line. The blue horizontal line in (b) shows the average value over the relatively thick t_{Co}^{eff}.

FT-02. The influence of MoC top layer on magnetic and microstructure of FePt(Ag, C) granular film. *J. Tsai*[1], C. Dai[1], J. Chen[1] and T. Hsu[1] *1. Department of Materials Science and Engineering, National Chung Hsing University, Taichung, Taiwan*

$L1_0$ ordered FePt thin film with (001) texture is the promising material for future heat-assisted magnetic recording (HAMR) media due to high uniaxial magnetocrystalline anisotropy and tunable Curie temperature (650-750K). To achieve high areal density (~2 Tb/in^2) for HAMR media, FePt granular film with uniformity columnar- and well-separated grains are necessary conditions. In this work, the (MoC, Ag, C) multiple segregants with different grains separation ability was doped in a different way to obtain columnar-like and granular FePt grains. The FePt(Ag, C) films were deposited on glass substrates by using magnetron sputtering under a working pressure of 10^{-3} Torr. The CrRu (002) seed-layer was grown on the glass substrate to induce the formation of a (002) textured MgTiON intermediate-layer, which promotes the epitaxial growth of (001) $L1_0$-FePt films. The FePt film was deposited at 470°C and thinner MoC layer with thickness ranged from 0.5 nm to 2 nm was toped on FePt at deposition temperature and post-annealed for 5 to 20 minutes. The FePt(MoC, Ag, C) granular film was formed after top layer segregants diffusion. The CrRu seed-layer and MgTiON intermediate-layer illustrate (002) reflection peak and the $L1_0$ FePt presents superlattice (001) and fundamental (002) reflection peaks in XRD pattern. The (002) oriented underlayer was promoted the formation of FePt hard phase with (001) orientation which is perpendicular to the film surface. From magnetic hysteresis loops, all the FePt(MoC, Ag, C) films show perpendicular magnetic anisotropy and the highest out of plane coercivity was 2.2T (8kOe for FePt single layer). The FePt(MoC, Ag, C) granular film show uniform and columnar-like grains evidenced in TEM images (Fig. 1 right). (Fig. 1(left) FePt single layer). The MoC is a suitable segregant to promote the columnar-like FePt grains from the top layer.

Magnetic Skyrmions are topologically protected spin textures which are promising candidates for spintronic and spinlogic devices [1]. Their stability and dynamics depend strongly on their topological properties. They can be realized in bulk systems with broken inversion symmetry or in ultra-thin multilayers structures which utilizes the broken symmetry at the interfaces. Two key parameters in those thin film structures are the perpendicular anisotropy and the Dzyaloshinskii-Moriya interaction (DMI). Both effects rely on a strong spin-orbit coupling at the interface between the ferromagnetic and non-magnetic layers. In those hetero-structures there arises a phenomenon called spontaneous magnetic polarization in the interface region [2]. This effect commonly known as proximity effect influence the DMI in the heterostructure. Our aim in this project is to understand the microscopic origin of DMI, the surface anisotropy at different interfaces and proximity effect in DMI using first principles simulations based on density functional theory. In those simulations we consider different constrained spin spiral configurations to extract DMI vector at the interface [3,4]. Further, we probe isotropic and anisotropic nature of DMI in those heterostructure mainly in Pt/Co interface.

FT-04. Field Cooling Direction Dependent Asymmetric Magnetization Reversal in Perpendicular Exchange Biased CoPt/FeMn Bilayers. *C. Pan*[1,3], T. Gao[2], T. Harumoto[3], Z. Zhang[1], y. Nakamura[3] and J. Shi[3] *1. School of Materials Science and Engineering, Tsinghua University, Beijing, China; 2. Department of Applied Physics and Physico-Informatics, Keio University, Yokohama, Japan; 3. School of Materials and Chemical Technology, Tokyo Institute of Technology, Tokyo, Japan*

Magnetic anisotropy and magnetization reversal process in ferromagnet (FM) /antiferromagnet (AFM) exchange bias (EB) system are crucial from the view of both fundamental physics and practical application [1]. Recently, asymmetric reversal process has been observed in many EB systems. In IrMn/CoFe and CoO/Fe EB structures [2-3], the field cooling (FC) direction has been set as the variable and shows a strong influence on the asymmetric reversal process. Reviewing present reports, the effect of FC treatment has been investigated almost in longitudinal EB structures, while rarely in perpendicular EB system, and the mechanism of asymmetric reversal in EB system is still unclear. So more effects on perpendicular EB system are highly required. In this work, we investigated magnetization reversal process of CoPt/FeMn bilayers with perpendicular EB by analyzing the evolution of magnetic domains. External field H_{FC} was applied in FC treatment with tunable angle θ (θ= 0°, 30° and 90°) relative to the film normal direction. As shown in Fig. 1, after FC, hysteresis loops show obvious different EB values and magnetic anisotropies. Meanwhile, asymmetry in domain nucleation densities of descending and ascending branches shown in Fig. 2 suggests the corresponding asymmetric reversal process in two branches of the hysteresis loops. Moreover, distinct domain evolution modes varying with the direction of H_{FC} indicates that FC treatment plays an important role in magnetization reversal process. Magnetization reversal mechanism deduced by the evolution of domain pattern and density are found to depend on the strength of magnetic anisotropy of FM layer and direction of uncompensated AFM spins caused by the relative angle between H_{FC} and easy axis of FM layer. The study of the magnetic anisotropy and magnetization reversal process described by domain theory provides useful information to quantitatively investigating the complex interactions present in EB systems.

FT-05. A comparative study: Role of Ta and Pt spacer layer on the domain structures in perpendicular exchange-biased CoPt/spacer layer/FeMn heterostructures. *C. Pan*[1,2], T. Gao[3], T. Harumoto[2], Z. Zhang[1], Y. Nakamura[2] and J. Shi[2] *1. School of Materials science and Engineering, Tsinghua University, Beijing, China; 2. School of Materials and Chemical Technology, Tokyo Institute of Technology, Tokyo, Japan; 3. Department of Applied Physics and Physico-Informatics, Keio University, Yokohama, Japan*

Perpendicular Exchange bias (PEB) effect has always been an attractive topic in information storage technology for long time. The concept of inserting non-magnetic (NM) spacer (V, W, Ru and Au) between ferromagnetic (FM) and antiferromagnetic (AFM) layers were previously demonstrated [1-2], which indicates that the spacer layers play a crucial role at the interfacial coupling. However, the specific mechanisms are still under debate. In this work, we investigates magnetic anisotropy and magnetization reversal process of CoPt/FeMn heterostructure spaced by Ta and Pt layers by observing the magnetic domains. The non-magnetic layer Ta and Pt spacer layers with varying thickness (t_{Ta}, t_{Pt}) from 0 ~ 1 nm were inserted to modify the exchange coupling between CoPt and FeMn, and their effects are shown as Fig. 1. Direct observation of magnetic domain configuration shown in Fig. 2 reveals the evolution of domain pattern and domain size with increasing thickness of spacer layer. For CoPt/Ta/FeMn, the average domain size and the contrast of upward domain show mono-trend descent with the thickness of Ta. While for CoPt/Pt/FeMn, the domain size and contrast show maxima at t_{Pt} =0.25 nm, which is in accordance with the magnetic properties measured by hysteresis loops. Therefore, different functions of spacer layer and interfacial spin configuration may be responsible for the dissimilar domain behaviors in these two hetero-structures. On the other hand, canting alignment of FeMn spins was verified and the effect of anisotropy induced by AFM layer to the FM domains can be manipulated by inserting spacer layer before and after field cooling. This study indicates inserting NM layer is an alternative to manipulate the coupling strength between FM and AFM layers and offers deeper understanding of EB systems.

FT-06. XPS Analysis on $ZnFe_2O_4$ Thin Films Growth and its Influence in the Magnetic Behavior. *J. Gil Monsalve*[1], C. Ostos[1], J. Ramírez[2], E. Ramos[2], J. Uribe[1], J.A. Osorio[1] and O.L. Arnache[1] *1. Universidad de Antioquia, Medellín, Colombia; 2. Universidad de los Andes, Bogotá, Colombia*

Surface analysis of zinc ferrites and its correlation with magnetic measurement, can provide further information to understand effects like the spin Seebeck effect in magnetic insulators [1-2]. For this purpose, $ZnFe_2O_4$ (ZFO) thin films of approximately 90 nm thick were grown on Si (111) substrates by RF magnetron sputtering at 500 °C. Sputtering gas pressure was kept at 28 mTorr using a mixture Ar/O_2 at a ratio 2:1, 1:2 as well as pure Ar. The ZFO films were characterized by perfilometry, X-ray diffraction, X-ray photoelectron spectroscopy (XPS) and vibrating sample magnetometry (VSM). Comparing all the samples obtained at different atmospheres, the samples deposited under Ar/O_2 ratio of 1:2 exhibited a highly crystallographic orientation and the closest stoichiometric composition between Fe/Zn with a value of 1.97. XPS results showed that the Zn 2p spectra exhibits binding energies at 1021 eV and 1044 eV, which corresponds to Zn $2p_{3/2}$ and Zn $2p_{1/2}$ electrons in the Zn^{2+} oxidation state. Also, Zn $2p_{3/2}$ signal in all samples consisted of a single sharp peak corresponding to tetrahedrally coordinated zinc. Unlike the bulk sample where only Fe^{3+} ions in B sites were observed by Mössbauer spectra, for the thin films, XPS spectra indicated the presence of Fe^{2+} and Fe^{3+} species in the films; additionally, only for the films

deposited in pure Ar atmosphere, the appearance of a single low-intensity peak at the low binding energy side, indicates the formation of Fe ions (Fe^0) reduced by Ar ion sputtering. The O 1s spectrum presented oxygen ions different on the surface. It is known that the ZFO in bulk is governed by a weak superexchange interaction among Fe^{3+} ions (J_{BB}) with magnetization saturation (M_s) of about 1.2 emu/g [3-5]; however, with the enhancing of the M_s for the ZFO in our films, we hypothesize that Fe ions migrate to A sites and the interaction J_{AB} dominates the magnetic properties over the J_{BB} interaction. At room temperature, the number of μ_B per unit cell obtained was 8.03, whereas the ferromagnetic component is more notorious at 77 K with 14.27 μ_B/unit cell. Finally, we conclude that the best growth conditions were those obtained on samples prepared under 1:2 Ar/O_2 ratio.

FT-07. Effect of Co on the Magnetic Properties and Magnetic Domain Structure for FePt/ (Fe, FeCo) Nano-composites. *T. Sato*[1], K. Ohwada[1], F. Nakagawa[1], M. Doi[1] and T. Shima[1] *1. Graduate school of Engineering, Tohoku Gakuin University, Tagajo, Japan*

Rare earth permanent magnets have been widely used in various applications such as motors for hybrid vehicles and micro devices and hard disk drives. Especially, Nd-Fe-B sintered magnets exhibit high $(BH)_{max}$. However, these magnets contain environmental and geographical issues. Therefore, the development of high performance magnet is urgently required. Recently, nano-composite magnet has expected to increase hard magnetic properties through the exchange–coupling between the soft and the hard magnetic phases [1, 2]. However, there is no report that high-performance magnet has been obtained. In this study, an assembly of FePt/ (Fe, FeCo) nano-composites have been fabricated by electron beam lithography (EBL), and their magnetic properties and magnetic domain structure have been also investigated. FePt films were prepared using ultra-high vacuum magnetron sputtering system. On MgO (100) single crystal substrate, the Fe seed layer of 1 nm and Au buffer layer of 40 nm were first deposited at room temperature (RT). Then, it was annealed at T_a= 300 °C. After that FePt layer of 10 nm was deposited at 300 °C, and then it was annealed at 500 °C. $L1_0$ ordered FePt/ (Fe, FeCo) nano-composites were microfabricated the EBL. The outer diameter (D_{od}) of the FePt rings was fixed at 2.0 μm, while the inner diameter (D_{id}) was changed from 0.8 to 1.8 μm. The film structure was evaluted X-ray diffraction (XRD), the magnetic properties were measured by a superconducting quantum interference device (SQUID) magneto meter. Magnetic properties of microfabricated FePt/ (Fe, FeCo) nano-composites were measured by magneto-optical Kerr effect (MOKE), shapes and magnetic domain structure were observed by using atomic force microscope (AFM) and magnetic force microscopy (MFM). From XRD patterns, the FePt (002) fundamental peak, FePt (001) and (003) super lattice peaks were clearly observed. The coercivity of FePt/ Fe nano-composites was increased from 4.5 kOe for D_{id}= 1.8 to 6.0kOe for D_{id}= 0.8 μm. In addition, remarkable "Bull's eye contrast" in the magnetic domain patterns has been clearly observed for both D_{id}= 1.2 and 1.4 μm. Magnetic properties for FePt/ FeCo nano-composites with changing Co content will be discussed at the conference.

FT-08. Toward fabrication of $L1_0$-FeCo thin films assisted by the nitrogen surfactant effect. *Y. Takahashi*[1,2], T. Miyamachi[2], T. Iimori[2], T. Hattori[2], T. Koitaya[3], K. Yamamoto[3], T. Yokoyama[3], F. Komori[2] and M. Kotsugi[1] *1. Tokyo University of science, Katsushika, Japan; 2. The Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan; 3. Institute for Molecular Science, Myodaiji, Japan*

An $L1_0$-type ordered FeCo alloy is theoretically predicted to have large perpendicular magnetic anisotropy among transition metal alloys [1], attracting great attention as a rare earth-free permanent magnet. The precisely controlled thin film growth of alternating Fe and Co layers using pulsed laser deposition have been used for the preparation of $L1_0$-FeCo thin films [2]. However, the degree of order of the $L1_0$ structure is considerably low due to atomic-scale structural and magnetic disorder at the Fe/Co interface and resultingly the perpendicular magnetization has not yet been achieved. Toward realizing high quality FeCo alloy thin films, we here focus on the fabrication method utilizing the nitrogen surfactant effect of a monatomic layer iron nitride (Fe_2N). High lateral lattice stability of Fe_2N[3], and surfactant nitrogen during the deposition of Fe and Co layers can effectively suppress the interdiffusion at the Fe/Co interface, leading to atomically flat and homogeneous surface and interface in FeCo alloy thin films. In this study, we investigated structural and magnetic properties of 1 monolayer (ML) Co on Fe_2N/Cu (001), the initial step for the fabrication of FeCo alloy thin films by means of the nitrogen surfactant effect, using scanning tunneling microscopy (STM) combined with x-ray magnetic circular dichroism (XMCD). We first confirmed from XMCD measurements the strong in-plane magnetic anisotropy of bare Fe_2N as previously reported [4]. STM measurements revealed that adding Co 1 ML on Fe_2N results in the formation of Co_2N/Fe/Cu (001) via nitrogen surfactant effect. Accordingly, relative increase in the out-of-plane magnetization of Fe to the in-plane magnetization was observed. We found that the out-of-plane magnetization of Fe was further increased by additional alternative deposition of Fe and Co (Co_2N/Fe/Co/Fe). The results indicate that the nitrogen surfactant effect is efficiently suppress the interdiffusion at the Fe/Co interface and keep atomically flat surface/interface in FeCo atomic layers, possibly reflecting the intrinsic out-of-plane magnetization of $L1_0$-FeCo.

FT-09. Magnetic properties of CoPt/TiN films tuned by nitrogen. *H. An*[1], C. Pan[2] and J. Shi[3] *1. College of New Materials and New Energies, Shenzhen Technology University, Shenzhen, China; 2. School of Materials science and Engineering, Tsinghua University, Beijing, China; 3. School of Materials and Chemical Technology, Tokyo Institute of Technology, Tokyo, Japan*

Heat-assisted magnetic recording (HAMR) media, which can drastically increase the areal recording density, is expected to be the most promising recording media for the next generation of the high-density hard disk drives. As primary candidates for the HAMR materials, $L1_0$ FePt and CoPt structure have attracted researchers' interests due to their high magnetocrystalline anisotropy and large coercivity. Much effort has been devoted on enlarging the perpendicular coercivity, reducing the grain size, averaging the grain distribution, etc. To realize such objectives, (100) oriented MgO seed layer is widely used on amorphous substrates to promote the $L1_0$ ordering for FePt/ CoPt. However, the small surface energy of MgO (1.1 J/m^2) can result in a large contact angle between FePt/CoPt and MgO, which is not favorable for the epitaxial growth. Furthermore, it promotes the formation of in-plane variants and lead to a large in-plane coercivity. In this work, we use TiN instead of MgO on glass substrates as seed layer for the deposition of $L1_0$ CoPt. TiN has similar structure with MgO, but owns a larger surface energy (1.28 J/m^2), which is more suitable for the epitaxial growth of $L1_0$ CoPt. TiN was deposited from a Ti target by magnetron sputtering in a mixture of N_2 and Ar gases. By optimizing the flow rate ratio between N_2 and Ar, we successfully deposited highly (100) oriented TiN films on glass substrates. Then we deposited a 4 nm-thick CoPt layer on the TiN layer by varying the

thickness of TiN layer from 10 to 100 nm, respectively. Largest perpendicular magnetic anisotropy energy was obtained in the CoPt/TiN bilayer film with a 30 nm-thick TiN layer. Furthermore, we introduced N_2 into Ar atmosphere for the CoPt deposition to investigate the effect of N_2 incorporation on the magnetic properties of CoPt. As shown in Fig. 1, the magnetic properties of CoPt can be efficiently tuned by changing the N_2 flow rate ratio. Our work may provide a piece of information for other studies on the HAMR media.

FT-10. Magnetic Anisotropy of CoV_2O_4 Thin Films Investigated through Torque Magnetometry. *C.J. Thompson*[1,2] and C. Beekman[1,3]
1. National High Magnetic Field Lab, Tallahassee, FL, United States; 2. Materials Science and Engineering, Florida State University, Tallahassee, FL, United States; 3. Physics, Florida State University, Tallahassee, FL, United States

We have grown thin films of the spinel vanadate CoV_2O_4 (CVO), a geometrically frustrated spin system, on $SrTiO_3$ substrates, resulting in an orthorhombic structure rather than the cubic structure of bulk [1]. The bulk structure has a collinear ferrimagnetic transition at T_N = 150 K, and a magnetic transition at T* = 90 K that has been suggested as a transition to a non-collinear state showing spin canting, accompanied by orbital ordering and a weak first order structural phase transition [2,3]; the orthorhombic thin film form strengthens the 90 K transition [1]. We have performed torque magnetometry measurements to investigate the magnetic structure and anisotropy of the system in two magnetic phases: below T*, and in the ferrimagnetic state. By investigating the torque response as we rotate films in various applied fields, we identify easy axes for each state, as well as find unusual hysteretic behavior in the low temperature regime (Fig. 1). Work at Florida State University is supported the National Research Foundation, under grant NSF DMR-1847887 Use of National High Magnetic Field Laboratory user facilities was supported by NSF Cooperative Agreement No. DMR-1157490 and DMR-1644779, and the state of Florida.

FT-11. Controlling the angle between magnetic moments of adjacent magnetic layers. Z. Nunn[1] and *E. Girt*[1] *1. Physics, Simon Fraser University, Burnaby, BC, Canada*

The rapid increase in magnetic memory storage density and the design of new magnetic devices over the last three decades has been made possible by the discovery of interface-induced phenomena in ferromagnetic/non-magnetic multilayers. The interlayer exchange coupling is one of the interface effects, which plays a crucial role in many magnetic based applications. It has been intensively studied since its discovery, for over 30 years. However, this phenomenon has not been used to its full potential, since traditional non-magnetic coupling layers only allow for controlling collinear orientation (antiferromagnetic or ferromagnetic) of magnetic moments of the ferromagnetic layers. Recently, we discovered a new class of magnetic coupling layers [1], which can be inserted between two ferromagnetic layers to control the relative orientation of the magnetic moments of ferromagnetic layers from 180 to 0 degrees. Here we present a systematic study of non-collinear coupling of two Co layers separated by one of these discovered coupling layers, the magnetic RuFe (Fig.1). By varying the concentration of Fe in RuFe coupling layer, the angle between Co magnetic moments can be precisely controlled. Fig.2 shows how the coupling angle between Co magnetic moments, θ, varies as a function of Fe concentration in RuFe and RuFe thickness, *d*. Additionally, the biquadratic coupling strength in Co/RuFe/Co is isotropic and several times larger than ever observed, approaching 4 mJ/m^2. These unique properties allow for the study and fabrication of new magnetic structures that have potential for improving current state-of-the-art spintronic devices.

FT-12. Seed- and buffer layer control in the perpendicular magnetic anisotropy of sputter-deposited $L1_0$ FePd thin films. *X. Wang*[1,2], D. Zhang[1], J. Wang[1] and D.B. Gopman[2] *1. University of Minnesota, Twin Cities, MN, United States; 2. National Institute of Standards and Technology, Gaithersburg, MD, United States*

Thin ferromagnetic films with perpendicular magnetic anisotropy (PMA) show great potential for ultrahigh density spintronic devices due to their superior thermal stability and scalability. Materials possessing bulk PMA, such as manganese-based Heusler alloys and $L1_0$ Fe-based alloys, could deliver superior scaling compared to their interfacial anisotropy counterparts. $L1_0$ FePd in particular has been shown to have desirable properties, including large magnetic anisotropy energy ($K_u > 10^6$ J/m^3), low Gilbert damping ($\alpha<0.01$) and good annealing stability.[1] However, incorporating this material into a spintronic device remains challenging.[2] We grew a series of seed (SL) and buffer (BL) layers of the form SL(15 nm)/BL(4 nm) grown on a (001)-cut MgO substrate to explore possible alternatives for growing $L1_0$ FePd with the *c*-axis oriented perpendicular to the plane. Structures of Mo/(Pt, Ru, Ir)/FePd, Cr/(Pt, Ru, Ir)/FePd and Ir/FePd were deposited onto MgO (001) substrates at 350 °C with 2.0×10^{-9} Torr base pressure. X-ray diffractometry demonstrates that the Mo-buffered samples undergo a 45 degree rotation of the BL/FePd bilayer relative to the seed layer (e.g. Mo(100)||BL(110)||FePd(110)), which does not permit PMA. On the other hand, the Cr-seeded samples and the Ir-buffered sample with no seed layer all had the following relationship (MgO(100)||SL(100)||FePd(100)) and correspondingly showed PMA, with saturation magnetization M_s exceeding 1000 kA/m, $\mu_0 H_K^{eff}$ as high as 0.7 T and $\alpha < 0.01$. X-ray diffractometry and transmission electron microscopy will be presented in conjunction with results of ferromagnetic resonance spectroscopy (Fig. 2), Kerr magnetometry (Fig. 1(a)) and domain imaging (Fig. 1(b)), as well as vibrating sample magnetometry, to correlate the alternative microstructure introduced to the FePd layer by each seed/buffer combination.

FT-13. Pinning of Ferromagnetic Domains in Interconnected Pentagonal Spin Ice Lattices. E. Saavedra[1], J. Escrig[1,2] and *J.L. Palma*[3,2] *1. Fisica, Universidad de Santiago, Santiago, Chile; 2. Center for the Development of Nanoscience and Nanotechnology CEDENNA, Santiago, Chile; 3. Basic Science - Eng. School, Universidad Central de Chile, Santiago, Chile*

The magnetization reversal process of interconnected pentagonal spin ice systems was investigated using micromagnetic simulations and experimental measurements. Five different systems were investigated, beginning with the interconnected Shakti lattice [1] and introducing deformations with the idea of obtaining pentagonal tiling [2] (belonging to the P4 group) until reaching an interconnected square lattice. In all pentagonal lattices, ferromagnetic domains are pinned, acting as isolated domains in an antiferromagnetic lattice, with Cairo tiling being the lattice that allows pinning more domains. Experimental measurements on a Cairo lattice of larger dimensions show that the shape of the hysteresis curve is invariant to the size of the bars that make up the interconnected pentagonal spin ice systems.

FT-14. Control of an Asymmetric Bloch Wall in a Ferromagnetic Rectangular Disk. *S. Lee*[1], H. Han[1], M. Kang[1], H. Ok[1], M. Im[2] and K. Lee[1] *1. School of Materials Science and Engineering, Ulsan National Institute of Science and Technology (UNIST), Ulsan, The Republic of Korea; 2. Center for X-ray Optics, Lawrence Berkeley National Laboratory, Berkeley, CA, United States*

In a patterned ferromagnetic nanodisk, a flux-closure domain structure such as a Landau pattern is formed to reduce a magnetostatic energy [1]. For a relatively thicker patterned film with a few tens of nm, a flux-closure domain structure accompanying with in-plane Landau pattern should be formed along the thickness direction, resulting in a three-dimensional (3D) flux-closure domain structure [2-3]. In a rectangular shaped ferromagnetic disk, the 3D flux-closure structure, the asymmetric Bloch wall (ABW) is formed [4]. The ABW structure can be classified into two types of rotation sense (i.e. clockwise (CW) or counter-clockwise (CCW)) (shown in Fig.1.). Since those states have exactly the same energy, they are degenerate states and they appear at the same probability. To control those states, it is required to break the symmetry of two states. For example, asymmetric geometry was utilized for control the ABW states [5]. In this presentation, we propose an efficient way to control the rotating sense of ABW through the external magnetic field based on micromagnetic simulation. From magnetic transmission soft x-ray microscopy (MTXM) at the Advanced Light Source [6], this method were verified experimentally.

FT-15. Gettering templates for nanoscale patterning of magnetic materials. W. Qiu[1], L.V. Chang[1] and *D. Litvinov*[1] *1. University of Houston, Houston, TX, United States*

We have explored low-temperature local reduction of non-magnetic CoO and $[CoO/Pd]_N$ multilayers using Ta and Ti gettering layers, effectively achieving patterning of magnetic nanostructures without the physical removal of magnetic materials. Local conversion of magnetic oxides is based on reduction of thin film magnetic oxides, e.g. CoO or $[CoO/Pd]_N$, sandwiched between gettering layers (Ta or Ti). The exothermic reduction/oxidation reaction (e.g. 5CoO + 2Ta = 5Co + Ta2O5 - 1.15 kJ/g) is promoted by annealing at 200-300 °C. The effect is similar to the ones exhibited by thermite nanocomposites. CoO thin films and $[CoO/Pd]_N$ multilayers were deposited using UHV DC magnetron sputtering with a base pressure of 5×10^{-8} Torr. The process pressure for all films is 5m Torr. CoO films are deposited by reactive magnetron sputtering in argon and oxygen; all other materials (Co, Pd, Ta, Ti) are deposited by magnetron sputtering in argon. The results of 5-minute annealing of a CoO thin films sandwiched between Ti seed (15 nm) and capping (30 nm) layers are illustrated in Figures 1 and 2. Initial saturation magnetization, M_S, of CoO is negligible and increases to approximately 1300 emu/cc as the temperature reaches 200-300 °C. The highest M_S of annealed CoO approaches the M_S of pure Co thin film. This presentation will detail the results of our study of applying Ti and Ta gettering layers for the conversion of magnetic oxide and magnetic oxide multilayers into magnetic thin films. The application of the technology for magnetic film patterning using structured gettering templates will also be presented.

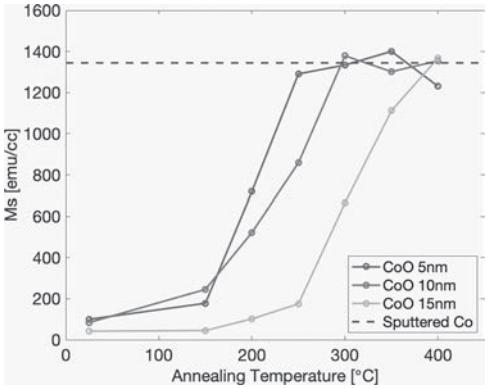

Figure 1. The saturation magnetization of annealed CoO thin film sandwiched between Ti seed and capping layers as a function of annealing temperature. An emergence of magnetization is observed for annealing at 150 °C and a full conversion is achieved for temperatures above 200 °C. The saturation magnetization of the annealed CoO is comparable to the saturation magnetization of sputtered Co.

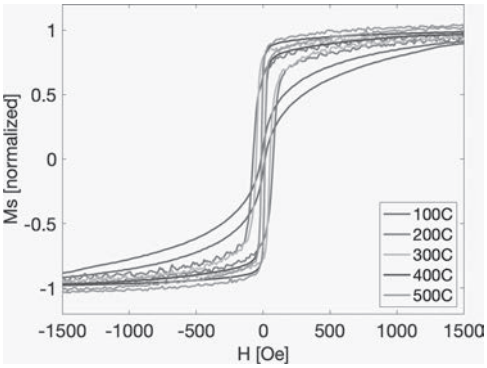

Figure 2. M-H loops of Ti (15 nm) / CoO (5 nm) / Ti (30 nm) films annealed at different temperatures.

FT-16. Sputtered high perpendicular magnetic anisotropy CoPt thin film on flexible substrate at low temperature. *A. Sun*[1] and G.C. Hermosa[1]
1. Department of Chemical Engineering and Materials Science, Yuan Ze University, Taoyuan, Taiwan

In order to prepare magnetic biosensor on flexible substrate, high magnetocrystalline anisotropy constant (K_u) material with high perpendicular magnetic anisotropy (PMA) and good chemical corrosion resistance must be deposited at lower temperature. A CoPt film with a rhombohedral $L1_1$ structure has similar magnetic properties to $L1_0$ FePt film and could be prepared at 300°C, which is regarded as a potential candidate for biosensor. According to the $L1_1$-CoPt unit cell, Co and Pt atoms stack layer-by-layer along the easy axis [111] direction. Hence, alternative sputtering Co and Pt layer-by-layer structure might be easily obtained $L1_1$-CoPt(111) during the annealing process, due to the relatively shorter diffusion length. Furthermore, the film would present high PMA because the easy axis is vertical to the substrate plane. Therefore, CoPt films were prepared by alternative sputtering of Co and Pt layers on glass and flexible PI substrates at low temperature in this study. The effects of different repetitions (n) as well as annealing temperatures of the magnetic layer and underlayer on magnetic properties of $[Co/Pt]_n$ films are compared. Results showed that $[Co/Pt]_n$ films annealed at 100°C had a high PMA ($S_\perp$>0.98) and a high K_u (~1.12×10^7 erg/cm^3), which were close to the properties of $L1_1$-CoPt film prepared at higher temperatures (~300°C) as seen in previous works. In addition, the maximum PMA and K_u were obtained at n = 4. Increasing repetition also increased residual stress and further reduced perpendicular magnetic properties. Thus, better magnetic properties would be obtained in the thinner case. Furthermore, it was proven that coercivity (H_c) was strongly affected by the grain size of the magnetic layer, which was strongly related to the grain size in the Pt underlayer. Thus, H_c became tunable by controlling the grain size of the Pt underlayer due to the epitaxial growth at the CoPt/Pt interface. In this work, $L1_1$-CoPt, with outstanding magnetic properties, could be prepared at lower temperatures (~100°C). It strongly enhanced low temperature applications of hard magnetic alloy thin films, such as magnetic electronic components with high K_u and PMA on flexible substrate.

FU-01. First-principles Prediction of Switchable Metallic Ferroelectricity in Multiferroic Tunnel Junctions. L. Jiang[1], W. Chen[1], B. Yang[1], X. Zhang[2], Y. Wang[3] and *X. Han*[1] *1. Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2. Department of Physics and the Quantum Theory Project, University of Florida, Gainesville, FL, United States; 3. Department of Physics and Astronomy, Vanderbilt University, Nashville, TN, United States*

Coexistence of metallicity and ferroelectricity has been a curiosity without a practical application, both because free-electron screening due to metallicity prevents the polarization from being switched by an electric field, diminishing the value of ferroelectricity, and because metallicity is usually achieved by doping, which leads to disorder and is often detrimental to other electronic properties. Here, we predict via first-principles calculation a switchable metallic ferroelectric barrier in $(Co_2)_9$-TiO_2-$(BaO\text{-}TiO_2)_m$-CoO-Co (m = 4, 5, 6, 7, 8, 9) multiferroic tunnel junction without doping. Due to the uncompensated charge layer at the $BaTiO_3$ (BTO) interface in this system, the BTO barrier has a tendency to acquire electrons. When two metal electrodes are very close to BTO but not bonded with BTO, charge transfer still occurs from the electrodes to the barrier through tunneling. Such an electrode proximity effect moves the Fermi energy close to the barrier conduction band. When the polarization orientation points from the electrode with a CoO layer to the other electrode (upward polarization), this effect is accentuated by the large polarization of the CoO layer relatively to that of BTO, leading to a larger electrostatic potential drop on the interface containing CoO, thus further causing the entire BTO barrier region to become metallic. Increasing the polarization of BTO by applying strain turns off the metallic ferroelectric, so that the polarization can be reversed by an electric field. When the polarization is reversed (downward polarization), the Fermi level remains in the band gap almost everywhere in the BTO barrier, maintaining an insulating state. This metallic-insulating BTO difference between two polarization configurations leads to a large tunneling electroresistance.

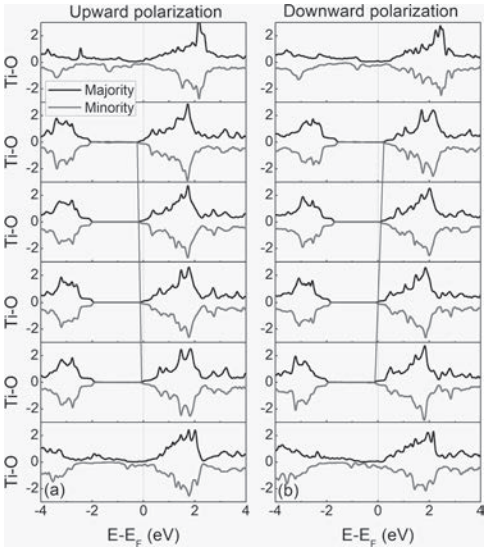

Fig. 1. Layer-resolved DOS of TiO_2 layers in the $(Co_2)_9$-TiO_2-$(BaO\text{-}TiO_2)_5$-CoO structure as a function of energy. From top to bottom, the DOS figures correspond to the TiO_2 layer in the Co_2-TiO_2 interface to the TiO_2 layer in the TiO_2-CoO interface. (a) and (b) are the DOS for polarization pointing up and down, respectively. The blue solid line connects the CBM of each TiO_2 layer. The black (red) line is the DOS of majority (minority).

FU-02. The Magnetic Properties of Multiferroic $Sr_3Fe_2F_{12}$. *Y. Yu*[1], W. Mi[1], L. Sun[2], S. Zhou[3], Q. Li[1], J. Du[2] and Q. Xu[1] *1. School of Physics, Southeast University, Nanjing, China; 2. School of Physics, Nanjing University, Nanjing, China; 3. Institute of Ion Beam Physics and Materials Research, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany*

The strong ionic bonding between the 3d transition metal (TM) ions and F^- ions in fluorides may break the contradicting requirement of the out shell electronic filling of 3d TM ions due to the covalent bonding with O^{2-} ions in oxide perovskites [1]. It has been reported that $Sr_3Fe_2F_{12}$ is ferroelectric with high Curie temperature of 922 K [2]. The partial contribution of the displacement of Fe^{3+} ions for the ferroelectric reversal indicates the possible multiferroicity and magnetoelectric coupling in $Sr_3Fe_2F_{12}$ [2]. However, till now, the reports on magnetic properties of $Sr_3Fe_2F_{12}$ are still lacking [3]. In this work, pure phase $Sr_3Fe_2F_{12}$ powders were prepared by solid state reaction using SrF_2 and FeF_3 powders as raw materials with molar ratio of 3.4:3, which has been confirmed by X-ray diffraction patterns. The morphology was studied by scanning electron microscope which shows the layered growth, and the Fe ions are in +3 valence state from X-ray photoelectron spectroscopy. The zero field cooled (ZFC) and field cooled (FC) temperature dependent magnetization (M-T) curves are shown in Fig. 1(a). Two kinks can be observed at 47 K an 29 K, respectively, suggesting two antiferromagnetic transitions [4]. A bifurcation between FC and ZFC M-T curves happens at T_{N1} of 47 K, suggesting a magnetic relax system. The field dependent magnetization (M-H) curves show that clear hysteresis can be observed below T_{N1}, indicating the occurrence of weak ferromagnetism. Similar

phenomena have been observed in $K_{0.6}FeF_3$ [4]. This might be related to the spin canting due to the Dzyaloshinskii-Moriya (DM) interaction. The two antiferromagnetic transitions with magnetic relaxation below T_{N1} might be related to the complicated arrangements of FeF_6 octahedra, leading to the complicated exchange interaction between Fe^{+3} ions [2].

FU-03. Structural and Multiferroic Properties of Fe/Ni Co-doped $Bi_{3.15}Nd_{0.85}Ti_3O_{12}$ Ceramics. *S. Bhardwaj*[1], R.K. Mahajan[1] and S. Kumar[2] *1. Department of Materials and Metallurgical Engineering, Punjab Engineering College (Deemed to be University), Chandigarh, Chandigarh, India; 2. Department of Applied Sciences, Punjab Engineering College (Deemed to be University), Chandigarh, Chandigarh, India*

Polycrystalline Lead free samples of $Bi_{3.15}Nd_{0.85}(Ti_{3-x}Fe_{x/2}Ni_{x/2})O_{12}$ ($0.0 \le x \le 0.5$) were synthesized by conventional solid state reaction method. X-ray diffraction analysis confirms the formation of single phase with orthorhombic unit cell upto x=0.3 content matched with JCPDS No. 89-7500 shown in Figure 1. For x > 0.3, weak impurity peak encircle in figure 1 belong to bismuth iron oxide ($Bi_2Fe_4O_9$), which is attributed to non-stoichiometry induced by higher substitution. Raman spectroscopy was carried out to further investigate the effect of substitution on lattice structure. The broadening and reduction in the intensity with substitution in Raman modes confirms the local distortions in the lattice [1]. The ceramic with x=0.3 holds the best properties including pure phase, large remanant polarization and magnetic properties among all the synthesized compositions. The ME coupling coefficient (α) is calculated to observe the extent of coupling between the two ferroic orders [2]. The values of α has shown a linear behaviour with the applied magnetic field for all the synthesized samples as shown in Figure 2. The maximum value of α was observed for x=0.3 composition which is 0.67 mV $cm^{-1}Oe^{-1}$ The possible mechanism for M.E. coupling is considered to be interaction between electric and magnetic sub-lattices through the stress or strain transmitting from one sub-lattice to another [3]. The present work gives the existence of Fe/Ni co-doped $Bi_{3.15}Nd_{0.85}Ti_3O_{12}$ ceramic as room temperature multiferroic material.

FU-04. Analysis of Phase Segregation Using Rietveld Refinementand and Magnetic Properties of Mn Doped BCT Solid Solutions. *A. Chawla*[1], M. Singh[1] and A. Singh[1] *1. Physics, Guru Nanak Dev University, Amritsar, India*

Multiferroics are the materials which exhibit more than one ferroic properties like ferroelectricity and ferromagnetism simultaneously. This simultaneous presence of magnetic and electric ordering in materials is useful for many applications such as multistate memory devices, transducers, sensors, and microwave phase shifters etc. Transition metal ions (like Fe^{3+}, Mn^{3+}, Co^{2+} etc.) can be used for inducing magnetic character in otherwise strong ferroelectric materials [1–2]. In present work, Mn ions were incorporated in to lead free ferroelectric barium calcium titante (BCT). The polycrystalline samples of $Ba_{0.96}Ca_{0.04}Ti_{(1-x)}Mn_xO_3$ for $0.01 \le x \le 0.15$ were synthesized using conventional solid state reaction route. The XRD analysis shows that the samples crystallize in pure tetragonal structure (space group – P4mm) for $x \le 0.02$ while an additional phase (hexagonal, space group – P63/mmc) was detected in all other samples. The percentage of segregated phase was calculated using Rietveld refinement and was found to increase with increasing x. The P-E measurements revealed that all the samples exhibit ferroelectric behaviour. However, the remnant polarisation was found to decrease with increasing concentration of Mn ions. The samples started to exhibit magnetic character with Mn concentration as low as 3 mol %. However, the magnetic behaviour remains paramagnetic even with Mn concentration as high as 15 mol %. The oxidation state of the Mn ions in the samples was determined via fitting of virgin magnetic hysteresis curves using Brillouin function.

FU-05. Enhancement of multiferroic properties in (1-x)$GaFeO_3$-(x) $CoFe_2O_4$ nanocomposites. *T. Han*[1], Y. Wang[1] and B. Chen[1] *1. Department of Applied Physics, National University of Kaohsiung, Kaohsiung, Taiwan*

Multiferroic materials have rendered a revival of intensive research due to their application potential as next generation devices. However, there remains considerable scope for improvement of multiferroic behavior at room-temperature (RT). During the past several years, some elegant strategies such as particle size reduction, doping and ferroelectric-magnetic composite architecture have been employed to develop the RT multiferroic materials. Among various multiferroic materials, gallium ferrite, $GaFeO_3$ (GFO), is the most promising candidate which exhibits ferrimagnetism, piezoelectricity and magnetoelectric effects [1, 2]. Although the magnetization has been enhanced by substitution of various divalent or trivalent ion-doped GFO [3,4], but few attempt has been made to enhance the magnetization of the multiferroic system like GFO by using some other strong magnetic host of ferrite family in the nanocomposite state. In this work, therefore, we report on the characterization of (1-x)$GaFeO_3$-(x)$CoFe_2O_4$ (denoted as GFO-CFO) nanocomposites with x = 0, 0.17, 0.375, 0.5 and 1. The main objective of this work is to enhance the multiferroic properties of GFO in GFO-CFO nanocomposite at RT. The X-ray diffraction patterns confirmed that the nanocomposites consisted of orthorhombic GFO and cubic spinel CFO phases. It is also confirmed that there is no inter-diffusion between both phases. In addition, the magnetic characterization indicates that the magnetization of GFO-CFO nanocomposite was drastically enhanced compared to that of the pristine GFO. The value of RT saturation magnetization and coercive field increased to 53.8 emu/g and 1262.8 Oe, respectively. Furthermore, the inclusion of CFO enhanced magnetization and dielectric constant, as well as improved the ferroelectric properties of GFO. We conclude that magnetization, permittivity, and ferroelectricity of GFO have been significantly modulated by a spinel magnetic host of CFO probably due to the interfacial strain effect on GFO. The results will be also interesting for applications of the multiferroic nanocomposite in magnetoelectric devices.

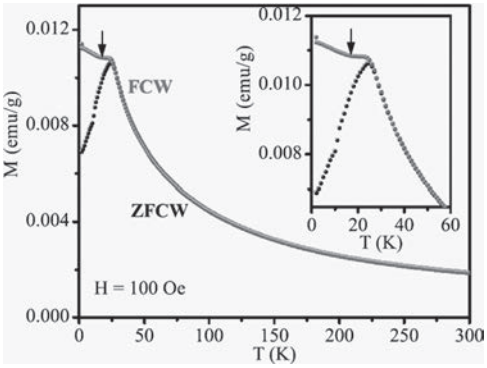
FU-06. Multiferroic properties of $Bi_{1-x}R_xFeO_3$ polycrystalline films on the glass substrates (R = La, Pr, Nd, Sm and Ho; x = 0.05-0.15). T. Lin[1], *H.W. Chang*[2], C.R. Wang[3], D. Wei[1] and C. Tu[4] *1. Institute of Manufacturing Technology and Department of Mechanical Engineering, National Taipei University of Technology, Taipei, Taiwan; 2. Department of Physics, National Chung Cheng University, ChiaYi, Taiwan; 3. Department of Applied Physics, Tunghai University, Taichung, Taiwan; 4. Department of Physics, Fu Jen Catholic University, Taipei, Taiwan*



Perovskite $BiFeO_3$ (BFO) with ferroelectric and magnetic orderings at room temperature (RT) has attracted much attention for potential applications in advanced spintronic and memory devices based on the electric-magnetic couplings. However, the major problem in BFO is a large leakage current and needs to be overcome. The ion modification using rare-earth (R) cations was reported as an effective method to reduce leakage and thus enhance ferroelectric properties [1-2], but the effect of doping R element on magnetism properties is still unclear. In this study, $Bi_{1-x}R_xFeO_3$ (BRFO) (R = La, Pr, Nd, Sm and Ho; x = 0.05-0.15) polycrystalline films (x = 0.05-0.15) were deposited on optimized 20-nm-thick Pt bottom electrode on glass substrates at 450°C via pulsed laser deposition (PLD). XRD result shows that perovskite single phase is confirmed in all studied BRFO films. With increasing x, the microstructure refinement and the flattened surface are observed. The studied BAFO polycrystalline films exhibit coexistence of good ferroelectric and ferromagnetic properties. Remanent polarization ($2P_r$) of 60-120 μC/cm^2 and electrical coercive field of 180-300 kV/cm are obtained, while the saturation magnetization of 4.91-17.8 emu/cm^3 and coercivity of 400-600 Oe are attained for the substitution of La, Pr, Nd, Sm and Ho. BHFO exhibit the highest saturation magnetization (M) of 17.8 emu/cm^3 related to the highest magnetic moment of 10.6 μ_B of Ho among R. Besides, M is also affected by the result of suppressed spiral spin configuration from the distortion degree of the structure with different ionic radius of R. As the result, the magnetic properties are mainly dominated by the radius and the magnetic moment of R ion. The multiferroic properties with R substitution and as a function of its content x are also discussed in this presentation.

FU-07. A comparative study of spin-glass transition in $Ca(Fe_{1/2}Nb_{1/2})O_3$ and $Ba(Fe_{1/2}Nb_{1/2})O_3$. *A. Kumar*[1], A. Chaudhary[1] and D. Pandey[1] *1. School of Materials Science and Technology, Indian Institute of Technology (Banaras Hindu University), Varanasi, India*

The origin of the spin-glass (SG) phase in the well-known multiferroic $Pb(Fe_{1/2}Nb_{1/2})O_3$ compound remains controversial due to the complications introduced by the coexistence of SG and long-range ordered (LRO) antiferromagnetic (AFM) phases [1-2]. We have addressed this controversy through a comprehensive study on a Pb-free systems like $Ba(Fe_{1/2}Nb_{1/2})O_3$ (BFN), $Sr(Fe_{1/2}Nb_{1/2})O_3$ (SFN), and $Ca(Fe_{1/2}Nb_{1/2})O_3$ (CFN), which does not exhibit LRO AFM transition [3-5]. The SG transition is confirmed by the appearance of a cusp in the temperature dependence of dc magnetization M(T) with a SG freezing temperature T_f ~25K, and bifurcation of the zero-field cooled and field-cooled magnetization M(T) below the irreversibility temperature (T_{irr}). Using ac susceptibility measurements, we show that the spin dynamics follows power law / Vogel-Fulcher law type critical dynamics which diverges at T_{SG}~ 24K with an attempt time τ_o ~10^{-6}s suggesting cluster spin-glass (CSG) behaviour. The field dependence of T_f(H) and T_{irr}(H) is shown to follow de Almeida-Thouless (A-T) line which separates the ergodic and non-ergodic phases in the H-T plane. The existence of the glassy phase below T_{SG} is further confirmed by the observation of slow non-exponential decay of thermoremanent magnetization (TRM) with time, memory and rejuvenation effects and unidirectional exchange bias effect in the M-H hysteresis loop of field-cooled samples. The neutron powder diffraction patterns reveal the absence of any magnetic peak due to LRO AFM phase but show a broad diffuse peak due to the presence of ~2nm size AFM spin-clusters which are responsible for the CSG freezing in Pb-free systems.

FU-08. Strain modulated structure distortion and magnetic properties of orthorhombic $LuMnO_3$ thin films. H. Cao[1], *A. Zhang*[1], Y. Tang[1], J. Cui[1], L. Yang[2] and X. Wu[2] *1. Hohai University, Nanjing, China; 2. Nanjing University, Nanjing, China*

Epitaxial orthorhombic $LuMnO_3$ films were prepared on (001)-$LaAlO_3$ substrates by pulsed laser deposition (PLD). The results of structural investigation reveal that the out-of-plane parameter c slowly increases with decreasing thickness of films because of the tensile strain in the films. The lengths of in-plane Mn-O bonds expand with the enhancement of strain, which is proved by Raman scatting. The temperature dependence on magnetization M(T) curves proves that the magnetic transition temperatures T_N obviously increases with decreasing thickness of the films. The variation of in-plane Mn-O bonds under strain is discussed. The increasing of magnetic transition temperatures T_N is ascribed to evolution of the magnetic structure by strain. These results show that the magnetic transition temperature of LuMnO3 films can be sensitively manipulated by the strain of the films.

FU-09. Electric field induced magnetic anisotropy in [Co/Ni]/PMN-PT multiferroic heterostructures. *S. Ishikawa*[1] and T. Taniyama[1] *1. Department of Physics, Nagoya University, Nagoya, Japan*

Electric field control of magnetic anisotropy is currently being investigated extensively due to their potential for use in low energy dissipative spintronic devices. In particular, interfacial multiferroics composed of a ferromagnetic layer and a ferroelectric layer have attracted tremendous interest, since strong magnetoelectric coupling at the interface provides electric field controllability of magnetism [1][2]. In this study, we demonstrate electric field induced perpendicular magnetic anisotropy (PMA) in [Co/Ni] multilayer/PMN-PT interfacial multiferroic heterostructures. Au(2)/Pt(3)/[Co(t)/Ni(0.5)]$_8$/Pt(5)PMN-PT(111) heterostructures (thickness in nm) were fabricated by using molecular beam epitaxy in ultrahigh vacuum under a base pressure of ~10^{-10} Torr. X-ray diffraction measurement ensures the epitaxial growth of the multilayers. Magnetization of the heterostructures with a different Co layer thickness reveals switching of the magnetic anisotropy between the in-plane and the perpendicular magnetization orientation at a critical Co layer thickness (t=0.8 nm). Magnetooptical Kerr measurements were done in in-plane magnetic fields for [Co(0.8)/Ni(0.5)]$_8$ multilayers close to the critical layer thickness under electric fields across the PMN-PT at room temperature. The remanent in-plane magnetization is found to show a monotonic decrease by a factor of 13% with increasing electric field up to 6 kV/cm. The results clearly demonstrate that electric field induced PMA evolves in the multilayer. We consider that the modulation in PMA by an electric field arises primarily from the magnetoelastic effect in the [Co(0.8)/Ni(0.5)]$_8$ multilayer; compressive strain is transferred to the [Co(0.8)/Ni(0.5)]$_8$ multilayer via inverse piezoelectric effect of PMN-PT, enhancing the PMA due to a change in the orbital angular momentum. A possible modulation of the electronic structures due to charge accumulation is not likely since the polarization charges at the Pt/PMN-PT interface are effectively screened by the thick Pt layer. This work was supported in part by JST CREST Grant Number JPMJCR18J1, JSPS KAKENHI Grant Numbers JP17H03377, JP18F18353, the Asahi Glass Foundation, and the Kato foundation for Promotion of Science.

FU-10. Magnetization reversal of [Co/Pd] perpendicular magnetic film fabricated onto (Bi,La)(Fe,Co)O_3 multiferroic film by applying electric field to multiferroic / magnetic laminated film. *S. Yoshimura*[1], N. Oshita[1] and M. Kuppan[1] *1. Graduate School of Engineering Science, Akita University, Akita, Japan*

Multiferroic materials with magneto-electric effect have been receiving greater attention because of their promising applications in the design of multifunctional devices with low power consumption. In these days, we succeeded to fabricate the highly-qualified $BiFeO_3$-based thin films with ferromagnetism and ferroelectricity by using reactive pulsed DC sputtering method and also demonstrated the inducement of magnetic domain by applying the local electric filed [1]. However, the magnetic properties of the films were not sufficient for device application. If the multiferroic film can control the magnetization direction of high functional magnetic film fabricated onto the multiferroic film by applying electric field to the laminated film, the multifunctional devices will be realized easily. In this study, we fabricated laminated film with (Bi,La)(Fe,Co)O_3 (BLFCO) multiferroic film / [Co/Pd] perpendicular magnetic film with dotted structure, and also demonstrated the magnetization switching of [Co/Pd] dot by applying the electric field. Figure 1 shows the schematic images of application of local electric field to BLFCO/[Co/Pd] laminated film and MFM images of laminated film (A) before and (B) after application of local electric field. Before application of local electric field (A), both of [Co/Pd] dots show de-magnetized domain structure. However, after application of local electric field (B), the magnetic contrast of dot (left) which was applied electric field became small. Figure 2 (a) and (b) show the line profiles of [Co/Pd] dots at line a and b of figure 1(B). The line profile (b) indicates de-magnetized domain structure, but the line profile (a) indicates 86%-upward magnetized domain structure. These results indicate that downward magnetic moment of 75% was reversed to upward by applying electric field. Therefore, we can say, the demonstration of magnetization switching of [Co/Pd] dot by applying the electric field was succeeded.

FU-11. Studies of Fe^{3+} Doped Barium Zirconate Titanate Nano Films for Energy Storage Applications. *M.K. Bhattarai*[1], S. Dugu[1], K.K. Mishra[1], A. Instan[1] and R. Katiyar[1] *1. Physics, University of Puerto Rico, Rio Piedras, San Juan, PR, United States*

Nature-friendly ABO_3 type multiferroic perovskite nano films were fabricated on $La_{0.67}Sr_{0.33}MnO_3$ (LSMO) buffer layer deposited on MgO (100) single crystal substrates by using a pulse laser deposition technique. The tetragonal multiferroic heterostructure thin films were found to be oriented along (100) direction consisting of alternate $Ba[(Zr_{0.30}Ti_{0.70})_{0.99}Fe_{0.01}]O_3$ (BZTF) and $Ba(Zr_{0.30}Ti_{0.70})O_3$ (BZT) layers with total thickness ~ 300 nm. Homogeneous distribution of grains with roughness of ~ 3- 5 nm were observed from surface topography studies using atomic force microscopy(AFM). Dielectric measurements on Au/BZT/BZTF/LSMO and Au/BZTF/BZT/LSMO metal-insulator-metal capacitors using an impedance analyzer in the temperature range 100-650 K at several frequencies ranges 0.1-100 kHz suggests their relaxor behavior concomitant with the slim hysteresis P-E loop feature. The distribution of magnetic nano clusters was

observed from the temperature dependent magnetization studies using a physical properties measurement system (PPMS). The charge-discharge energy storage performance was estimated from P-E loops at room temperature. The high dielectric constant, larger breakdown strength and, better energy storage density values suggest that the grown heterostructure thin films are suitable multiferroic for high energy storage and memory applications.

FU-12. Voltage Control of Magnetism in $Fe_{75}Al_{25}$/PMN-32 PT Multiferroic Heterostructures. *V. Sireus*[1], E. Menéndez[1], A. Quintana[1,2], I. Fina[3], B. Casals[3], R. Cichelero[3], m. kataja[3], M. Stengel[3,4], G. Herranz[3], G. Catalan[4,5], D. Baró[1], S. Suriñach[1] and J. Sort[1,4] *1. One of the main strategies to control magnetism by voltage is the use of magnetostrictive-piezoelectric hybrid materials, such as ferromagnetic/ferroelectric heterostructures. However, when such heterostructures are subjected to an electric field, piezostrain-mediated effects, electronic charging and voltage-driven oxygen migration may simultaneously occur, complicating the interpretation of the magnetoelectric effects and often leading to misinterpretations. We engineer a ferromagnetic/ferroelectric hybrid consisting of a magnetically soft and isotropic 50 nm-thick $Fe_{75}Al_{25}$ (at. %) thin film on top of a <110>-oriented PMN-32PT ferroelectric crystal which allows us to disentangle magnetoelectric effects. The large thickness of the FeAl layer allows us to dismiss any possible effect arising from charge accumulation, the high resistance to oxidation of FeAl ensures virtually no voltage-driven oxygen migration processes, leaving strain as the only mechanism to modulate the magnetoelectric response. Along the in-plane [001] direction of the ferroelectric crystal, the remanence of the hysteresis loops follows a butterfly-like dependence with the applied electric field, while, along the [1–10] direction, a non-volatile loop-like behavior is observed. This behavior arises from the asymmetry of the polarization reversal for this crystallographic orientation of the ferroelectric substrate. The results clearly evidence the need for controlled systems and systematic characterization to understand and optimize magnetoelectric effects in artificial multiferroic heterostructures.

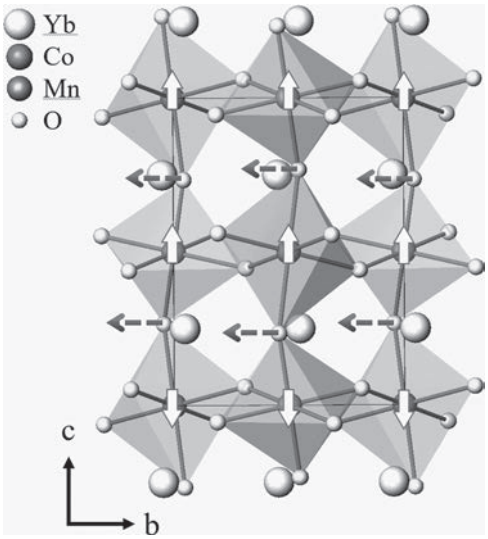
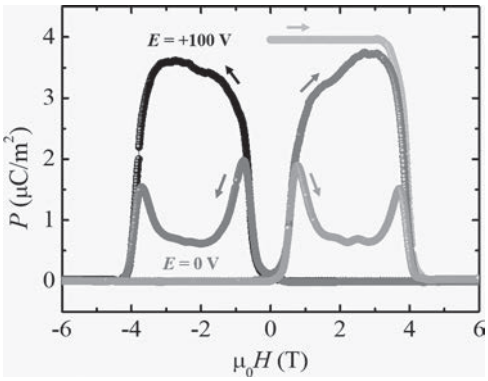
FU-13. Room Temperature Multiferroicity in Fe and Mn-enriched Gallium Ferrite Thin Films. *S. Dugu*[1], S. Kumari[2], M.K. Bhattarai[1], A. Instan[1], D.K. Pradhan[3] and R. Katiyar[1] *1. Department of Physics, University of Puerto-Rico, San Juan, PR, United States; 2. Department of Physics, Pennsylvania State University, University Park, PA, United States; 3. Geophysical Laboratory, Carnegie Institute for Science, Washington, DC, United States*

Multiferroic materials showing the magnetically driven ferroelectricity have interesting properties that can be used for novel technologies, such as fast writing, power saving, and non-destructive data storage. Multiferroicity is typically observed at low temperatures. However, the materials with room temperature multiferroic are highly desirable for device applications. In pure gallium ferrite (GFO), Magnetic transition temperature (T_C) is observed at 220 K. However, T_C can be tuned to above RT by increasing Fe contents. Herein, we report the dielectric, morphological, piezoresponse force microscopic (PFM) and magnetic properties of ~ 200nm of $Ga_{0.6}Fe_{1.4}O_3$ and $Ga_{0.6}(Fe_{0.98}Mn_{0.02})_{1.4}O_3$ thin films deposited by pulsed laser deposition (PLD) method. Temperature-dependent magnetization behavior studied from 10-395 K with both field-cooled and zero-field-cooled conditions identify T_C at around 370 K and 350 K respectively for the above materials. The AFM studies revealed that the surfaces of thin films are smooth and homogeneous, free of microcracks, pores or holes with an average surface roughness of around 2-3 nm. The existence of ferroelectricity at the nanoscale has been confirmed by PFM measurement. The contrast observed within upward polarization, and downward polarization in the PFM phase and amplitude images of both films indicates re-orientation of the ferroelectric polarization in these compounds. On doping Mn in GFO, dielectric loss is significantly reduced that enhances the applicability of the material. The observed RT multiferroic (ferrimagnetic and ferroelectric) behavior with reduced leakage current in these compounds makes them suitable for nanoscale multifunctional device applications such as spintronics and sensors.



FU-14. Room temperature lead-iron-tungsten/lead-zirconate-titanate nanoscale multiferroic thin films. *K.K. Mishra*[1], M.K. Bhattarai[1] and R. Katiyar[1] *1. physics, University of Puerto Rico, San Juan, PR, United States*

The discovery of single-phase magnetoelectric multiferroic materials are of great scientific interest because of their fascinating coupling mechanisms between spin and polarization order parameters. Herein, we report fabrication, dielectric, ferroelectric and magnetic measurement of a room-temperature magnetoelectric multiferroic $0.6Pb(Zr_{0.53}Ti_{0.47})O_3$-$0.4Pb(Fe_{0.67}W_{0.33})O_3$ (0.6PZT-0.4PFT) thin film. Highly oriented 0.6PZT-0.4PFT thin films of thickness ~300 nm was deposited on $(LaAlO_3)_{0.3}(Sr_2AlTaO_6)_{0.7}$ substrates by following laser ablation processes in oxygen atmosphere using pulsed laser deposition technique. Diffraction studies revealed that the film had pseudocubic phase with (100) orientation. Surface topography studies via atomic force microscopy suggest a smooth and homogeneous distribution of grains on the film surface with surface roughness ~2 - 4 nm. The dielectric measurements as a function of temperature (100-700 K) were carried out in Pt/0.6PZT-0.4PFT /LSMO metal-dielectric-metal capacitors, fabricated using D.C. sputtering technique, exhibited a high dielectric constant of ~2200 at room temperature and showed a diffused behavior at several frequencies around 515 K. The measured polarization hysteresis loop is well saturated at room temperature with P_r = 23.4 μC/cm^2, P_s= 70.31 μC/cm^2 and coercive field E_c = 127 Oe, attributed to its ferroelectric behavior. To understand the magnetic ordering in the thin film, we employed magnetization studies as a function of magnetic field using PPMS down to 4 K. An irreversible magnetic ordering is evident from the ZFC and FC magnetization curves. A saturated magnetization *M-H* loop with remanent magnetization of 82.4 emu/cm^3 was observed at room temperature. These results suggest that our thin films are multiferroic (ferroelectric-ferromagnetic) at room temperature. The presentation will discuss the results in details.



FU-15. Multiferroic behavior in double-perovskite Yb_2CoMnO_6. *J. Kim*[1], Y. Choi[1] and N. Lee[1] *1. Physics, Yonsei university, Seoul, The Republic of Korea*

We investigated the magnetic and magnetoelectric properties of single-crystalline double perovskite Yb_2CoMnO_6, which crystallizes in a monoclinic $P2_1/n$ structure. The crystals of Yb_2CoMnO_6 were grown by a conventional flux method with Bi_2O_3 flux. The size of a large crystal was 1x3x6 mm^3.[1] The up-up-down-down spin ordering of the Co^{2+} and Mn^{4+} moments emerges along the *c*-axis at T_N = 52 K, and the additional order of Yb^{3+} moments arises at T_{Yb} = 20 K. Below T_N, the ferroelectricity develops along the *b*-axis because of cooperative oxygen displacements via the symmetric exchange striction of up-up-down-down spin structure.[2] We observed magnetically-controlled ferroelectric polarization with strong hysteretic behavior, strongly correlated with the variation of isothermal magnetization. Interestingly, the magnetic-field dependence of ferroelectric polarization appears to be quite different relying on the presence of electric fields during magnetoelectric current measurement. This result suggests that ferroelectric domains are substantially affected by both of electric and magnetic fields. Our observations based on strong magnetoelectric coupling in Yb_2CoMnO_6 enrich fundamental and applied research on magnetic materials through the scope of distinct characteristics in double perovskites.

[1] H. Y. Choi et al., *Crystals* 7, 67 (2017) [2] J. Blasco, *Physical Review B* 96, 024409 (2017)

In Yb_2CoMnO_6, the direction of polarization is along the b-axis. Displacements of O^{2-} ions are induced by the exchange striction in the up-up-down-down spin structure.

The magnetic-field dependence of ferroelectric polarization was quite different relying on the presence of electric fields during magnetoelectric current measurement. (Red) under 0 V/cm (Black) under 2300 kV/cm

FU-16. Experimental and Computational Studies of Changes in Phonon Frequencies with Fe Concentration in $CuAl_{1-x}Fe_xO_2$ Delafossites.
M. Aziziha[1], S. Akbarshahi[1], S. Ghosh[2], P. Pramanik[2], G. Panapitiya[1], J.P. Lewis[1], S. Thota[2], A. Romero[1], M.S. Seehra[1] and M.B. Johnson[1]
1. Physics and Astronomy, West Virginia University, Morgantown, WV, United States; 2. Physics, Indian Institute of Technology, Guwahati, India

Delafossite (A1+M3+O2-2) are a less-studied family of complex oxides. In particular, CuAlO2 is p-type complex oxide semiconductor with a fundamental indirect bandgap with possible applications in opto-electric, photo-catalysis, and spintronic devices when doped with a magnetic ion. Previously, we reported on the magnetic properties of CuAl1-xFexO2 (x = 0, 0.01, 0.05, and 0.1) powders, prepared by a solid-state reaction at 1,100 °C. These samples show Curie-Weiss variation of magnetic susceptibility and antiferromagnetic exchange interaction between Fe3+ ions [1]. Long-range magnetic order expected based on some computational predictions was not found, [2] although our high-resolution hysteresis measurements demonstrated a small ferromagnetic component due to hematite impurities [3]. New results reported here include: Rietveld refinement of x-ray diffraction data for phase analysis and the calculation of the Goldschmidt tolerance factor for CuAlO2 and CuFeO2 to confirm their R-3m space group; room-temperature electron spin resonance (ESR) data confirm the presence of Fe3+ ions; and Raman and Fourier- transform infrared (FTIR) spectra to investigate changes in the phonon frequencies with Fe doping. Regarding the latter results, the Raman active modes at Eg = 419 cm-1 and Alg = 767 cm-1 for x = 0 [4] undergo red-shifts for x > 0, so that for x = 0.10 Eg = 412 cm-1 and Alg = 754 cm-1. Also, with increase in x, both modes broaden significantly and the intensity ratio of Eg to Alg modes decreases. In FTIR spectroscopy, six modes are observed; these modes also red shift vs. x. These red shifts are consistent with the expansion of the lattice with increased Fe content, which weakens the M–O bonds. Observed line broadening results from the red shifts and heterogeneity introduced by Fe-doping. Finally, we report density functional theory (DFT) calculations on CuAl1-xFexO2 to understand the influence of Fe-doping on the structure and vibrational modes. All plane-wave DFT calculations were performed using VASP. PBE+U method and spin-polarized Fe are considered. Using the finite displacement method, the variations of the phonon modes with x are calculated and compared to the experimentally observed variations.

In multiferroic composites, nanoscale structure plays an important role in the control of strain transfer between the two materials. Traditional planar stack structures are substrate-clamped and have limited interface, but three-dimensional porous composites allow for a high interfacial surface area between the magnetostrictive and piezoelectric components, as well as allowing for higher strains because of the greater flexion of a mesoporous material. Here, we synthesized mesoporous cobalt ferrite (CFO) via a sol-gel evaporation induced self-assembly technique utilizing block copolymer templating. The pores were then conformally coated via atomic layer deposition with bismuth ferrite (BFO) at varying thicknesses to allow for differing residual porosities of the resultant composite. Using *ex situ* electrically poled SQUID magnetometry measurements, we determined that these composites indeed decrease in out-of-plane saturation magnetization with application of an electric field under 1MV/m. We have found that the strength of this magnetoelectric coupling increases with an increased residual porosity, up to a decrease in saturation magnetization to half the unpoled value in the composites with the thinnest BFO layer. High-resolution X-ray diffraction confirms that more residual porosity allows for greater strains in the magnetic material. Thus, despite having a lower overall volume of ferroelectric material, the magnetoelectric coupling is enhanced by the greater film flexion because of increased porosity.

FU-18. Theory of electro active magnetic excitation in frustrated Heisenberg models.
S. Miyahara[1] *1. Fukuoka University, Fukuoka, Japan*

In magnetoelectric mulitferroics, a strong coupling between magnetization and electric polarization induces an electro active spin wave excitation (so called electromagnon excitation) [1], where electric component of light can excite a spin wave excitation through the magnetoelectric couplings.

A typical example of the electromagnon is an electro active spin wave excitation in helical magnets. The spin wave can be simultaneously excited by both magnetic and electric components of light and the cross correlation effects of them can be observed as nonreciprocal direction dichroism in absorption under external magnetic fields [2]. We investigate the dynamics of spin-wave spin current in the J_1-J_2 classical Heisenberg model under external magnetic fields and clarify that the spin-wave spin current in the conical magnets can be excited by both magnetic and electric component of light and show the non-reciprocal property, i.e., the way of the propagation of the spin wave depends on the direction of the propagation. Such nonreciprocal properties can be tuned not only by the external magnetic fields but also the external electric fields due to the magnetoelectric coupling. The coupling between magnetization and electric polarization induces electro active excitation even in spin gap systems. In the Heisenberg system, the spin gap excitation from the singlet ground state to the triplet excitation cannot be excited by magnetic components of light. However, such a spin gap excitation can be excited by electric component of light. As a typical example, we show that the spin gap excitation in the orthogonal dimer models, which explanin the magentic propeties of $SrCu_2(BO_3)_2$ [3], can by excited by the electric components of light.

FU-19. Non collinear magnetic textures at strained interfaces of $La_{0.67}Sr_{0.33}MnO_3$ on $LaAlO_3$. *A. Burema*[1], J. van Rijn[1] and T. Banerjee[1]
1. University of Groningen, Groningen, Netherlands

Strain engineering at interfaces of ultrathin films in strongly correlated oxides has triggered the study of new non-collinear magnetic textures such as conical, cycloidal, and skyrmions. Most studies require heterostructures that couples a metal with large spin-orbit coupling and a thin magnetic film and uses surface sensitive techniques such as STM [1], MOKE [2] or MFM [3] to study the engineered textures. In our work [4] we have observed magnetic textures in thin films of ferromagnetic $La_{0.67}Sr_{0.33}MnO_3$ (LSMO) on $LaAlO_3$ substrates without any additional heavy metal layer. We study this utilizing a Hall bar geometry and analyze the different components of charge and spin transport to establish this. We find strain to be a critical parameter governing the observed magnetotransport characteristics in LSMO. A systematic study of strain-dependent magnetic behavior reveals a magnetic phase transition from an antiferromagnetic insulating to a ferromagnetic metallic state with an applied magnetic field, figure 1 [4]. We will discuss in particular, the angular dependence of magneto transport with respect to the applied current with varying temperature and magnetic field strength. We show that this leads to an interplay between competing magnetic phases that exhibit non-collinear magnetic textures at different phase transition boundaries and is brought about by temperature induced changes in the anisotropy energy. This is also corroborated by our anisotropic magnetoresistance studies performed at similar interfaces. Such magnetic textures at oxide interfaces have rich potential to be used in new magnetic memory devices and their manipulation by electric fields.

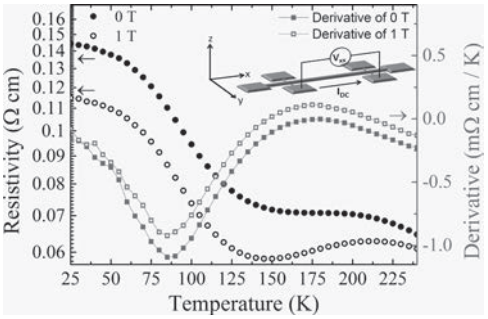

Fig 1 resistivity versus temperature, The solid dots are the resistivity without any magnetic field applied. The open black dots represent the resistivity under the application of 1 T out-of-plane. The application of a magnetic field causes the resistivity slope to change from negative to positive in the temperature region 150 to 225 K, indicating a change from insulating to metallic behavior [4].

FU-20. Electrically detected magnetic resonances in CMR oxides revealed by broadband magnetotransport. *R. Mahendiran*[1] *1. Physics Department, National University of Singapore, Singapore*

Although magnetoresistance of colossal magnetoresistive oxides with direct current passing through samples has been widely reported, little is known about magnetoresistive property of these oxides in response to alternating electrical current [1,2,3]. I discuss the room temperature magnetoimpedance in bulk samples of $La_{0.7}Sr_{0.3-x}Ca_xMnO_3$ ($0 \le x \le 1$) subjected to ac current excitation of frequency f = 1 MHz to 3 GHz and dc magnetic fields (-5 kOe < H < 5 kOe). The ground state changes from ferromagnetic (FM) for $x < 0.20$ to paramagnetic (PM) for $x \ge 0.24$ at 300K. It is shown that ac magnetoresistance is not only higher in magnitude than dc magnetoresistance but shows interesting features: It is negative and shows a single peak at $H_{dc} = 0$ below certain frequencies in FM samples but transforms into positive double peaks at $H_{dc} = \pm H_p$ and the double peak feature shift towards higher magnetic fields with increasing frequency of the ac current. Surprisingly, the ac magnetoresistance in PM samples is also negative and displays a single peak at 500 MHz, which transmutes into an abrupt increase at a critical field value for $f > 700$ MHz. A plot of H_{dc} corresponding to the double peak/ critical field versus frequency suggest that the curves are linear for PM samples and non-linear for FM samples [4]. These observed anomalies in the ac magnetoresistance are attributed to electron paramagnetic resonance for $x \ge 0.24$ and ferromagnetic resonance for $x < 0.20$. Thus, we are able to electrically detect paramagnetic and ferromagnetic resonances in these conducting magnetic oxides through a simple magnetoimpedance measurement. I will show that this technique can be also extended to insulating oxides by illustrating results on YIG and La_2NiMnO_6. Our results are important from view the viewpoints of current interest in electrical detection of magnetization dynamics in magnetic nanostructures.

FV-01. Magnon Valves Based on YIG/NiO/YIG All-Insulating Magnon Junctions. C. Guo[1], C. Wan[1] and *X. Han*[1] *1. Institute of Physics, Chinese Academy of Sciences, Beijing, China*

Besides of electron spins, other quasi-particles such as magnons can also behave as carriers of angular moment. Recently, magnonics dealing with magnon-based spin current or magnon accumulation has become an emerging hot topic and attracted wide attentions. Instead of regulating transport of spin-polarized electrons, a magnon valve regulates flow of magnons, a low-energy collective excitation state of magnetic insulators such as $Y_3Fe_5O_{12}$ (YIG). In magnetic insulators, when a temperature gradient is applied, a nonuniform spatial distribution of magnons would contribute to a magnon current, i.e., spin Seebeck effect. Analogous to a spin valve based on giant magnetoresistance (GMR) effect [1,2] or tunneling magnetoresistance (TMR) effect [3,4], we show that an all-insulating magnon junction composed of a magnetic insulator (MI1)/antiferromagnetic insulator (AFI)/magnetic insulator (MI2) sandwich ($Y_3Fe_5O_{12}$/NiO/$Y_3Fe_5O_{12}$) can completely turn a thermogradient-induced magnon current on or off as the two $Y_3Fe_5O_{12}$ layers are aligned parallel or antiparallel[5]. When the temperature gradient is applied, the magnon current with spin would flow from one FMI to the other FMI through the AFMI. Then setting a heavy metal Pt on the top FMI, one could detect an electrical signal via Inverse Spin Hall Effect, which reflects the magnetizations of both FMI layers, similar to TMR effect in MTJ. Furthermore on-off ratio of the so-call magnon junction can be increased to 100%. This magnon junction may play an important role in the future magnonic device [5,6].

FV-02. Spin Transport in Disordered Semiconductors Probed via the Spin Hall Effect. *S.M. Bleser*[1], D.J. Wesenberg[1], R.K. Bennet[1], M. Roos[1] and B.L. Zink[1] *1. Physics & Astronomy, University of Denver, Denver, CO, United States*

Progress in spintronics requires continued study of spin injection and transport in a wide range of materials. Amorphous semiconductors are one class of materials not yet explored in detail despite theoretical predictions of long spin lifetimes. [1] This is due in part to the challenge of injecting spin into high charge resistivity materials using magnetic tunnel junctions and non-local or lateral spin valves. Here we describe an experimental demonstration of a method to measure spin transport in these systems using spins injected and detected via the spin Hall effect. [2] The method is a modification of experiments used to study spin currents in magnetic insulators. Here we have studied thin film samples of amorphous germanium (a-Ge) with and without a "guard-rail," an additional Pt strip that protects the spin detector from charge leakage effects. We electrically generate a spin signal by injecting a current density in one platinum strip to generate a transverse spin current via the Spin Hall Effect (SHE) and detected on a second platinum strip that generates a non-local voltage signal via the Inverse Spin Hall Effect (ISHE) between temperatures of 200 – 370 K. With an unguarded detector strip and a separation distance of 10 μm we see a positive non-local voltage signal throughout the entire temperature range and with a guarded detector strip at a separation distance of 60 μm we see a negative non-local voltage signal. This suggests that the inclusion of a "guard-rail" between the injector and detector blocks a significant portion of the electrical signal and allows the spin signal to pass relatively unaffected. We provide further confirmation of spin transport using non-local resistance measurements in applied out-of-plane magnetic field, which show the characteristic response of the Hanle effect. This implementation of a "guard-rail" could shed light on spin transport mechanisms in a wide range of high-resistivity semiconductor systems by eliminating charge transport signals.

SHE-driven non-local resistance in *a*-Ge. Addition of a "guard rail" eliminates charge contributions and shows the expected negative slope for spin effects.

Hanle effect measurement in *a*-Ge confirms spin transport over long distances.

FV-03. Ferromagnetic Resonance and Inverse Spin Hall Effect in Permalloy/Pt bilayers. S. Martin-Rio[1], A. Pomar[1], L. Balcells[1], C. Frontera[1] and *B. Martinez*[1] *1. Magnetic Materials and Complex Oxides, ICMAB-CSIC, Bellaterra, Spain*

The temperature dependence of magnetodynamical physical effects such as Spin Pumping and Inverse Spin Hall effect (ISHE) has been measured in a set of Py/Pt bilayers as a function of the Pt thickness. Additionally, important physical parameters such as Gilbert damping, saturation magnetization and anisotropy field has been determined as well. It is found that the Gilbert damping follows a non-monotonic behaviour with temperature (Fig. 1a), as reported in other systems [1]. Previous measurements on the temperature dependence of Spin Pumping and ISHE [2] in this system have the serious drawback of requiring the use of complex fabrication process to prepare the samples. In this work we present an easy-to-implement FMR setup for measuring all of those effects and parameters straightforwardly. It is found that the amplitude of the FMR absorption curves is constant from room temperature to approximately 100K and then it starts to decrease. Because of this reduction, it is of major relevance to normalise the measured ISHE voltage with the FMR absorption amplitude in order to obtain physically coherent results. The resulting normalised ISHE voltage, depicted in Fig. 1b, follows a inverse linear relation with temperature.

FV-04. Probing Phase Transition and Anisotropy Using the Spin Hall Magnetoresistance in EuO_{1-x} and La_2NiMnO_6. *K. Mallick*[1], A.A. Wagh[1], A. Ionescu[2], C.H. Barnes[2] and A.P. Kumar[1] *1. Physics, Indian Institute of Science, Bangalore, India; 2. Physics, University of Cambridge, Cambridge, United Kingdom*

Spin Hall magnetoresistance (SMR) has attracted a lot of attention recently as a tool for studying magnetic phases and associated phase transitions. In this regard, we investigate two ferromagnetic materials La_2NiMnO_6 (LNMO) and EuO_{1-X}, both predicted to be promising candidates for spintronics. LNMO is among the few ferromagnetic insulators which has a Curie temperature close to room temperature (T_C =280K). Thin films of this material allow tunability of its crystallographic and magnetic properties by varying deposition conditions, thickness and lattice strain. Interestingly, SMR measurements on bilayers of epitaxial LNMO films and Pt, exhibit features distinctly different from polycrystalline LNMO/Pt. While the temperature dependence of SMR seems to follow the bulk magnetization in polycrystalline films, the observed behavior in epitaxial films appears to be dominated by the interface magnetic anisotropy. The isotropic nature of the bulk of the film became evident from spin Seebeck and SQUID magnetometry experiments. We could track the evolution of this surface anisotropy as a function of temperature employing systematic magnetic field orientation dependent SMR measurements in out-of-plane and in-plane geometries. In addition, we observe SMR and anisotropic magnetoresistance (AMR) in bilayers of Pt/EuO_{1-X} thin films. The presence of oxygen vacancies manifested in a metal-insulator transition as well as an enhanced curie temperature. The AMR persisted up to room temperature, exhibiting two sign crossovers. On the other hand, the onset of SMR occurred only below Curie temperature and did not undergo any sign change. We deduce possible explanations for such behavior based on the temperature dependence of EuO_{1-X} bandstructure and spin mixing conductance of the Pt/EuO_{1-X} interface.

FV-05. Optimized 3d/5d heavy metals interfaces: Spin-Hall effect and THz emission. *H. Dang*[1], J. Hawecker[3], Q. Barbedienne[1], J. George[1], S. Collin[1], P. Bortolotti[2], J. Tignon[3], S. Dhillon[3] and H. Jaffres[1] *1. Unité Mixte de Physique CNRS-Thales, Palaiseau, France; 2. Thales Research and Technology, Palaiseau, France; 3. LPA, ENS, Paris, France*

Recently, the THz emission may be realized in heterostructures either in heavy metallic (HM) [1] or in Rashba system [2]. The heterostructures are composed of ferromagnetic (FM) and spin-orbital active materials via Inverse Spin Hall effect (ISHE) in picosecond scale using time-dependent spectroscopy (TDS) techniques. The experiments consist in exciting their magnetization and spin-currents within the FM layer via a femtosecond laser and in measuring the relaxation of the correlated spin and charge currents responsible for the THz dipolar emission. Some experimental works have been done to optimize the THz emission by using different materials, geometries of structures, techniques to fabricate the samples, etc. In parallel, some theoretical models were proposed to explain the dynamic of the spin current in ultrafast range [3]. However, the physics of the THz emission in those structures has not been well understood. Hence, we are working to optimize the THz emissions of 3d/5d transition-metal based multilayers such as Co/Pt, NiFe/Au:Ta and NiFe/Au:W. The first idea is to reduce the Spin Memory Loss (SML) at the interface between Co and Pt by including Au or Ti monolayers (MLs). Then, those samples are analyzed using experiments combining Radio frequency-spin-pumping-ISHE measurements and TDS –THZ spectroscopy. We obtain that the insertion of Au or Ti MLs based materials in Co/Pt structures may enhance either the THz or the ISHE signals depending on the layer sequences. In particular, the Co/Au (Ti) MLs/Pt systems evidence an increase of the ISHE signal by a decrease of the SML, conjugated to a decrease of the FMR-linewidth and the THz emission. From that, we propose a strict correlation between the THz signals and related Spin-Mixing conductances (SMC), then discuss a connection between THz and spin loss phenomena. The second idea is to optimize the spin current in HM by a spin-sink layer such as Au:W. We show that the THz emission of Co/Pt/spin-sink layer is slightly higher than the emission of Co/Pt. This system also follows the strict correlation between THz signal and SMC.

FV-06. Direct optical detection of charge to spin conversion in heavy metals using modulation. *O. Van't Erve*[1], C.H. Li[1] and B. Jonker[1]
1. Naval Research Laboratorium, Washington, DC, United States

MOKE is often used to detect changes in magnetization caused by spin orbit torque in heavy metal (HM)/ ferromagnetic metal (FM) heterostructures, where the spin current created by spin Hall effect (SHE) in the HM creates the torque on the magnetization in the FM. A disadvantage of using heterostructures to measure the SHE is the ambiguous role of interface transparency. Methods that do not rely on the transparency of the interface with a FM are thus preferential in determining the real SHE angle of the HM. One such method is to use the direct optical detection of the charge to spin conversion by magneto optical Kerr effect (MOKE).[1] However, In ref [2] and [3], the authors conclude that it is impossible to measure a current-induced MOKE signal, due to heating effects. Nonetheless many groups have since shown convincing results on the optical detection of current induced spin polarization using magnetization-induced second harmonic generation. [4] While heating effects can contribute to the measured MOKE signal, Marui et. al. [5] have used a double modulation technique to separate the current induced heating effects caused by changes in the refractive index of the film from that in magnetization caused by spin orbit torque in a FM/HM heterostructure. Here we show that by applying a similar modulation technique to separate out the heating effect from the spin Hall effect of a single layer HM, we can unambiguously demonstrate that spin Hall effect can indeed be measured using a commercially available MOKE system.

A current trend in spintronics is an increased focus on antiferromagnetic materials, as active spin-transport components, which is also known as antiferromagnetic spintronics. Especially non-collinear antiferromagnetic materials, such as $IrMn_3$, are of special interest. These non-collinear antiferromagnets have due to the net chirality of their spin structures additional spin Hall properties that are not available in ordinary non-magnetic materials. Here we studied films of $IrMn_3$, which were grown with magnetron sputtering system on (100)MgO substrates. We investigated MgO/$IrMn_3$/ferro(para)magnetic/Ti heterostructures. The Ti(2 nm) layer is used to protect the surface properties of $IrMn_3$, permalloy (Py) or platinum (Pt). The $IrMn_3$ was characterized by superconducting quantum interference device (SQUID) magnetometry, magnetotransport measurements, transmission electron microscopy and X-ray diffraction. We studied systematically the transport properties of the $IrMn_3$/ferro(para)magnetic material samples as a function of temperature. The results show that is possible manipulates the surface states of this type of antiferromagnet via electrical means. FV-08. Two spin-channel model for spin Hall effect in 3D micromagnetic simulations. *X. Wang*[1], A. Goncharov[2], P. Van Der Heijden[2] and V. Lomakin[1] *1. Electrical Computer Engineering, University of California, San Diego, La Jolla, CA, United States; 2. Western Digital, San Jose, CA, United States*

Spin Hall effect (SHE) leads to spin accumulation occurring at normal metal – ferromagnetic interface, which can lead to spin torque. Numerical simulations of spin Hall effect are typically done via a simplified model Slonczewski's-like models, which do not account for size and shape effects related to the structure composition. There exist more advanced models for perpendicular currents [1-3]. The two spin-channel model (TSCM) [3] is particularly attractive as the parameters it uses can be directly obtained from experiments. Here, we extend the TSCM to account for SHE and the related spin accumulation and spin torque at interfaces between ferromagnetic and normal material. For such an interface, torques are generated due to spin accumulation at non-magnetic layer, with charge current flowing parallel to the interface. In TSCM, two currents are defined: charge current and spin current. The charge current is represented as the sum of the gradient of charge chemical potential and the curl of the spin chemical potential. The spin current is represented as a combination of the gradient of spin chemical potential and certain components of the charge chemical potential. The charge and spin chemical potentials are coupled between each other inside nonmagnetic layer via the interface. Once the spin and charge chemical potentials and the resulting spin and charge currents are found, the spin torque at the interface can be directly obtained. Such calculations account for size, shape, and material related effects of both normal and ferromagnetic layers. We validated the model with respect to analytical solutions for specific two-layer geometry [4] and studied a set of additional more complicated structures. Figure 1 shows the magnetization dynamics for a SHO oscillator in a cylinder of both radius and height to be 5 nm made of a material with CoFe put on top of a normal layer. The dynamics shows that the simplified model results in inconsistent precession, whereas TSCM results in robust precession. The differences are due to size dependent effects and non-uniform magnetization dynamics.

FV-09. Spin currents in all-oxide heterostructures. S. T S[1], S. Kanikrishnan[1] and *M. Rao*[1] *1. Physics, IIT Madras, Chennai, India*

Generation, transportation and detection of spin in a controlled manner are very important in spintronic devices for efficient switching mechanisms in a magnetic tunnel junction (MTJ). The conversion of charge current to spin current is known as spin Hall effect (SHE) and the inverse phenomenon is inverse SHE (ISHE). The detection of spin is usually realized by the ISHE. Spin Hall magnetoresistance (SMR) arises due to the simultaneous effect of SHE and ISHE in a bilayer heterostructures consisting of a ferromagnetic (or ferrimagnetic) insulator (FMI) and a normal metal (NM). [1,2,3] Magnetic Proximity Effect (MPE) observed in YIG/Pt complicates the spin transport scenario with additional effects such as Anomalous Hall effect (AHE) which attenuate SMR signal.[4,5]. Our group has successfully studied Ga: ZnO insertion on Bi: YIG/Pt and observed SMR signals, but the increase in spurious paramagnetic signal hampered the SMR signals with increasing Ga: ZnO thickness[6]. A solution for this is to employ antiferromagnetic moments, which are quite stable to stray fields and MPE. Recent studies in this direction have proved successful in generating spin current using antiferromagnets NiO/Pt, Cr_2O_3/W, CuIr and $SrMnO_3$/Pt layers[7]. Also, groups have reported that spin current can be used as a detection method to probe interface magnetism[8]. We have fabricated Antiferromagnetic oxide and metal oxide heterostructures through pulsed laser deposition and demonstrated the generation of spin current through angle-dependent magnetoresistance measurements (ADMR). We have varied the deposition conditions such that the magnetic interactions changes from antiferromagnetic to ferromagnetic order and we could identify the magnetic behaviour through spin transport studies carried out in this bilayer samples. The spin current generated in $SrIrO_3$ has other higher order magnetoresistance components along with spin Hall magnetoresistance. We would be presenting our experimental observations on spin transport studies carried out in these bilayers.

Spin current manipulation is at the core of spintronics. The spin–orbit interaction (SOI) in nonmagnetic materials is now used to create and detect spin currents. For instance, the spin Hall effect (SHE) and its inverse[1] allow performing the interconversion between charge and spin currents in bulk materials[2]. Edelstein Rashba effects, at interfaces or on the surfaces of topological insulators, can also ensure these conversions and are becoming highly competitive[3]. In this context, nanostructures that allow detecting the SHE electrically are of prime interest in view of SO-based logic devices[4] and nonvolatile magnetic random access memories (MRAMs), altogether with applications for spin–orbit torque experiments. Here, we focus on how these interconversions can be made electrically, using three different cross-shaped nanostructures. We apply the measurement configurations to the case of the spin Hall effect in Pt using CoFe electrodes to detect or inject spins. Both the direct and inverse spin Hall effects can be detected, with spin Hall signals up to two orders of magnitude higher than that of nonlocal measurements in metallic lateral spin valves, and with a much simpler fabrication protocol (the obtained spin signals are in the 10 mΩ range). We compare the respective signal amplitudes of the three proposed geometries. Finally, we show that finite element method calculations allow extracting from these measurements the spin Hall angle and the spin diffusion length of Pt. These results are also a step toward the development of computational magnetic devices, such as a nonvolatile memory with a single nanomagnet or spin–orbit based logic circuits[4]. Finally, we emphasize that these device geometries, can also be used to study the spin-charge interconversion at Rashba interfaces or surfaces of topological insulators.

The spin Hall angle (SHA) is one of the most important quantities in controlling the conversion efficiency between charge and spin currents. It has been reported there exists a correlation between the SHA and the structure of nonmagnetic metals (NM) in ferromagnet (FM)/NM heterojunctions [1]. In this study, we present our investigation on the influence of the FM structure on SHA in Py/Ta bilayers. The FM structure is modified by reversing stacking order of the bilayers and characterized by transmission electron microscopy (TEM) and X-ray diffraction (XRD). The SHA, θ_{SH}, is obtained firstly by the conventional method in spin-torque ferromagnetic resonance(ST-FMR) technique as described in Ref. [2], where only in-plane (IP) spin-orbit torque (SOT) is considered. Since a significant out-of-plane (OP) SOT has been observed in Ta/FM bilayers [3,4], we then extracted IP and OP SOTs and re-evaluate their corresponding SHAs, $\theta_{\parallel}$ and $\theta_{\perp}$, by employing the method in Refs. [5,6]. As shown in Fig. 1(a), fast Fourier transforms (FFTs) for the TEM images show a Py (111) texture is observed in sub./Ta/Py [7], while no such texture is detected in sub./Py/Ta. This modification of the FM structure

is also confirmed by XRD patterns in Fig. 1(b). The SHAs extracted from ST-FMR results are shown in Fig. 1(c). Without considering the OP SOT, the θ_{SH} is nearly one times larger in magnitude in sub./Ta/Py (-0.083) than that in sub./Py/Ta (-0.044). After considering the OP SOT, the $\theta_{\parallel}$ is not distinctly affected by the FM structure but the $\theta_{\perp}$ of sub./Ta/Py is around twice as large as that for sub./Py/Ta. We ascribe the FM structure dependent SHA to the interfacial symmetry breaking between FM and NM, which is tuned by the work functions due to different crystalline structure of FM. The emergence of the Py (111) structure enlarges the interfacial symmetry breaking and thus enhances the Rashba effect at the FM/HM interface. Our results highlight the importance of out-of-plane SOT in Py/Ta bilayers and demonstrate a simple and feasible way to manipulate SHA as well as SOTs via tuning FM structure.

The inverse spin Hall effect (ISHE) in a ferromagnetic material (FM) has been attracting much attention due to its importance in spintronic applications [1,2]. The ISHE, which converts spin currents into charge currents, is an effective method to detect spin currents. In this work, we report the observation of ISHE on permalloy (Py) thin films under ferromagnetic resonance (FMR) conditions. Experimentally, a series of Py thin films of thicknesses (t_{Py}) ranging from 5 to 40 nm were fabricated on rectangular silicon substrates. The dimensions were 1.5 mm × 3.0 mm for all samples. The FMR measurement was performed with a Bruker EMX electron spin resonance system. The samples were put in the center of a TE_{102} cavity, while a nanovoltmeter (Keithley 2181A) was connected to the samples to measure the electrical voltage. An electrical charge current (I_c) is recorded around the resonance field (H_r) for each sample. I_c as a function of t_{Py} is shown in Fig. 1. The electrical currents are attributed to ISHE and magnonic charge pumping (MCP) in Py [3]. The spin Hall angle (θ_{SHE}) and spin diffusion length (λ_{Py}) for Py are determined to be 0.034 % and 7.0 nm, respectively. The anomalous Hall effect (AHE) of Py is measured, and the anomalous Hall angle (θ_{AHE}) for Py is estimated as 0.005 %. The spin Hall angle of a FM is related to its anomalous Hall angle as $\theta_{SHE} = (1/p)\theta_{AHE}$ [1,2,4], where p is the spin polarization of the material. In our study, the value of p is estimated to be 0.14 for Py, comparable to the values reported in previous works [5]. The contribution from skew scattering to the θ_{SHE} of Py cancels out the intrinsic/side-jump contributions [4,6], hence yielding a small value of θ_{SHE}.

FV-13. Composition dependent spintronic THz emission of rare earth transition metal alloys combined with Pt.
M. Fix[1], R. Schneider[2], R. Heming[2], S. Michaelis de Vasconcellos[2], R. Bratschitsch[2] and M. Albrecht[1] *1. Institute of Physics, University of Augsburg, Augsburg, Germany; 2. Institute of Physics and Center for Nanotechnology, University of Münster, Münster, Germany*

Bilayers of ferro-/ferrimagnetic (FM/FIM) thin films and nonmagnetic metal (NM) layers have shown to be THz emitters when excited by femtosecond laser pulses [1,2]. Amplitude and frequency of the emitted THz radiation can be tuned by varying the film thickness, the electrical conductivity, the magnetic properties of the FM layer, and the spin-Hall conductivity of the NM layer [3]. However, the microscopic processes leading to the THz radiation and the role of the magnetic states especially for more complex magnetic layers are not fully understood, yet. Here we report on systematic studies on the THz emission of magnetron sputter deposited 20 nm thick ferrimagnetic Tb_xFe_{1-x} [4] and Gd_xFe_{1-x} ($0 \le x \le 1$) alloys combined with 5 nm thick Pt layers. The FIM layers show a great variety of different magnetic states depending on the composition, temperature, and applied magnetic field [5]. Thus, they are ideal candidates to investigate the role of different magnetic states on the emitted THz radiation. The samples were characterized by SQUID magnetometry and THz emission spectroscopy. Figure 1a shows the measured THz intensity with respect to the Tb content x for the Tb_xFe_{1-x}/Pt sample series. The measured THz radiation is mainly caused by the Fe electrons [2,4,6]. The high THz signals for $0.03 \le x \le 0.15$ derive from the reduced electrical conductivity compared to Fe/Pt. The decreased signal for higher x and the local maximum for $x = 0.5$ are attributed to the reduced Fe content and the in-plane magnetic moment of the Fe sublattice, which is schematically drawn in figure 1b. An inversion of the THz signal for $0.45 \le x \le 0.55$ (figure 1c) can be explained by the inverted alignment of the Fe magnetic moments. The small signals for high x are caused by

induced paramagnetic moments. Our study provides deeper insights into the role of complex magnetic materials used in spintronic THz emitters and will contribute to future optimized emitter designs.

FV-14. Extrinsic Spin Hall Effect in Inhomogeneous Systems.
T. Funato[1] and H. Kohno[1] *1. Science, Nagoya University, Nagoya, Japan*

In spintronics, the spin Hall effect (SHE) plays a key role in the realization of spin-to-charge conversion[1]. Recently, several experimental studies suggested that the spin Hall angle of copper with weak spin-orbit interaction (SOI) are augmented by natural oxidation treatment, and attracted intense research attention[2,3]. As a related phenomenon, Okano et al. reported an experimental result that suggests the vorticity of electron flow arising from the gradient of oxidation induced spin accumulation (spin-vorticity coupling) and generated a spin current[4]. However, the mechanism of the enhancement of spin Hall angle by natural oxidation treatment is still incompletely understood. As one of the solution, our theoretical study focuses on the extrinsic SHE due to impurities with distribution gradient. We consider nearly free electrons subject to impurities with SOI. Assuming a spatially linear distribution of impurities, we treat the average of the distribution non-perturbatively and the fluctuation perturbatively. We analyze the spin accumulation and spin current in linear response to an electric field. In this presentation, we report spin accumulation and spin current calculated by including ladder vertex corrections due to impurity scattering with SOI. On the basis of the results, we discuss the relation between the induced spin accumulation and spin current, and estimate the order of magnitude of the effect.

FV-15. Spin pumping and large field-like torque at room temperature in sputtered amorphous W_xTe_{2-x} film.
Y. Fan[1], H. Li[3], D. Mahendra[2], J. Held[3], A. Mkhoyan[3] and J. Wang[1] *1. Electrical Engineering, University of Minnesota, Minneapolis, MN, United States; 2. Physics, University of Minnesota, Minneapolis, MN, United States; 3. Materials Science & Engineering, University of Minnesota, Minneapolis, MN, United States*

To improve the efficiency of spin orbit torque, materials with large charge spin conversion efficiency has become a research hotspot. Among these materials, WTe_2 has attracted a significant attention due to its potential type II Weyl semimetal properties, which leads to large conduction and strong spin orbit coupling at Weyl points existing in bulk. [1] However, molecular beam epitaxy[2] or mechanical exfloliation[3] is still the most common preparation method for tungsten dichalcogenide thin films, which is impractical for industrialization. In this work, we prepared W_xTe_{2-x} (x=0.85) film by magnetic sputtering method and studied the spin to charge and charge to spin conversion at room temperature in sputtered MgO/W_xTe_{2-x} (x=0.85)/CoFeB/MgO/Ta heterostructures. Spin pumping measurements at different frequencies is used to characterize the spin to charge efficiency as shown in Fig (a). The resulted spin to charge conversion ratio is J_C/J_S~0.05. Second harmonic measurement is carried out for the charge to spin conversion ratio. The resulted value for damping like torque and field like torque at different W_xTe_{2-x} thickness is shown in Fig (b). We found the system exhibits a large field like torque (~0.1) compared to heavy metals[4] while the damping like torque is small (~0.0005). The damping like torque value will change sign when changing thickness, which indicates a competition between the interfacial and bulk scheme. High resolution transmission electron microscopy images show that the W_xTe_{2-x} layer is amorphous, which may increase resistivity and induce large interface scattering[5], thus contribute to the large field like torque. This work broadens the methods to prepare materials with large spin-orbit coupling and pave the way to application.

FW-01. Nonlinear Dynamics of Two Spin-Transfer-Torque Nano-Oscillators Coupled via Magnetostatic Fields. *D. Mancilla*[1], A.O. Leon[2], R. Arias[3], S. Allende[1] and D. Altbir[1] *1. Universidad de Santiago de Chile, Santiago, Chile; 2. Pontificia Universidad Católica de Valparaíso, Valparaíso, Chile; 3. Universidad de Chile, Santiago, Chile*

A great deal of attention has been focused on the study of spin- transfer-torque nano-oscillators (STNOs) during the past years. This is due to their several potential applications in the implementation of magnetic field sensors, in telecommunications, and recently in neuromorphic computing [1]. While the dynamics of a single oscillator has been well characterized by the experimental, analytic, and numerical points of view, the behavior of several coupled elements is not fully understood yet. In this work, an analytical and numerical study of the nonlinear dynamics of two magnetostatically coupled spin valves driven by spin-transfer-torques [2] is presented considering uniform magnetization in each oscillator, i.e., under the macrospin approximation. In particular, we study the role that the position of the oscillators plays in the synchronization phenomenon. We observe that for most values of the current density, the system exhibits a synchronized motion of the magnetizations. In this regime, the difference between the oscillation phases of the free layers remains nearly zero for an *in-phase* mode and π for an *antiphase* mode. The transition between the two modes, when the current density is increased, is characterized by a *mixed-mode* state in which both the antiphase and in-phase modes participate with a finite amplitude of oscillation [3]. These results can be used as one step in the quest for the design and control of arrays of STNOs. 1.Introduction The spin-MOSFET is expected to show a high performance in integrated circuits [1]. Highly efficient spin injection into semiconductors from ferromagnet is important for the realization of spin-MOSFET. However, it is difficult to realize efficient spin injection due to the conduction mismatch problem [2]. In order to enhance the efficiency of spin injection, it was proposed to use a half-metal theoretically having a spin polarization of 100% [2]. Co-based full Heusler alloys are expected to be a source of spin injection into semiconductors because of its high Curie temperature, small lattice mismatch with GaAs and high spin polarization. In this study, we focused on $Co_2Fe_{0.4}Mn_{0.6}Si$ (CFMS) and aimed to fabricate high quality thin films on GaAs substrates for the realization of high efficiency of spin injection. 2.Experiment procedure A structure of CFMS (30nm)/Ta (5nm) was deposited by magnetron sputtering on undoped GaAs (100) substrates. The annealing temperature (T_a) of CFMS layer was between 200 and 600°C. The magnetic properties of CFMS thin film were analyzed by vibrating samples magnetometer (VSM). The films with same structure were also deposited on GaAs (undoped)/n-GaAs (100μm) substrates at T_a= 400°C, which has the maximum saturation magnetization of CFMS films. The Si-doped densities in n-GaAs layer were $1\times10^{19}cm^{-3}$. For detecting spin injection signal, we performed 3- terminal Hanle measurement. 3.Experiment result Fig. 1 shows the annealing temperature dependence of saturation magnetization of CFMS thin films deposited on the undoped GaAs substrate. The saturation magnetization increased with increasing annealing temperature, and the maximum M_S~ 925 emu/cc was obtained at T_a= 400°C. The obtained high M_s indicates high B2 ordering in the CFMS films. Fig. 2 shows the Hanle signal using n-GaAs substrate under different bias current at 10K. The spin relaxation time calculated from narrow Hanle signals is about 7 ns, which is comparable to theoretical value [3] and previous report [4]. The result indicates that the spin-injection into GaAs was successfully demonstrated using highly ordered CFMS films.

FW-03. Room-temperature spin-dependent transport through Sb-doped Ge in vertical spin-valve devices. *T. Shiihara*[1], M. Yamada[1], M. Honda[1], S. Yamada[1,2] and K. Hamaya[1,2] *1. Graduate School of Engineering Science, Osaka University, Toyonaka, Japan; 2. Center for Spintronics Research Network, Graduate School of Engineering Science, Osaka University, Toyonaka, Japan*

For germanium (Ge)-based spintronic devices on a silicon (Si) platform [1], it is important to clarify the influence of dopant species on spin transport in Ge channel layers. Up to now, room-temperature (RT) spin transport in phosphorus (P) doped n-type Ge has been demonstrated by using lateral spin valves [1,2]. For P-doped n-Ge, the spin relaxation mechanism was dominated by the short-range spin scattering due to the spin–orbit coupling of impurities rather than the spin–orbit interaction in the host materials [1,3]. Because the strength of the spin–orbit coupling in arsenic (As) and antimony (Sb) is generally larger than that of P, we can speculate that the observation of the spin transport in Sb-doped n-Ge is difficult at RT. Here we report on spin transport in Sb-doped n-Ge at RT by using vertically stacked spin-valve structures and discuss the influence of Sb. By combining solid phase epitaxy and molecular beam epitaxy with Sb doping, we fabricated a CoFe/Sb-doped Ge (15~ 20 nm)/Fe_3Si structures on Si(111) [4,5]. Flat interfaces without forming reaction layers can be confirmed [Fig. 1(a)], similar to our previous work [1]. Figure 1(b) shows a representative magnetoresistance curve of a vertical spin-valve device at RT. A hysteretic feature depending on the magnetization states between parallel and anti-parallel can be observed. The observed spin signal (ΔRs) is one order of magnitude larger than that in p-Ge [1,5]. From the experimental conditions and electrical properties of the device, we can assume that the carrier concentration in the Sb-doped Ge layer is $n \sim 1 \times 10^{19}$ cm^{-3}, leading to the resistivity of ~ 0.6 mΩcm and other parameters [5,6]. If the theory by Fert and Jaffrès [7] is used, we can roughly estimate the spin diffusion length (λ) of Sb-doped n-Ge to be ~ 150 nm at RT, smaller than that of P-doped n-Ge (~ 440 nm) at RT [2]. Therefore, this study experimentally clarifies that the dopant species in Ge channel layers can affect the spin transport in group-IV semiconductors. This work was partly supported by JSPS KAKENHI (16H02333 and 17H06120).

Advance Products Development Center, TDK, Ichikawa, Japan*

Magnetologic gate (MLG) using spin accumulation and spin transport in the semiconductor was proposed as an path way to realize a reconfigurable and energy saving circuit [1,2]. MLG is composed of two spin xor device consisting three ferromagnetic (FM) electrodes contacting semiconductor spin channel. Si is one of the candidate for the spin channel because it has a good spin coherence and large spin drift effect which is required for the spin xor operation was demonstrated [3]. In this study, we demonstrate the spin xor operation with Si spin channel at room temperature. The device geometry and measurement circuit of the spin xor operation are schematically shown in Fig. 1. Nondegenerate n-Si channel was contacted by Co/Fe electrodes through MgO tunnel barriers (labeled as A, B, and M in Fig. 1). The spin xor device outputs three values by changing magnetization directions of two input electrodes A and B. Here, each input, i.e. 0 or 1, is defined by the magnetization of the FM electrode as shown in Fig. 1. The magnetization of the electrode M was kept 1. Spin polarized electrons were accumulated by a source current (I_s) under the FM electrodes A and B, and three different output states were measured on the electrode M depending on the relative configuration of the input magnetization. I_s was set to be 1.2 mA. Then, electrochemical potentials under electrode B for (0,0) and (1,1) of input states are modified to the equal each other by spin drift effect, resulting in three different output signals in electrode M. Fig. 2 shows the experimental demonstration of the spin xor operation with Si spin channel. Clear three outputs were obtained from the electrode M as requested for the MLG-operation. Detailed discussion is given in the presentation.

FW-05. Non linear spin dynamics induced in magnetically coupled CoFeB/Pt/NiFe trilayer. *M. Yafuso*[1] and T. Kimura[1,2] *1. Department of Physics, Kyusyu University, Fukuoka, Japan; 2. Research Center for Quantum Nano-Spin SCiences, Fukuoka, Japan*

In magnetic multilayers, the magnetic property is known to be modified by the interlayer coupling in magnetic multilayers. In addition, a ferromagnetic resonance (FMR) in one ferromagnetic layer produces the non-equilibrium spin currents injection into another ferromagnetic layer, leading to the modulation of the magnetization dynamics through the spin-transfer torque. Therefore, if the resonant frequencies for two ferromagnetic layers are close to each other, un-conventional magnetic features such as coherent resonance may be realized. For this purpose, here, we investigate the resonant magnetic property in a CoFeB/Pt/NiFe trilayer. The CoFeB/Pt/NiFe trilayer has been prepared by the magnetron sputtering under the base pressure of 10-8 Pa. The crystal and static magnetic properties have been evaluated by X-ray diffraction and vibrating-sample magnetometer, respectively. The resonant property was investigated by differential FMR measurement. Figure 1 shows the representative FMR spectra for the trilayer under GHz microwave irradiation. The FMR peaks for two ferromagnetic layers were clearly observed. For a comparison, the FMR spectra for the CoFeB/Pt and NiFe/Pt were plotted together with the trilayer's spectrum. We emphasize that the difference of the FMR field between two ferromagnetic layer becomes smaller than that for the monolayer case. More interestingly, as seen in Fig 2, the damping constant for the CoFeB layer is found to increase with increasing the microwave power. We analyze these unconventional features can be explained by taking into account the thermal spin injection due to the FMR heating.

FW-06. SMR based spin Hall measurement technique for in-plane magnetization. D. Kim[1], *J. Kim*[2], C. Yun[2], S. Joo[1], B. Lee[3] and K. Rhie[2] *1. Center for Nanometrology, Korea Research Institute of Standards and Science, Daejeon, The Republic of Korea; 2. Department of Display and Semiconductor Physics, Korea University, Sejong, The Republic of Korea; 3. Department of Physics, Inha University, Incheon, The Republic of Korea*

Spin Hall angle measurement technique is well developed at heavy metal/ferromagnet which has perpendicular magnetic anisotropy (PMA). However, a DC current based spin Hall angle measurement for in-plane anisotropy (IPA) has not been yet developed. We present a simple spin hall magnetoresistance (SMR) technique that measures spin Hall angle without any worry of artifacts which could be introduced in RF based spin Hall measurement. SMR signal is measured with applied field transverse to current. SMR peak shifts its maximum as applied current is increased, since spin Hall torque is added to the torque induced by transverse field. This shift yields spin Hall angle of heavy metal layer. For a Pt/CoFeB bilayer, we obtained $\theta_{SH}^{eff} = 0.045$, $l_s = 2.49$ nm, which is a reasonable value.

The R-H curve measured with two direct current flow in the Pt/CoFeB bilayer.

FW-07. Multi-State Magnetic Tunnel Junction with Inhomogeneous Magnetic Anisotropy for Neuromorphic Computing. *Z. Zhang*[1,2], G. Xu[1], Y. Zhang[1], K. Zhang[1], J. Nan[1], Z. Zheng[1], J. Wang[1], G. Wang[1], Y. Zhang[1,2] and W. Zhao[1] *1. Fert Beijing Research Institute, BDBC, School of Microelectronics, Beihang University, Beijing, China; 2. School of Electronics and Information Engineering, Beihang University, Beijing, China*

In this work, we propose a magnetic tunnel junction (MTJ) with inhomogeneous magnetic anisotropy (IMA) to conduct the multi-state magnetoresistance (MR) and spike-timing-dependent plasticity (STDP) function. In this MTJ, a series of regions with weaker perpendicular magnetic anisotropy (PMA) can be formed through treating the surface of the free layer, for example, irradiation [5]. As shown in Fig. 1, the PMA constant of the free layer is $6.5x10^5$ J/m^3 and the PMA constants of the inhomogeneous regions are from $3.0x10^5$ J/m^3 to $4.8x10^5$ J/m^3. By applying the COMSOL and Mumax[3] micromagnetic simulation platforms, the MR variation and magnetic dynamics induced by the current are investigated. When the working voltage is applied on the two terminals of the MTJ, the spin-polarization current will be injected into the free layer. The region with weaker PMA can be easier to be switched, which implies that these regions could be switched more quickly than the other regions with strong PMA. When the working voltage is removed, the partial switching state can be maintained due to the nucleation of domain walls and skyrmions, which leads to the multi-states of the MR. As illustrated in Fig. 2a, the resistance will increase with the augmentation of the working current. For example, eight stable resistance states are achieved by increasing the current density from $0.9x10^{10}$ A/m^2 to $6.5x10^{10}$ A/m^2. Moreover, we study the potentiation and depression process of the device. Fig. 2b shows that the relative resistance will increase with the duration time of the applied working current at the potentiation process, while the depression process can be implemented by switching the direction of the current. This time-dependent relative resistance implies that the proposed MTJ can emulate the STDP function [2-3]. This work provides a promising alternative for high-density memory and neuromorphic computing [4-7].

FW-08. Field-Free Control of Exchange Bias by Spin Polarized Currents. *H. Kim*[1], S. Je[2], D. Jung[3], K. Lee[3] and J. Hong[1] *1. Department of Emerging Materials Science, DGIST, Daegu, The Republic of Korea; 2. Center for X-ray Optics, LBNL, Berkeley, CA, United States; 3. School of Materials Science and Engineering, UNIST, Ulsan, The Republic of Korea*

In the trilayers structure consisting of ferromagnetic (FM) alloy CoFeB/antiferromagnetic (AFM) IrMn/heavy metal (HM) Pt layers, we show that the spin polarized current of HM layer can control the spin alignment state in the neighboring antiferromagnetic material as well as the corresponding exchange bias effect in the ferromagnet coupled to the antiferromagnet. To directly inject the spin current into AFM layer, the CoFeB (5 nm)/IrMn (8 nm) bilayers were deposited at room temperature by magnetron sputtering on a wire-patterned Pt(8 nm)/Ta(4 nm) without an external magnetic field. Initial development of the exchange bias effect in the as-deposited film was measured as the in-plane current was increased progressively. AFM domains of the as-deposited film are expected to be randomly oriented, which is reflected in the measured hysteresis loop measured by Magneto-Optical Kerr Effect magnetometer system as shown in Fig. 1(a) (1st hysteresis loop). Upon increasing the in-plane currents of 10 and 20 mA, hysteresis loops exhibit increased exchange bias and squareness representing the increased degree of spin axes alignment. After the injection of 30 mA current, the well-defined square hysteresis could be measured with H_E of -250 Oe. To confirm the exchange bias setting with the polarized spins, the pulse current of

opposite polarity (-I) was applied and the switching in the exchange bias was measured. Figure 1(b) and 1(c) display hysteresis loops for two exchange biased states after injecting the positive and negative pulse currents of ±30 mA in sequence resulting in H_E's, of -250 and +250 Oe, respectively as well as repeatedly switching the exchange bias. It was demonstrated that the spin currents from the SHE in the Pt layer could be injected into AFM layer and that the injected spins work to align the magnetic moments in the AFM. Use of spin current to control the magnetization of AFM is expected to enhance the applications of AFM in spintronics technology.

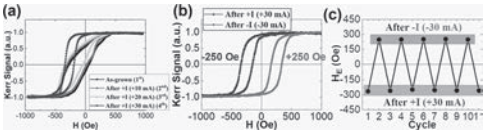

FIG. 1. (a) Change of magnetic hysteresis loops after injecting various magnitude of in-plane current. (b) Exchange bias reversal after the injection of pulse current in two opposite directions (±I), respectively. (c) Repeatable switching of the exchange bias

FW-09. Shape Anisotropy Effects on Spin-Torque Oscillators.

X. Chao[1], M. Jamali[1], *B.R. Zink*[1] and J. Wang[1] *1. University of Minnesota, Minneapolis, MN, United States*

Spin-torque oscillators are promising candidates for hard disk drive read head sensors, neuromorphic computing, and telecommunicationsdue to their frequency tunabilityby a direct current or a magnetic field [1-3]. A narrow linewidth and a large quality factor are of great importance for these applications. Previous studies have indicated that the spin-torque oscillation linewidth depends on the temperature, current, and in-plane field angle [4-6]. Here, we have investigated the spin-torque oscillations in MgO-based magnetic tunnel junctions (MTJs) and demonstrated the impact of the MTJ shape anisotropy on the oscillation linewidth as a function of current. Our experimental results might be significant for the device optimization.

GA-01. Biomedical Applications of Magnetic Nanoparticles: Remote Control of Cells. *J. Dobson*[1] *1. Biomedical Engineering, University of Florida, Gainesville, FL, United States*

The use of magnetic micro and nanoparticles for biomedical applications was first proposed in the 1920s as a way to measure the rheological properties of the cytoplasm. Since that time, particle synthesis techniques and functionality have advanced significantly. Magnetic micro and nanoparticles are now used in a variety of biomedical applications such as targeted drug delivery, MRI contrast enhancement, gene transfection, immunoassay and cell sorting. More recently, magnetic micro and nanoparticles have been used to investigate and manipulate cellular processes both *in vitro* and *in vivo*. This talk will focus on our work developing Magnetically Activated Receptor Signaling (MARS) – a magnetic nanoparticle–based technique for activating cell surface receptors and controlling the activity of biomolecules such as growth factors. The basic principles involve surface functionalization of magnetic nanoparticles (MNPs) with molecules targeting specific cell surface receptors. We have investigated antibodies targeting specific ion channels (e.g. TREK-1), surface receptors (e.g. PDGFRα & β) and peptides (e.g. RGD) targeting integrins. The particles bind to the receptors and, upon the application of a high-gradient external magnetic field, energy is transferred to the particles. The energy delivery induces a conformation change in the receptor, activating the specific biochemical signaling pathway associated with that receptor. By targeting specific receptors, we have been able to control ion channel activity, activate bone and cartilage matrix formation, and control the differentiation of human mesenchymal stem cells both *in vitro* and *in vivo*. We have developed this technology for applications in cell engineering/regenerative medicine and stem cell therapy The MARS technology has applications in regenerative medicine, drug screening and cell engineering.

GA-02. GMR Biosensing – A Versatile Biosensor Platform for Noninvasive Cancer Diagnostics. *S. Wang*[1,2] *1. Materials Science and Engineering, Stanford University, Stanford, CA, United States; 2. Electrical Engineering, Stanford University, Stanford, CA, United States*

Blood borne biomarkers, such as secreted proteins, circulating tumor DNA (ctDNA) and circulating tumor cell (CTC), have garnered much attention as minimally invasive cancer biomarkers for the "liquid biopsy" of tumors over the past decade. In this talk, we will describe three magnetic-nanoparticle-based diagnostic tools that have been used to assess cancer in peripheral blood successfully: 1) Stanford spin-off MagArray Inc. has launched REVEAL, a cancer-specific blood test that may aid clinicians in characterizing indeterminate pulmonary nodules (4-30mm) in current smokers aged 25-85. The REVEAL Score (Figure 1) is calculated using an algorithm based on the measurement of 3 clinical factors and 3 blood proteins associated with the presence of lung cancer. The GMR biosensor assay is optimized to rule out lung cancer with a negative predictive value (NPV) of ≥ 94%. 2) We have developed sequence-specific capture of hypermethylated or mutated genes of interest from cfDNA for early detection of colorectal cancer (CRC). With downstream analysis of polymerase chain reaction (PCR) products on giant magnetoresistive (GMR) biosensors and high-resolution melt analysis for a highly multiplexable assay, we have achieved a sensitivity of 0.01% mutant/methylated allele fractions. Our optimized assay has the ability to detect down to 16 pg (~4 genome equivalents) of hypermethylated DNA spiked-in to 3.5 mL of plasma. 3) We have utilized the MagSifter and immunocytochemistry combined with automated image analysis and machine learning techniques (random forest, transfer learning) for the enumeration and diagnosis/prognosis of non-small cell lung cancer (NSCLC) derived CTCs in patient samples, which are well suited for therapy selection and monitoring.

GA-03. Magnetic Particle Imaging and Guided Magnetic Hyperthermia. *P. Goodwill*[1], D. Hensley[1], Z. Tay[2], E. Yu[1], B. Kettlewell[1], R. Orendorff[1], M. Weber[1], K. Fields[1] and S. Conolly[2] *1. Magnetic Insight, Inc., Alameda, CA, United States; 2. Bioengineering, University of California, Berkeley, Berkeley, CA, United States*

Magnetic Particle Imaging (MPI) is an emerging tracer imaging technique that directly detects superparamagnetic iron oxide (SPIO) nanoparticles with exceptional contrast and high sensitivity at millimeter-scale resolutions[1]. MPI's contrast is similar to nuclear medicine, but without the complex workflow, safety, and half-life limitations of a radioactive tracer. These capabilities help fill in some of the gaps of current technologies and position MPI as complementary to anatomical imaging techniques such as MRI and X-ray/CT. The magnetic properties of the nanoparticle tracers seen by MPI define the technique's image resolution and sensitivity. This is because the MPI signal arises from the interaction between a magnetic nanoparticle, a strong magnetic field gradient, and a time varying magnetic drive field.[2,3]. Our group and others have begun testing MPI on animal models. We have used long circulating PEG coated nanoparticles to image the brain, detect cancers,[5] detect gut bleeds,[6] and visualize traumatic brain injury.[7] MPI's high sensitivity also makes it well suited for cell tracking [8-10]. For example, we have tracked therapeutic neural stem cells for three months[8] and the biodistribution of mesenchymal stem cells post administration.[9] In the future, we see opportunities for MPI tracking of immune therapies or immune cells to sites of inflammation such as cancer. Magnetic Fluid Hyperthermia (MFH) is a promising magnetic nanoparticle (MNP)-based therapy for diseases such as cancer [11,12]. Currently, MFH largely relies on nanoparticle localization (e.g., via direct injection of MNPs) for therapy localization. Here we describe how MPI and MFH can be combined into new instrumentation that incorporates strong field gradients to enable a second form of spatial localization, magnetic localization. Based on creation of a "field-free region" (FFR) using spatial gradient fields, this approach allows us to have flexible control over which MNPs are actuated (heated) anywhere within a subject to millimeter-scale accuracy [13-15]. We recently constructed prototype hardware for combined MPI-MFH (FIG 2), which uses gradient fields to spatially locate MNPs to be heated. MNPs coincident with the FFR are free to rotate and can be heated or actuated more generally, while MNPs away from the FFR are locked in place, unable to rotate. We are then able to target regions of interest (ROIs) located anywhere in the body while avoiding regions containing MNPs, such as the liver. A user's workflow would be comprised of determining ROIs using a first imaging modality, such as MPI, that this then co-registered to the MPI-MFH system. ROIs include target regions and regions that must be avoided in therapy. Using this information, a therapeutic trajectory is then generated and applied. A therapeutic trajectory generally consists of serially heating target regions. Beyond treatment of diseases using direct injection of MNPs into an ROI, we are also interested in enabling new RF actuation applications using systemic injection of MNPs followed by local targeting. For example, we can locally release drug [16] (break thermally labile bonds/nanocarriers) without requiring active chemical targeting. MPI combined with MFH enables targeted heating with tailored therapies while avoiding regions of MNP accumulation in healthy tissue, potentially opening the door to applications that do not require direct injection. Further, combining MPI image-guided MFH could one day be used in workflows similar to image-guided radiation therapy or image-guided high intensity focused ultrasound.

GA-04. Wireless Stress Sensor Based on Magnetoelastic Microwires for Biomedical Applications. *P. Marin*[1], D. Archilla[1], E. Navarro[1], J. López[1] and m. Vélez[2] *1. Instituto de Magnetismo Aplicado, Universidad Complutense de Madrid, Madrid, Spain; 2. Instituto de Catálisis, Consejo Superior de Investigaciones Científicas, Madrid, Spain*

In recent years, much interest and effort have been devoted to develop soft magnetic materials due to their technological potential [1]. Amorphous microwires are one of the most widely studied soft materials. They are

fabricated by means of extracting melt-spinning Taylor technique [2]. Those microwires are composed by a metallic core and a Pyrex cover both in the micrometer range. The ratio between the total diameter and the magnetic core, often called aspect ratio, is one of the key parameters of such microwires, since magnetic properties depend dramatically on it. Many properties of these materials have been deeply studied both from the point of view of the basic physics and the applications. This is the case of the giant magnetoimpedance effect [3], bistability, ferromagnetic resonance [4], and magnetoelastic resonance [5]. It is easy, also, to find much literature regarding microwave-related applications of microwires or microwire-based materials [6]. In the frequency range of GHz, some experimental and theoretical studies of the effect of the magnetization on the scattering properties of a single microwire have been developed [7]. This kind of work gives experimental evidence showing that the microwave scattering by a single microwire depends on the magnetic permeability with sufficient strength to be experimentally detected as an effect of the GMI. This dependence was used to show the potential of such microwire as a wireless field and/or stress sensor. Experimental results are followed by a theoretical approach where the influence of the microwire magnetic state in its microwave reflection features is taken into account. Besides these investigations on magnetic microwires, it should be stated that technological development has spurred the growing interest in the investigation of new biosensors aimed at simplifying present-day diagnostic methods and thereby improving medical care, so that it improves the quality of life of the patients and allows for outpatient treatment for a number of pathologies, avoiding unnecessary hospital admissions. Magnetic sensors are at the helm of technological development seen in this field over the last decades, offering numerous advantages attributed to their elevated sensitivity, reduced size, systems without the need for an external source of energy, and wireless connections. The use of wireless sensor network (WSN) technologies offers the possibility of developing implantable biomedical sensors allowing for the monitorization and follow-up of certain physiological parameters with precise and, up until now, unthinkable measurements. The aim of the present work is to show the physical fundamentals and the particular biomedical applications of magnetic microwires as wireless stress sensors. Two main applications will be described. On one side we proposed a flexible magnetic element able to be integrated both in artery and prosthesis suitable for wireless localized blood pressure monitoring. The sensor made of a ring of glass-covered magnetic microwire is simple and inexpensive and could be detected by means of a simple exciting and detecting set up able of emitting and detecting microwaves simultaneously applying a low-frequency magnetic field. The reflectivity of the microwire is determined by mechanical changes. In the experimental study, a piece of a cardiovascular prosthesis and a piece of an artery both sensed with a ring of magnetic microwire have been situated in a hydraulic setup simulating cardiovascular human circuit. Reflectivity changes of the sensor show its capability of measuring pressure variations in the circuit. The same kind of material and based also in the same kind of experiment has been used to wirels determine colagen density and stress distribution to determine stress distribution on bioreactors.

GA-05. Rotating magnetic fields in particle manipulation: Applications in attacking microbes, transport through tissues, and drug delivery.

L. Mair[1] and I. Weinberg[1] *1. Weinberg Medical Physics, Inc, North Bethesda, MD, United States*

Magnetic particles in the presence of rotating magnetic fields have the ability to impart mechanical shear to biological systems. Such shear can be used to induce separation of microbes from biofilms, enhance the transport of particles undergoing magnetophoretic transport through viscoelastic media, or enable directed transport via surface-mediated particle tumbling. In this talk we will review some of the most promising particles which rely on rotating magnetic fields for their application in medicine, and discuss three ways in which we are using rotating magnetic fields to enhance particle functions in future medical settings. Specifically, we will discuss using rotating magnetic particles to treat microbial biofilms, to enhance the transport of particles through brain tissue, and to deliver drugs to the targeted regions of the cortex and spinal cord *in vitro*. We will discuss the manipulation of hard magnetic particles in the frequency range of 1 Hz to 1000 Hz, and lay out paths forwards for further improving the application of magnetic particles in medicine, as well as how these manipulation schemes may interface with medical imaging modalities such as MRI and ultrasound.

GB-01. Spin Coherence Length in Ferrimagnetic CoGd. *Y. Lim*[1], B. Khodadadi[1], J. Li[2], D. Viehland[2] and S. Emori[1] *1. Physics, Virginia Tech, Blacksburg, VA, United States; 2. Materials Science and Engineering, Virginia Tech, Blacksburg, VA, United States*

Ferrimagnets consisting of transition metal and rare-earth metal sublattices are promising materials exhibiting efficient spin torque switching and ultra-fast magnetization dynamics [1,2]. Recently, a long transverse spin coherence length of >10 nm for the ferrimagnetic CoTb has been reported, despite the strong spin-orbit coupling of Tb [3]. Here, we determine the spin coherence length in CoGd which has weaker spin-orbit coupling than CoTb by using broadband ferromagnetic resonance (FMR) spin pumping on NiFe(7 nm)/Cu(4 nm)/CoGd(t nm) [4]. A coherent spin current is pumped from the resonantly excited NiFe layer and decoheres in the CoGd spin sink. Gilbert damping in the NiFe spin source is enhanced with spin decoherence in CoGd, such that the relationship between the measured damping and CoGd thickness provides direct insight into the spin coherence length in CoGd. Such a measurement shows that the CoGd layer actually acts as a good spin sink layer, as evidenced by a significant increase of damping (Fig 1). We also find that the enhanced damping saturates at the CoGd thickness of ~2 nm or less, comparable to the trend observed for ferromagnetic Co spin sink structures (Fig. 2). This suggests that the spin coherence length in ferrimagnetic CoGd layer is short, similar to that in ferromagnetic metals. Our results point to the need for further studies on the spin coherence length in ferrimagnets.

For decades, ferromagnetic materials have dominated the field of information technology. Recently, however, there has been a boost of new research in antiferromagnetic (AFM) materials. While these materials to-date have primarily been used to manipulate the magnetization reversal in adjacent ferromagnets through exchange bias, researchers today strive to harness the potential applications of antiferromagnetic materials for low power spintronics devices. In particular, new studies have proven AFM insulators to be excellent conductors of DC spin currents with intriguing temperature dependent transmission properties [1-4], however it is unclear to what extent coherent AC spin currents can be transmitted through an AFM material. We used X-ray detected ferromagnetic resonance (XFMR) [5-7] to study spin dynamics in $Ni_{80}Fe_{20}$/Ag/CoO/Ag/$Co_{75}Fe_{25}$ multilayers [8]. We were able to excite and observe AC spin current propagation from the $Ni_{80}Fe_{20}$ source to the $Co_{75}Fe_{25}$ sink layer at different temperatures around the CoO antiferromagnetic transition. By utilizing the element resolved phase information, we can unambiguously distinguish between different contributions to the magnetic excitation and identify the spin current signal. Our findings show that a coherent AC spin current is transmitted through antiferromagnetic CoO, and that transmission is strongly enhanced around its Neel temperature

(see Fig.1). Additionally, in order to investigate the mechanisms behind the AC spin current transmission through antiferromagnetic CoO in detail, we utilized linearly polarized x-rays for the dynamic XFMR measurements, enabling sensitivity to the spin axis rather than only the spin direction and allowing to observe spin excitations even in the absence of a net magnetic moment.

GB-03. Spin Polarization Characterization by Spin Hall Magnetoresistance in Ferrimagnetic Pt/$Co_{1-x}Tb_x$ bilayers. Y. Xu[1,2], J. Zhao[1,2] and *D. Wei*[1,2] *1. State Key Laboratory of Superlattices and Microstructures, Institute of Semiconductors, Chinese Academy of Sciences, Beijing, China; 2. Center of Materials Science and Optoelectronics Engineering, University of Academy of Science, Beijing, China*

Rare earth-transition metal (RE-TM) ferrimagnets have compensation of magnetic properties duo to the competition between antiferomagnetically coupled sublattices. They have received great attentions and are utilized in varies of spintronics devices. For example, the high efficiency of SOT has been realized in Pt/CoTb near the compensation point of magnetization for the small magnetic moments [1], while the fast domain wall motion is achieved in FeCo/Gd near the compensation point of angular momentum for fast dynamic behaviors [2]. The spin polarization (*P*), which is directly related to all spin related transport phenomena, could also exhibit the compensation. The possible degrade of *P* due to the compensation must be considered for any practical application of ferrimagnetic materials for spintronics devices. However it is barely mentioned probably due to the difficulty in probe the *P*. Here we provid a convenient way to characterizing the spin polarization of the RE-TM ferrimagnets via the spin Hall magnetoresistance (SMR). We study the spin transport behavior in Pt/$Co_{1-x}Tb_x$ bilayers by varying x and temperature, and an anomalous behavior of SMR near the temperature compensation point of magnetization (T_M) was observed. As the shown by Fig.1, the R_{AH} has a sharp sign change at T_M =238 K, where the AMR also vanishes. In contrast, the SMR has a minimum below T_M. As shown by Fig. 2, we attribute this phenomenon to the compensation and dramatical change of *P* of $Co_{1-x}Tb_x$ alloy, which modulate the degree of the absorption for the longitudinal spin current flowing from Pt layer. The spin polarization was extracted from the SMR and plotted in Fig.2 (b), and the temperature compensation point of spin polarization (T_P) was determined to be at T_P =220 K.

Scalable and energy efficient spin-orbit logic has been very recently pointed out by Intel as technologically suitable computing alternative to CMOS devices [1]. It comprises an electrically driven memory element, with a spin-orbit-based detection of the state performed by spin-to-charge conversion. In this talk, we show that the *ferroelectric Rashba semiconductor Germanium Telluride* [2] offers memory as well as both electric and spin-orbit readout in a silicon-compatible semiconductor. Indeed, GeTe possesses giant bulk *Rashba-like spin texture*, which can be reversed by its non-volatile *ferroelectricity*, paving the way to the electric control of *spin-to-charge conversion*. We have already proved the existence of two opposite spin textures in GeTe thin films, corresponding to opposite ferroelectric states [3]. Here, we first demonstrate the *switchability of the ferroelectric polarization* in films of GeTe *through gate electrodes,* enabling the *electric control of charge transport and spin-to-charge conversion*. The switching is obtained through voltage pulses and measured as resistance variation of metal/GeTe heterojunctions. The modulation of resistance is due to the different local band bending induced at the metal/semiconductor interface by the screening of the polarization charge. Piezoresponse Force Microscopy correlated the microscopic distribution of ferroelectric domains with the electrical resistivity of the junction. The low-voltage control is provided by the coercive voltage (3-7 V), with *modulation of resistivity up to 800%.* The switching is robust, with *endurance up to 10^5 cycles*. The number of subsequent voltage pulses, their amplitude and duration, as well as ferroelectric minor loops, enable a continuous distribution of intermediate resistive states. The control over ferroelectricity enables the electric control of spin-to-charge interconversion. The latter is studied by spin Hall magnetoresistance [4] and spin pumping [5] in Fe/GeTe heterostructures [6], where the magnetic layer serves as detector or injector of spins, respectively. Finally, we show how to obtain *carrier compensation* of the intrinsic and degenerate *p*-doping of GeTe, keeping alive Rashba effect and ferroelectricity, towards the realization of single-compound spin-orbit logic devices.

GB-05. Effects of a Molecular C_{60} Interface on the Spin-dependent scattering of YIG/Pt. *S. Alotibi*[1], M. Ali[1], B. Hickey[1] and O. Céspedes[1] *1. University of Leeds, Leeds, United Kingdom*

We have studied the Spin Hall magnetoresistance (SHMR) in YIG/Pt interfaces with and without a C_{60} overlayer. The SHMR is generated by a current flow in thin (~nm) heavy metal layers with a large spin orbit coupling (SOC) deposited on a magnetic insulators. A spin current (Js) is generated in the metallic layer, perpendicular (⊥) to the electronic current. When the direction of the magnetisation (M) in the ferrimagnet is parallel to Js, the spin current is reflected from the interface and back into the metal due to the inverse spin Hall Effect. However, if the direction of the M and spin polarisation are ⊥, the Js propagates into the insulator as spin waves. Thus, the SHMR can be observed by rotating the M vector. This effect has generated large interest and it is critical in the study of spin orbit scattering and its applications, e.g. for devices such as spin torque MRAM [1, 2]. At metallo-molecular interfaces, the electronic properties of both materials are changed due to charge transfer and hybridisation. Previously, it has been shown that this can lead to the emergence of spin ordering.[3]. This interfacial effect is also critical in spin filtering and spin transport effects.[4]. Here, we have studied the effect of C_{60} interfaces on the SHMR and low field, anisotropic magnetoresistance (AMR) generated in YIG/Pt. We find that conducting interface formed between C_{60} and Pt layers results in lower resistance%. The SHMR of Pt layers between 1.5 and 5 nm is enhanced by up to a factor 6 with C_{60} see Fig.1. Thus, the spin Hall angle Θ_{SH} is bigger for Pt/C60 than Pt, which we attribute to an enhancement of the SOC by the C_{60}. The AMR at fields ≤10 mT can be correlated with the M of the YIG surface. This low field AMR is also enhanced by the C_{60}, in particular when the field is applied out of plane see Fig.2. This is all consistence with an enhanced spin orbit scattering in Pt induced by a C_{60} overlayer, and molecules could then be used to improve the performance of spin orbit torque devices.

GB-06. Large Anomalous Hall Effect in Amorphous $Fe_{1-y}Co_ySi$ Thin Films. *J. Karel*[1,2], D. Bouma[3,4], S. Bennett[1], A. Nguyen[1] and F. Hellman[3,4]
1. Materials Science and Engineering, Monash University, Melbourne, VIC, Australia; 2. ARC Centre of Excellence in Future Low-Energy Electronics Technologies, Monash University, Melbourne, VIC, Australia; 3. Materials Science Division, Lawrence Berkeley National Lab, Berkeley, CA, United States; 4. Physics Department, University of California Berkeley, Berkeley, CA, United States

Magnetoresistive random access memory (MRAM) utilizing spin orbit torque (SOT) based switching has emerged as a promising non-volatile memory candidate, and amorphous materials offer a unique prospect with respect to this technology. They lack long range order, and theory has predicted that disorder may lead to an enhancement in spin orbit torques.[1,2] Moreover, amorphous materials are extremely tolerant to defects, meaning less stringent manufacturing requirements and thus lower costs. This work will present a study of the anomalous Hall effect (AHE) in a series of amorphous $Fe_{1-y}Co_ySi$ ($0<y<1$) thin films. The mechanisms used to describe the spin Hall effect (SHE) borrow directly from the physics of the AHE; therefore, a large AHE may point to a large SHE and a potential application in SOT-MRAM. A large AHE was found in amorphous $Fe_{1-y}Co_ySi$ thin films with y = 0-0.3 (representative plot Figure 1a). The magnitude of the Hall resistivity is larger than previously reported in the bulk crystalline analog (e.g. $Fe_{0.9}Co_{0.1}Si$ ~2μΩcm at 5K).[3] This large effect persists up to room temperature. Figure 1b shows that the magnetic moment is also larger than previously reported in bulk crystalline $Fe_{1-y}Co_ySi$ (e.g. y=0.1 M_s~50 emu/cm^3).[3] Similar enhancements in magnetization have been reported in amorphous Fe_xSi_{1-x}($0.45<x<0.65$) thin films in comparison to the crystalline analogue.[4] The origins of this large AHE will be discussed. Specifically, we will show that the results suggest the intrinsic mechanism (e.g. non-zero Berry curvature) may play an important role. In these amorphous materials, the possible dependence of the AHE on the intrinsic mechanism is remarkable because it indicates a local atomic level description of a Berry phase in a system that lacks lattice periodicity.

GB-07. A first-principles study on the spin anomalous Hall effect of $L1_0$-type alloys. *Y. Miura*[1], K. Nawa[1] and K. Masuda[1] *1. Research Center for Magnetic and Spintronic Materials(CMSM), National Institute for Materials Science(NIMS), Tsukuba, Japan*

Recently, spin anomalous Hall effect (SAHE) which is spin Hall effect (SHE) in ferromagnetic metals has attractive much attention [1,2]. SAHE can generate spin orbit torque (SOT) to magnetization of another ferromagnetic layer through the non-magnetic spacer in magnetic junctions. SOT magnetization switching by the SAHE has an advantage compared with SOT switching by SHE of nonmagnetic metals, because the direction of spin quantum axis of injected electrons related to direction of torque can be controlled by the magnetization direction of the ferromagnetic layers. According to the previous theoretical study[1], the most important parameter to realize large SOT in ferromagnetic layers is a ratio of spin anomalous Hall conductivity (SAHC) σ_{xy}^{spin} to anomalous Hall conductivity (AHC) σ_{xy}, i.e., $\zeta=\sigma_{xy}^{spin}/\sigma_{xy}$. In this work, we investigate and discuss the intrinsic SAHC and AHC on the basis of the firs-principles calculations and the linear response theory. We focused on the $L1_0$-type FePt and FeAu alloys. We assumed that the magnetization is directed parallel to the [001] direction (c-axis), the electric field is applied along [110] direction of fcc lattice, and Hall current flows perpendicular to them. Fig. 1 shows the spin-resolved AHC of $L1_0$-FePt and FeAu. We found that FePt has large AHC σ_{xy}=761[Ω^{-1}cm^{-1}], and SAHC of FePt is σ_{xy}^{spin}=498[Ω^{-1}cm^{-1}]. The SAHC is smaller than that of the AHC, resulting in the small ζ less than 1. This is attributed to relatively large spin-flip AHC $\sigma_{xy}^{\downarrow\uparrow}$ due to strong spin-orbit interaction of Pt. On the other hand, SAHC of FeAu is σ_{xy}^{spin}=472[Ω^{-1}cm^{-1}], which is much larger than that of the AHC σ_{xy}=79[Ω^{-1}cm^{-1}], resulting in the large ζ=5.9. The large ζ in FeAu is originated in the small spin-flip AHC $\sigma_{xy}^{\downarrow\uparrow}$ due to the absence of majority-spin local density of states of Au *d* orbitals of FeAu. This work was supported by Grant-in-Aids for Scientific Research (S) (JP16H06332) from the JSPS.

GB-08. Nonlinear planar Hall effect. P. He[1], *S. Zhang*[2], D. Zhu[1], S. Shi[1], O. Heinonen[2], G. Vignale[3] and H. Yang[1] *1. Department of Electrical and Computer Engineering, and NUSNNI, National University of Singapore, Singapore; 2. Materials Science Division, Argonne National Laboratory, Lemont, IL, United States; 3. Department of Physics and Astronomy, University of Missouri, Columbia, MO, United States*

An intriguing property of a three-dimensional (3D) topological insulator (TI) is the existence of surface states with spin-momentum locking, which offers a new frontier of exploration in spintronics. Here, we report the observation of a new type of Hall effect in a 3D TI Bi_2Se_3 film [1]. The Hall resistance scales linearly with both the applied electric and magnetic fields and exhibits a π/2 angle offset with respect to its longitudinal counterpart, in contrast to the usual angle offset of π/4 between the linear planar Hall effect and the anisotropic magnetoresistance. This novel nonlinear planar Hall effect originates from the conversion of a nonlinear transverse spin current to a charge current due to the concerted actions of spin-momentum locking and time-reversal symmetry breaking, which also exists in a wide class of noncentrosymmetric materials [e.g., WTe_2 and the 2DEG on the $SrTiO_3$(001) surface] with a large span of magnitude. It provides a new way to characterize and utilize the nonlinear spin-to-charge conversion in a variety of topological quantum materials. We will also reveal the correlation

between nonlinear planar Hall and the novel bilinear magneto-electric resistance (BMER) previously discovered in 3D topological insulators [2,3] and at the $SrTiO_3$(111) surface [4]. The work by P. H, D. Z, S. S, and H. GB-09. Interface Magnetic Property Impact on Spin Injection and Pumping in YIG/Ultrathin Magnetic layer/Pt Systems. *H. Yuasa*[1], T. Niimura[1], Y. Kurokawa[1], R. Weber[2] and A. Berger[2] *1. Kyushu University, Fukuoka, Japan; 2. nanoGUNE, San Sebastian, Spain*

The ultrathin magnetic layers were inserted into the interface between YIG and Pt so as to control spin pumping and injection. Although we reported that the spin Seebeck effect (SSE) voltage was increased by the ultrathin magnetic layer insertion between YIG and Pt [1], the reasonable explanation has not been given yet. In this report, we additionally measured spin Hall magnetoresistance (SMR) which are originated from spin pumping, having reciprocal relationship with spin injection generating SSE voltage. The sample structure is SiO_2 wafer/YIG 50 nm/M 0.3 or 0.6 nm/Pt 5 nm where M denotes Cr, $Ni_{80}Fe_{20}$, $Co_{90}Fe_{10}$, $Fe_{50}Co_{50}$ and Fe. As shown in Fig. 1, spin Seebeck coefficient S and ΔR of SMR have the strong correlation as expected, indicating the spin pumping and spin injection were equally controlled by the inserted layers. In order to reveal the reason of SSE and SMR improvement, it is necessary to study magnetic properties of the inserted layers. Figure 2(a) shows the ΔR as a function of bulk-M_s of inserted layers in literature. Although the higher Ms leads the higher ΔR as expected from [2], the M_s is not an actual magnetization here. Unfortunately, the inserted layers are too thin to measure the actual magnetization by macroscopic M-H loop. Therefore, we applied Generalized Magneto-Optical Ellipsometry (GME) to investigated the magnetic properties of ultrathin inserted layers, since GME is sensitive to the surface and the ultrathin inserted layers and YIG possess the different optical constants [3]. Figure 2(b) is ΔR dependence on |α|, where |α| is the off-diagonal element of the reflection matrix due to the longitudinal Kerr effect and denotes a magnetization near the surface. ΔR was obviously decreased as increasing |α|, which is opposite to the relationship of ΔR and bulk-Ms in Fig. 2 (a). Taking into account YIG effect, it is important to extract the original magnetization of inserted layer from |α|. It is the important step to discuss the interface magnetic property impact on spin injection and pumping.

GB-10. Spin transport in a magnetic insulator with charge current induced zero effective damping. *M. Althammer*[1,2], T. Wimmer[1,2], L. Liensberger[1,2], S. Geprägs[1], M. Weiler[1,2], R. Gross[1,2] and H. Huebl[1,2] *1. Walther-Meißner-Institut, Bayerische Akademie der Wissenschaften, Garching, Germany; 2. Physik-Department, Technische Universität München, Garching, Germany*

Pure spin currents, i.e. the flow of angular momentum without an accompanying charge current represents a new paradigm in the field of spintronics. Most importantly, pure spin currents can be transported by fermions, i.e. by electrons, in electrical conductors as well as by bosons, i.e. by quantized magnetic excitations, in magnetically ordered insulators. Interestingly, heterostructures consisting of spin-orbit coupled metals with magnetically ordered insulators allow to investigate pure spin current transport in both regimes and their interconversion at the interface. We here present our recent experiments [1] on the control of magnon spin transport via a DC charge current injected pure spin current. To this end, we utilize three electrically isolated platinum (Pt) electrodes deposited on an ultrathin yttrium iron garnet (YIG) film. Employing all-electrical injection and detection mechanisms, we provide evidence for efficient spin transport manipulation by a DC charge current in these devices. At large charge current densities we can compensate the effective magnetic damping in the YIG layer underneath the central Pt strip. We then investigate the magnon spin transport through this volume by electrical magnon transport experiments utilizing the remaining two Pt strips to the left and right of the central Pt strip. From these measurements we extract a zero resistance spin transport in the regime of magnetic damping compensation. We discuss the origin of the observed non-linear effects and threshold behavior in the frame work of magnon Bose-Einstein condensation [2] induced by a DC charge current. Above a critical DC current, the magnon density is sufficient to form a magnon condensate and eventually trigger auto-oscillations of the magnetization. We compare these different phases to our diffusive magnon transport experiments to explain the observed a zero-resistance state below the injector strip.

GB-11. Mutual spin-pumping in the antiferromagnetically exchange coupled Py/Ru/Py trilayers - dependence on the external magnetic field. *S. Sorokin*[1,2], R. Gallardo[3], K. Lenz[1], C. Fowley[1], G. Atcheson[4], J. Fassbender[1], J. Lindner[1] and A.M. Deac[1] *1. Institute of Ion Beam Physics and Materials Research, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany; 2. Institute for Physics of Solids, Technische Universität Dresden, Dresden, Germany; 3. Universidad Tecnica Federico Santa Maria, Valparaíso, Chile; 4. School of Physics, Trinity College Dublin, Dublin, Ireland*

We investigate magnetization dynamics in asymmetric interlayer exchange coupled Py/Ru/Py trilayers using vector network analyzer-based ferromagnetic resonance (VNA-FMR) and electrically-detected ferromagnetic resonance (ED-FMR). Two different FMR modes are observed, as expected for coupled systems, and the two above mentioned approaches are compared. We show, that, unlike in the spin-flop and saturated regimes, which are fairly well understood, in the field range where the two layers remain antiferromagnetically (AF) oriented in static measurements, the changes exhibited in the frequency-field dependence connected only with the changes in the dynamical terms in the coupled Landau-Lifshitz-Gilbert (LLG) equations. On the other hand, it was predicted that the two modes have different linewidth, due to mutual spin-pumping between the layers [1, 2]. This was to-date experimentally confirmed for symmetric Py/Ru/Py synthetic antiferromagnets, in the saturated regime, where the linewidth difference between the modes was practically field-independent [3]. Here, we show, that by changing magnetic field in the AF regime, one can tune the linewidth difference between the modes in case of asymmetric layers. Moreover, a connection between the non-monotonic frequency-field dependence and the variation of the linewidth difference in the AF regime is established, which to our knowledge, was not previously reported in the literature.

GB-12. Effect of Interface Roughness Spin Scattering on Spin-current Transport in YIG/NiO/Pt Heterostructures. *L. Jin*[1], H. Zhang[1], Z. Zhong[1] and K. Jia[1] *1. University of Electronic Science and Technology of China, Chengdu, China*

In this work, the spin current transport in YIG/NiO/Pt heterostructures were investigated by spin Hall magnetoresistance and inverse spin Hall effect (ISHE) measurements. By inserting antiferromagnetic insulator NiO, the magnetic proximity effect on Pt atoms induced by YIG and anomalous spin Hall voltage can be efficiently blocked. The ferromagnetic resonance and ISHE measurements verify that the ferromagnetic/antiferromagnetic exchange coupling inhibits the transmission of the spin current at the YIG/NiO interface when the NiO layer is thick. Atomic force microscopy and Spherical aberration corrected transmission electron microscopy prove that the strong interface roughness spin scattering between NiO and Pt can largely improve the inverse spin Hall voltage and spin Hall magnetoresistance when the NiO layer is thin or even discontinuous. This interface roughness related spin scattering mechanism based on antiferromagnetic materials is a new discovery and have great potential in the construction of high-speed spintronic devices.

GB-13. Anisotropic Enhancement of Spin current in Epitaxial Co based Co/Pt/Co trilayer. *J. Ryu*[1], R. Thompson[2], J. Park[1], M. Kohda[2,3], J. Yuk[1], J. Nitta[2,3] and B. Park[1] *1. Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Daejeon, The Republic of Korea; 2. Materials Science, Tohoku University, Sendai, Japan; 3. Spintronics Research Network, Tohoku University, Sendai, Japan*

Spin currents generated by strong spin-orbit coupling in ferromagnet(FM) and heavy metal(HM) provide intriguing physical phenomena. For conventional spin orbit toques(SOTs) in FM/HM systems, the generated spin current is polarized along an in-plane direction[1,2]. In FM/HM/FM trilayers, however, SOTs induced by out-of-plane polarized spin currents are reported, enabling field-free magnetization switching[3,4]. Here, the spin currents in epitaxial Co based Co/Pt/Co trilayers are investigated. We find spin currents present anisotropic enhancements depending on the magnetization of the epitaxial Co. In-plane magnetized Co(4.0nm) is epitaxially grown on an MgO(110) substrate, as the bottom Co has its *c*-axis aligned with MgO[001] (Fig.1(a)) [5]. Therefore, epitaxial Co shows strong magnetocrystalline anisotropy in-plane, where the easy axis and the hard axis correspond to [001] and [-110], respectively (Fig.1(b)). Ta(0.5nm)/Pt(1.5nm)/Co(0.6nm) is subsequently deposited, leading to the perpendicular anisotropy of the top Co layer. Harmonic Hall measurements are performed to investigate spin currents for injected current J_c directions along the easy and hard axes. At an azimuthal field angle of φ_B=0° and 90°, a conventional 2nd harmonic voltage V_{2f} for damping-like and field-like SOT appears for J_c along the easy axis. Strikingly, however, the amplitude of V_{2f} is drastically increased when the external field is applied at φ_B=120°(300°)(Fig.2(a)). Moreover, for J_c along the hard axis, the enhanced is observed at φ_B=30°(210°). The peak of V_{2f} as a function of φ_B in Fig.2(b) clearly suggests that the spin currents generated in epitaxial Co/Pt show an anisotropic enhancement of SOT depending on the bottom Co magnetization state rather than by conventional SOTs in the Pt/Co top layer. Furthermore, field-free switching is achieved for devices aligned with the angle of maximum enhancement of the spin current.

GC-01. High Speed and Low Energy Spin-Transfer Switching of Perpendicular Magnetic Tunnel Junction Nanopillars at Low Temperature. *L. Rehm*[1], G. Wolf[2], B. Kardasz[2], M. Pinarbasi[2] and A.D. Kent[1] *1. Center for Quantum Phenomena, Department of Physics, New York University, New York, NY, United States; 2. Spin Memory Inc., Fremont, CA, United States*

Thermal fluctuations play a central role in the understanding of spin-transfer induced magnetization switching, both the switching time scale and probability. However, systematic spin-transfer switching experiments as a function of temperature have not been conducted on perpendicularly magnetized magnetic tunnel junctions (pMTJs). Here we investigate switching characteristics of 40, 50, and 60nm diameter circular pMTJ nanopillars with CoFeB free layers over a broad range of time scales τ from ms to ns. Figure 1 shows the switching characteristics of a 40nm pMTJ at several temperaturesfor a slow continuous voltage ramp. The resistance in the antiparallel state (R_{AP}) increases significantly as the temperature decreases from room temperature to 4K, resulting in a factor of two increase in TMR (to 214%), while the P state resistance is nearly independent of temperature. Also, the switching voltages increase at low temperatures and R_{AP} decreases with read bias voltage, consistent with the voltage bias opening conduction channels by creating magnetic excitations. We demonstrate pulsed switching from 295 down to 4K with pulse durations below 5ns, thereby probing the ballistic spin-torque switching regime. Figure 2 shows switching phase diagrams of the same device at 4K. We observe reliable sub-ns switching for both switching directions with characteristic time scales of 0.94 and 1.03ns for AP→P and P→AP direction, respectively. This results in low write energies of 66 (AP→P) and 270 fJ (P→AP), comparable to write energies found in metallic spin-valves with a Py free layer [1]. Surprisingly, we observe a speed-up of the reversal in both switching directions at 4K compared to the 295K data at the same overdrive V/V_c. We will also present measurements in the thermally assisted regime ($\tau \geq 10\mu s$), extracting the thermal stability factor and characteristic switching voltage for several temperatures.

GC-02. Low Tc, low Ms CoFeBX alloy free layers for perpendicular STT-MRAM. *S. Couet*[1], S. Rao[1], J. Swerts[1], S. Van Beek[1], K. Sankaran[1], R. Carpenter[1], S. Mertens[1], W. Kim[1] and G.S. Kar[1] *1. IMEC, Leuven, Belgium*

Current STT-MRAM technology relies on MgO/CoFeB based magnetic tunnel junctions (MTJs) for high TMR, high (interfacial) PMA and low switching current [1,2]. CoFeB as a magnetic material has however limited room to modify its properties such as saturation magnetization Ms, damping α or Curie temperature Tc. We have doped the CoFeB alloy with variable quantity of heavy metals such as Ta & W. This enables to reduce and control the Ms and Tc of thick (~20nm) CoFeBX films, as shown in Fig. 1. The low heavy metal content ensures that damping remains low for efficient spin transfer torque. 2-3nm thin CoFeBX alloys have been integrated as free layer material in a state-of-the-art 400C compatible bottom pinned STT-MRAM stack. These CoFeBX alloys retain similar junction interface properties (TMR, RA, PMA) as CoFeB, indicating the new alloys mostly behave like CoFeB, albeit with lower Ms and Tc. Indeed the alloy is showing a faster moment reduction with temperature, as shown in Fig. 2. Comparing the standalone thick (20nm) vs MTJ integrated thin film (2-3nm), a shift of the Tc to slightly higher value (for the thin integrated film) is visible. This possibly is being induced by the different interfaces and reduced thickness. The lower Ms enables to stabilize PMA in relatively thick films of about 3-4nm using a double MgO free layer structure. The electrical performance (retention & switching dynamics) of scaled 40nm diameter devices will be presented, highlighting the potential benefits of these alloys for STT-based MRAM.

GC-03. Superlattice MTJ for Energy Efficient STT-MRAM. A. Sharma[1], A. Tulapurkar[1] and *B. Muralidharan*[1] *1. Electrical Engineering, Indian Institute of Technology Bombay, Mumbai, India*

Superlattice structures offer tremendous possibilities to utilize non-trivial resonant tunnelling physics for device applications[1]. In the recent work [2], in the context of spintronic devices, superlattice structures designed to exhibits anti-reflective resonant physics has been proposed to enhance the performance magnetic tunnel junctions (MTJ). Here, we present an energy efficient spin transfer torque-magnetic random access memory (STT-MRAM) device based on anti-reflective superlattice magnetic tunnel junctions(AR-SLMTJ). Utilizing the non-equilibrium Green's function spin transport formalism self-consistently coupled with stochastic magnetization dynamics, we predict that cells comprising of AR-SLMTJ structures, as shown in Fig. 1(a), are capable of exhibiting an ultra-high peak tunnel magnetoresistance (TMR»5 * 10^4 %) and a large spin transfer torque in comparison with a traditional trilayer MTJ cell. Owing to the large spin current injection efficiency in the AR-SLMTJ, the switching bias voltage reduces significantly in these devices. It can be seen clearly from Fig. 1(b) and (c) that for nearly same switching time the AR-SLMTJ based STT-MRAM cell is nearly 1200% more energy efficient than a traditional trilayer MTJ based STT-MRAM cell. The reason for this energy efficient switching lies in band pass spin filtering physics accompanied in the AR-SLMTJ devices.

GC-04. Perpendicular Magnetic Tunnel Junctions with Low M_s Free Layer for Reduction of STT Switching Current. *K. Nakamura*[1], H. Maehara[2,3], H. Tomita[1,3], K. Nagasaka[1,3], S. Bosu[1,3], Y. Tanaka[1], A. Gomi[1] and N. Watanabe[1] *1. Tokyo Electron Technology Solutions Limited, Nirasaki, Japan; 2. Tokyo Electron Limited, Akasaka, Japan; 3. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan*

MgO based perpendicular magnetic tunnel junctions (p-MTJs) have been developed for spin-transfer torque magnetic random access memory (STT-MRAM) applications [1-3]. Recently, STT-MRAM is expected to be adopted to last level cache (LLC) as a replacement for SRAM because of the feature such as non-volatility and excellent scalability. However, one major challenge of STT-MRAM to overcome for LLC application is to reduce the write current in terms of low power consumption. Reduction of saturation magnetization (M_s) and damping constant of free layer of the p-MTJ is generally effective for reduction of the write current [4,5]. Moreover, realization of an efficient free layer is requisite for low write current without sacrificing other MTJ properties (e.g. MR ratio and annealing stability). In this study, we demonstrated p-MTJs with low M_s free layer having high annealing stability for reduction of STT switching current. The p-MTJs were prepared on thermally oxidized Si wafers using high vacuum magnetron sputtering system (Tokyo Electron EXIM™). All metallic layers were deposited using

dc sputtering and MgO tunnel barrier layer was fabricated by natural oxidation process after metallic Mg layer deposition. Fig. 1 (a) and (b) show MR ratio and STT switching properties of p-MTJs annealed at 400°C for 1h, respectively. Areal moment ($M_s t$) of the low M_s free layer is 142 μemu/cm^2, whereas that of conventional composite free layer comprising CoFeB and metallic spacer layer is 224 μemu/cm^2. Critical current (I_{c0}) of p-MTJ with the low M_s free layer is about 50% lower than that of p-MTJ with the composite free layer, while there is no significant difference in MR ratio between them. MR ratio of 174% and I_{c0} of 41 μA were obtained at resistance area product (RA) of 5.1 Ωμm^2 in sub-40 nm sized p-MTJ with the low M_s free layer. Low write current can be achieved without sacrificing MR ratio by employing the low M_s free layer. More detailed results will be discussed in the presentation.

GC-05. How to tilt magnetic moments in STT-MRAM devices. *Z. Nunn*[1] and E. Girt[1] *1. Simon Fraser University, Burnaby, BC, Canada*

In spin transfer torque magnetic random access memory (STT-MRAM) devices, memory writing is most efficient when there is a non-collinear alignment between the free and fixed layer [1]. All perpendicular STT-MRAM structures require it's collinear symmetry to be broken with thermal fluctuations, leading to probabilistic switching, large current densities and/or switching times [2]. We discovered a new form of interlayer coupling that can reliably control the relative angle of adjacent magnetic moments [3]. This coupling provides stable tilted magnetic moments at any angle out of the plane of the device which allows for the creation of novel STT-MRAM structures that have superior operational performance in comparison to all perpendicular STT-MRAM structures [4]. The design shown in Fig.1 has all the benefits of perpendicular STT-MRAM with the advantage of an initial offset of magnetizations adjacent to the tunneling magnetoresistance (TMR) layer, giving an instant STT when current is applied. Our results show that this new from of interlayer coupling can be fully integrated into MRAM devices as the coupling materials can be annealed at high temperatures, are fully conductive, and can be scaled to nanometer size devices. Non-collinear coupling is a when the relative angle of adjacent magnetizations is controlled using interlayer exchange coupling as shown in Fig. 1. Due to the isotropic nature of interlayer coupling, non-collinear coupling can be combined with ferromagnetic layers that have perpendicular anisotropy to create stable tilted magnetizations. Ferromagnetic layers of Co, Fe, Ni and their alloys can be directly non-collinear coupled using a RuFe interlayer. Fig. 2 shows the measured coupling angle in a Co|RuFe|Co structure as a function of RuFe thickness and composition. For thicknesses between 0.5-0.8 nm the coupling angle was found to be constant, which from a fabrication point of view is very important in order to utilize non-collinear coupling in applications as small thickness errors do not contribute to large changes in coupling angle.

GC-06. Ultrathin Perpendicular Free Layers for Lowering the Switching Current in STT-MRAM. *T. Santos*[1], N. Smith[1], G. Mihajlovic[1], J. Li[1], M. Carey[1], J. Katine[1] and B. Terris[1] *1. NVM Research, Western Digital, San Jose, CA, United States*

A primary challenge in the creation of a commercial spin-transfer torque magnetic random access memory (STT-MRAM) technology is lowering of the switching current needed to switch the magnetization of the free layer when writing a bit in the MRAM cell, while maintaining high thermal stability for data retention. Because the switching current is directly proportional to the thickness of the free layer, reducing the free layer thickness is a route toward lowering the switching current. The typical free layer stack consists of double MgO-CoFeB interfaces and a non-magnetic, metallic layer inserted within the free layer [1]. Reducing the free layer thickness is challenging, as the magnetic properties, such as M_S, degrade for very thin perpendicular free layers, which will lower thermal stability, and the damping parameter α often increases [2], which is expected to increase the switching current. In addition, tunnel magnetoresistance decreases for very thin CoFeB [3]. We have modified the free layer design such that we can reduce the free layer thickness well below 1.4nm while minimizing the magnetic dead layer, so that high $M_S > 1500$ emu/cm^3, and thus high thermal stability, is maintained. Our ferromagnetic resonance (FMR) measurements (see Fig. 1) show that in comparison to a free layer of equivalent thickness using the typical stack design, our modified stack has higher effective perpendicular anisotropy field $H_{K\perp}$, damping α as low as 0.004, and a 3-fold reduction in the inhomogeneous broadening ΔH (which is due to anisotropy non-uniformity), as low as ~ 0.1 kOe. We will discuss these improvements to the free layer properties. Such high-quality, ultrathin free layers are promising for lowering the switching current.

GC-07. Spin-transfer torque MRAM with reliable 5 ns writing. *G. Hu*[1], J. Nowak[1], M. Gottwald[1], J. Sun[1], d. Houssameddine[1], J. Bak[1], S. Brown[1], P. Hashemi[1], Q. He[1], J. Kim[1], C. Kothandaraman[1], G. Lauer[1], H. Lee[1], T. Suwannasiri[1], P. Trouilloud[1] and D. Worledge[1] *1. IBM T J Watson Research Center, Yorktown Heights, NY, United States*

Spin-transfer torque magneto-resistive random access memory (STT-MRAM) is an emerging non-volatile memory with a unique combination of high speed, and high endurance due to its unique switching mechanism. Significant investment and progress have been made in recent years with product demonstration from all major semiconductor manufacturing companies [1-5]. Despite its potential for high speed applications, there has been no demonstration of reliable switching of STT-MRAM devices below 10 ns pulse-width and the first generation embedded STT-MRAM products are limited to applications with write pulses longer than 50 ns. We report reliable 5 ns switching of STT-MRAM devices by demonstrating 100% write-error-rate (WER) yield at 1e-6 write-error floor of 256 devices at a nominal device size of 43 nm and a resistance area product (RA) = 11 Ω-μm^2. These devices show steep WER slope (20 mV/decade) tight distributions (1 sigma of 3.6% and 4.5% for write 0 and write 1 respectively at WER = 1e-6) and clean WER curves with no free layer related anomalies. A single device was demonstrated to have less than 1e-10 write-error rate with 5 ns write pulse. Promising 3 ns switching performance, with 94% WER yield at 1e-6 write-error floor of 64 devices was demonstrated in 50 nm devices with RA = 6.6 Ω-μm^2. In this talk, we will also discuss reference layer related WER anomalies and the results from the improved reference layers to address the issue.

GC-08. Reference layer engineering for back-hopping control in scaled perpendicular magnetic tunnel junctions (MTJs). *S. Rao*[1], S. Couet[1], R. Carpenter[1], W. Kim[1], K. Garello[1] and G.S. Kar[1] *1. IMEC, Leuven, Belgium*

Over the past decade, significant advances in the state-of-the art of STT-MRAM technology have been achieved by engineering the ferromagnet/insulator interface in MTJs [1,2]. Perpendicular magnetic anisotropy (PMA) arising at this interface is critical to obtain a high TMR and efficient switching. Therefore, to enable full commercialization, a high switching probability or low write error rate (WER), is required, a large PMA is critical. Past reports have indicated that weak free (FL) or reference (RL) layers can result in increased error rates due to unintentional switching, otherwise known as back-hopping [3, 4]. In this study, we investigate in-depth the occurrence of this back-hopping in 400 °C-compatible pMTJs as a function of the RL thickness. STT-mediated switching studies show consistent back-hopping in the P-AP switching direction, while the AP-P switching direction is not impacted, as seen in Fig. 1. For a fixed diameter, we also demonstrate that the window between full switching and back-hopping is maximized for the thickest RL. This observation is attributed to RL magnetization flipping as can be deduced from the electron flow direction. We find that TMR increases with RL thickness, due to an increased spin filtering efficiency, which is at a cost of RL pinning field (Fig. 2). Temperature-dependent switching studies also show that back-hopping is inversely proportional to the RL PMA, thus highlighting the importance of engineering the RL PMA over pinning field. To address the challenges of back-hopping in scaled devices, we will also discuss the switching behaviour for diameters from 150 nm down to 50 nm, in the context of voltage bias and pulse-widths. We will also discuss the dynamical nature of back-hopping, and the inverse dependence on applied pulse-widths.

GC-09. Asymmetric Reliability Performance of Mg-inserted MTJ. *K. Chen*[1], C. Cheng[1], J. Wei[2], Y. Wu[3] and Y. Tseng[1] *1. National Chiao Tung University, Hsinchu, Taiwan; 2. Industrial Technology Research Institute, Hsinchu, Taiwan; 3. Taiwan Semiconductor Research Institute, Hsinchu, Taiwan*

Inserting Mg between CoFeB and MgO is a common strategy to reduce damping [1] and interface traps [2] in STT-MRAM. This work demonstrates notable asymmetric reliability performance in Mg-inserted MTJ for low (parallel) and high (antiparallel) resistance states. In a SAF-layer/CoFeB(3Å)/Ta(2Å)/CoFeB(12Å)/MgO(7Å)/Mg(3Å)/CoFeB(12Å)/Ta(3 Å)/CoFeB(8Å)/Capping-layer MTJ, we obtain a lower switching voltage, a greater breakdown voltage and a longer endurance in the high resistance state (HRS) than those of the low resistance state (LRS). Upon breakdown the LRS exhibited a two-step reversal characteristic, suggesting that a reversal pinning-effect arose as breakdown approached. Nevertheless, this was absent to the case of HRS. Such LRS/HRS performance asymmetry was reduced with the removal of Mg insertion. We observe the phenomenon in 80-, 130- and 180-nm MTJs, indicating it as a universal concern in MTJ scaling. The real-time breakdown effect was explored by in-situ synchrotron x-ray for MTJ with/without Mg insertion. Upon breakdwon, the CoFeB/MgO interface appeared to reconstruct differently for the cases of with/without Mg. We conclude that the interfacial reconstruction during MTJ operation is critical to the asymmetric performance.

GC-10. Electric-Field Control of Interlayer Exchange Coupling for Efficient Magnetization Switching. *S. Sayed*[1], N. Roschewsky[2], C. Hsu[1] and S. Salahuddin[1] *1. EECS, University of California, Berkeley, CA, United States; 2. Physics, University of California, Berkeley, CA, United States*

Electrical switching of nano-magnets is of great current interest for efficient non-volatile memory applications. Technological advancements in the state-of-the-art current controlled spin-torque (ST) based mechanisms are limited by the large switching current density requirement and exhibit a trade-off between the switching energy and the speed. In this talk, we will discuss that magnetization switching solely by the interlayer exchange coupling (IEC) between the fixed and the free magnets, may exhibit several benefits over the ST-switching. Specifically, the switching energy and the speed becomes decoupled and the speed can be independently tuned by the dynamic parameters like Gilbert damping and the magnetic anisotropy. We argue that the IEC can be controlled with an electric-field via resonant tunneling phenomena within a double-barrier magnetic tunnel junction structure, if the two oxide barriers are separated by a metal that is well-known for exhibiting a large IEC. Using non-equilibrium Green's function (NEGF) method, we show that the proposed structure exhibits a bias-dependent oscillatory IEC with sizable magnitude that may switch the free magnet to have either a parallel or an antiparallel configuration with respect to the fixed magnet, depending on the sign of the IEC. The new configuration will retain when the electric-field is removed because the equilibrium IEC is negligible due to the presence of the oxide barriers. We further argue that the current in the two-terminal structure can be significantly lowered with proper design and material choices, which could lead to significant lowering in the energy-delay product for magnetic memory applications. This work was supported by ASCENT, one of six centers in JUMP, a SRC program sponsored by DARPA.

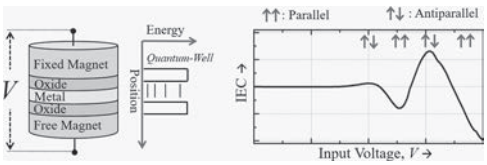

Fig.1 Proposed structure to control interlayer exchange coupling (IEC) between the fixed and the free magnets using an electric-field or a voltage. A quantum-well is formed between the oxide barriers, which are separated by a metallic spacer that exhibits a large IEC.

GC-11. Integration of Tb/Co Multilayers within Ultrafast Optically Switchable p-MTJ. *L. Avilés Félix*[1], C. Davies[2,3], G. Li[3], L. Álvaro Gómez[1], M. Rubio-Roy[1], S. Aufftet[1], A. Kirilyuk[2,3], T. Rasing[3], L. Buda-Prejbeanu[1], B. Dieny[1], R. Sousa[1] and I. Prejbeanu[1] *1. Université Grenoble Alpes, CNRS, CEA, Grenoble INP, IRIG-SPINTEC, Grenoble, France; 2. FELIX Laboratory, Radboud University, Nijmegen, Netherlands; 3. Radboud University Nijmegen, Institute for Molecules and Materials, Nijmegen, Netherlands*

Rare earth/transition metal (RE/TM) systems have been used to achieve perpendicular anisotropy in RE/TM multilayers. The discovery of all-optical switching of the magnetization, achieved on ultrafast timescales using femtosecond laser pulses have generated a renewed interest in these type of systems for data-recording applications. In particular, the ultrafast speed of the switching process permits a significant improvement in the writing speeds associated with magnetic memory devices. This work reports the development of perpendicular magnetic tunnel junction, incorporating a multilayered stack of Tb/Co that can be all-optical addressed via helicity-independent single-shot switching of the magnetization. Toggling of the magnetization in the Tb/Co multilayered stack was observed using both 40 femtosecond- and 3 picosecond-long laser pulses with fluences below 5mJ/cm^2. As illustrated in Fig. 1, these results could be achieved for Co-rich compositions of the multilayer, either alone or embedded in a tunnel junction stack coupled to a CoFeB electrode on an MgO barrier. This result is maintained even after annealing at 250°C. After annealing, a TMR signal of 30% and RxA value of 19Ωμm^2 was obtained. The stability of the multilayer degrades for higher annealing temperatures. This is due to a loss of the interface sharpness that could be compensated by the increase of the number of bilayer repetitions. The annealing stability of the multilayer was improved using a Ta insertion layer, at the cost of reducing the strength of the perpendicular anisotropy and magnetic coercivity. These results open the way to the development of hybrid spintronic photonic systems with unique features of THz MTJ switching speeds and fJ switching energies. The authors acknowledge the funding support from project SPICE (EU ITC 2020 grant agreement No. 713481)

GC-12. Reduced Exchange Interactions in Perpendicular Magnetic Tunnel Junction Free Layers with Insertion Layers. *J. Beik Mohammadi*[1], Y. Chen[1], B. Kardasz[2], G. Wolf[2], M. Pinarbasi[2] and A.D. Kent[1] *1. Center for Quantum Phenomena, Physics, New York University, New York, NY, United States; 2. Spin Memory Inc, Fremont, CA, United States*

Perpendicular magnetic tunnel junctions are widely used in spintronic devices such as in magnetic random-access memories. The free layer is typically formed by CoFeB layers with a thin non-magnetic insertion layer to enhance the perpendicular magnetic anisotropy (PMA) to achieve long-time thermal stability of the memory device. However, the exchange constant of the layer is equally important as it sets the length scales for micromagnetic structure, the energy barrier for thermally activated switching and the spin torque switching efficiency [1]. We present a systematic study of the exchange constant of on a full pMTJ layer stack that allows for the optimization of its magnetic properties. We study a series of samples with CoFeB/W(t_W=0 to 0.7 nm)/CoFeB free layers (FL) while the reference and synthetic antiferromagnetic layers (SAF) layers of the pMTJ stack remain unchanged. Magnetization measurements were taken as a function of temperature, from 5 to 400 K. The well-separated switching field of individual layers enables characterization of their magnetic moments. The exchange constant of individual layers is then determined by fitting $m(T)=M_s(T)/M_s(0\ K)$ vs. T data to Bloch's $T^{3/2}$ law [3]. Figure 1(a) shows m(T) for a single CoFeB layer (brown symbols) and pMTJ free layers with 0.1 to 0.3 nm W thickness (triangular symbols). We observe a significant reduction of the exchange constant of the free layer as W is introduced (Fig. 1(b)). Further, we determined the effective magnetization of the free layer from ferromagnetic resonance measurements at room temperature (Fig. 1(c)). The sign of changes from negative to positive, indicating perpendicular anisotropy, for 0.2 nm W. Therefore, W insertion enhances the PMA, while it leads to a dramatic reduction in the exchange constant. We will discuss the implications that the reduced exchange constant has on thermal stability and switching dynamics of pMTJ devices [3]. This project is supported by Spin Memory Inc.

GC-13. Resonant surface acoustic wave (r-SAW) assisted spin-transfer-torque switching of a perpendicular magnetic tunnel junction (p-MTJ). *A.R. Roe*[1], D. Bhattacharya[1] and J. Atulasimha[1] *1. Mechanical and Nuclear Engineering, Virginia Commonwealth University, Richmond, VA, United States*

As the technology of spin transfer torque random access memory (STTRAM) matures, devices with lateral dimensions ~11 nm with extremely low switching error rates, ~7×10^{-10} [1], have been demonstrated. However, the energy dissipation remains high at ~100 fJ/bit. This motivates research that allows aggressive scaling of STTRAM, while drastically reducing energy dissipation in the write process. We numerically study the use of a resonant dynamic stress created by surface acoustic waves (SAW) used in conjunction with spin-transfer-torque (STT) to significantly reduce the write energy. While SAW alone has been experimentally shown to manipulate the magnetization state of larger nanomagnets [2], and prior work has shown that low frequency SAW can be used in conjunction with STT to switch in-plane magnetization in nanomagnets of lateral dimensions ~100 nm [3], competitive scaling to 50 nm and below is infeasible with this approach in p-MTJs where thickness of the soft magnetic layer is typically limited to ~1 nm. We will present Landau-Lifshitz-Gilbert (LLG) simulations with a dynamic stress of 100 MPa applied to a circular nanomagnet with moderate magnetostriction (~350 micro-strain) and 50 nm diameter and 1.5 nm thickness with

thermal noise. We show that the small anisotropy changes due to low amplitude SAWs, which are resonant with the magnetization dynamics of the nanomagnet (soft layer of p-MTJ), are sufficient to deflect the magnetization significantly (precess with a conical angle of ~45° as shown in Fig 1). Thus, the STT write current to reverse the magnetization is reduced by ~2 times, leading to a ~4 fold decrease in write energy compared to the case without SAW at the same switching error rate. This shows a path for scaling p-MTJ lateral dimensions while reducing write energies. Further optimization and lower damping could result in more competitive scaling and lower write energy. Authors acknowledge NSF grant CCF-1815033.

GD-01. A Family of Intrinsic Magnetic Topological Insulators $(MnBi_2Te_4)(Bi_2Te_3)_n$, $n = 0, 1, 2$. *A. Isaeva*[1,2], A. Zeugner[1], A. Wolter[2], J. Facio[2] and H. Bentmann[3] *1. Technische Universität Dresden, Dresden, Germany; 2. Leibniz IFW Dresden, Dresden, Germany; 3. University of Würzburg, Würzburg, Germany*

Topological quantum materials constitute one of the most vibrant contemporary directions of condensed matter research and material science. Presently one of the central challenges in the field is to understand how topologically non-trivial electronic states evolve in the presence of strong electronic correlations and magnetism. In turn, this interplay is believed to unleash a plethora of novel topological phenomena as well as pathways to exploit them for spintronic device concepts. Following theoretical advances material candidates are emerging. For a long while, the magnetic doping approach was one of the central routes to explore the interplay with magnetism in the paradigmatic TIs like Bi_2Te_3. Recent advances have provided access to long-sought Bi_2Te_3-derivatives with a periodic Mn sublattice, the layered van der Waals compounds $(MnBi_2Te_4)(Bi_2Te_3)_n$, n = 0,1,2 [1-3]. These natural heterostructures are built by varying sequences of septuple and quintuple layers and represent the first intrinsically magnetic topological insulators. I will present our structural, magnetic, transport and angle-resolved photoemission spectroscopy measurements of $MnBi_2Te_4$ ($n = 0$) and $MnBi_4Te_7$ ($n = 1$) that corroborate a combination of the non-trivial band topology and a long-range magnetic order in this class of materials [4-7]. Our team highly values the careful optimization of crystal-growth techniques and accurate determination of chemical purity and crystal structure. To obtain high-quality single crystals, the synthetic conditions have been thoroughly optimized with respect to temperature profiles and starting materials. We establish ubiquitous off-stoichiometry of the materials, $Mn_{1-x}Bi_{2+2x/3}Te_4$ (x = 0.15) and $Mn_{1-x}Bi_{4+2x/3}Te_7$ ($0.15 \le x \le 0.25$) by single-crystal X-ray diffraction [3, 5, 7]. Furthermore, all of $(MnBi_2Te_4)(Bi_2Te_3)_n$ are thermodynamically stable only in narrow high-temperature ranges at around 873 K that strongly challenges their crystal-growth [3, 5]. For $MnBi_2Te_4$, temperature- and field-dependent magnetization measurements establish a 3D AFM order below $T_N = 24$ K. It originates from an antiferromagnetic coupling between the septuple layers, which exhibit ferromagnetic intralayer coupling. Competing AFM and FM couplings are indicated as well by the small and positive value of the Curie-Weiss temperature. This magnetic ground state and a centrosymmetric space group entail the $Z_2 = 1$ topological classification and render $MnBi_2Te_4$ as the first antiferromagnetic topological insulator [4]. The expected Mn(II) out-of-plane magnetic state is confirmed by the magnetization, X-ray photoemission, X-ray absorption and linear dichroism data. Angle-resolved photoemission experiments provide evidence for a surface state forming a gapped Dirac cone [4,6]. For $MnBi_4Te_7$, which is diluted by the insertion of (Bi_2Te_3) layers between the septuple $(MnBi_2Te_4)$ ones, we find several competing magnetic states below $T_N = 13$ K by a variety of experimental techniques and uncover the complexity of the paramagnetic state. We use angle-resolved photoemission measurements in broad temperature and photon-energy ranges to directly confirm the topological surface states on the (0001) surface of both possible surface terminations. These observations are complemented with first-principle density-functional calculations that corroborate the proximity in energy of different magnetic states, confirm the inverted character of the electronic band structure and show how the band topology is affected by the different magnetic orders. Based on that, a preliminary phase diagram of possible topological states in $MnBi_4Te_7$ dependent on the magnetic structure can be sketched. $MnBi_4Te_7$ is the first realization of a band-inverted material with intrinsic net magnetization [7]. We envision that their versatile magnetic and electronic properties will establish $(MnBi_2Te_4)(Bi_2Te_3)_n$ as a unique material platform for the realization of tunable topological quantum phenomena.

GD-02. Incommensurate Magnetic Order from 1-D Correlated Topological Bulk States. *J.L. Lussier*[1] *1. Physics, Kent State University, Kent, OH, United States*

The onset of incommensurate magnetic order (IC) in a periodic crystalline lattice has many different origin including next-nearest-neighbor interaction in insulators, coupling to lattice displacements or electron band filling in a metal. In the latter, IC order is often explained by the onset of spin/charge density waves. However, it is possible to calculate the reciprocal space position of incommensurate magnetic satellites seen in diffraction experiments of systems with metallic characters using a one-dimensional topological Dirac equation. In such an approach, the IC magnetic order originates from the onset of fluctuating correlated topological bulk states and is characterized by an average wave vector from crystallographic Bragg planes defining the moving center of mass of the magnetic electrons. This novel approach works particularly well with f-electron systems with itinerant characters, like in Ce-compounds, but also also in the High-Tc BSSCO and in the skyrmion-lattice system with no inversion symmetry MnSi. The phenomenological algorithm for the calculation of the IC satellites is given in details.

GD-03. RIXS With In-Situ Magnetic Field: Towards Understanding The Complex Magnetism Of Li_2IrO_3. *A. Ruiz*[1], A. Allen[1], V. Nagarajan[2], N. Breznay[3], J. Analytis[2] and A. Frano[1] *1. University of California San Diego, La Jolla, CA, United States; 2. University of California, Berkeley, CA, United States; 3. Harvey Mudd College, Claremont, CA, United States*

Unconventional magnetism appears in correlated electron systems with strong spin-orbit coupling. 5d iridate compounds coordinated in a honeycomb lattice like Li_2IrO_3 are a promising avenue to realize the peculiar

anisotropic, frustrated magnetism scenario of Kitaev's Hamiltonian [1, 2] which could host a quantum spin liquid ground state. Experimentally, the material displays a degeneracy of magnetic ground states upon the application of a magnetic field [3]: one incommensurate spiral and a commensurate 'zigzag' phase. The mechanism by which the magnetic order and the associated low-energy excitations vary with magnetic field is unknown. Measuring the excitation spectrum associated with each of the two magnetic phases is challenging for two reasons: the energy scale of said excitations is low and thus at the limit of experimental resolution of RIXS spectrometers, and the application of in-situ magnetic fields within RIXS chambers is highly challenging. Using the state-of-the-art RIXS spectrometer at Sector 27 of the Advanced Photon Source, we have overcome both challenges to measure the spin excitations of both spiral and commensurate phases by tracking low-energy excitations near their respective q-vectors in an applied magnetic field of 2 Tesla (as well as 0 Tesla). We have identified magnon branches near each q-vector. Surprisingly, the magnon velocity near the spiral q-vector is much higher than the expected *sin(qa/2)* behavior, possibly suggesting a larger magnetic coupling strength than previously thought. This data may provide insight into the interactions between pseudo-spins in this fascinating material. Finally, we will discuss how the application of modest magnetic fields within modern high-resolution RIXS setups is now possible and will open up interesting new avenues of research in exotic 5d-magnetism.

GD-04. Topological Classification of Magnetic Plateaux and Haldane Phases in Quantum Spin Chains. *I. Maruyama*[1] and S. Miyahara[2]
1. Department of Information and Systems Engineering, Fukuoka Institute of Technology, Fukuoka, Japan; 2. Department of Applied Physics, Fukuoka University, Fukuoka, Japan

Topological phases cannot be characterized by local order parameters and require non-local or new quantities for phase characterization. One of historical examples is the Haldane phase, which is one of the symmetry protected topological(SPT) phases. As a phase characterization method for these phases, a fractionally quantized Berry phase has been proposed [1]. Recently, the fractionally quantized Berry phase has successfully classified the SU(N) AKLT chains [2]. To demonstrate its ability for coupled molecular magnets, we have studied spin-1/2 Heisenberg multimer (N-mer) chains, i.e., highly frustrated N-leg ladders. The models have been studied as a generalization of an orthogonal dimer chain [3]. In the case of symmetric frustration it has been known that there are magnetization plateau phases which have exact ground states written as direct product states, except for the Haldane phase. The definition of the Berry phase requires a spin-twisted ground state and it is not a direct product state. We calculated the Berry phase numerically with using the spin-twisted ground state obtained by the Lanczos method. As a result, we obtained exact fractional quantization $2\pi/N$ of the Berry phase in dimer (N=2) and tetramer (N=4) chains [4]. For example, in the coupled tetramer case, six magnetic plateaux existing in the phase diagram are classified by four kinds of Berry phases, 0, $\pi/4$, $\pi/2$, and $3\pi/4$. We have found that the exact quantization of the Berry phase arises from translational symmetry of local multimer, including S=2 Haldane phase. In addition, we discuss nonzero Berry phase of S=2 Haldane phase when the model has XXZ and on-site anisotropies, in order to study new internal symmerty of the even S Haldane phases, which have no SPT order. This work is supported in part by JPSJ KAKENHI Grant Number JP17H02926. The computation is partially carried out using the computer facilities at Research Institute for Information Technology, Kyushu University.

Kitaev quantum spin liquid (QSL) is a highly frustrated state in topological magnets with excitations from fractional particles[1,2,3]. Via time reversal symmetry breaking (e.g. ordered state below T_c), fractional particles can show non-Abelian exchange statistics, which offers topological quantum computing immune to de-coherence[4]. An open question is how the spin liquid like fraction excitations emerge from the magnons of the ordered state. Here, we report the Raman scattering result on three-dimensional magnet β-Li_2IrO_3. We identified the temperature dependence of the magnons for the first time and demonstrated how they melt into the fractional excitations expected from the QSL state.

The honeycomb lattice of α-$RuCl_3$ is a potential candidate to study the Kitaev model. The predicted ground state for such a model is a Quantum Spin Liquid (QSL). There is significant interest in studying the Kitaev interaction in α-$RuCl_3$, which orders antiferromagnetically below 6 K. In the magnetic phase, the Kitaev exchange energy is in the order of the antiferromagnetic (AFM) energy [1,2]. Interestingly, above an applied magnetic field of approximately 8 T, long-range magnetic order is suppressed and the QSL phase is recovered [3,4]. Inelastic light scattering, such as Raman spectroscopy, has been theoretically shown to be a direct probe of the itinerant Majorana fermions excitation [5,6]. Subtle hints of this fractionalized spin excitation had been experimentally observed in the broad scattering continuum in α-$RuCl_3$, where the typical bosonic thermal behavior of the

quasiparticles that typically make up these scattering continua was found to be fermionic [7,8,9]. Initially we identified two distinct A_g and B_g Raman responses of this scattering continuum in bulk α-$RuCl_3$ using angle-resolved Raman spectroscopy [10]. It was shown that the Fano resonances resulted from these responses come from the interaction of two different Raman phonons and a 2-Dimensional continuum. We extend this work to measure the temperature dependence of the scattering continuum down to 4 K, and in magnetic field up to 9 T. Implications on the anisotropic Kitaev exchange energies are discussed based on previously calculated Raman response, where $J_x = J_y \neq J_z$ (where x, y, z label the 3 different Ru-Ru directions in the 2D honeycomb lattice) [6].
